

Cognition in Flux

Proceedings of the 32nd Annual Meeting of the Cognitive Science Society

Portland, Oregon, August 11-14, 2010

Edited by

Stellan Ohlsson

University of Illinois at Chicago

Richard Catrambone

Georgia Institute of Technology

Austin, TX: Cognitive Science Society

How to cite a paper in these Proceedings:

APA formatted citation for a 6-page paper:

Author, A. & Author, B. (2010). This is the title of the paper. In S. Ohlsson & R. Catrambone (Eds.), *Proceedings of the 32nd Annual Conference of the Cognitive Science Society* (pp. NUMBERS). Austin, TX: Cognitive Science Society.

APA formatted citation for a published abstract:

Author, A. & Author, B. (2010). This is the title of the abstract [Abstract]. In S. Ohlsson & R. Catrambone (Eds.), *Proceedings of the 32nd Annual Conference of the Cognitive Science Society* (p. NUMBER). Austin, TX: Cognitive Science Society.

APA formatted citation for a talk (or poster) presentation:

Author, A. & Author, B. (2010, August). This is the title of the talk or poster. Paper (or Poster) presented at the 32nd Annual Conference of the Cognitive Science Society. Portland, OR.

Table of Contents

Table of Contents	i
Introduction	1
Organizing Committee	3
Program Committee	4
Awards	5
Sponsors	7
Invited Plenary Presentations	8
Symposia	9
Tutorials and Workshops	13
Foundations: Steps to Unification	
<i>Wild Systems Theory: Overcoming the Computational-Ecological Divide</i>	15
Jerome Scott Jordan	
<i>Framing and Resource Activation: Bridging the Cognitive-Situative Divide Using a Dynamic Unit of Cognitive Analysis</i>	19
Luke Conlin, Ayush Gupta, David Hammer	
<i>Modeling Personality and Individual Differences: The Approach-Avoid-Conflict Triad</i>	25
Karl Fua, William Revelle, Andrew Ortony	
<i>Understanding the Brain as an Endogenously Active Mechanism</i>	31
William Bechtel, Adele Abrahamsen	
Language: Novel Approaches	
<i>Likability-Based Genres: Analysis and Evaluation of the Netflix Dataset</i>	37
Andrew Olney	
<i>Constructing Typing-Time Corpora: A New Way to Answer Old Questions</i>	43
Uriel Cohen Priva	
<i>Large-Scale Acquisition of Feature-Based Conceptual Representations from Textual Corpora</i>	49
Barry Devereux, Nicholas Pilkington, Thierry Poibeau, Anna Korhonen	
<i>Are Random Representations Accurate Approximations of Lexical Semantics?</i>	55
Brendan Johns, Michael Jones	
Induction: Basic Processes	
<i>A Neural Model of Rule Generation in Inductive Reasoning</i>	61
Daniel Rasmussen, Chris Eliasmith	

<i>The Effects of Domain and Type of Knowledge on Category-Based Inductive Reasoning</i>	67
Aimée Kay Crisp-Bright, Aidan Feeney	
<i>Learning hypothesis spaces and dimensions through concept learning</i>	73
Joseph Austerweil, Thomas Griffiths	
<i>The Role of "Explaining Away" in Human Abstract Rule Induction</i>	79
Colin Dawson, LouAnn Gerken	
Cognitive Architecture: Central Processing	
<i>An Analysis of the Working Memory Capacity Paradox</i>	85
Eddy J. Davelaar	
<i>Working Memory Load Affects Device-Specific but Not Task-Specific Error Rates</i>	91
Maartje Ament, Anna Cox, Ann Blandford, Duncan Brumby	
<i>An examination of the ERP correlates of recognition memory using state-trace analysis.</i>	97
Emily Freeman, Simon Dennis, John Dunn	
<i>Modeling Change in Recognition Bias with the Progression of Alzheimer's</i>	103
James Pooley, Michael Lee, William Shankle	
Social Cognition: Alignment in Dialogue	
<i>Context, Syntactic Priming, and Referential Form in an Interactive Dialogue Task: Implications for Models of Alignment</i>	109
Kathleen Carbary, Ellen Frohning, Michael Tanenhaus	
<i>Converging Hands or Converging Minds?</i>	115
Lisette Mol, Emiel Krahmer, Alfons Maes, Marc Swerts	
<i>Vocal Interaction Dynamics of Children With and Without Autism</i>	121
Anne S. Warlaumont, D. Kimbrough Oller, Rick Dale, Jeffrey A. Richards, Jill Gilkerson, Dongxin Xu	
<i>Virtually accommodating: Speech rate accommodation to a virtual interlocutor.</i>	127
Laura Staum Casasanto, Kyle Jasmin, Daniel Casasanto	
Education: Knowledge and Strategies	
<i>Connecting the Visible to the Invisible: Helping Middle School Students Understand Complex Ecosystem Processes.</i>	133
Sameer Honwad, Cindy Hmelo-Silver, Rebecca Jordan, Catherine Eberbach, Steven Gray, Suparna Sinha, Ashok Goel, Swaroop Vattam, Spencer Rugaber, David Joyner	
<i>Response Times and Misconception-like Responses to Science Questions</i>	139
Andrew Heckler, Thomas Scaife, Eleanor Sayre	
<i>Effects of Problem Context on Strategy Use within Functional Thinking</i>	145
Katherine McEldoon, Caroline Cochrane-Braswell, Bethany Rittle-Johnson	
<i>The Application of the Less is More Hypothesis in Foreign Language Learning</i>	150
Simone Chin, Alan Kersten	

Decision Making: Sequential Choices

- Are People Successful at Learning Sequential Decisions on a Perceptual Matching Task?* 156
Reiko Yakushijin, Robert Jacobs
- The Impact of Perceptual Aliasing on Exploration and Learning in a Dynamic Decision Making Task* 162
Lisa Zaval, Todd Gureckis
- Human foraging behavior: A virtual reality investigation on area restricted search in humans* 168
Christopher Kalff, Thomas Hills, Jan Malte Wiener
- Learning in Multiple-cue Judgment Tasks* 174
Bettina von Helversen, Joerg Rieskamp

Symposium: Success in Theory of Mind

- Success in Theory of Mind* 180
Rose Scott, Adam Petrashek, Noah Goodman, Rebecca Saxe, Renee Baillargeon, Ori Friedman

Foundations: Representation

- Disentangling Representation from Conceptualisation* 182
Nancy Salay
- Thought, Language and Mental Representation* 188
Jonathan Trigg, Michael Kalish
- What Is Domain Specificity (and Why Does It Matter)?* 194
Muhammad Ali Khalidi
- Cognition for action: an architectural account for "grounded interaction"* 200
Anthony Harrison, J. Gregory Trafton

Language: Role of Syntax

- The avoidance of ambiguity during conversation: More than mere priming or mimicry?* 206
Jennifer M. Roche, Rick Dale, Roger J. Kreuz
- Syntax Drives Phonological Choice - Even Independently of Word Choice* 212
Marie Nilsenova, Marije van Amelsvoort
- Corpus Evidence for Age Effects on Priming in Child Language* 218
Jeffrey Gerard, Frank Keller, Themis Palpanas
- Understanding acceptability judgments: Additivity and working memory effects* 224
Laura Staum Casasanto, Philip Hofmeister, Ivan Sag

Induction: Facilitating Factors

- The Role of Linguistic Labels in Categorization* 230
Sophia Deng, Vladimir Sloutsky
- The Price is Right: A High Information Access Cost Facilitates Category Learning* 236
Michael Wood, Michael Fry, Mark Blair

<i>Effects of generative and discriminative learning on use of category variability</i>	242
Anne Hsu, Thomas Griffiths	
<i>Category Learning Through Active Sampling</i>	248
Doug Markant, Todd Gureckis	
Cognitive Architecture: Encoding & Retrieval	
<i>SARKAE - Modeling the Co-Evolution of Event Memory and Knowledge</i>	254
Angela Nelson, Richard Shiffrin	
<i>Looking at Nothing Indicates Memory Search in Multiattribute Decision Making</i>	260
Frank Renkewitz, Georg Jahn	
<i>Motor Simulation in a Memory Task: Evidence from Rock Climbing</i>	266
Giovanni Pezzulo, Laura Barca, Alessandro Lamberti Bocconi, Anna M. Borghi	
Social Cognition: Joint Attention	
<i>Enactive Social Cognition</i>	272
Tobias Schlicht	
<i>Building a Model of Infant Social Interaction</i>	278
Joshua Lewis, Gedeon Deák, Hector Jasso, Jochen Triesch	
<i>The Emergence of Referential Gaze and Perspective-taking in Infants</i>	284
R. Joanne Jao, Marybel Robledo, Gedeon O. Deák	
<i>Joint perception: gaze and beliefs about social context</i>	290
Daniel Richardson, Chris Street, Joanne Tan	
Education: Meta-Cognitive Aspects	
<i>Teaching Students Self-Assessment and Task-Selection Skills with Video-Based Modeling Examples</i>	296
Tamara van Gog, Danny Kostons, Fred Paas	
<i>Confidence without Competence in the Evaluation of Scientific Claims</i>	302
Andrew Shtulman	
<i>Individual Differences as Predictors of Learning and Engagement</i>	308
Sidney D'Mello, Claire Williams, Patrick Hays, Andrew Olney	
<i>Do Tutors' Content Knowledge and Beliefs About Learning Influence Their Assessment of Tutees' Understanding?</i>	314
Stephanie Herppich, Jörg Wittwer, Matthias Nückles, Alexander Renkl	
Decision Making: Risk	
<i>Risk attitude in decision making: A clash of three approaches</i>	320
Eldad Yechiam, Eyal Ert	
<i>Making Assessments While Taking Sequential Risks</i>	326
Avishai Wershba, Timothy Pleskac	
<i>Testing Two Explanations for the Disjunction Effect in Prisoner's Dilemma Games: Complexity and Quasi-Magical Thinking</i>	332
Evgenia Hristova, Maurice Grinberg	

<i>Mentalizing in games: A subtractive behavioral study of Prisoner's Dilemma</i>	338
Antonio Napoli, Danilo Fum	
Symposium: Prospective Perception	
<i>Prospective Perception</i>	344
Jerome Scott Jordan, Jessica Witt, Michael Riley	
Conceptual Spaces: Examples and Methods	
<i>Constructing Spatial Concepts from Universal Primitives</i>	346
Yang Xu, Charles Kemp	
<i>Replicating Color Term Universals through Human Iterated Learning</i>	352
Jing Xu, Thomas Griffiths, Mike Dowman	
<i>Similarity judgments reflect both language and cross-language tendencies: Evidence from two semantic domains</i>	358
Naveen Khetarpal, Asifa Majid, Barbara Malt, Steven Sloman, Terry Regier	
Language: Speech Perception	
<i>Adults' self-directed learning of an artificial lexicon: The dynamics of neighborhood reorganization</i>	364
Neil Bardhan, Richard Aslin, Michael Tanenhaus	
<i>Perceptual Advantage from Generalized Linguistic Knowledge</i>	369
Bozena Pajak	
<i>A rational account of perceptual compensation for coarticulation</i>	375
Morgan Sonderegger, Alan Yu	
<i>Effects of Pragmatic Inference on Phoneme Identification</i>	381
Hannah Rohde, Marc Ettlinger	
Induction: Differential Factors	
<i>Individual Differences in Attention During Category Learning</i>	387
Michael Lee, Ruud Wetzels	
<i>Categorisation, Deference and Cognitive Style</i>	393
Nick Braisby, Sharon Hanlon	
<i>When Comparison Helps: The Role of Language, Prior Knowledge and Similarity in Categorizing Novel Objects</i>	399
Clare Sims, Eliana Colunga	
<i>Category Learning and Adaptive Benefits of Aging</i>	405
Angela Merritt, Linnea Karlsson, Edward Cokely	
Cognitive Architecture: Higher-Order Structure	
<i>Encoding higher-order structure in visual working memory: A probabilistic model</i>	411
Timothy Brady, Joshua Tenenbaum	

<i>Expertise in Visual Art is Associated with Altered Perceptual Strategies Within and Across Domains: Evidence from Eye Tracking</i>	417
Kuba Glazek, Robert Weisberg	
<i>Melody Recognition: Effects of Articulation Format</i>	423
Stephen Wee Hun Lim, Winston D. Goh	
<i>On the Relationship Between Entropy and Meaning in Music: An Exploration with Recurrent Neural Networks</i>	429
Greg Cox	

Social Cognition: Human-Robot Interaction

<i>Simulating Cognitive Coping Strategies for Intelligent Support Agents</i>	435
Azizi Ab Aziz, Jan Treur, Michel Klein	
<i>An Adaptive Integrative Ambient Agent Model to Intervene in the Dynamics of Beliefs and Emotions</i>	441
Zulfiqar Ali Memon, Jan Treur	
<i>Proposing Artificial Subtle Expressions as an Intuitive Notification Methodology for Artificial Agents' Internal States</i>	447
Takanori Komatsu, Seiji Yamada, Kazuki Kobayashi, Kotaro Funakoshi, Mikio Nakano	
<i>Experiments for Assessing Floating Reinstatement in Argument-based Reasoning</i>	453
Iyad Rahwan, Jean-Francois Bonnefon, Mohammed Iqbal Madakkatel, Ruqiyabi Naz Awan, Sherief Abdallah	

Education: Transfer

<i>Optimizing Learning Environments: An Individual Difference Approach to Learning and Transfer</i>	459
Daniel Belenky, Timothy Nokes	
<i>The Effects of Similarity and Individual Differences on Comparison and Transfer</i>	465
Samuel Day, Robert L. Goldstone, Thomas Hills	
<i>Seeing Language Learning Inside the Math: Cognitive Analysis Yields Transfer</i>	471
Ken Koedinger, Elizabeth McLaughlin	
<i>Initial Evidence of the Effects of Linguistic Framing on Transfer</i>	477
Randi A. Engle, Adam Mendelson, Phi D. Nguyen	

Decision Making: Non-Optimality

<i>Impatience as Intertemporal Egoism</i>	483
Daniel Bartels, Oleg Urminsky	
<i>WIN!! vs. win: Impact of "Outcome" Salience on Illusion of Control</i>	489
Stefania Mereu, Alejandro Lleras	
<i>Signs of Non-Linearity in Base-Rate Neglect</i>	495
Christopher Erb, Heidi Kloos	
<i>Mathematically Modeling Anchoring Effects</i>	501
Jessica Choplin, Mark Tawney	

Symposium: The Philosophy of Affective Neuroscience

<i>The Philosophy of Affective Neuroscience</i>	507
Rami Gabriel, Jaak Panksepp, Stephen Asma, Glennon Curran	

Poster Session 1

<i>Response Choice When Telling Lies</i>	509
Emma Williams, Lewis Bott, Michael Lewis, John Patrick	
<i>Does Practice Narrow the Radius of Spatial Interference in Mental Images?</i>	510
Don Lyon	
<i>A Sense of Order: Numerical ordering ability predicts complex mental arithmetic performance</i> ..	511
Ian Lyons, Sian Beilock	
<i>Imaginary affordances shape children's preference judgments</i>	512
Tania Henetz, Daniel Casasanto	
<i>Testing fMRI predictions of a Cognitive Model of the Problem State Multitasking Bottleneck</i>	513
Jelmer Borst, Niels Taatgen, Hedderik Van Rijn, Andrea Stocco	
<i>Grounded Congruency Effects Between Vertical Meaning and Vertical Responding: Not Replicated</i>	514
Lauren McDonough, Christine Wilson-Mendenhall, Lawrence Barsalou	
<i>MIReR: Media Integration Reflection Resource</i>	515
Andreea Danieleescu, Ellen Campana	
<i>Social Influences on the, um, Use of, uh, Fillers</i>	516
Esther Walker, Evan Risko, Alan Kingstone	
<i>Probability estimation by mice in an interval timing task</i>	517
Aaron Kheifets, C. Randy Gallistel	
<i>The Specificity of Non-Arbitrary Sound-to-Meaning Correspondences in Spoken Language</i>	518
Christina Y. Tzeng, Lynne C. Nygaard, Laura L. Namy	
<i>Pattern Recognition Principle Theoretical Model of Mind-Brain Functioning</i>	519
Gilberto de Paiva	
<i>Individual Differences in Explaining Noisy Data</i>	520
Daniel R. Little, Richard M. Shiffrin	
<i>Making a good impression (formation model): a more complete account of processing</i>	521
Tei Laine, Swati Gupta, Brian M. Monroe	
<i>The representation of idiom words in the mental lexicon</i>	522
Simone Sprenger, Hedderik van Rijn	
<i>Assessing the Effectiveness of Wayfinding Directions</i>	523
Alycia Hund, Amanda Padgitt	
<i>How Agent Placement Can Influence Perceived Boss/Co-worker Agreement in a Simulated Work Environment</i>	524
Justin L. Matthews, Teenie Matlock	

<i>The structure of event representations: behavioral, imaging, and computational investigations ...</i>	525
Anna Schapiro, Timothy Rogers, Matthew Botvinick	
<i>Pair Analysis and Joint Action Theory: A Research Protocol to Study Cognition and Interaction in Visual Analytics</i>	526
Richard Arias Hernández, Linda T. Kaastra, Brian D. Fisher	
<i>The Importance of Visual Modeling in Children's Understanding of Physical Science</i>	527
Nancy L Stein, Marc W. Hernandez	
<i>Reversing the side-effect effect: the 'Rational Scientist' explanation</i>	528
Kevin Uttich, Tania Lombrozo	
<i>MHP/RT: Model Human Processor with Real Time Constraints</i>	529
Makoto Toyota, Muneo Kitajima	
<i>CCE: Cognitive Chrono-Ethnography</i>	530
Muneo Kitajima, Makoto Toyota	
<i>On the diversity of folk morality: Measuring classical positions in moral philosophy</i>	531
Stephanie Müller, Bernd-Christian Otto, Edward Cokely	
<i>Linguistic Control in Monolingual and Bilingual Language Learners</i>	532
James Bartolotti, Viorica Marian	
<i>Intent discerning agent for more intuitive visualizations</i>	533
Tera Marie Green, Steve DiPaola	
<i>A Difference in Working Memory Capacity among Chinese Speakers Using Different Computer Word Typing Methods</i>	534
Jenn-Yeu Chen, Cheng-Yi Li	
<i>Cognitive Arithmetic revisited: Effects of equation presentation format</i>	535
Michael C. W. Yip	
<i>The Capacity to Discover: Working Memory and the Ability to Use Self-Explanation to Discover Early Algebra Concepts</i>	536
Marci DeCaro, Bethany Rittle-Johnson	
<i>Number, Language, and Object Individuation</i>	537
Lisa Cantrell, Linda B. Smith	
<i>The Cognitive and Motor Performance of Children with Functional Articulation Disorders</i>	538
Rong-Ju Cherng, Hung-Yi Chen, Jenn-Yeu Chen, Yung-Jung Chen	
<i>I let the music speak: a model of music perception that predicts speech segmentation</i>	539
Geraint Wiggins	
<i>Peer Reviewing in Undergraduate Psychology Students</i>	540
Joanna Salapska-Gelleri	
<i>Training University Students on the Balance Scale Problem</i>	541
Thomas Scaife, Andrew Heckler	
<i>Verb tense and aspect in scene descriptions in a humanoid robot</i>	542
Carol J. Madden, Stéphane Lallée, Peter Ford Dominey	

<i>The importance of being present: The effect of a real or videotaped person on visual attention ...</i>	543
Kaitlin Laidlaw, Tom Foulsham, Gustav Kuhn, Alan Kingstone	
<i>Exploring Phonological Levenshtein Distance Effects in Auditory Lexical Decision</i>	544
Lidia Suárez, Seok Hui Tan, Melvin J. Yap, Winston D. Goh	
<i>How is children's exploratory play influenced by evidence conflicting with their theory?</i>	545
Tessa J. P. van Schijndel, Maartje E. J. Raijmakers	
<i>Causal reasoning in decision making: A test of causal model theory of choice</i>	546
Motoyuki Saito, Tsuneo Shimazaki	
<i>Gaze movement and language production when talking about events in live-recorded video clips ..</i>	547
Monique Flecken, Christiane von Stutterheim, Mary Carroll	
<i>Fluency and cognitive control in judgment: Influences of memory and elaborative encoding</i>	548
Paula Parpart, Edward T. Cokely	
<i>Bridging the Implementation Gap: From Sensorimotor Experience to Abstract Conceptual Knowledge</i>	549
Anna Koop, Leah Hackman, Rich Sutton	
<i>An examination of learner control during web-based instruction</i>	550
Jessica Federman, Ryan Morris, Lisa Dragoni	
<i>The Linguistic Distribution of Relational Categories</i>	551
Micah Goldwater, Jon Willits	
<i>Multisensory stimuli improve numerical matching abilities of preschool children</i>	552
Kerry Jordan, Joseph Baker, K.S. Rodzon	
<i>Wayfinding Tasks and Heuristics</i>	553
Simon J. Buechner, Christoph Hölscher	
<i>Auditory distraction during semantic processing: Data and a model</i>	554
Philip Beaman, John Marsh, Dylan Jones	
<i>How to Foster the Integration of Text and Diagrams: An Eye Tracking Study on the Use of Signals in Multimedia Learning</i>	555
Katharina Scheiter, Alexander Eitel	
<i>Cognitive Modeling Repository</i>	556
Jay Myung, Mark Pitt	
<i>The hindsight bias in temporal predictions of animated automobile accidents</i>	557
Dustin Calvillo, Dayna Gomes	
<i>Strategies for multitasking: An fMRI study of individual differences in multitasking ability</i>	558
Winston Jones, Jarrod Moss, Stephanie Doane	
<i>Facilitation in Second Language Word Meaning Evaluation from Masked Primes</i>	559
Robert Zheng, Fernando Rubio, Dan Woltz	
<i>Physical design tools support and hinder innovative engineering design</i>	560
Jooyoung Jang, Christian Schunn	

<i>Seductive Images and Metacomprehension of Science Texts</i>	561
Allison Jaeger, Jennifer Wiley	
<i>Emotion and association-memory</i>	562
Christopher Madan, Christine Lau, Jeremy Caplan, Esther Fujiwara	
<i>The Effects of Alcohol Use on Creative Problem Solving</i>	563
Andrew Jarosz, Gregory Colflesh, Jennifer Wiley	
<i>Tapping into Student Knowledge about Science Systems</i>	564
Jodi Davenport, Edys Quellmalz, Mike Timms	
<i>Preschoolers writing of multidigit numbers: From an additive to multiplicative representational system?</i>	565
Sandra Street, Richard Prather, Cody Stitzel, Linda Smith, Kelly Mix	
<i>Knowledge about the role of illustrations on motivation for reading</i>	566
Hideaki Shimada	
<i>Effects of Self-Explanation and Prompts Depend on the Students' Need for Cognition</i>	567
Kyung Soo Do, Hyo-hee Lee, Hanna Kim	
<i>Engineering Models of Human Behavior</i>	568
Spyridon Revithis	
<i>Attention for Action: Attentional Modulation by the Hands</i>	569
Holger Schultheis, Laura Carlson, Richard Abrams	
<i>The effect of conventionality and aptness on suppression of metaphor-irrelevant meaning</i>	570
Tomohiro Taira, Takashi Kusumi	
<i>A Categorization of Face Recognition Deficits in Congenital Prosopagnosia</i>	571
Rainer Stollhoff, Jürgen Jost, Ingo Kennerknecht	
<i>Focusing on the Intermediate Event Makes the Chain Structure More Learnable</i>	572
Kyung Soo Do, JaeHyuk Choi	
<i>Effects of Physical Structure and Creators' Intentions on Judgments of Function</i>	573
Kyung Soo Do, Kyuhee Kim	
<i>A Computation Model synthesizing the Rule based and Experience based Cognitive Processes of Chinese Characters</i>	574
Sau-chin Chen, Jon-Fan Hu, Ping Li	
<i>Virtual Brainstorming: Avatar Visibility and Group Size</i>	575
Thomas Ward, Matthew Guerdat, Beverly Roskos-Ewoldsen	
<i>Semantic richness modulates early word processing within left-lateralized visual brain areas and enhances repetition priming</i>	576
Milena Rabovsky, Werner Sommer, Rasha Abdel Rahman	
<i>The role of stimulus familiarity in non-linguistic sequence learning</i>	577
Jennifer A. Sturm, Kenny Smith	
<i>The Development of Numeracy: Fingers Count!</i>	578
Marcie Penner-Wilger, Lisa Fast, Jo-Anne LeFevre, Brenda L. Smith-Chant, Sheri-Lynn Skwarchuk, Deepthi Kamawar, Jeffrey Bisanz	

<i>Location, Location, Location: Environmental constraints on interpreting spatial terms</i>	579
Kevin Mickey, Laura Carlson, Scott Freunds Schuh	
<i>Goals and the Perception of Distance and Time in Virtual Spaces</i>	580
Angie Johnson, Kenny Coventry, Emine Mine Thompson	
<i>Artificial Cognitive Systems for Human-like Situation Awareness Ability</i>	581
Soo-Young Lee	
<i>Comprehension and a Complex Task: A construction-integration study of individual performance in a non-routine task situation</i>	582
Paul Ladny, Jordan McGuire, Randy J. Brou, Stephanie M. Doane	
<i>Competitive Routes to Belief and Their Impact on Future Learning</i>	583
Carlos R. Salas, Thomas D. Griffin	
<i>Unique and Additive Effects of Self-Explaining and Contrasting Cases on Learning Fraction Division</i>	584
Shanta Hattikudur, Pooja G. Sidney, Martha W. Alibali	
<i>When dog is more wolf than bone: Computational and electrophysiological evidence for featural organization of semantic memory</i>	585
Sarah Laszlo, Blair Armstrong, Joseph MacInnes, David Plaut, Kara Federmeier	
<i>Hindsight bias in judgments of others' performance on inattentional blindness tasks</i>	586
Alan Penaloza, Dustin P. Calvillo, Richard Brooks , Dayna M. Gomes	
<i>A decision science blind to decision procedures would be "unfair": The effect of decision process on decision-outcome satisfaction and subsequent choice in a performance environment</i>	587
Daniel DeCaro, Joseph Johnson	
<i>A Functional, Hormonal, and Computational Study of Sex Differences in Working Memory</i>	588
Brandon Abbs, Jill Goldstein	
<i>Now You See It, Now You Dont: Social Attention in a Magic Trick, Live and On Video</i>	589
Robert Teszka, Evan Risko, Gustav Kuhn, Alan Kingstone	
<i>Declarative and procedural memory abilities as predictors of successful adult language learning</i> ..	590
Katherine Brill, Mandy Faretta, Francis Wong, Patrick Wong, Kara Morgan-Short	
<i>A Bird's-Eye View of Numerical Discrimination in the Wild</i>	591
Alexis Garland, Jason Low, K.C. Burns	
<i>Distinguishing first-line defaults and second-line conceptualization in reasoning about humans, robots, and computers</i>	592
Daniel Levin, Megan Saylor, Simon Lynn	
<i>Cross-Modality Strategy Transfer: A behavioral study of strategic discrimination skill acquisition and transfer across auditory and visual modalities</i>	593
Hao Bai, Paul Ladny, J. Gregory Trafton, Randy J. Brou, Stephanie M. Doane	
<i>"That's what she said": The effect of emotional prosody on the interpretation of intent.</i>	594
Jennifer M. Roche, Rick Dale	

<i>Turn that frown upside down and to the left: Memory for faces is affected by their gravitational orientation</i>	595
Nicolas Davidenko, Stephen Flusberg	
<i>Individual Differences in Successful Second Language Learning: The Roles of Working Memory and Intelligence</i>	596
Brendan McCarthy, Mandy Faretta, Francis Wong, Patrick Wong, Ph.D., Kara Morgan-Short, Ph.D.	
<i>Individual differences in anticipatory eye-movements: Vocabulary size is associated with speed of noun-verb integration</i>	597
Arielle Borovsky, Jeffrey Elman	
<i>Reasoning through Mindful Actions: Effect of Instruction and Spatial Ability on Understanding Dynamic Systems</i>	598
Margaret Chan

Cognition in Flux

Stellan Ohlsson and Richard Catrambone
Conference Co-Chairs

The slogan “Cognition in Flux” was chosen to emphasize two points. First, cognitive research is to a large extent research into how cognition changes over time. Second, the field of cognitive research – our shared theoretical vocabulary and our repertoire of research practices -- is itself continually changing. Both points are well illustrated by the content of program for the 2010 meeting of the Cognitive Science Society.

Explaining change is a central enterprise in the cognitive sciences. We received approximately 850 submissions, covering all areas of cognitive research. The majority of those submissions focused on cognitive change in some form, whether it be through models of subsymbolic learning, developmental studies of word learning, experimental evaluation of training procedures, classroom studies of instructional techniques, or through models of brain-like computations.

The fact that cognitive science itself is changing is equally evident in the submissions. Perhaps the most stunning trend over the past three decades is the dissemination of cognitive science concepts, techniques and results to all areas of study that pertain to humans, social entities and computational entities. From its core concerns with memory representations, processing limits and problem solving strategies 30 years ago, the perspective of cognitive science has rolled outwards in an ever widening circle to reach areas of inquiry that were once thought to lie outside its reach. The 2010 program included papers that presented cognitive perspectives on blame and punishment, the explanatory coherence of religious thought and the detection of fraud in corporate email networks, to mention only a few of the topics that would have raised eyebrows three decades earlier.

The labels for sessions and tracks that emerged out of the pool of accepted papers reflected this widening ring of influence. We had, for the first time, a track on Social Cognition; with deliberate provocation, we included the session on Human-Robot Interaction in that track. Another interesting trend is that work on perception and action, the input-output devices relegated to the periphery of the cognitive system in the first decades of cognitive science, has migrated towards the center of focus. This trend was represented by multiple sessions on perception or action, and by several of the symposia. Another remarkable feature of the 2010 program is the extraordinary attention paid to issues regarding language. The entire track B and all but the first two sessions of track A were devoted to research on various aspects of language, and even so the topic of language spilled over into sessions in other tracks.

As the stock of research topics grows broader, the repertoire of research techniques grows also. This is necessarily so. A viable scientific enterprise does not define itself by its methods but by its questions. Methods are tools, and as the research questions morph, so do the tools for answering them. There was much evidence for the evolution of tools in the 2010 program. The Internet provides new ways of collecting data, and ways of collecting new types of data. New computational techniques are applied to reverse

engineer the mental representations of experimental subjects. New modes of analyses reveal novel phenomena. If we had any bias in organizing the program, it was a bias against basing sessions and tracks on the similarity of methods in favor of basing them on the similarity of research questions. Hence, there were no tracks on Bayesian models, studies of children or the use of eye movement recordings. Instead, papers that included Bayesian models, observations on children or eye movements were sorted with other papers that addressed the same or some conceptually related research question.

Of the approximately 850 submissions, 270 or 30 % were included in the program as talks. The two poster sessions on Thursday and Friday afternoon included more than 200 posters each. Papers and abstracts are included in full in these proceedings. The program also featured invited talks, tutorials, workshops and symposia. The latter are listed. We hope that the Proceedings will serve as a useful collection of cutting-edge papers.

CogSci 2010 Awards

Marr Prize

The Marr Prize, named in honor of the late David Marr, is awarded to the best student paper at the conference. All student first authors were eligible for the Marr Prize for the best student paper. The Marr Prize includes an honorarium of \$1,000 and is sponsored by The Cognitive Science Society.

The winner of the 2010 Marr Prize for Best Student Paper is:

Hyowon Gweon and Laura Schulz

Is it me or the world? 16-month-olds distinguish competing hypotheses about the cause of failed interventions

Saturday, 1:00 p.m., Track D

Computational Modeling Prizes

Four prizes worth \$1,000 each are awarded for the best full paper submissions to CogSci 2010 that involve computation cognitive modeling. The four prizes represent the best modeling work in the areas of perception/action, language, higher-level cognition, and applied cognition. These prizes are all sponsored by The Cognitive Science Society.

The winners of the 2010 Computational Modeling Prizes are:

Applied Cognition

Eldad Yechiam and Eyal Ert

Risk attitude in decision making: A clash of three approaches

Thursday, 12:00 noon, Track G

Perception/Action

Celeste Kidd, Steven T. Piantadosi, and Richard N. Aslin

The Goldilocks Effect: Infants' preference for stimuli that are neither too predictable nor too surprising

Saturday, 10:00 a.m., Track B

Language

Yang Xu and Charles Kemp

Constructing spatial concepts from universal primitives

Thursday, 1:30 p.m., Track A

Higher-Level Cognition

Daniel Rasmussen and Chris Eliasmith

A neural model of rule generation in inductive reasoning

Thursday, 10:30 a.m., Track C

Awards, Cont'd

Cognition and Student Learning (CaSL) Prize

The Cognition and Student Learning (CaSL) Prize is an honorarium of \$1,000 that is awarded to the best paper on research conducted on a topic directly related to cognitive science, educational practice, and subject matter learning. This prize is sponsored by the Institute of Education Sciences (IES).

The winner of the 2010 Cognition and Student Learning Prize is:

Daniel Oppenheimer, Connor Diemand-Yauman, and Erikka Vaughan
Fortune Favors the Bold (and the Italicized): Effects of Disfluency on Educational Outcomes

Saturday, 11:30 a.m., Track F

Student Travel Awards

Travel awards have been provided to students whose papers were accepted as oral presentations with the highest reviewer rankings, and who indicated a need for travel funding. The Robert J. Glushko and Pamela Samuelson Foundation generously sponsored \$10,000 for student travel awards for these papers.

The 2010 Travel Awards went to:

Jamie Alexandre	Kyle Jennings	Ben Rottman
Daniel Belenky	Brendan Johns	Solveig Bosse
Christopher Carroll	Artem Kaznatcheev	Peggy Tausche
Colin Dawson	Celeste Kidd	Haley Vlach
Heeyeon Y. Dennison	Itamar Lerner	Jing Xu
Hyowon Gweon	Khetarpal Naveen	Yang Xu
Nicholas Gwynne	Peter Pantelis	Benjamin Zinszer
Harry Haladjian	Daniel Rasmussen	

Awards Committee

Laura A. Carlson (co-chair), Thomas F. Shipley (co-chair), Erik M. Altmann, Felice Bedford, Gary Dell, Frank H. Durgin, Cynthia Fisher, Art Graesser, Scott Johnson, Barbara Landau, Jeffrey Lidz, Mark McDaniel, Ennio Mingolla, Willis F. Overton, Thomas J. Palmeri, Hal Pashler, Terry Regier, Alexander Renkl, Michael K. Tanenhaus, John Trueswell.

CogSci 2010 Sponsors

We sincerely thank the sponsors of the 32nd Annual Meeting of the Cognitive Science Society for their support of the conference awards and the tutorials, and for supporting student participation through reduced registration fees and coverage of travel costs.

Invited Plenary Presentations

Rumelhart Prize Lecture:

Emergence of Semantic Structure from Experience

James McClelland, Stanford University.

Thursday, August 12, 3:00 – 4:00 p.m.

A Hierarchical Competing Systems Model of the Emergence and Early Development of Executive Function

Philip Zelazo, University of Minnesota.

Thursday, August 12, 9:15 – 10:15 a.m.

Accelerated Learning through Adaptive, Data-Driven Instructional Design

Marsha Lovett, Carnegie-Mellon University.

Friday, August 13, 8:45 – 9:45 a.m.

Bridge Over Troubled Water: From Cognitive Science to Designing Digital Instruction

Peter Gerjets, University of Tübingen.

Saturday, August 14, 8:45 – 9:45 a.m.

Symposia

Rumelhart Prize Symposium:

Graded, Distributed, and Interactive: How Parallel Distributed Processing Has Influenced Cognitive Science.

Friday, August 13, 10:00 – 11:30 p.m.

This symposium honors the career of James L. McClelland, winner of the 2010 Rumelhart Prize. When Jay entered the field, cognitive science looked very different: representations and processes were thought to be modular, independent, symbolic, and discrete, and the discipline proceeded independently from neuroscience. Through computational modeling, elegant empirical studies, and close attention to neuroscience, Jay's work contributed to an alternative view: that cognitive representations are graded and not discrete; that representations and processes are highly distributed and non-modular; that cognitive processes are highly interactive and not functionally independent; and that information about the brain importantly constrains theories of cognitive functioning. This symposium illustrates how these themes have shaped current thinking in influential research on the graded nature of sublexical representations, the interactive nature of language comprehension and perception, the distributed nature of neural representations revealed by multi-voxel pattern analysis, and the functional and neuroanatomical organization of the semantic system.

Timothy T. Rogers, Bruce Hayes, Michael Spivey and Nikolaus Kreigeskorte

Invited Symposium 1:

Abductive Reasoning: Inferring Explanations.

Friday, August 13, 10:00 – 11:30 p.m.

The American philosopher Charles Peirce used the term abduction to describe inference to explanatory hypotheses, including both the initial generation of hypotheses and their evaluation, which is now commonly called inference to the best explanation. This symposium will discuss current interdisciplinary work on abduction, including research in artificial intelligence and linguistics (Hobbs), psychology (Lombrozo), philosophy (Magnani), and computational neuroscience (Thagard).

Paul Thagard, Jerry Hobbs, Tania Lombrozo, and Lorenzo Magnani.

Invited Symposium 2:

Balancing Internal and External Cognition: A Learning Process.

Friday, August 13, 10:00 – 11:30 p.m.

Human cognition is able to accomplish amazing feats, even though it has to deal with limited cognitive resources. A solution to dealing with cognitive limitations is to outsource as much as possible to the outside world: instead of relying on representations in the head we rely on representations in the world. In this symposium we will examine the relationship between information in the head and in the world, and how to optimize it. This can be in terms of finding the optimal division of labor between internal and external, to examine learning processes that converge to such an optimal solution, to study how external representations can lead to optimal teaching solutions, and how good performance in multitasking can be related to internal and external control.

Niels Taatgen, Wai-Tat Fu, Ken Koedinger, and Andrew Howes.

The following symposia are listed in the order in which they were presented:

Success in the Theory of Mind

Thursday, August 12, 10:30 a.m. – 12: 00 noon.

Peter wants to get the beer he left in the refrigerator. Predicting Peter's behavior correctly is usually an easy matter, but understanding how people correctly predict his behavior with ease is a much more difficult task. Thirty years of research on theory of mind has focused on the interesting few cases in which fail to reason about mental states correctly. However, it is perhaps more interesting to explore the common, reliable cases of successful theory of mind reasoning. This symposium presents cutting-edge research using several different experimental approaches to studying the processes involved in successful instances of theory of reasoning, as well as the processes involved in developing the ability to succeed consistently across the life span. In this symposium, research employing a variety of measures – with toddlers, preschoolers, school-age children, and adults – takes aim at current debates central to the field and delivers weighty results.

Rose Scott, Adam Petrashek, Noah Goodman, Adam Cohen, Rebecca Saxe, Renee Baillargeon, Ori Friedman and Tamsin German

Prospective Perception

Thursday, August 12, 12:00 noon – 1:30 p.m.

Recent data indicate that perception is inherently prospective (i.e., anticipatory). The purpose of this symposium is to examine the research of three scholars who approach prospective perception from three different theoretical perspectives: the Theory of Event Coding, the Economy of Action theory, and the Ecological Theory. The panelists will examine differences among these theories and address the extent to which prospective perception research affords a means of potentially integrate these three theories.

Jerome S Jordan, Jessica Witt and Michael Riley

The Philosophy of Affective Neuroscience

Thursday, August 12, 1:30 – 3:00 p.m.

This panel showcases the interdisciplinary cutting edge innovations of the cognitive sciences. It is the unique meeting of the founder of Affective Neuroscience with an interdisciplinary set of scholars who follow the implications of this work through the philosophy of psychology, the philosophy of Self, and neuroscience and law.

Rami Gabriel, Jaak Panksepp, Stephen Asma and Glennon Curran

Symposia, Cont'd

The Mechanics of Embodiment

Friday, August 13, 12:30 – 2:00 p.m.

There currently exist a large number of interesting and intriguing empirical effects regarding embodied cognition. A critical next step in the development of embodied theories is to flesh out ideas in terms of implemented computational models. This symposium features speakers who currently are working toward that goal. These researchers describe and discuss challenges for embodied models. The major focus is on presenting current efforts to model human cognition in a physical agent with sensory and motor capabilities, implementing the perceptual symbols systems framework, and modeling the dynamic on-line influences of integrated sensori-motor processes.

Giovanni Pezzulo, Angelo Cangelosi, Michael Spivey, Lawrence Barsalou, Martin Fischer and Ken McRae

Developmental and Computational Perspectives on Infant Social Cognition

Friday, August 13, 2:00 – 3:30 p.m.

Adults effortlessly and automatically infer complex patterns of goals, beliefs and other mental states as the causes of others' actions. Yet before the last decade little was known about the developmental origins of these abilities in early infancy. Our understanding of infant social cognition has now improved dramatically. Even preverbal infants appear to perceive goals, preferences, and even beliefs from sparse observations of intentional agents' behavior. Furthermore, they use these inferences to predict others' behavior in novel contexts and to make social evaluations.

Noah Goodman, Chris Baker, Joshua Tenenbaum, Chris Lucas, Kiley Hamlin, Tamar Kushnir, Tomer Ullman and Elizabeth Spelke

Emerging Insights from Eye-Movement Research on Category Learning

Friday, August 13, 3:30 – 5:00 p.m.

This symposium brings together four talks on eye-tracking and categorization. Each talk focuses on a different aspect of categorization and demonstrates how eye-tracking can extend our knowledge. One recent trend in category learning is the use of alternative training procedures. The inference learning task is the most popular of these procedures and in the first talk Aaron Hoffman presents eye-tracking data illuminating the differences between inference learning and categorization. Bob Rehder then presents his recent work on understanding the learning difficulties associated with Parkinson's disease. Marcus Watson discusses work using eye-tracking to inform our understanding of the basic issue in category learning: error. Finally, Mark Blair discusses the relationship between working memory, attention and performance in a category learning task.

Bob Rehder, Mark Blair, Aaron Hoffman and Marcus Watson

Symposia, Cont'd

Dynamic Decision Making

Saturday, August 14, 10:00 – 11:30 a.m.

The experimental study of decision-making has historically focused on simple single-trial judgment or reasoning tasks. However, real world behavior often necessitates on-line decision making, planning and sequentially organized behavior. The goal of the proposed symposium is to bring together researchers who are working to understand the cognitive processes underlying dynamic decision-making, defined as tasks or contexts that are structured as a sequence of interdependent decision. A symposium on this topic is particularly timely since research in this area is having a tremendous impact on the field of psychology. The key topics covered are: how people plan sequences of actions to accomplish goals; the neurobiology of sequential decision-making and planning; how cognitive representations of the task environment support planning and decision-making; and how people balance exploration and exploitation to arrive at effective decision strategies in unknown environments.

Todd Gureckis Jared Hotelling, Michael Lee, Bradley Love and Dylan Simon

Bridging the Gap: From Cognitive Anthropology to Cognitive Science

Saturday, August 14, 11:30 a.m. – 1:00 p.m.

Although cognitive anthropology once was a pioneer in the cognitive revolution and founding member of the cognitive sciences, over the years its participation and influence have diminished – to the detriment of both cognitive anthropology and cognitive science. Meanwhile, though, interactions between culture and cognition are increasingly recognized as being of prime interest for cognitive science. Among the most important issues that call for anthropological expertise is the question of cognitive and/or linguistic universals. Anthropology, with its expertise in culture and language, thus becomes an invaluable partner for cognitive science research. But only recently have initiatives been launched to re-calibrate the relationships among the subfields of cognitive science. This seminar will review such initiatives.

Andrea Bender, Sieghard Beller, Giovanni Bennardo, James S Boster, Asifa Majid and Douglas Medin

Flux: Fundamental or Frivolous?

Saturday, August 14, 1:00 – 2:30 p.m.

A broad range of findings across the cognitive sciences has emerged, revealing surprising flexibility and dynamic flux in a large range of cognitive domains. These include exciting new discoveries of neuroplasticity well into adulthood, of great cognitive variability as a function of the statistical properties of one's environment (from the patterns in natural language to those in embodied experience), and discoveries of the surprisingly dynamic microstructure of cognition. Do such findings demonstrate that many fundamental aspects of cognition are indeed quite flexible? Or does a finding that some aspect of cognition is flexible mean that it is therefore not fundamental? Or is flux the only truly fundamental thing about cognition in the first place? The talks in this symposium will speak to these questions from a variety of perspectives (incorporating ideas from development, neuroscience, computational studies, and cross-cultural approaches) and they aim to help us clarify our thinking about what such findings mean.

Lera Boroditsky, Helen Neville, Christina Karns, Arthur Markman and Michael Spivey

Workshops and Tutorials

All workshops and tutorials took place on Wednesday, August 11.

All Day Workshops

The Invited Workshop on Cognitive Social Sciences – Grounding the Social Sciences in Cognition?

Organizer: Ron Sun

9:00 a.m. – 17:00 p.m., Room A105

Compositional Connectionism in Cognitive Science II: The Localist/Distributed Dimension

Organizers: Ross W. Gayler and Simon D. Levy

9:00 a.m. – 17:00 p.m., Room A106

Semantic Development: An Interdisciplinary Approach

Organizers: David Barner and Susan Carey

9:00 a.m. – 17:00 p.m., Oregon Ballroom 204

Workshop on Understanding, Predicting and Mitigating Error in Routine Procedural Tasks

Organizers: Anna L. Cox, Duncan P. Brumby, and Jonathan Back

9:00 a.m. – 17:00 p.m., Room B110-111

Half Day Workshop:

Staying in the Academic Pipeline: Growing Professionally in an Economic Drought

Organizers: Janet van Hell, Laurie Feldman, Judith Kroll, and Suparna Rajaram

13:30 – 17:00 p.m., Room B115-116

All Day Tutorials

An Introduction to Agent-Based Computer Modelling for Cognitive Research

Organizer: Paulo Blikstein

9:00 a.m. – 17:00 p.m., Room 107-108

Bayesian Models of Inductive Learning

Organizers: Thomas L. Griffiths, Charles Kemp, and Joshua B. Tenenbaum

9:00 a.m. – 17:00 p.m., Oregon Ballroom 201

Doing Bayesian Data Analysis with R and BUGS

Organizer: John K. Kruschke

9:00 a.m. – 17:00 p.m., Room B113-114

Dynamic Field Theory: Conceptual Foundations and Applications in the Cognitive and Developmental Sciences

Organizers: Gregor Schoner, Anne Schutte, and Sammy Perone

9:00 a.m. – 17:00 p.m., Room B112

All Day Tutorial

Nengo and the Neural Engineering Framework: Connecting Cognitive Theory to Neuroscience

Organizers: Chris Eliasmith and Terrence C. Stewart
9:00 a.m. – 17:00 p.m., Room A109

Half Day Tutorials:

Tutorial on Model Comparison Methods

Organizers: Jay I. Myung and Mark A. Pitt
9:00 a.m. – 12:30 p.m., Room B115-116

Building Models of Learning and Expertise with CHREST

Organizers: Peter C. R. Lane and Fernand Gobet
9:00 a.m. – 12:30 p.m., Room A104

The CLARION Cognitive Architecture

Organizers: Nicholas Wilson, Michael Lynch, and Ron Sun
13:30 p.m. – 17:00 p.m., Room A104

Wild Systems Theory: Overcoming the Computational-Ecological Divide via Self-Sustaining Systems

J. Scott Jordan (jsjorda@ilstu.edu)

Department of Psychology, Illinois State University, Campus Box 4620
Normal, IL 61790-4620

Abstract

For years, there has been a tension between computationalist cognitive scientists who utilize the notion of representation and efficient-cause in their accounts of mind, and dynamical-systems oriented ecological psychologists who eschew representationalism and efficient-cause in favor of multi-scale, contingent interactions and embodiment. The present paper presents a recently-developed theory of embodiment, Wild Systems Theory (WST), that was developed to overcome this rift. WST conceptualizes organisms as multi-scale self-sustaining embodiments of the phylogenetic, cultural, social, and developmental contexts in which they emerged and in which they sustain themselves. Such self-sustaining embodiments of context are *naturally* and *necessarily* about the multi-scale contexts they embody. As a result, meaning (i.e., content) is constitutive of what they are. This approach to content overcomes the computationalist need for representation while simultaneously satisfying the ecological penchant for multi-scale contingent interactions.

Keywords: representation; phenomenology; embodiment; philosophy.

Wild Systems Theory

For years, there has been a tension between computationalist cognitive scientists who utilize the notion of representation and efficient-cause in their accounts of mind, and dynamical-systems oriented ecological psychologists who eschew representationalism and efficient-cause in favor of multi-scale, contingent interactions and embodiment. Wild Systems Theory (WST) is a new theory of embodiment that was developed to overcome this rift. My central thesis is that organisms (i.e., bodies) *are* meaning (and ultimately mind), precisely because they constitute embodiments of the external constraints (i.e., contexts) they have had to phylogenetically, as well as ontogenetically internalize in order to sustain themselves (Jordan, 1998). Within this framework, fins constitute an embodiment of the hydrodynamic properties of water, bones, an embodiment of the constraints that need to be overcome in order to propel a body through a gravity field, and teeth, an embodiment of the make-up of plants and what it takes to release the chemical energy they contain. In every case, these embodiments are *naturally* and *necessarily* “about” the environmental constraints they evolved to address. It is this necessary “aboutness” that I want to define as meaning and, ultimately *mind*.

But does this notion of internalized constraints really naturalize meaning and, ultimately mind? One could argue that the body of a submarine, the body of a car and the body of certain farm tools also constitute embodiments of water,

gravity and plants, respectively. Do they really constitute *meaning*? Of course, I have to say yes, but I would also add that this is not the type of meaning that ultimately evolved into mind. To be sure, the designers of submarines, cars and farm tools constructed such bodies so that their internal structure reflected the external constraints within which they have to function. The difference between these bodies however, and biological bodies is the means by which they sustain themselves. Biological bodies do so by continuously taking in, transforming, and dissipating energy. Non-biological bodies do not. It is my position that it is this wild, interactive-internalization of local context (i.e., energy transformation) that afforded, and continues to afford biological systems the means by which their embodied meaning was and is capable of evolving into mind. This is because the work (i.e., energy transformation) that constitutes biological bodies is *self-sustaining*. That is, it produces products that feed back into and sustain the work. Kauffman (1995) recognized this principle at the chemical level and referred to it as *autocatalysis*. Specifically, an autocatalytic (i.e., self-sustaining) chemical system is one in which the work (energy transformations) taking place among molecules, produces its own catalyst. By producing its own catalyst, the work sustains itself, as well as the system as a whole. Kauffman conceptualizes such work as a self-sustaining metabolism and argues that the emergence of such systems constituted the emergence of living systems.

According to Wild Systems theory, such self-sustaining “work” constituted a type of meaning—what Jordan and Ghin (2006) refer to as *content*—that proved capable of evolving into mind. It constituted *meaning* because the work, as well as the global whole it sustained, was naturally and necessarily “about” the external constraints the system had to embody in order to sustain itself. It constituted *content* because it gave rise to (i.e., was *for*) the global whole (i.e., the body) it sustained, while the body (i.e., the sustained global whole) synergistically provided a sustained context in which the internal work could be *for* something (cf., Bickhard, 2001; Jordan & Ghin, 2006). And it proved capable of affording the evolution of mind because it constituted a potential fuel source (i.e. encapsulated energy). That is, the energy entailed in such a system could be captured by another system. But to be capable of doing so, the latter had to internalize (i.e., embody) all the constraints that needed to be addressed in order to capture the energy encapsulated in the former. Said another way, once plant energy was widely available, it provided a context in which a system could emerge that sustained itself on plant energy. From this perspective, herbivores can be seen as

embodiments of the constraints that need to be internalized in order for a system to sustain itself on the energy encapsulated in plants, and carnivores, the constraints to be addressed to sustain a system on the energy encapsulated in herbivores. What we have here then, is a continuing recursion on a simple theme; specifically, *the fuel source dictates the consumer*. From this perspective, the world of nature is conceptualized as a self-organizing energy transformation hierarchy (Odum, 1988; Vandervort, 1995) in which any newly emerging systems constitute embodiments of the constraints they have to address to sustain themselves within this transformation hierarchy.

According to WST, within the context of such a self-sustaining hierarchy, *mind* emerges when systems emerge that are capable of embodying (i.e., internalizing) *virtual* content. By virtual, I simply mean content that is “about” events that are non-existent in the present context. Take, for example, a lion chasing a gazelle. Lotka (1945) recognized that in order to capture the energy entailed in the gazelle, the lion must propel itself as a whole on an *anticipatory* pursuit curve. What makes the pursuit curve anticipatory is the fact the lion runs toward a location the gazelle does not yet occupy. In short, it propels itself toward the gazelle’s *future*. The reason it can do so is because it has embodied (i.e., internalized) the constraint of having to capture a moving energy source. Specifically, certain structures in the lion’s cerebellum have access to both the movement commands leaving motor cortex, and the immediate sensory consequences of the resultant movements. These cerebellar structures project back up to motor cortex and influence its activity. This is important, for it affords the lion the ability to embody (i.e., internalize), in the weights of its cerebral-cerebellar circuitry, patterns between motor commands and their resultant sensory effects. Thus, as the lion garners experience controlling its body in relation to moving prey, successful command-feedback patterns become embodied in the cerebral-cerebellar circuits. And given these cerebral-cerebellar loops influence motor cortex and function at a time scale of 10-20 milliseconds, versus the 120 millisecond time-scale between motor commands and sensory feedback, the system can basically control its propulsion on *virtual* feedback (Clark, 1997; Grush, 2004) and, as a result, propel itself toward internalized (i.e., embodied) *virtual* prey locations (i.e., where the prey will be in the next 200 or so milliseconds).

There are five important points to be made about such *virtual* content. First, it is not virtual in the sense it does not exist. To the contrary, it does exist. It is virtual in the sense it is about *future* body-prey states. Second, it is possible for the lion to embed (i.e., embody) such content within its brain because neural networks function according to the principle of self-sustaining work. Hebb (1949) recognized this aspect of neural work and referred to it as the cell-assembly; the notion that neurons sustain themselves by becoming part of a neural network. Edelman (1989) also noted this principle in the developing brain, and referred to it as *Neuronal Darwinism*. In short, the work of being a

neuron (i.e., producing action potentials and forming synapses with other neurons) sustains the neuron. Thus, patterns of neural activity sustain themselves, and factors that cause neural patterns to repeat (i.e., command-feedback patterns in cerebral-cerebellar loops and their relationship to prey patterns) become embedded (i.e., embodied) within these self-sustaining neural patterns.

Third, all of this embodied work is naturally and necessarily about the external (as well as internal) contexts (patterns) that have to be addressed in order for the work to sustain itself; from the single neuron, to the neural circuit, to the neuro-muscular system, to the organism as a whole. Thus, there is no epistemic divide between internal and external states (including virtual states)—organisms are reciprocally nested eco-systems of self-sustaining work. They are a representation, at every level, of the phylogenetic, as well as ontogenetic constraints their species has had to overcome in order to sustain itself.

This leads to the fourth point. Virtual content emerged in self-sustaining systems precisely because of their need to capture energy that was on the move. The virtual content therefore, is necessarily about the *other*. That is, it is not just about the command-feedback patterns in the lion’s brain, but rather, the relationship between command-feedback patterns and their relationship to prey patterns. The point I’m after here is that the virtual content is inherently *other-relative*. If we assume that the ability to chase gazelles phylogenetically emerged prior to the ability to have self-consciousness about chasing gazelles, it seems to be the case that *others* were in the brain before the *self* was. In short, the brain has never been alone. This claim is supported by the discovery of areas in the brain (i.e., mirror neurons) that are active both when one plans a goal related action, as well as when one observes another execute such an action (Rizzolatti, Fadiga, Fogassi, & Gallese, 2002). This means that as others produce goal-directed actions, they simultaneously put my brain in a planning state for the same goal-related action. The discovery of such mechanisms indicates that resonance (i.e., doing what others are doing) constitutes the default value in human interaction. Kinsbourne (2002) agrees with this position and argues that infant imitation is actually uninhibited perception “on the fly”. Only as the cortex develops inhibitory circuits, he argues, are we able to “not” resonate to the actions of others. He cites echopraxia as further evidence of this claim. Rizzolatti et al. agree with this notion of resonance, and distinguish between low- and high-level resonance. While the former refers to the ability of an organism’s body movements to entrain similar movements in conspecifics (e.g., a school of fish moving together, or a flock of birds flying together), the latter refers to resonance at the level of goal related actions (e.g., a chimp watching another eat a peanut, or a person watching another dance). Collectively, these findings indicate that the *other* was embodied in the structure of the brain very early on, and has been there ever since.

And finally, the fifth point about virtual content is that it sets the stage for the emergence of phenomenal self-experience (Ghin, 2005; Metzinger, 2003). For since neural networks emerge and function according to the principle of self-sustaining work, the virtual content embedded in a brain is always available for “capture” by newly-emerging neural networks (Grush, 2004). The content of these new circuits will necessarily constitute an abstraction from the content embedded and sustained in the network it is tapping into.

As systems emerged that were capable of externalizing and sharing virtual content (i.e., communicate), the ability to “capture” such content required the system be able to distinguish its own, internally-generated virtual content from that entering the system from the outside. These are the constraints that I believe forced the emergence of “self” and “other” (Jordan, 2003c; Jordan & Knoblich, 2003; Knoblich & Jordan, 2003). In short, the self emerges as foreground amidst a background of virtual others, and it does so in order to sustain itself with those others in virtual contexts (i.e., within a world of ideas). The phenomenal self then garners its content (i.e., phenomenal properties) as do all self-sustaining systems; from the fact it is naturally and necessarily “about” the context (i.e., the externalized virtual content of others) it must embody in order to sustain itself.

The idea that the other has always been there, embodied within us, seems to render communication more an act of self-sustaining resonance among embodied others than an act of information exchange between lone cognizers. It does so because self-sustaining systems do not need to “perceive” their environment in order to be “about” it. Rather, they are naturally and necessarily about the contexts they have embodied, including the context of others. Environments therefore, including the world of others, modulate (versus ‘cause’) what self-sustaining systems are “about”. Communication therefore, at least among self-sustaining embodiments, is an act of reciprocal modulation (i.e., resonance). And in order for such resonance to sustain itself, participants must generate work (e.g., eye-contact, gestures and head nods) to sustain the joint modulation. In short, communication itself is a self-sustaining process. Instead of constituting work among chemical systems embedded in a pre-biotic soup however, it constitutes work among embodied others embedded in a sea of virtual meaning.

Overcoming the Divide

Given its ability to satisfy the concerns of both computationalists and ecological psychologists without violating the assumptions of either, WST might be in a position to integrate the two theories. As regards computationalism, WST address the notion of representation by arguing that all aspects of an organism constitute representations, in that, all aspects of the organism constitute embodiments of context. In short, an organism represents all the scales of context that have had to be addressed for it to phylogenetically emerge and sustain itself. Representation, therefore, is not a property that

distinguishes brains for other aspects of an organism. What distinguishes brains however, is the time-scale at which embodiment takes place. The emergence of a particular memory emerges and sustains itself at a much faster set of time scales than the time-scales by which individual neurons, neural nets, and entire brains emerge and sustain themselves. Regardless of this difference however, representation is there at every time-scale of self-sustaining work.

In addition to addressing representation in an ecologically-friendly way, WST also addresses computationalism’s reliance on efficient cause as an explanation of content manipulation. Computationalism is led to efficient-cause by its assumption there exist specific levels in a cognitive architecture that are sufficiently isolated from other levels to enable them to ‘bear’ content. This assertion is proving increasingly difficult to defend as neuroscience provides more and more data indicating the immensely recursive, interconnected nature of neural organization. WST address this issue by conceptualizing neural dynamics in terms of multi-scale, contingent interactions. Given such embodiments are naturally and necessarily about the contexts they embody, WST encounters no need to pose sufficiently isolated ‘vehicles’ of content. Content is constitutive of what self-sustaining embodiments are. And conscious and cognition are not so much computational processes that take place in specific levels of a cognitive architecture, as they are emergent levels of self-sustaining work whose ‘aboutness’ cannot be reduced to any one level of work. Consciousness and cognition are irreducibly ‘about’ all such levels of work.

Abstract

Theory in cognitive science often splits into those who treat cognition as occurring in individual minds those who treat it as situated or distributed, as irreducibly a matter of an individual-in-a-setting or of multiple individuals and artifacts. Prominent accounts have treated this split as between incommensurable paradigms (Sfard, 1998), competing theories (Greeno, 1997), and as complementary perspectives (Cobb, 1994). In the present paper, however, we argue that the accounts can be seen as theoretically continuous, differing in the scale of dynamics, such that a "society of mind" (Minsky, 1988) model of individual cognition is theoretically continuous with a "mind of society" model of social cognition. We sketch our framework and show how it leads to this continuity. We also argue that the relevant scale in any instance should be guided by the evidence, rather than based on purely *a priori* commitments.

Keywords: Modeling cognition; situated cognition; distributed cognition; resources; framing, education, collaborative learning

Theoretical Backdrop

Cognitive science has undergone dramatic advances that have forced us to question our basic assumptions of the nature of mind and its relation to the world. This progress has followed a path analogous to the conceptual changes in astronomy over the centuries. As astronomers have extended their gaze outward into the cosmos, they have revolutionized our view of the world and our place in it. These revolutions have been patently decentralizing—the Copernican revolution displaced the Earth from the center of the universe, and Einstein's cosmology went so far as to remove the very concept of 'center' from the universe.

A similarly decentralizing pattern of revolutions has also been the fruit of our gaze inward, using the tools and trade of cognitive science. While ancient views of consciousness assumed a central role for the heart, neuroscience has followed Hippocrates in focusing on the brain as lexicon of mental life (Finger, 2001). Descartes in particular placed the "center of consciousness" squarely between the ears by

postulating that the connection between spirit and body occurs in the pineal gland near the center of the brain. Modern cognitive science has shown that Descartes was wrong not only about the function of the pineal gland, but that the very concept of a 'center' can apply to consciousness and cognition—there is apparently no single place or time in the brain where it all 'comes together' (Dennett & Weiner, 1993). Vision provides a case in point: we have moved away from the assumption that the visual cortex functions something like a neural correspondence of our visual field, finding instead that vision is hierarchically distributed over various parts of the brain (Felleman & Van Essen, 1991)¹.

This decentralized view of mind has been highlighted by researchers working within the traditions of situated and distributed cognition. Sitativity theorists claim that cognition cannot be defined apart from the situation in which it takes place and so take the appropriate unit of analysis the individual-in-a-setting (Greeno, 1997; Greeno & Moore, 1993; Lave, Murtaugh, & de la Rocha, 1984). In a commonly cited example, Lave et al. (1984) argued that whether or not a person knows how to find 3/4 of 2/3 a cup of cottage cheese depends critically on how the person takes up the affordances of the situation at hand; whereas the person may be unable to solve the problem via manipulation of symbolic fractions, they may still get the correct result by manipulating the physical objects. Theorists of distributed cognition have decentralized the mind even further by considering how information processing can be distributed across multiple individuals as well as artifacts. Hutchins (1995) has detailed a paradigmatic example by arguing that it is the cockpit—not any individual pilot—that remembers the safe landing speed of an airplane.

¹ Even if one of the area of cortical 'projection' is damaged, so that a blindsight patient reports seeing nothing at all, their 'visual location' capabilities can be quite intact, as evidenced by their ability to 'guess' well above the level of chance where an object is in their field of 'vision'.

Meanwhile, researchers in the ‘cognitivist’ tradition have resisted extending the border of cognition past the most intuitively obvious one—the brain. Where we draw the line around cognition has important consequences for how educational research is carried out, the conclusions we can draw from such research, and the recommendations we can then provide to practitioners. Anderson, Reder, and Simon (1996), for example, argued that the educational implications of situated theories of learning are often misguided. They advocated for the importance of training by abstraction, in contrast to training purely through concrete examples as situated theories would seem to favor. In his counter, Greeno (1997) took issue with this characterization but did point out a specific instructional consequence of situated cognition: teaching algorithmic skills is insufficient for achieving one of the main goals of education, namely getting students to “reason successfully in their everyday activity outside of school” (p. 7).

The cognitivist, situated, and distributed perspectives appear to have drastically different ontologies of mind. After all, there seems to be a vast ontological divide between claiming that it is a person who is remembering, rather than a cockpit. Such conceptual differences have contributed to the miscommunication between these camps, as several researchers have noted (e.g., Greeno, 1997; Sfard, 1998).

In this paper, we sketch a framework for cognitive analysis that has the potential to bridge these major ontological rifts in cognitive science. This is afforded, in part, by the dynamic unit of cognitive analysis we adopt in our model. We suggest heuristics for basing the unit of analysis on the data, rather than prescribing the cognitive unit based purely on theoretical commitments. Our account thus has the potential to unify or coordinate these perspectives.

Our Theoretical Framework

We work from a view of mind as a complex, dynamic system involving manifold cognitive resources, a generalization in line with schema theory (Bartlett, 1932, Rumelhart, 1980), Minsky’s (1988) “society of mind” in which cognition is distributed within the mind across manifold “agents,” and diSessa’s “knowledge in pieces” (1993). “Resources” is a generic term for cognitive elements at various grain sizes that may be in different states of activation at any given moment (Hammer, et. al. 2005). For example, a student might explain the motion of a ball tossed into the air by saying it slows down as the force from your hand ‘dies away,’ but a moment later claim that it stops at the top of the trajectory because gravity has exactly balanced by the force from your toss². Rather than assume the student is utterly confused, we find it productive to explain the dynamics of reasoning in terms of activation of

fine-grained cognitive elements – “dying away” in one instance and “balancing” in the other (diSessa, 1993) – and the contextual features that cue these different resources. On this view, the phenomenology of reasoning is understood in terms of the activations of resources, of which there must be many kinds, including conceptual resources such as for understanding causal mechanisms (diSessa, 1993) or mathematical expressions (Sherin, 2001), as well as epistemological resources (Hammer & Elby, 2002), which will be of more central concern here. Resources often activate in stable patterns, and in what follows we will be concerned with the dynamics and patterns of resource activations, in particular with what the evidence suggests is involved in their formation and stabilities.

We refer to these patterns as “frames,” (Hammer, et. al. 2005), building from accounts in the literature of frames as structures of expectation (Bateson, 1955; Minsky, 1988; Tannen, 1993) that undergird our sense of “what is it that is going on here” (Goffman & Berger, 1974). In the analyses below, we focus on the dynamics of how students, as individuals or as groups, frame what they are doing primarily with respect to knowledge, which we refer to as *epistemological framing* (Redish, 2004).

Phenomenological and ontological views of framing

Describing a frame as a sense of ‘what is going on’ may be called a phenomenological view of framing. Most accounts in the literature on framing are phenomenological, focused on evidence of how individuals or groups understand what is taking place, as well as how individuals send “metamessages” (Bateson, 1955; Redish, 2004) to signal how they are framing the situation, in order to help each other interpret the accompanying message. For instance, a student who uses a rising intonation while offering an idea may convey more uncertainty than if they had delivered the idea with a falling intonation (Ward & Hirschberg, 1985).

Our account also incorporates an ontological view of framing by describing frames in terms of coherent activation patterns of resources. For instance, Rosenberg, Hammer, & Phelan (2006) found that when students framed their discussion of the rock cycle as “storytelling” they stably activated a set of epistemological resources including ‘knowledge as fabricated stuff’, ‘knowledge as mental imagery’, and ‘knowledge as connectable through causal relations.’

Dynamics of framing. The phenomenological accounts in the literature cited above emphasize the dynamic nature of framing—Tannen (1993) prefers the gerund to emphasize the dynamic process, citing Bartlett’s account of schemas as “active organized settings.” The ontological view suggests models of framings as emergent patterns in a complex system. We may ask, then, what contributes to the dynamics of the system?

We suggest that the stability of a framing, as a pattern of activations, may just as easily involve manifold resources within an individual mind as across minds or across minds

² Phenomenological primitives (DiSessa, 1993) are examples of resources, but this by no means exhausts the set nor scale of resources.

and materials. That is, given an ontology of mind as comprised of manifold resources—a society of agents or a complex system of conceptual primitives—it is natural to expect dynamics that involve particular resources of one mind interacting with particular resources of others. To put this succinctly, a “society of mind” view of individuals (Minsky, 1988) should be consistent and continuous with a “mind of society” view of social cognition. It is a question of the scale of the relevant system (or subsystem) that is involved in the particular phenomena under study.

Thus we look for evidence of what contributes to the dynamics, and we expect that the relevant unit of analysis may vary from the individual (or perhaps even smaller) to much larger groups. Here, we limit ourselves to groups of four. We look for evidence, as we elaborate below, in the data for the scale of the dynamics involved for any particular instance.

Dynamic Unit of Analysis

Since both resources and frames exist at many different grain sizes, and may be activated on many levels at once, it makes little sense to limit our empirical studies to one level of analysis. Roth (2001) has also argued for the need to dynamically focus on multiple ‘zoom’ levels while analyzing cognition, and has provided some of the epistemological justification for doing so. Mandelblit & Zachar (1998) have laid out ontological considerations that allow for a dynamic unit of analysis, and have discussed how such a tack may be useful in bridging disparate traditions in cognitive science.

Epistemological considerations One good reason to seek out a dynamic unit of analysis is to avoid the temptation of doing *a priori* science. By rigidly adhering to only one cognitive unit, we may be effectively telling the world how it ought to be. If the individual is the unit of cognition, this is something that should be empirically supported, not just theoretically presumed.

Perhaps the gravest risk of such myopia is that of missing salient data. We all know that our perceptions are contingent on our attention. So if we focus our attention merely on the individual as the cognitive unit, we risk missing critical data relevant not only to the behavior of that individual, but also the group or situation of which she is a part (e.g. a jury in deliberation, a romantic couple in an argument, or a group of students working on a problem). As Roth (2001) puts it, “[b]y changing focus and by zooming, phenomena pertaining to different fields of attention become visible and are of different grain sizes and time scales” (p. 55).

Ontological considerations In motivating the concept of a dynamic unit of analysis, Mandelblit & Zachar (1998) describe several varieties of fundamental unity. Each of these various forms of unity “is formed under *different environmental restrictions* and is characterized by *different patterns of correlation*” (p. 234, emphasis in original).

Physics provides many illustrative examples: The electron, for instance, is considered a spatially integrated unit in some circumstances (e.g. a point charge, or a small sphere of charge), but becomes an inseparable part of a dynamically integrated unit called a “Cooper pair” within a superconductor. Although such an ontological commitment violates some of our intuitions about what an “object” is, it is underwritten by the explanatory and predictive success of the BCS theory of superconductivity.

A dynamic unit of analysis also has explanatory and predictive power in the social sciences. It is often noted that people can form groups that are more (or less) than the sum of their parts, and although this may sound like mere rhetoric, it becomes a matter of practical significance when considering the differences between how individuals and groups act and make decisions. That crowds behave coherently as a unit and in ways that differ substantially from how the individuals that comprise them might otherwise act has long been noted (see McPhail & Wohlstein, 1983 for a review), and has important consequences in many areas including, for example, fire safety (Cocking & Drury, 2008). Research on small groups has found important differences between how individuals and groups make decisions, something that has important consequences for some of our most influential decision makers, such as juries. Studies of simulated juries suggest that juries are, as Moscovici & Doise (1994) have put it, “something other than a dozen jurors” (p. 110) since they polarize towards the majority opinion regardless of what that opinion is (e.g., Myers & Kaplan, 1976). Although such research is far removed from our own work, it does highlight the need for a way of incorporating multiple units of analysis into a theoretical framework of decision-making, behaviors, and cognition.

Empirical considerations Our empirical work has led us to posit a set of heuristics for identifying the cognitive unit, which is to say the scale at which the evidence suggests the dynamics of framing occur: *clustering*, *persistence*, *resistance*, and *transitions*. Each of these guides us in making a reliable identification of the unit of cognitive analysis at various grain sizes and time scales. We describe these heuristics in greater detail elsewhere (Conlin, Gupta, & Hammer, forthcoming).

Scherr & Hammer (2009) provides an illustrative example of the work that motivated these heuristics. They found that in small student groups working on physics tutorials, various behaviors tended to cluster together both within and across the students. They identified four distinct clusters, which were sufficient to account for most of the time spent in tutorial. These clusters can be stable for several minutes on the level of the student group. Scherr & Hammer also provided instances in which a cluster was resilient to bids from students to change clusters. The groups, when they did transition, tended to do so abruptly and synchronously. These clusters and the timing of the transitions were coded

with over 90% inter rater reliability, within 5 seconds accuracy.

These four behavioral clusters indicated four distinct epistemological frames (Scherr & Hammer, 2009). One frame corresponded with disproportionate quality of evidence for a measure of scientific reasoning (Conlin, Gupta, Scherr, & Hammer, 2009,). We will now offer two brief analyses of video data from these tutorials in order to illustrate the utility of having a dynamic unit of cognitive analysis.

Data & Discussion

The data comes from an algebra-based introductory physics course in which the students participated in worksheet-guided inquiry discussions (i.e., ‘tutorials’). The students were mostly pre-med majors, and the worksheets focused on conceptual and epistemological issues in physics.

The students get many conflicting metamessages from the tutorials—messages about how to interpret what sort of activity they are engaged in and how to act accordingly. For example, students are given a worksheet, and this document can be framed in many contrasting ways. For instance, they may see the worksheet as “something to be completed,” an interpretation they have long associated with worksheets in their school experience. On the other hand, they may see them as “something to guide them through their discussion,” which was explicitly encouraged in several ways. One metamessage meant to encourage such a framing is the seating arrangement: there are four stools placed around a table so that the students faced inward, which is a common way of setting up a classroom for a discussion.

The tension between these alternate interpretations is typically never resolved once-and-for-all by the students. Rather, what we have found is that their behaviors indicate that their framing of the tutorial changes over multiple time scales—over the course of a few minutes, or over the whole hour of tutorial, or over the course of the semester. We have focused primarily on the minute-to-minute dynamics in framing.

Clustering heuristic applied to the individual

Throughout the course of the tutorial, the students exhibit a range of behaviors. It has been observed that a small set of behaviors tend to cluster together for each individual student in the tutorial. For instance, a student’s gaze angle, hand position, and posture do not vary independently from each other but rather consistently cluster together in a few distinct sets. Two such sets are depicted in Figure 1. A downward gaze tends to cluster with hands on the table (often writing or resting) and a hunched-over posture (Fig 1a), while a horizontal gaze angle clusters with hands off the table (often gesturing) and an upright posture.

Figure 1: (a) and (b) Two different behavior clusters for an individual

Clustering heuristic applied to the group

The same clusters of behaviors that are found on the individual level also are found at the group level. In fact, it was at the group level the behavioral clusters first drew Scherr’s attention via abrupt and synchronous transitions by the group from one cluster to another. The clusters persist across individuals from tens to hundreds of seconds and just four distinct group-level behavioral clusters were enough to account for about 86% of time spent in a single tutorial session.

The tutorial groups’ behavioral clusters serve as a robust and reliable indicator of the group’s framing of the activity. There is a high degree of inter rater reliability (95% on the cluster code, 90% on the timing of the transitions). The coding is done without a transcript³ and the analysis of discourse confirms the nature of the frame. The fact that the group spends most of the tutorial transitioning back and forth synchronously between the same set of activities indicates that it is appropriate to take the group (as well as the individual students) as the unit of analysis.

In what follows, we present two cases from our corpus of data and analyze them in light of our empirical heuristics. The first case supports taking the group to be the unit of cognitive analysis, while the second does not.

Case of group level cognitive analysis

This case comes from a tutorial on Newton’s third law, during which the students are to find the speed a car gains when hit by a truck of twice the mass that loses 5m/s. In the first part of clip, the students are all looking down, so there is clustering of gaze angle across students. They are also hunched over, speaking softly, with their hands on their desks and their eyes on their worksheet. This is what Scherr and Hammer (2009) called the *blue* behavioral cluster (Fig 2a).

There is a sharp transition in behavior, in which the students all sit up, make eye contact, use animated voices, and gesture prolifically. This is what Scherr & Hammer (2009) called the *green* behavioral cluster (Fig 2b).

³ The coding can be reliably done without even listening to the content of the speech.

Figure 2: The blue (a) and green (b) behavioral clusters.

Analysis of the group's discourse also falls in line with this transition. While in the blue cluster, the students are making intuitive guesses of the answer to a tutorial question (e.g., "Car speeds up by five"), with little or no justification provided. Along with the transition to the green behavioral cluster comes a corresponding transition in the substance of their discourse. They begin to describe the mechanism at work in the physical situation described in the worksheet question, as evidenced by metaphorical gestures of the collision as well as an analysis of the group's mechanistic reasoning (Russ, Scherr, Hammer, & Mikeska, 2008). When taking the behavior and discourse in conjunction, it becomes apparent that the group as a whole is changing activities from what might be called *completing the worksheet* to one of *having a discussion*. This transition also comprises a shift in activated conceptual and epistemological resources that are distributed across individuals, such that the activities of *completing the worksheet* and *having a discussion* are frames definable at the group level.

Case of individual level cognitive analysis

A contrasting example comes from a different group, working on a shadows and light tutorial, in which they are asked whether the light made by a bulb shining through a through an aperture onto a screen will move up or down when the bulb is lifted, and why (Lising & Elby, 2005).

Figure 3: Lack of clustering of behaviors across students.

In this clip, there is no cohesive clustering of behaviors across students, and there is a lack of cohesion in their speech. Although their discourse centers on the same conceptual content, they are at this moment engaged in very different epistemological activities.

One student, Veronica, provides an intuitive explanation for why the light would go down as the bulb goes up, using gestures and colloquial speech. Another student, Jan, provides an 'explanation' that amounts to a gerrymandered list of physics vocabulary. When Veronica objects, "you're

making it too complicated," Jan explains that she is "just trying to make it more physics oriented." Veronica retorts, "It is physics oriented. It's just how it is." Even though they both report taking part in a 'physics oriented' activity, through their activities and speech they express very different notions of what 'physics oriented' entails. For Veronica it apparently means explaining 'how it is,' while Jan thinks using words like "vectors" and "polarized" make it more 'physics oriented.' Their individual behaviors cluster with individualized epistemological and conceptual stances, and thus do not warrant a group level of analysis (for this interaction).

A Common Basis for Cognition in Action

There has been disagreement over the nature of the distinction between cognitivist, situated, and distributed accounts of cognition. This disagreement has fueled debate over how the debate can be settled, whether it can be settled, and even whether it *should* be resolved. While Anderson, Reder, and Simon (1996) have suggested the debate largely concerns the use of language, Greeno (1997) has contended that the issue can be settled as it becomes clear which tradition is better equipped for doing productive empirical work.

Others have argued that the distinction between cognitive and situated accounts of cognition lie with their preferred metaphors for learning. According to Sfard (1998) cognitivists follow a long tradition of viewing learning as an *acquisition* of knowledge, while situativity theorist view learning as an evolution of *participation* within a community of knowing. Rather than resolve their apparently incompatible ontological claims, she argues that they should be considered incommensurable and complementary. She thereby advocates for the peaceful coexistence of the paradigms, since "empirical evidence is unlikely to serve as an effective weapon in paradigm wars" (1998, p. 12).

We argue that our alternative account affords an ontological continuity between the cognitivist and situated/distributed traditions. Thus, in our account we can avoid the metaphorical paradigm war by distilling the choice of metaphor to an empirically informed decision about the unit of analysis. We therefore avoid surrendering to incommensurability, which if taken seriously leads to formidable methodological problems (and if taken *too* seriously descends into naïve relativism). Cobb and Bowers (1999) have also noted the need for a common basis for communication between these paradigms in order to avoid methodological problems. We hope that our account will provide such a basis, since it is founded upon established theories of cognition and is compatible with the connectionist principles that undergird both sides of the cognitivist/situativist divide.

Conclusion

We have described an account of cognition, in terms of resources & framing (Hammer, et. al., 2005), that provides

an ontological and epistemological basis for connecting these traditions within cognitive science. This connection is made possible by adopting a dynamic unit of analysis that can be grounded in the data, rather than based on entrenched theoretical commitments. We have provided empirical heuristics for assessing the unit of analysis. Finally, we have shown two contrasting empirical analyses to demonstrate the empirical nature of the unit of analysis as afforded by the resources & framing account.

One of the most remarkable aspects of cognition that science has uncovered is its decentralized nature—we have learned that there is no one place where our perception, thought, and conscious experience all ‘come together.’ Given the decentralized, distributed, and contextually sensitive functioning of the brain during cognition, it is not such a stretch to extend the distributed nature of cognition past the skull and into the surrounding environment. Although this may seem counterintuitive, the empirical and theoretical gains made by doing so may warrant the refinement of that persistent intuition that our minds reside in—and are confined to—our heads.

Abstract

Personality is the unique patterning of affect, behavior, cognition and desires in individuals across time and situations. This patterning can occur on different information processing levels, specifically, the Reactive, Routine, and Reflective levels (Ortony et al., 2005), across these four domains. Reinforcement Sensitivity Theory (RST; Gray & McNaughton, 2000) provides a biological account of the functional subdivision of the reactive level into the approach, avoidance, and conflict systems. These systems differ in their sensitivities to different classes of cues, giving rise to personality differences. But, individuals also differ at the routine and reflective levels in terms of how they respond (cognitively, affectively, behaviorally and motivationally) to approach situations, avoidance situations, and internal conflicts. In this paper, we discuss how the approach-avoidance-conflict (AAC) triad can be used as a broad framework for incorporating personality and individual differences into theories of human cognitive architectures. We also present work in progress on a computer implementation of the AAC triad at the reactive level.

Keywords: Reinforcement Sensitivity Theory, Personality, Behavior, Affect, Motivation.

Introduction

A trolley is hurtling along a track toward five children, all of whom are tied to the track. Should you flip a switch to divert the trolley onto another track on which only one child is tied so that only one life is sacrificed instead of five?

The moral dilemma posed by this well-known “trolley problem” illustrates the presence of high level motivational conflicts that arise when incompatible goals and values are coactivated. In this case, one would want to save the five lives but at the same time avoid taking the life of another. The recognition that the conflict exists results in rumination and reasoning as an individual seeks to resolve the conflict. Internal conflicts of this kind often occur in social situations, as for example, when a person wants to approach a potential date while also wanting to avoid rejection. Such conflicts lead to indecisive behavior such as dithering between approach and shyly looking away, and paying greater attention to hints that might inform the individual if approach (or shying away) would be a more suitable course of action.

Important in the present context is the fact that individuals differ in how they perceive and weigh alternatives (taking a life versus not saving a life), and how they handle different (approach or avoidance) goals and conflicts. Reward oriented individuals are prone to engage in riskier behavior, such as brazenly approaching a potential date. In the same situation, punishment oriented (averse) individuals will be more likely to shy away for fear of rejection. Yet others, who are

prone to indecisiveness, are likely to spend time ruminating about the pros and cons of approaching and avoiding. We believe that this patterning of affect, behavior, cognition and motivation occurs across all three information processing levels proposed by Ortony et al. (2005) in their (ONR) model, from the reactive (lowest) to the reflective (highest). For instance, chronically goal/reward oriented individuals tend to exhibit more pro-social behavior (e.g., attending lively parties, dating more often; Paunonen, 2003), and are biased toward speed (maximizing hits) rather than accuracy (avoiding misses) when completing simple reactive tasks (Higgins & Spiegel, 2004).

Many models of the human cognitive architecture have been proposed, for example in cognitive psychology (Anderson & Lebiere, 1998; Ortony et al., 2005; Broadbent, 1971), personality psychology (Carver et al., 2009; Revelle, 1993), and artificial intelligence (Sloman & Chrisley, 2005; Newell, 1990). Many of these architectures, such as H-CogAff, ACT-R, and Soar, are highly elaborated and have been studied in great detail. However, although personality is a key moderator of individuals’ affect, behavior, cognition and motivations, there has been little effort to include an account of personality and individual differences in these architectures. On the other hand, computational models of personality focus on describing specific aspects (e.g., the motivational aspect; Read et al., 2010) of personality but not the systematic integration of personality in the broader framework of cognitive, affective, motivational, and behavioral processes.

In this paper, we argue that there are three main classes of sensitivities (sensitivity to cues for reward, cues for punishment, and internal conflict), related to approach, avoidance, and conflict resolution (AAC) respectively, and that the AAC framework has implications for how different cognitive processes interact with each other and how the mechanisms driving personality and individual differences can be modeled systematically. Behavioral/motivational processes are commonly studied in terms of approach and avoidance (e.g., Carver et al., 2009; Elliot & Thrash, 2002). An individual’s sensitivities to cues for reward and for punishment refer to how that individual’s approach and avoidance systems react to and learn from such cues. Inspired by RST, we propose that conflict resolution is a third component that should be considered in conjunction with the approach-avoidance pair, and that it is associated with the sensitivity to conflicts. We define sensitivity to conflicts as the threshold beyond

which incompatible behavioral tendencies activate the conflict system—a system that we take to be distinct from the approach and avoidance systems and that is responsible for triggering conflict resolution processes (e.g., information gathering and rumination). Differences in the three kinds of sensitivities underlie broad personality dimensions such as the Giant 3 (Extraversion-Neuroticism-Psychoticism; Eysenck et al., 1985) or the Big 5 (Openness, Neuroticism, Conscientiousness, Extraversion, Agreeableness; Costa & McCrae, 1992; Goldberg, 1990). The AAC triad allows us to study how personality arises in individuals and how it influences cognitive processes like strategizing or resolving dilemmas, enabling us to address questions such as why, in the same situation, the plans an extravert makes differ from those of an introvert?

We believe that a theory of human cognitive architecture should be capable of accommodating differences in the ways in which different individuals feel, want, think, and act. To this end, our current work examines the structure of the reactive, routine and reflective levels (in the ONR model) in terms of the AAC triad, and looks at how these structures influence the organization of different parameters in systems. Our goal here is to propose a general framework that augments existing architectures to help in thinking about personality, and to elucidate how high and low level processes interact with each other.

The Approach-Avoidance-Conflict (AAC) Triad: From the Reactive to the Reflective Level

The Reactive Level

According to the ONR model, at the lowest level, behavioral responses to environmental cues are immediate and reactive. Automatic responses like the instinctive flight at the sight of a predator belong to this level. Reinforcement Sensitivity Theory (RST; Gray & McNaughton, 2000) was originally developed as an animal model of fear and anxiety, and has also been extensively studied in personality psychology (Corr, 2008; Smillie et al., 2010). RST proposes three functionally distinct subsystems—the Behavioral Approach System (BAS), the Fight-Flight-Freeze System (FFFS) and the Behavioral Inhibition System (BIS), each responding to different classes of cues with different sensitivities. RST offers neurobiological evidence that low-level, rapid behavioral responses, which we think of as the reactive level, have, at least functionally, the approach-avoid-conflict triadic structure.

The Approach-Avoid-Conflict Triad in RST The BAS, FFFS and BIS handle approach, avoidance, and conflict respectively. The approach system (BAS) is associated with the dopamine system and reacts to cues for reward, and is implicated in the learning of reinforcing signals of reward. The reactivity of BAS is highly correlated with trait extraversion and an individual who has an overactive BAS is prone to exhibit impulsive approach behaviors toward hedonic rewards.

Similarly, the avoidance system (FFFS) handles cues for punishment. The FFFS is primarily associated with fear, panic and avoidance behaviors, resulting from the activation of the periaqueductal grey, medial hypothalamus and amygdala regions of the neural system. The avoidance system is specifically modulated by panicolytic (suppression) and panicogenic (stimulating) drugs; individuals with a high sensitivity to cues for punishment are susceptible to phobias and panic attacks.

A major part of RST focuses on the functions of the conflict system (BIS). This system is associated with the septohippocampal system (SHS) and its major role is to detect conflicts and trigger appropriate conflict resolution behavior. The BIS handles two forms of conflicts: conflicts in motivations, and conflicts in expectations. Motivation conflicts occur between or within the approach and avoidance systems. An example of an approach-avoid conflict is the desire to escape from a burning building conflicting with the desire to save a trapped loved one. Expectation conflicts occur either when a stimulus is detected but not expected (novelty) or when an expected stimulus is absent. Examples would be suddenly seeing a furtive shadow in your house at night (novelty), or turning on the lights expecting to see a burglar but seeing an empty room instead (absent expected stimulus). The BIS detects such expectation violations with a comparator (the CA3-comparator in the SHS) that compares the signal (presence or absence of an expectation) from the entorhinal cortex stream and the signal (presence or absence of an actual stimulus) from the medial septum. When conflicts are detected, the BIS sends inhibiting signals to the conflicting systems to inhibit prepotent responses, and triggers behaviors such as information gathering. Importantly, the BIS does not actually resolve conflicts but rather triggers potentially appropriate higher-level cognitive processes and behaviors to do the resolution. Unlike the FFFS, the BIS has been shown to be insensitive to panicolytics/panicogenics but instead responds to anxiolytic/anxiogenic drugs. The BIS is therefore a separate system that is specifically associated with anxiety (as opposed to fear that is associated with the FFFS) and is implicated in Generalized Anxiety Disorders. The BIS is also highly correlated with trait anxiety and neuroticism. At least from a functional standpoint, different individuals must possess different thresholds (sensitivities to conflict) for the activation of the conflict system, and these thresholds are independent of and exist in parallel with the sensitivities to cues for reward and punishment that reside in the approach and avoidance systems respectively.

The Routine Level

The routine level resides between the reactive and reflective levels and deals with habitual, routinized behaviors. It deals with expectations over a longer time span than the moment-to-moment activities in the reactive level. While the reactive level is concerned with cues and their immediate implications, such as hearing a gunshot close by and instinctively taking cover, the routine level deals with more sophisticated

expectations and implications of cues. For example, the series of actions one executes after making the decision to drive home—getting into one's car, putting the key into the ignition, and turning the key with a foot on the brake.

As in the reactive level, individual differences can be analyzed at the routine level in terms of approach, avoidance and conflicts. Consider individuals at a party. In this case, a conceivable routinized behavior is the act of approaching and talking to a stranger. Extraverts, having a high sensitivity to cues for reward, may have learned that a stimulating conversation is rewarding, and so tend to engage in such approach behaviors. On the other hand, individuals who are highly sensitive to punishing cues tend to be afraid of approaching others at parties (Costa & McCrae, 1980) and so tend to engage in routine avoidance behaviors such as staying away from large groups. Individuals who are sensitive to conflicts (who can also, independently, differ in their sensitivities to cues for reward and punishment) easily feel frustration or annoyance if a conversation turns out to be less stimulating than expected, or feel anxious and unsure when the conversation partner shows signs of boredom, prompting the individual to try even harder to make the conversation work. This latter case should be differentiated from ones in which an individual is very sensitive to cues for punishment, in which case the individual will likely back off and try to avoid conversation altogether.

The Reflective Level

Often known also as the deliberative level, the reflective level is the home of high-level cognitive processes such as planning and conscious reasoning. The reflective level functions as the overall executive control that 'oversees' the operation of the lower levels. However, we want to suggest that the reflective level also embodies the same triadic AAC structure with individual differences in the corresponding sensitivities.

Of course, appeal to the approach-avoidance dyad in studies of motivation is anything but a new idea. It can be found in numerous theories (see Elliot 1999 for review), and it is widely recognized that individuals differ in their sensitivities to reward and punishment on the reflective level (Carver & White, 1994; Torrubia et al., 2001). Although most such studies have been designed to assess aspects of RST (which is reactive) in humans, the items in instruments used to do this in fact tap into routine and mainly reflective level processes. For example, the Sensitivity to Punishment, Sensitivity to Reward questionnaire (SPSR; Torrubia et al., 2001), includes items such as

- Does the good prospect of obtaining money motivate you strongly to do some things?
- Do you often renounce your rights when you know you can avoid a quarrel with a person or an organization?
- Do you think a lot before complaining in a restaurant if your meal is not well prepared?

The behaviors that correspond to such items obviously involve very reflective processes. Similarly, Regulatory Focus theory (Higgins, 1997) shows that there are chronic individual differences in motivation. A promotion-focused individual is concerned with nurturance-related motivations and is therefore sensitive to cues for reward. In contrast, a prevention-focused individual focuses more on security related needs, resulting in a bias toward cues for punishment. Regulatory Focus theory has been studied in a wide variety of contexts including goal pursuit and moral judgments, indicating that at least the approach-avoidance structure and individual differences in sensitivities to different classes of cues do exist on the reflective level.

However, the conflict system and individual differences in sensitivity to conflicts have received much less attention than the approach-avoidance pair, even though it is just as important an aspect of the motivation system. As already mentioned, conflicts arise within and between the approach and avoidance systems, but an individual's sensitivity to conflicts is independent of the sensitivities to cues for reward and punishment. It might be tempting to equate sensitivity to conflict with sensitivity to cues for punishment, but as the sample item from the SPSR questionnaire about complaining in a restaurant indicates, there is a difference between experiencing the conflicting desires of seeking redress and avoiding potential unpleasantness with the restaurant staff, on the one hand, and simply having a high desire to avoid unpleasantness, on the other. The experience of conflict triggers rumination about the choice that the individual faces, whereas the desire to avoid the unpleasantness of a confrontation could have been avoided by the person just leaving when the service was bad. Functionally, sensitivity to conflicts is the threshold that determines *when* a conflict is experienced and produces a separate class of affective states and behaviors from those that result from simple approach or avoidance. The rumination, anxiety, and heart-wrenching despair that arise when one is forced to make choices are the products of internal conflicts and are not mere amalgams of behavior or affect produced in the approach-avoid systems. If one thinks of approach and avoidance tendencies as having different activation levels, then the sensitivity to conflicts is the threshold above which activation levels of incompatible motivations are experienced as internal conflict, while sensitivities to cues for reward and punishment influence how fast the respective activation levels change.

Connecting the Levels

The structure described in the previous sections provides a general framework for organizing personality parameters and for suggesting how these parameters might influence processes on the reactive, routine, and reflective levels. In appealing to the AAC structure we, of course, do not mean that, for example, a reflective level module should be split into three; we are certainly not proposing an approach-planning module, an avoidance-planning mod-

ule and a conflict-planning module, each associated with a distinct brain region. Rather, we are suggesting that there exist at least three broad classes of parameters which influence an individual's selection of and access to different classes of strategies, or memories, or knowledge. We argue that broad personality dimensions arise from systematic differences in the set points of these parameters and should be modeled as such in cognitive architectures.

The patterning of a person's sensitivities is consistent across the different levels of processing. So, for example, a person who is highly sensitive to cues for reward reacts and learns faster to cues for reward, engages more readily in habitual behaviors that he or she associates with reward, and values high level achievement goals. The consistency also implies that the relative relationships between the different sensitivities are preserved across levels. Therefore, a person who has a relatively higher sensitivity to cues for punishment than rewards will exhibit this difference in sensitivities across the three processing levels. The absolute magnitude of the sensitivities on each level can differ, but the relationships should remain consistent. Inconsistencies in the biases could explain behaviors that might be viewed as uncharacteristic of a person, as for example, when a person who typically values safety and security indulges in a spur-of-the-moment risky behavior such as reckless gambling.

Another consequence of the AAC structure is that similar systems on the three levels might be more tightly coupled than they are to others. That is, other things being equal, an activated approach system on the reactive level is more likely to cause responses in the approach systems on the routine and reflective levels, acting as a mechanism for the endogenous generation of related higher level goals and actions (e.g., Cacioppo et al., 1993). Consider the case of being the target of a scathing remark. The immediate reactive response might be to lash out and perhaps even to retaliate physically. However, because of the fear of reprisal and possible physical harm to oneself, the immediate response is suppressed. The reaction to the stimulus (insult) can trigger higher level processes, for example, to devise an elaborate plan for exacting revenge that acts to suppress the reactive level urge. The reverse also holds, where higher level goals and values, being more persistent, bias the perception of and sensitivity to different cues at the reactive and routine levels. An example is the cognitive bias that results from different task framing which influences actual task performance. Anxious students who want to do well, but are afraid of being seen as incompetent, perform better when the task is reframed to emphasize its difficulty (Born et al., 2002; Weiner & Schneider, 1971). In the case of the reframed task, the system that deals with wanting to avoid appearing incompetent is less activated because the task is perceived as being highly difficult anyway, and therefore reduces conflict with the approach system, resulting in lower state anxiety and allowing approach system behaviors (e.g., persisting in performing the task) to manifest themselves.

Implementing the AAC triad on the Reactive Level

Our prototype implementation of the AAC structure on the reactive level is inspired by RST and is combined with the Cues-Tendency-Action (CTA) re-parameterization of the Dynamics of Action model (Revelle, 1986; Atkinson & Birch, 1970). CTA models the dynamic interaction between cues and tendencies within and between the approach, avoidance and conflict systems. In particular, it models the interaction between conflicting tendencies and actions. It also includes the feedback mechanism for the interaction of consummatory actions with the behavioral tendencies. The hybrid RST-CTA architecture is shown in Figure 1.

The model is implemented on a set of virtual characters using the Twig animation system (Horswill, 2009). Screenshots from the simulation are shown in Figure 2. The focus of our simulation is the yellow child, who interacts with the red child, the ball, and the yellow adult—his parent. The yellow child perceives the other “objects” (i.e., the red child, ball, and adult) in the environment as stimuli. An input stimulus perceived by the agent (yellow child) is a tuple comprising the object, the object's action and the object's distance from the agent, in the form $I = (\text{name}, \text{action}, \text{distance})$. For example, $I = (\text{red child}, \text{play}, 2.3)$ indicates that the yellow child sees the red child playing 2.3 distance units away.

The expectation module (Figure 1a) uses the input I to form an expectation about what type of cue the stimulus is along four dimensions—reward (R+), non-reward (R-), punishment (P+) and non-punishment (P-). For instance, the red child is a cue for both reward (R+, playmate) and punishment (P+, aggressive child), the degree of which is scaled by his action (R+ is higher if the red child is being friendly) and distance (an aggressive child is less threatening if he is further away). The agent also uses the current stimulus (I) and information he has about its current action (A) to generate an expectation of what he should expect at the next moment. For example, a hostile red child is expected to approach the agent aggressively after issuing a threat (see Figure 2b) and the expected action will be flagged as highly punishing (P+), and if the agent runs back to the adult, he will expect to attain a certain amount of safety when he is close to the adult (P-).

The behavioral tendencies (Figure 1b) react to the input stimulus based on how the stimulus is evaluated along the four dimensions (R+, R-, P+, P-) with different sensitivities. A stimulus can cause changes to more than one behavioral tendency. In the case of the red child who is both a R+ and P+ to the yellow child, the presence of the red child activates the yellow child's tendencies to both approach and avoid. The module also responds to consummatory actions taken by the agent at a rate defined by the sensitivity S_{cons} (Figure 1h). For example, the act of playing with a ball is a consummatory action that reduces the tendency to continue playing.

The BIS module (Figure 1c) detects conflicts in behavioral tendencies and expectations, and responds by activating information-gathering behavior and inhibiting the conflicting

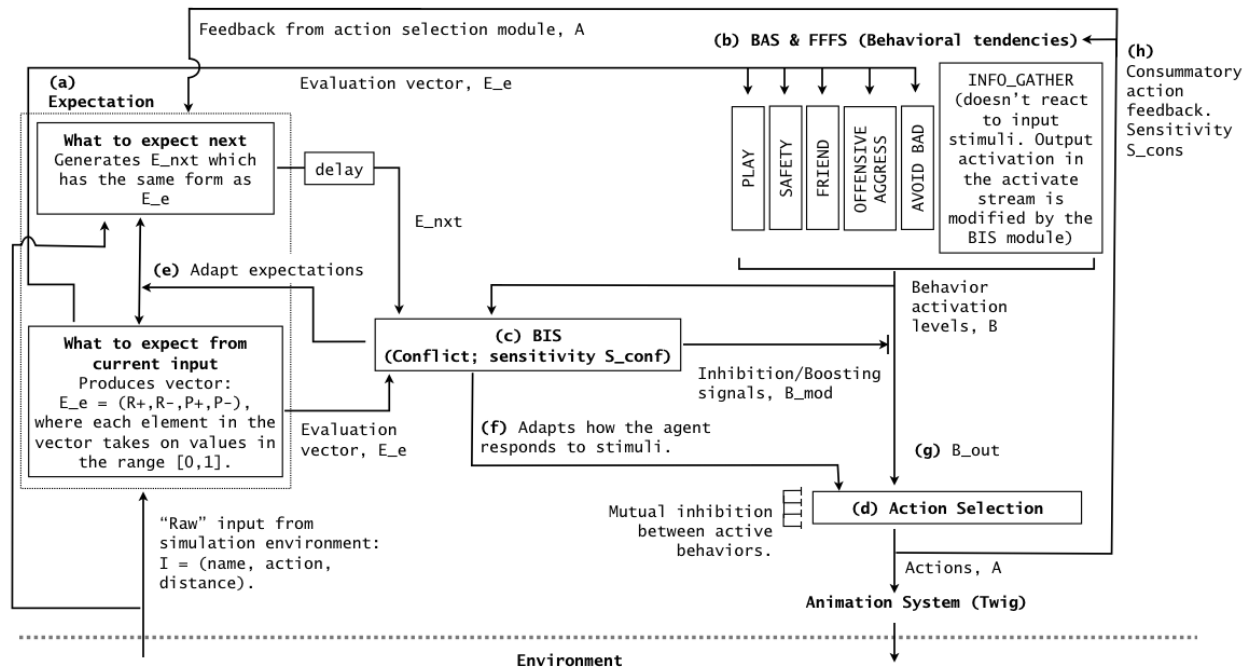

Figure 1: The RST-CTA model on the reactive level

tendencies (Figure 1g). In Figure 2a, the yellow child wants to approach the red child but is also afraid that the red child might hurt him, causing the yellow child to inhibit his actions and look nervously at the red child. A child with high sensitivity to conflict (trait anxiety) will pause more often. On the other hand, if the yellow child has low sensitivity to conflict and high sensitivity to reward (extraversion), he will engage in “riskier” behavior and approach the red child with less hesitation. The BIS module also sends learning signals to adapt expectations and actions (Figure 1e and 1f). For example, if the red child threatens the yellow child, the yellow child will expect physical aggression from the red child to follow. An expectation violation occurs when the red child does not follow up his threat with physical violence. This causes the yellow child to eventually learn that a vocal threat from the red child is less of a cue for punishment. If the red child is friendly instead of aggressive, a yellow child who is highly sensitive to reward will react more strongly to the R+ component of the stimulus and learn more quickly that the red child is much more of a cue for reward (Figure 2c).

The action selection module (Figure 1d) receives the activation levels of the behavioral tendencies and activates the actions corresponding to the behavioral tendency with the maximum activation level. The appropriate commands associated with the selected action, A, is passed to the Twig animation system.

Conclusion

Personality and individual differences are coherent patterns of thoughts, feelings, desires and behaviors within individuals.

Inspired by RST, we have proposed that personality can be organized and investigated in terms of approach, avoidance, and, importantly, conflict on the reactive, routine, and reflective levels, where an individual is consistent in his/her sensitivity to different types of cues on all three levels. We believe that this organization is useful for examining the influence of personality on other cognitive processes such as planning and moral deliberation. We also hope that the proposed structure might be informative for applications that require integrating personality into AI systems, such as in interactive games and drama, and various kinds of simulations of, for example, interpersonal interactions.

Abstract

Although a reactive framework has long been dominant in cognitive science and neuroscience, an alternative framework emphasizing dynamics and endogenous activity has recently gained prominence. We review some of the evidence for endogenous activity and consider the implications not only for understanding cognition but also for accounts of explanation offered by philosophers of science. Our recent characterization of *dynamic mechanistic explanation* emphasizes the coordination of accounts of mechanisms that identify parts and operations with computational models of their activity. These can, and should, be extended to incorporate attention to mechanisms that are not only active, but endogenously active.

Keywords: philosophy of science; mechanistic explanation; dynamics; endogenous brain activity, resting state fMRI, brain default network

Introduction

Observe a living organism, from a bacterium to a fellow human being, and you see an endogenously active system. Introspect and you will observe, as did William James, a continual flow of thoughts. If pressed, most cognitive scientists will acknowledge that neural systems—from individual neurons to the brain as a whole—exhibit endogenous activity. That is, some of the activity is internally (Greek *endo*) produced (German *gennan*); the causes and control of this activity is inside the system rather than reactive to inputs from outside the system. But cognitive scientists tend to disregard this when designing studies. Those in psychology present discrete stimuli in structured tasks designed to permit statistical analysis of the behavioral effects of independent variables. Those in neuroscience, following the tradition of Charles Scott Sherrington (1923), commonly treat the brain as a reactive system in which sensory inputs initiate neural processing that results ultimately in motor responses. They may stimulate specific neurons or provide sensory inputs with specific properties so that recorded neural activity can be analyzed in terms of responses to inputs. In both fields, variations in activity that cannot be associated with an input are treated as random fluctuations (noise). There is no doubt that this reactive framework in psychology and neuroscience has been enormously productive in identifying the parts, operations, and organization of the mechanisms responsible for cognition. It soon reaches its limits, though, in seeking accounts of the orchestrated functioning of those components: their dynamics and coordination in real time.

The investigation of endogenous activity, though less influential, has historical roots nearly as deep as those of the reactive approach. It was promoted by Thomas Graham Brown (1914), for example, who studied decerebrate and deafferented cats in Sherrington's laboratory at Liverpool from 1910 to 1913. He found that the isolated spinal cord, even when not receiving inputs, generates patterns of activity comparable to those exhibited during motor behavior elicited by stimuli. Brown's emphasis on endogenous activity initially was largely ignored (for discussion, see Stuart & Hultborn, 2008) but was revived several decades later when biologists recognized a class of neural circuits—*central pattern generators*—whose self-sustaining patterns of activity generated rhythmic motor behavior even in the absence of sensory input. After Wilson and Wyman (1965) pioneered this construct in their account of locust flight, others identified central pattern generators in the brain stem and spinal cord for walking, swimming, respiration, circulation, and other behaviors for which oscillatory control was crucial (Grillner, 2003). Endogenous activity has received far less attention from those studying sensory processing and central cognition rather than motor control, despite indications of endogenous oscillatory activity in cerebral cortex using techniques ranging from single cell recording to EEG and fMRI. In the next section we describe highlights from this research and in the subsequent section briefly explore the implications for reconstruing how we understand cognitive activity. Most important, if the conception of the brain as endogenously active is taken seriously, it profoundly challenges the reactive perspective that has dominated much of cognitive science as well as neuroscience: stimuli or tasks must be regarded not as initiating activity in an inactive system, but rather as perturbing endogenous dynamic behavior.

The slow pace at which these fields are achieving a change of perspective is unsurprising considering the history of other sciences. Although Max Planck was exaggerating when he said "A new scientific truth does not triumph by convincing its opponents . . . but rather because its opponents eventually die . . .," the considerable costs and uncertain benefits of change make it a tough sell. Uneven acceptance of Einstein's revolutionary proposals is a familiar example. Less remarked upon is the delayed impact of changes in the sciences on *philosophy* of science. For example, this young field (which did not even have a journal until 1934) did not exhibit acute concern with the epistemological foundations of science until it was confronted with Ein-

stein's proposals and their aftermath—a response that necessarily involved at least a short delay. However, delays in uptake have been far greater for developments in sciences other than physics, notably the biological and cognitive sciences. Philosophers of science did not even recognize the dominant mode of explanation in these sciences—mechanistic explanation—until the 1990s and especially after 2000. More recently, we have argued that such developments as computational modeling of the dynamics of cognitive and neural mechanisms require philosophers of science to extend their notion of mechanism to include *dynamic mechanistic explanation*. In the last section of this paper we will briefly characterize these two explanatory frameworks and consider how the philosophical understanding of dynamic mechanistic explanation can incorporate the implications of scientific work on endogenous activity.

Evidence that the Brain is Endogenously Active

Although lesion and stimulation techniques have been important in identifying brain regions involved in different cognitive activities, since the mid-20th century the greatest insights have come from techniques in which researchers record brain activity of individual neurons (single or multi-cell recording) or brain regions (EEG and fMRI). Most commonly these techniques have been employed within the reactive framework in which stimuli are presented or tasks are assigned, responses within the brain recorded, and these responses pooled for analysis to remove variability not associated with the intervention.

Each of these techniques, though, also has been employed in ways that reveal endogenous brain activity. Notably, Rodolfo Llinás employed intracellular recordings to identify systematic variations in the conductance of calcium ions across neural membranes. He showed how the manner in which these conductances varied through time enabled neurons in the inferior olive, a brainstem nucleus, to function as single-cell oscillators “capable of self-sustained rhythmic firing independent of synaptic input” (Llinás, 1988, p. 1659). (For a review of evidence and models showing how these intrinsic oscillations when combined with synaptic processes can generate synchronous thalamocortical oscillations, see Destexhe & Sejnowski, 2003.)

A second line of evidence for endogenous brain activity, consistent with that of single-cell recording, emerged from earlier studies by Hans Berger (1929) pioneering the identification of distinctive waveforms in electroencephalograph (EEG) recordings of brain activity. When he presented no stimuli or task demands but simply had subjects sit awake with their eyes closed, he obtained high-amplitude oscillations between 8 and 12 Hz that he dubbed *alpha waves*. When subjects instead viewed a stimulus or solved a problem, alpha waves were supplanted by lower-amplitude, higher-frequency *beta waves* (12-30 Hz). Soon thereafter it was determined that the EEG signal captured, not action potentials, but rather synchronized sub-threshold electrical potentials across a population of neurons. In the 1960s, the

development of digital EEG and of powerful statistical techniques for decomposing complex EEG signals into component waveforms brought further discoveries; notably, very high-frequency (25-100 Hz) *gamma waves* were prominent in addition to beta waves when people performed various cognitive tasks. Moreover, synchronized oscillations at all of these frequencies were found in both active and passive conditions, but at different amplitudes.

Thus, both single-cell recording and EEG studies have provided evidence for endogenous brain activity. In this paper we will focus on yet another line of evidence offered by recent work on *resting-state fMRI*. The BOLD (blood oxygen level dependent) signal employed in fMRI research registers the oxygen concentrations in the brain within areas that can be as small as 2 mm. Until recently fMRI research focused nearly exclusively on finding higher values in the BOLD signal when a task condition is compared to a control or resting state condition.¹ For example, semantic processing of words (task condition) would be contrasted to reading words aloud (control condition) or to lying still in the scanner with eyes closed (resting condition). The interest in neuroimaging during a resting state, rather than during task performance, developed from researchers' occasional observations that a number of brain areas routinely exhibited less activity in task situations than in the resting state. To explore further these intriguing observations, Shulman et al. (1997) conducted a meta-analysis of studies in which a task condition was compared to a non-task condition in which the same stimulus was present. They found that the areas commonly less active in task situations included posterior cingulate cortex (PCC), precuneus, inferior parietal cortex (IPC), left dorsal lateral prefrontal cortex (left DLPFC), and a medial frontal strip that continued through the inferior anterior cingulate cortex (ACC), left inferior frontal cortex, and left inferior frontal gyrus to the right amygdala. Turning the focus from the fact that these areas are less active during tasks to the fact that they are more active in the absence of task requirements, Raichle and his collaborators (Raichle et al., 2001) suggested that together these areas constitute a *default network*.

A major advance in understanding the default network resulted from analyzing the temporal dynamics of the BOLD signal. A pioneering dynamical analysis of fMRI data was provided by Biswal, Yetkin, Haughton, and Hyde (1995), who obtained BOLD signal values every 250 msec after a hand movement and identified spontaneous low frequency

¹ In referring to resting states, the assumption is not that the subject's brain is resting, but that he or she is not engaged in a specific task or responding to a specific stimulus. Often the subject is asked to fixate on a cross-hair or lie still in the scanner with eyes closed but not asleep. Fluctuations in activity that can be linked to physiological activity (cardiac or respiratory activity) are eliminated from the data through linear regression. In a critique of this research, Morcom and Fletcher (2007) focused on the privileging of the resting state. The insights into the default network on which we focus, however, do not rely on the resting state being privileged but simply as revealing ongoing activity in brain networks not employed in cognitive tasks.

(less than 0.1 Hz) fluctuations in sensorimotor cortex. These fluctuations were synchronized across the left and right hemispheres and with those in other motor areas, which was interpreted as evidence of functional connectivity among all these areas. Accordingly, the approach is referred to as *functional connectivity MRI* (fcMRI).

Employing fcMRI, Greicius, Krasnow, Reiss, and Menon (2003) demonstrated that if they used the PCC as a seed for statistical analysis, they could identify synchronized fluctuations in a large cluster of areas: medial prefrontal cortex (including inferior ACC and orbitofrontal cortex), left DLPFC, inferior parietal cortex bilaterally, left inferolateral temporal cortex, and left parahippocampal gyrus. Taking instead the inferior ACC as the seed area, they found correlated fluctuations in the PCC, medial prefrontal cortex/orbital frontal cortex, the nucleus accumbens, and the hypothalamus/midbrain. Since these regions were virtually the same as those showing activity in Shulman's resting state data, Greicius et al. construed this as evidence for "a cohesive, tonically active, default mode network" (p. 256) with two subnetworks.

While the default network exhibits greater activity in the resting state than in task conditions, the areas showing greater activity in task conditions still generate a BOLD signal in the resting state and one can find correlations in the dynamics across these areas (synchronized oscillations). These synchronized oscillations are, however, out of phase with those in the default network. Comparing the default network with one that exhibited greater activation in an attention-demanding task (intraparietal sulcus, frontal eye field, middle temporal region, supplementary motor areas, and the insula), Fox et al. (2005) described oscillations in the two networks as anticorrelated, whereas oscillations for different areas within each network were positively correlated. This shows that both the default network and the network involved in attention-demanding tasks are coordinating their activities within themselves in the absence of external stimulation or task demands.

Researchers subsequently identified additional networks using this strategy. That is, a set of areas with correlated dynamics (synchronized oscillations) under resting state conditions were posited to constitute a network, further evidenced by negative correlations with other networks (e.g., Mantini, Perrucci, Del Gratta, Romani, & Corbetta, 2007, differentiate six anticorrelated networks). Fox and Raichle (2007) concluded: "A consistent finding is that regions with similar functionality—that is, regions that are similarly modulated by various task paradigms—tend to be correlated in their spontaneous BOLD activity."

Although the oscillations revealed in fMRI are of a much lower frequency (< 0.1 Hz) than those usually reported in EEG (1-80 Hz), researchers have found ways to relate them. Mantini et al., for example, found that "Each brain network was associated with a specific combination of EEG rhythms, a neurophysiological signature that constitutes a baseline for evaluating changes in oscillatory signals during active behavior" (p. 13170). For example, the default net-

work showed positive correlations with amplitude in alpha and beta band oscillations while the attention network exhibited negative correlations in these frequency bands. These correlations may reflect systemic coherence in brain functioning. In the cortex of mammals, the amplitude (power density) of EEG oscillations has been found to be inversely proportional to their frequency ($1/f$). Even more interesting, the phase of lower-frequency oscillations seems to modulate the amplitude of those at higher frequencies, which results in a nesting relation between the frequency bands. (Lakatos et al., 2005, refer to this as "oscillatory hierarchy hypothesis") In addition, oscillations at lower frequencies tend to synchronize over more widely distributed areas of the brain than those at higher frequencies (Buzsáki & Draguhn, 2004). Such coupling can be particularly important when the brain is perturbed by a stimulus, since a modulation in low-frequency oscillations can, through phase-locking with higher-frequency oscillations, yield rapid changes at those frequencies.

The Significance of Endogenous Brain Activity for Understanding Cognition

One might acknowledge endogenous activity in various brain networks, but deny that it is of any cognitive significance. Perhaps it merely reflects basic metabolic activity and bears no implications for cognition. However, the fact that each network oscillates at a characteristic frequency, rather than fluctuating randomly, suggests that endogenous activity has implications for understanding brain activity generally—including activity during cognitive functioning. We briefly explore different ways in which endogenous activity may be important for understanding the brain as a system for cognition.

First, if a mechanism responds to a stimulus by increasing its activity, and that activity already is oscillating, response to the stimulus will vary depending on the phase of the oscillation when the stimulus arrives. This is true of individual neurons. If the membrane voltage of a neuron oscillates endogenously in a range below zero mV, as the evidence developed by Llinás and others indicates, then it will require stronger input to exceed the threshold for generating an action potential when it happens to be at its most negative phase. The same principle applies to populations of neurons whose oscillations are synchronized. In a variety of tasks in which a stimulus evokes a behavioral response, it is known that the response correlates with the magnitude of the BOLD signal. Fox, Snyder, Zacks, and Raichle (2005) therefore investigated whether these effects could be explained by synchronized spontaneous fluctuations in neuronal activity detectable with fMRI. Subjects were instructed to press a button with the right hand when a stimulus was detected, resulting in evoked activity in the left somatosensory cortex. The researchers hypothesized that the ongoing spontaneous fluctuations in the right somatosensory cortex provided an accurate measure of the spontaneous contribution to activity in the left somatosensory area at each timestep and succeeded in showing that these sponta-

neous fluctuations contributed significantly to the amplitude of blood flow in the left somatosensory areas after each stimulus. In fact, the task-related increased blood flow could be analyzed as a linear addition to the current amplitude of the spontaneous fluctuation. From this they inferred that the underlying spontaneous fluctuations affected perception and behavior. They supported this conclusion more directly in a subsequent study, in which they determined that spontaneous fluctuations accounted for variability in the force with which subjects pressed the button (Fox, Snyder, Vincent, & Raichle, 2007). When subjects were instructed as to how forcefully they should press the button, the pattern of neuronal activity was very different than that which arose when they were not instructed, allowing the investigators to discount the possibility that what they took to be spontaneous variability was in fact an evoked response. Thus, their study can be taken as initial evidence that the variability in endogenous brain activity is one source of the variability in measures of cognitive activity.

Second, endogenous activity in the brain's default network is the most obvious candidate for the neural underpinnings of *mindwandering* (Antrobus, Singer, Goldstein, & Fortgang, 1970). In one of the early fMRI studies using the resting state, Andreasen et al. (1995) queried subjects about what they were doing and elicited reports of being engaged in "a mixture of freely wandering past recollection, future plans, and other personal thoughts and experiences." Since these activities involve episodic memory, and episodic memory tasks are among those which do not lead to lower activity in the default network, Andreasen et al. and subsequent researchers (e.g., Buckner & Carroll, 2007) have suggested that the default network is involved in recalling personal experiences and anticipating future ones. Intriguingly, Li, Yan, Bergquist, and Sinha (2007) correlated trials on which subjects failed to detect stop signals in behavioral tasks with increased activity in the default network, as one would expect if that network were involved in a person thinking distracting thoughts about past and future experiences. One factor that renders problematic such a characterization of the activity of the default network is that the oscillatory behavior of the default network is maintained as well in sleep (Fukunaga et al., 2006) and under anesthesia (Vincent et al., 2007), when presumably spontaneous thoughts are not occurring.

Third, endogenous brain activity might be crucial for building and maintaining certain types of organization in the nervous system required for cognitive activity. There is growing evidence that the brain exhibits *small-world* organization (Watts & Strogatz, 1998) in which most connections link neighboring neurons, creating clusters that can collaborate in processing specific information, but a few long range connections enable overall coordination (Sporns & Zwi, 2004). There also is evidence that while most brain areas have connections to only a few other areas, some have a large number of connections, thereby constituting hubs. Such an architecture provides a highly efficient organization for information processing, and it is notable that the default

network itself exhibits a small-world architecture with hubs. An important question is how such organization might arise. Rubinov, Sporns, van Leeuwen, and Breakspear (2009) advanced the intriguing possibility that oscillatory neurons, developing connections when synchronized, might self organize into a small world network with hubs. In support of this proposal they described a model by Gong and van Leeuwen (2004) that employs a logistic map activation function for individual units that endogenously exhibit chaotic behavior. This enables the emergence of temporary patterns of synchronized oscillations even in the absence of external stimulation. A Hebbian learning procedure establishes new connections between pairs of units whose activity is synchronized and prunes those between unsynchronized units. Even when these networks begin with random connectivity, they develop clusters linked to each other through hubs. However, in real brains the initial state already involves local regions with interconnections and experience further shapes the emerging organization such that the outcome is a highly correlated brain capable of maintaining multiple anticorrelated networks. That is, the architecture of the information processing system may be shaped by both endogenous and exogenous activity.

In this section we have considered three suggestions as to how endogenous activity in the brain may contribute to its functioning as a cognitive system. Although it is too early to judge which will prove most fruitful, clearly the time for dismissing endogenous activity as mere noise has passed.

Endogenously Activity and Mechanistic Explanation

The evidence for endogenous activity in brains presents challenges not only to the ways in which cognitive scientists understand cognitive activity but also to philosophers' construal of the explanatory frameworks used in science. We mentioned above that these construals lag behind the sciences, often far more than necessary. Until recently, philosophical accounts of explanation focused primarily on laws and construed explanation as the subsumption of phenomena to be explained under these laws. While such an approach might work in physics, where there are many well established laws, it does not characterize explanations in the life sciences, where there are few laws but an abundance of phenomena to be explained (Cummins, 2000). What form of explanation is appropriate? In the past 20 years a number of philosophers of science have finally paid attention to biologists and, following their lead, construed explanation as the characterization of the mechanism responsible for a phenomenon of interest (Bechtel & Richardson, 1993; Bechtel & Abrahamsen, 2005; Machamer, Darden, & Craver, 2000; Thagard, 2006).

Although there are minor differences among these various accounts of mechanistic explanation, they concur in construing a mechanism as consisting of component parts, each of which performs one or more operations. Each operation produces change in another part that triggers or affects the operation of that part, and so forth. Cognitive psychologists,

traditionally have posited operations that transform, copy, or move representations without localizing them in parts of the brain. Cognitive neuroscientists (and growing numbers of cognitive psychologists) emphasize localization and choose operations at the appropriate grain for their brain recording technology (Bechtel, 2008).

Given the focus on specifying a mechanism to explain a given phenomenon, it is natural to conceive of the mechanism as having a specific beginning condition and continuing its operations until its task is completed. This sequential conception of mechanism is most clearly captured in the definition offered by Machamer, Darden, and Craver (2000): "Mechanisms are entities [parts] and activities [operations] organized such that they are productive of regular changes from start or set-up to finish or termination conditions." If the start or set up conditions involve a stimulus or task originating from outside the mechanism, we arrive at the construal of a mechanism not only as sequential but also as reactive.

This reactive conception of a mechanism accords well with the accounts offered in many areas of biology and cognitive science, but it is not adequate to characterize endogenously active systems as discussed in the previous sections. A sequentially organized mechanism will not exhibit endogenous activity. A minimal first step towards a mechanism capable of endogenous activity retains the general sequential conception of the overall functioning of the mechanism but allows operations that are viewed as later in the sequential order to feed back, either negatively or positively, on operations thought of as earlier. With even a single negative feedback loop it is possible to generate oscillatory behavior. It has long been known (Goodwin, 1965) that if the operations are appropriately non-linear *and* the system is open to sources of energy, these oscillations may be self-sustained and not dampen to a steady state over time. The same is true of mechanisms employing positive feedback or cyclic organization (see Bechtel & Abrahamsen, 2010).

Accommodating these organizational principles requires dropping the sequential characterization of a mechanism and instead coordinating accounts of parts and operations with accounts of their dynamics. The conception of mechanism hence becomes more dynamic: "A mechanism is a structure performing a function in virtue of its component parts, component operations, and their organization. The orchestrated functioning of the mechanism, **manifested in patterns of change over time in properties of its parts and operations**, is responsible for one or more phenomena" (Bechtel & Abrahamsen, in press). Accounts that utilize this conception exemplify what we have recently called *dynamic mechanistic explanation*. Often such accounts incorporate computational modeling of the real-time dynamics produced by feedback loops and other forms of cyclic organization. Moreover, a dynamic conception of mechanism and mechanistic explanation is compatible with the non-sequential organization, non-linear interactions, and openness to energy required for endogenous operation.

A self-sustaining oscillatory mechanism can account for the endogenous activity found in the brain, but now new explanatory tasks arise. First, the phenomenon of interest is typically not generated by a single oscillatory mechanism but by the coordinated behavior of multiple oscillators. Since Huygens we have known that if a signal can be passed between oscillators, they can synchronize their oscillations. However, depending on the particular ways in which oscillators are organized into a system, a population of oscillators can come to exhibit extremely complex behavior. Second, even a single oscillator can be perturbed by external inputs and the resulting change in its functioning can be complex. Complexity is even greater when a population of oscillators already exhibiting complex behavior is perturbed. These are the sorts of challenges faced in understanding how the brain, viewed as an endogenously active system, is presented with stimuli or tasks. Philosophical accounts of explanation must also reflect these challenges confronted in neuroscience and cognitive science.

Likability-Based Genres: Analysis and Evaluation of the Netflix Dataset

Andrew M. Olney (aolney@memphis.edu)

Institute for Intelligent Systems, 365 Innovation Drive
Memphis, TN 38152 USA

Abstract

This paper describes a new approach to defining genre. A model is presented that defines genre based on likability ratings rather than features of the content itself. By collecting hundreds of thousands of likability ratings, and incorporating these into a topic model, one can create genre categories that are interesting and intuitively plausible. Moreover, we give evidence that likability-based features can be used to predict human annotated genre labels more successfully than content-based features for the same data. Implications for outstanding questions in genre theory are discussed.

Keywords: Genre; topic model; Netflix; likability;

Introduction

Many web sites, e.g. Amazon, allow users to rate items along several dimensions, the most common being likability or overall satisfaction. These ratings allow other users to roughly estimate their own probable satisfaction with the item, leading to better item selection and better satisfaction with the web site itself. Moreover, the same rating information can be exploited by a website to make personalized recommendations for the user producing the ratings. In theory, highly accurate recommendations might influence the user to purchase additional products, again leading to greater profitability for the web site in question.

This process of tracking ratings and using ratings to make personal recommendations often falls under the classification of “recommender system” or “collaborative filtering,” and is a widely studied problem in the data mining/machine learning field (Resnick & Varian, 1997). To assist the development of new and better algorithms, some companies like Netflix have released large datasets containing hundreds of thousands of ratings by hundreds of thousands of users (*The Netflix Prize Rules*, 2010). These datasets can be analyzed in multiple ways, and an interesting perspective is to view them as a kind of graph or social network. By viewing users as nodes and items as edges, we can study how users are related to each other through item connectivity. Conversely, we can study how items are related to each other through users who have rated them. Another way of looking at this second scenario is as “mass criticism” wherein each user is afforded the same status as a critic, and the mass action of all critics determines not only the overall value of the item (through ratings) but also the association of an item with other items (through connectivity).

In film theory, criticism and genre theory are likewise intertwined (Stam, 2000), creating relationships between the value of film and its taxonomic place. Intuitively, a film might be called, “a good comedy” or “a poor horror,” in the sense that the genre defines a kind of rubric or context by which the film is evaluated. Genre theorists often attempt to go beyond

such normative characterizations to consider genre in terms of sociocultural effects between film, audience, and author. However, even in a more elaborated perspective, there are a number of outstanding issues in genre theory, which can loosely be divided into problems of definition and problems of analysis.

Problems of definition in genre theory include circularity and the monolithic assumption (Stam, 2000). The problem of circularity arises when one tries to define a genre in terms of features like those given in Table 1.

Table 1: Genre Features (Adapted from Chandler (1997))

Feature	Example
Time	Films of the 1930s
Author	Stephan King
Age of audience	Kid movie
Technology	Animated
Star	Sylvester Stallone
Director	Quentin Tarantino
Structure	Narrative
Ideology	Christian
Culture of origin	Bollywood
Subject matter	Disaster movie
Location	Western

A feature based analysis requires first assembling all the films representative of that genre and then analyzing their features. However, gathering the films requires knowing their genre in the first place, otherwise how would one know which films to assemble? A second problem of definition is the monolithic assumption, in which a film is assumed to belong to one and only one genre. While the monolithic assumption in some ways makes the task of genre definition simpler, it nevertheless ignores genres that are part of our public discourse, e.g. “romantic comedy.”

Genre theory is also plagued by problems of analysis. Some questions with regard to genre analysis of film are as follows (Stam, 2000). First, are genres real or imagined? In other words, are they merely analytic constructs, or do they have some status in the world. Second, are the number of genre categories finite or infinite? Third, are genres timeless or are they culture-driven and therefore trendy? Finally, are genres universal, or are they culturebound? As questions about genre, these four questions are inherently tied back to the definition of what genre is. Therefore to answer them, we must first define genre.

In this paper, we analyze the information implicit in user

ratings to build a model of genre. Our study focuses on the ratings from the Netflix dataset, which we incorporate into a probabilistic topic model (Griffiths, Steyvers, & Tenenbaum, 2007). Moreover, we show how the extracted genres can be used to predict human annotated genres with better performance than typical features used by genre critics. That a content-free analysis, based purely on likability ratings, can predict genres is surprising and provocative. We argue that the ability of a likability-based analysis to predict genre with more success than a traditional feature-based approach suggests that likability ratings not only represent a new way of considering genre, but they also represent a significant force in shaping genre categories, a force that is possibly more significant than the content itself.

Study 1: Modeling

Method

The data used in this study consisted of the Netflix dataset, which is freely available online (*The Netflix Prize Rules*, 2010). The dataset has a collection of information applicable to both training a model as well as evaluating the model using the Netflix API (*The Netflix Prize Rules*, 2010). In this study and succeeding studies, only the training data was used. The training data consists of two logical components. The first is a master file which lists for each movie a unique id, along with the title and release year for the movie. The second component is a folder which contains, for each movie id, the set of ratings given to that id by various users. Each rating is a triple consisting of user id, rating, and date of rating. Each rating is an integral number from 1 to 5. There are 17,770 movies in the dataset, 480,189 users, and 100,480,507 ratings. The dataset is sparse, meaning that not every user has rated every movie.

Topic models (Griffiths & Steyvers, 2002; Griffiths et al., 2007), also known in other communities as Latent Dirichlet Allocation (Blei, Ng, & Jordan, 2003), are a class of generative statistical models typically applied to text. Topic models use “bag of words” assumption, making them somewhat similar to methods such as latent semantic analysis (Landauer, Foltz, & Laham, 1998; Landauer, McNamara, Dennis, & Kintsch, 2007), however there are significant differences. Rather than reduce the dimensionality of the data according to an optimal least-squares approximation, topic models use a probabilistic model that assumes the data was generated by an underlying process involving hidden variables. Thus while LSA expresses the data along latent dimensions, i.e. singular vectors, which have no clear semantic interpretation, topic models express the data according to the topics that generated the data, and these topics are expressed as a collection of semantically related words, i.e. the words that are most probable given a topic.

More specifically, the standard topic model makes the following assumptions. For each document, there is an associated distribution of topics. Each of these topics has an associated distribution of words. Thus to generate a document,

one first probabilistically samples a from the distribution of topics, yielding a particular topic. One then probabilistically samples from the distribution of words associated with that particular topic, yielding a word. This process can be repeated to generate more words and more documents. Thus a topic model specifies how to generate the observed data; however a model may be fitted to existing data using probabilistic inference. Briefly, this is accomplished by randomly initializing the model and then using Gibbs sampling to reestimate the model’s parameters, iteratively, until the model converges. For more details see Griffiths, Kemp, and Tenenbaum (2008).

Though topic models have primarily been applied to text in the cognitive science community, the model itself is agnostic to the underlying data it represents, so long as that data has a form consistent with the assumptions of the model. One generalization of these assumptions would be as follows: data consists of a set of samples, each sample has a distribution of topics, and each item in the sample is generated from one of these topics. It doesn’t matter whether the samples are documents or whether the items are words. Using this intuition, it is fairly straightforward to map the Netflix dataset into a form consistent with the topic model. Indeed there are alternate mappings (Rubin & Steyvers, 2009), but in what follows we will only consider one.

Our mapping is as follows. Each customer is a mixture of genres, and each genre is a distribution over movies. To transform the existing Netflix dataset using this mapping, we collect all of the movies seen by a customer. The number of stars given that movie is represented by the number of times that movies label appears. For example, if a customer had only rated the movie “Whale Rider” and gave it three stars, then the customer would be represented as (Whale Rider, Whale Rider, Whale Rider), analogous to a document containing the same word three times. Under the assumptions of this mapping and the underlying topic model, each star in a customer’s rating can be generated by a different genre. For example two stars of “Whale Rider” might be generated by the drama genre, and one star might be generated by the foreign film genre.

The inference algorithm to fit our model to the Netflix data is identical to that used in typical topic models. However, given the large size of the dataset and the widespread availability of multi-core processors, we have created and make publicly available our code for fast parallel topic models in the C# language ¹. Inference parameters were as follows. The number of topics was 50, the prior for topics appearing in a document (α) was 1, and the prior for words appearing in a topic (β) was 0.01. The α and β smoothing parameters are typical (Steyvers & Griffiths, 2007). The model was run for 200 iterations.

Results

An initial inspection of the genres found by the model reveals intuitive categories, as displayed in Table 2. The intuitive

¹<http://andrewmolney.name>

Table 2: Selected Genres.

Genre 1	Genre 2	Genre 3	Genre 4
Bowling for Columbine	The Mummy Returns	Spirit: Stallion of the Cimarron	My Big Fat Greek Wedding
Fahrenheit 9/11	Bad Boys II	Brother Bear	Sweet Home Alabama
Whale Rider	Face/Off	Treasure Planet	How to Lose a Guy in 10 Days
Super Size Me	Behind Enemy Lines	The Lion King 1 1/2	Pretty Woman
Hotel Rwanda	Tomb Raider	Stuart Little 2	Legally Blonde
Maria Full of Grace	The Fast and the Furious	Garfield: The Movie	Two Weeks Notice
City of God	Rush Hour 2	Spy Kids 2	When Harry Met Sally
The Motorcycle Diaries	Gone in 60 Seconds	Home on the Range	Bridget Jones’s Diary
Spellbound	XXX: Special Edition	Scooby-Doo 2	13 Going on 30
Rabbit-Proof Fence	The Mummy	SpongeBob SquarePants	The Wedding Planner

appeal of these genres is consistent with word-based topics presented in the topic model literature (Steyvers & Griffiths, 2007). Each genre list is rank ordered by probabilistic membership. Therefore the first ranked film in each genre is the most probable film given that genre, and so on. This ranking is derived from the ϕ matrix of the topic model (Steyvers & Griffiths, 2007).

Consistencies in Table 2 are evident. For example, Genre 1 could be considered documentaries or biographically inspired independent films. Genre 2 consists of action films that veer towards the fantastic. Genre 3 is made up of animated films directed at children. And Genre 4 lists romantic comedies. However, inconsistencies are also apparent. For example is “Bad Boys II” really as fantastic as a film about mummies? Or are Michael Moore films really that much like “Whale Rider”? Under this critical view, what can be gleaned from Table 2 is somewhat mixed. On the one hand, it is clear that some sense of genre can be driven by likability ratings alone. On the other, it is unclear to what extent these ratings-driven genres correspond to typical film genres. Without a correspondence-based evaluation, it is unclear whether the genres in Table 2 represent strong coherent categories or an observer bias towards any category that might make them coherent.

Study 2: Correspondence-based Evaluation

Method

To carry out a correspondence-based evaluation of our model, it is necessary to find a large existing dataset with human annotated genres for each movie. Fortunately such a dataset exists and is freely available: the Internet Movie Database (IMDB). IMDB contains an enormous amount of information for a given film, ranging from the director and year of release to less commonly known information such as the art department. Including amongst the hundreds of pieces of information associated with each movie is a set of 28 genres, listed in Table 3.

Each film in IMDB is associated with one or more of the genres in Table 3. For example, the biopic, “Ray,” based on the story of Ray Charles, is labeled with Biography, Drama,

Table 3: IMDB Genres.

Documentary	Animation	Family	Sport
Crime	Drama	Mystery	Action
Sci-Fi	Comedy	Short	Game-Show
Romance	Fantasy	Adventure	Music
Thriller	Biography	History	Musical
Horror	Adult	War	Film-Noir
Reality-TV	Western	Talk-Show	News

and Music. How these genre labels were generated for IMDB is not clear, and interrater reliability for these genres is not available. The task of correspondence is then to match up every film in the Netflix dataset (which contains all the likability ratings) with the genres in the IMDB dataset. Unfortunately, this is less straightforward than it might first appear. The Netflix dataset is intentionally sparse, including only title, year, and ratings for each film.

IMDbPy is the Python-based software library used for manipulating the IMDB data (IMDbPy, 2010). IMDbPy provides a search capability for querying a particular title. This search capability purposely returns more than single title in order to accommodate alternate title forms. Using IMDbPy, a correspondence requiring an exact match of both year and title yields only 8,283 exact matches out of a possible 17,770. Relaxing the exact match requirement so that years match and titles match up to the colon yields an additional 1,082 matches.

Inspection of the data reveals that failures to match have a variety of reasons. First, typographic conventions differ between datasets, such that a foreign film may have its original title spelling in one dataset and an Anglicized title in another, e.g. “Character” and “Charackter.” In addition, year information may be off by one between the two databases. Sequels and series are a particular problem, such that one database may precede the name of an episode with the name of the series, whereas the other does not. Some errors also exist in the matched films. It is possible, though rare, for two films to be released in the same year with the same name. For

example, “Ray,” the biopic of Ray Charles, appeared in the same year as a genre short of the same name. Finally, because to the inconsistencies with series naming conventions and the partial match strategy described above, some within-genre mismatches can occur, e.g. “Star Trek: Insurrection” and “Star Trek: First Contact.” However, the distribution of genres is very similar in both the matched set and the original set, as shown in Table 4. Additionally, the correlation between the proportional distributions for original and matched sets is .978.

Table 4: Proportion of Genres.

Genre	Matched	Original
Action	0.14	0.12
Adult	0	0.02
Adventure	0.04	0.04

Thriller	0.02	0.01
War	0	0
Western	0.01	0.01

Once the 9,249 films were paired, the WEKA toolkit (Hall et al., 2009) was used to build two sets of predictive models. The first set uses as features only the distribution of topics associated with each movie, a row vector. For example, position 1 would be the probability that a movie belongs in genre 1, position 2 to probability a movie belongs in genre 2, and so on for all 50 genres. The second set of models uses as features a collection of information from IMDB, chosen to best match the features sometimes used by film critics to determine the genre of a film, as described in Table 1. These features are listed in Table 5.

Table 5: IMDB Features.

Feature	Type
Plot	NUMERIC
Title	NUMERIC
Actor1	NOMINAL
Actor2	NOMINAL
Director	NOMINAL
Year	NUMERIC
MPAA	NOMINAL
Genre	NOMINAL

A few features of Table 5 warrant brief remarks. Plot is a plot synopsis of the film. The two actor features are the first and second named actors on the billing, i.e. the stars of the film. MPAA is the rating of the film, e.g. PG-13. The other features are self-explanatory.

Some of these features are nominal, such as actor and director names, meaning that they are associated with a fixed set of labels as is genre in Table 3. However, the IMDB plot synopsis is an arbitrary string of considerable length, e.g. 500 words, and the title is a shorter but equally arbitrary string. In order to be usable features that two films could have in common, both plot and title were transformed using term frequency/inverse document frequency such that each word in the string became its own feature. This large set of features was considerably pruned using stop words and stemming, so that only 1,420 features remained. The WEKA command line used to convert plot and title to these numeric features was “StringToWordVector -R1,2 -W100 -prune-rate-1.0 -C -T -I -N0 -L -S -SnowballStemmer -M1 -WordTokenizer”.

In both the first and second sets, the genre class to be predicted is the first genre listed by IMDB. This restriction is due to WEKA’s inability to perform multi-class classifications, and implies that overall performance of the models is significantly lower than would be the case if any genre label associated with a movie was permitted as a correct answer.

The two differing data formats is what separates the first and second sets of models. Within each set, the same machine learning algorithms were used to predict genre. These include the following five models. First, ZeroR, which predicts the most prevalent class, e.g. Comedy. Secondly, NaiveBayes, which assumes features are independent and uses Bayes Rule to construct a classifier. Thirdly, AdaBoostM1 uses an ensemble of weak learners, in this case a decision stump, using the boosting approach (Schapire, 2003). Fourthly, J48 is a decision tree whose internal branching on attribute values is constructed to maximally discriminate amongst the training data. And finally, Ibk is an instance/prototype based classifier, i.e. k nearest neighbors where k has been set to 10 neighbors. These five algorithms were selected because they represent a cross section of the most widespread and effective machine learning techniques (Wu et al., 2007).

Each model was trained using 10 fold cross validation in

which the dataset is divided into ten bins, and the model trained 10 times, using a different bin as test data each time. Significant differences were measured using a paired samples t-test, $p = .05$, corrected for the variability introduced by cross validation (Nadeau & Bengio, 2003).

Results

The results of the predictive models are displayed in Table 6. Numbers shown indicate percent correct, aggregated across all genre categories. All significant differences are relative to the ZeroR model for each set.

Table 6: Results in Percent Correct.

Model	Likability Based	Content Based
rules.ZeroR	23.51	23.51
bayes.NaiveBayes	9.94	27.12
meta.AdaBoostM1	23.96	23.51
trees.J48	37.30	29.21
lazy.IBk	41.22	27.50

Interestingly there is a fair distribution of performance across all models for the first set (likability-based genres). The worst performer is NaiveBayes, worse than the ZeroR model, while the best performer is IBk-10, at 41%. All differences in this first set are significant.

Performance on the second set of models is worse than the performance on the first set. There is very little deviation away from ZeroR. All differences are significant, except AdaBoostM1, which is not significantly different from ZeroR. The best model of the second set, J48, has only 29% accuracy compared to 41% for IBk in the first set. This performance is particularly poor considering the base rate (ZeroR) is 23%.

Two important points are clear from this data. The first is that the likability-based genres are indeed strong and coherent, predicting the correct human annotated label in 41% of cases. The second is that the likability-based features are more successful at predicting the human annotated label than are the content-based features.

Discussion

Perhaps the most significant finding of both studies is that genres can be extracted from just ratings. Although the percent accuracy using just ratings is 41%, that is still a large figure given two observations. The first is that the 41% performance is based on a single genre classification, when IMDB allows multiple classifications. So 41% performance represents the lowest, most conservative figure. The second observation is that the likability-based performance is considerably higher than the content-based performance at 29%. This difference suggests that likability-based genre classification is a more accurate model of how humans classify film genres than is content-based classification.

The topic model we use makes very few assumptions, and yet the assumptions it does make are quite strong. The basic premise of the model is that people are a mixture of genres. These genres, in turn, generate the ratings observed. To claim that people are a mixture of genres, when genres are typically considered to be a property of artifacts, is a strong and radical claim. The results of the two studies presented above not only support this claim but also suggest that it should be taken seriously as a new approach to genre.

Suppose that likability-based genres are taken seriously. Are they useful, particularly in regard to existing genre studies? The current focus on film suggests that they are. Recall the complementary problems of genre definition and analysis discussed in the introduction. Using likability-based genres as a framework, these can be addressed straightforwardly.

As before, the problems of definition include circularity and the monolithic assumption (Stam, 2000). The basic problem of circularity lies in a supervised approach in which a critic tries to align film features with a given genre category. A likability-based model, as an unsupervised model, avoids this problem entirely because there is no initial assumption of genre used to define the features of genre. Instead, genre emerges from genre-agnostic likability ratings. The second problem of definition, the monolithic assumption, is addressed by the structure of the topic model. Under this model, every movie has some probability of membership in every genre. Study 2 above illustrates that it is not necessary to pigeonhole a movie into a genre in order to create meaningful genres: even using a probabilistic definition of genre, one can still approximate the monolithic assumption to 41% accuracy. Pluralistic genres, like “romantic comedy,” are not a special case but are represented in the same way as any other genre.

Using the likability-based definition of genre, we can also clarify problems of analysis that have been raised (Stam, 2000). First, are genres real or imagined? According to our approach, genres are only manifested through people’s preferences. Therefore they do not have any status in the world except as a consensus of preferences across large groups of people. On whether the number of genre categories finite or infinite, the structure of the topic model suggests that the number of genres is completely arbitrary, and is controllable using the parameter T , the number of topics. This suggests that likability-based genres are potentially infinite. Third, on whether genres are timeless or are trendy, the likability-based model suggests that they are trendy. Any new ratings that are assimilated into the model can change the resulting genres. As long as the people making the new ratings represent a new mixture of genres, the genres will shift towards the trendy. Finally, as to whether the genres are universal or culturebound, one can speculate that they are culturebound to the extent that one culture may rate movies consistently differently from another culture. This is intuitively plausible, e.g. Bollywood movies rated in India vs. the United States, and may be accounted for in the same way as the timeless or trendy prob-

lem.

Likability-based genres also extend beyond the traditional conceptualization of genre and correspond to the notion of intertextuality. In film, intertextuality has been described as having several properties (Stam, 2000). The first overarching property is that every film is necessarily related to every other film. Second, intertextuality is an active process, so rather than “belonging” to a genre, a film dynamically relates to other films. Finally, intertextuality involves not only all other films, but potentially other arts and media. Clearly the likability-based model corresponds to each of these three properties, by being based on the connectivity amongst all movies via ratings, using an active data-driven model, and using the abstract notion of rating, which can be applied to heterogeneous items like film, music, and books simultaneously. Thus the likability-based model can apply to modern intertextual theories of media in addition to traditional notions of genre.

In summary, likability-based genres offer a novel and useful way of considering genre: people are a mixture of genres. Likability-based genres can predict a significant percentage of genres in the Netflix dataset. Moreover, likability-based genres can also be used to address fundamental problems of definition and analysis in film theory. Likability-based genres can also be extended to broader frameworks than genre, such as intertextuality. However, likability-based genres as described in this paper do not represent a complete theory. In order to understand this phenomenon fully, it is necessary to understand how the ratings themselves are generated as well as how likability-based genres manifest in other contexts.

Constructing Typing-Time Corpora: A New Way to Answer Old Questions

Uriel Cohen Priva (urielc@stanford.edu)

Department of Linguistics, 450 Serra Mall
Stanford, CA 94305 USA

Abstract

Many current studies in linguistics and psycholinguistics require the use of phonetically labeled speech data. Collecting and annotating such data is expensive and slow. An alternative approach makes use of pre-labeled speech corpora, but these are available for very few languages, might not contain the desired linguistic environment, and the construction of new ones is still expensive and time-consuming. We present a fast and cost-efficient method for constructing a new type of corpus which retains many of the advantages of phonetically labeled speech, *typing-time corpora*. In this paper we show that an English typing-time corpus collected over the web is sufficient to replicate word frequency and neighborhood density effects. We then demonstrate the transferability of this method to less studied languages and to different orthographies. We show that a smaller Hebrew typing corpus collected over the web can be used to find lengthening effects in infrequent Hebrew words.

Keywords: Typing-time; Corpora; Frequency; Neighborhood density; Amazon Mechanical Turk

Introduction

Many studies in linguistics and psycholinguistics require either the precise annotation of durations and latencies for speech data gathered in carefully controlled experiments, or the availability of phonetically labeled corpora. For example, evidence for *neighborhood density* in production depends on measuring speech production latencies (Vitevitch, 2002). The study of *production difficulties* relies on measuring the lengthening of words in a difficult context (Fox Tree & Clark, 1997). Studies of *frequency* and predictability-dependent phonetic reduction (Van Son & Van Santen, 2005; Pluymaekers, Ernestus, & Baayen, 2005; Aylett & Turk, 2006; Bell, Brenier, Gregory, Girand, & Jurafsky, 2009) make use of corpora containing exact word and phone durations, such as the Switchboard Corpus (Godfrey & Holliman, 1997) and Buckeye Corpus of Conversational Speech (Pitt et al., 2007) for English, the Spoken Dutch Corpus (Oostdijk, 2000) and the Kiel Corpus of Spontaneous Speech (Kohler, Pätzold, & Simpson, 1995) for German.

However, neither the experimental approach nor the corpus-based one may be a feasible option when trying to address the problem of data availability in less studied languages. Subjects may not always be available on the one hand, and Switchboard-like corpora do not exist for most languages on the other hand. In addition, even when a corpus is accessible, it might not contain the relevant linguistic environments for addressing the

questions at hand. The creation of even a small-scale corpus is an expensive and time-consuming project, and therefore, there is much gain in finding a simpler alternative. In this paper, we propose a solution to this problem. We show that by wedding two methodological advancements, tracking typing speed and collection of data over the web, we can create an alternative both to experiments which require phonetic labeling and to phonetically-labeled corpora, *typing-time corpora* — corpora of typed data in which each letter and word is annotated with the time it took to type.

A number of studies (Weingarten, Nottbusch, & Will, 2004; Zesiger, Orliaguet, Boë, & Mounoud, 1994 among others) demonstrate that typing is sensitive to language-based effects. Weingarten et al. (2004) show that typing is sensitive to phonological and morphological properties of the words being typed. Zesiger et al. (1994) show that actual words are typed faster than pseudo-words and that frequent words are typed faster than infrequent words. These effects demonstrate that even though a typing task is different from spoken speech production, it does exhibit linguistic effects that are normally associated with speech.

Not only does typing time provides a window to linguistic performance, but it also holds a big advantage, as it allows the automatic gathering of large amounts of data through the web. A simple way to utilize this is by using Amazon Mechanical Turk (AMT), a virtual work marketplace created by Amazon.com. On AMT, requesters can upload work requests in the form of HTML pages, which workers can access online. Several researchers in the natural language processing community (Callison-Burch, 2009; Colowick & Pool, 2007; Snow, O'Connor, Jurafsky, & Ng, 2008 among others) make use of AMT to construct corpora for which human-labeled data is not available, or to annotate new data sets. In this paper, we demonstrate that extending the use of AMT to the construction of typing-time corpora provides an easy and cost-efficient alternative to laboratory experiments and extant corpora. We show evidence that supports the applicability of this methodology by constructing a typing time corpus for English, and using it to replicate two well known effects on language production: word frequency (Bell et al., 2009) and neighborhood density (Coltheart, Davelaar, Jonasson, & Besner, 1977; Vitevitch, 2002; Adelman & Brown, 2007). We then extend these results to a less studied language. We

show the effect of word frequency on typing time in a smaller Hebrew corpus, exemplifying that the paradigm holds even for relatively small typing-time corpora, and for different languages with varying orthographies.¹

Previous production studies

Frequency effects

Much current work in linguistics stresses the importance of word-frequency in the minute modulations in the duration of words, morphemes, syllables and phones in various contexts. These durations are taken from corpora of spontaneous or read speech in which phone durations were hand-labeled by linguists. Bell et al. (2009) show that frequent English words tend to reduce more than infrequent words. Pluymaekers et al. (2005) show the reduction of Dutch morphemes in predictable contexts. Aylett and Turk (2006) show reduction in predictable English syllables. Van Son and Van Santen (2005) show that some contextually predictable consonants are more likely to reduce.

Neighborhood effects

A wide range of studies has shown language users to be sensitive to the effects of neighborhood-density (Coltheart et al., 1977; Vitevitch, 2002; Adelman & Brown, 2007; Peereman & Content, 1997). Coltheart et al. (1977) defines the neighborhood density of a given word as “the number of words that can be produced by changing just one of the letters in the string to another letter, preserving letter positions.” Two different definitions of neighborhood density follow naturally from this one: Coltheart’s original spelling-based definition, in which the substitutions are of single orthographic characters, and a phonological definition, in which the substitution is based on phonemes. Peereman and Content (1997) argue that the best approximation of neighborhood density is phonographic, that is, the cases in which the spelling neighbor is also the phonological neighbor. Furthermore, neighborhood density has been shown to have different consequences in production and comprehension. For English, Vitevitch (2002) shows that a dense neighborhood facilitates spoken word production, whereas Vitevitch and Luce (1998) show that a dense neighborhood inhibits word comprehension.

Motivating typing-time corpora

The studies cited above demonstrate the benefit of investigating slight modulations of durations and latencies in spoken language production. However, many of them

¹The typing time approach is, of course, limited to languages that have a letter-based written standard (unlike, e.g., Chinese). While not all languages have such a written form, or any kind of written form at all, the proposed methodology would still allow access to a large number of currently less studied languages.

presuppose rather ideal experimental settings: a laboratory with accurate recording equipments, access to relevant human subjects in the proximity of that laboratory, sufficient time to label large amounts of data, and ample funds. The often easier alternative of using a pre-labeled speech corpus is not available when the linguistic environment being studied is not present in the corpus, or when no such corpus is present, as is in fact the case with most languages. Therefore, there would be much to benefit from a new methodology for investigating language production.

The following two sections describe the components of the solution we propose for this problem: an experimental approach to the collection of typing-time data, and the collection of large amounts of data over the web. By combining these methodologies we can create *typing-time corpora*, which provide an answer to the problem we presented above; they do not require any special equipment, subjects from remote locations can provide experimental data over the web, and no further labeling is required.

Online data collection

Even basic web technology allows the collection of data through the web. Every search request on the web involves sending data to some webserver, which can collect the data it receives. However, utilizing web technology for data collection requires finding enough workers to perform the specific task. Amazon Mechanical Turk (AMT) provides a simple platform to do so. AMT is a virtual marketplace in which requests and workers can interact. The requester uploads tasks in the form of HTML pages to the website and proposes to pay a given price for the completion of each task. Workers can choose among available tasks, perform them, and submit the results through AMT. The requester can then review and approve the results, which leads to the transfer of the proposed sum of money from his account to the workers’ accounts. AMT handles the overhead involving all other aspects of the interaction: the exchange of money and the collection of the results.

Several recent studies have already made use of AMT (Callison-Burch, 2009; Colowick & Pool, 2007). Colowick and Pool (2007) use AMT to find preferences for semantic scope ambiguity, and Callison-Burch (2009) uses AMT to evaluate the quality of automatic translations.

One possible concern with data collected this way is whether it can be as accurate as data collected under controlled conditions. However, Snow et al. (2008) compare the performance of AMT annotators with that of professional annotators, and they find that by increasing the number of annotators, untrained annotators over the web can match the performance of expert annotators. Increasing the number of data points per observation type is a key concept in handling noisy data collected

over the web. Since the gathering of data over the web is fast and inexpensive, enough data points can be collected to ensure that noisy data would be as sensitive as a smaller amount of data collected under ideal conditions.

Typing time experiments

Several studies have demonstrated that typing speed is affected by linguistic factors. Gentner (1982) shows that a sequence of keystrokes is more predictive of the time it would take to strike one key if the sequence does not span word boundaries. Gentner, Larochelle, and Grudin (1988) show that the same four-key sequence is typed faster in frequent words than in infrequent words of comparable length. Weingarten et al. (2004) show that typing is sensitive to morphological-syllabic boundaries, by comparing the lag between typing two specific keys, held constant across conditions, and varying between syllable and morpheme boundaries.

Since typing requires moving the hands and fingers to different locations on the keyboard, the baseline lag between the typing of a given key and the preceding key varies dramatically based on the preceding and possibly the following keystrokes. Gentner (1982) shows that almost 50% of the variability is controlled for if we control for the immediately preceding keystroke. He also shows that adding up to one more key to the preceding context of the target key, and up to one following key, can account for most of the location-based variability.

While typing time studies clearly show the potential of using typing time as a segue to assessing linguistic performance, the factorial methods used in Gentner et al. (1988) and Weingarten et al. (2004) are not always replicable in further languages. Weingarten et al. (2004), who investigate lexical access effects in German, keep the same two-key sequences while varying the morphological and syllabic environment. However, many languages would not necessarily allow the same two-key sequence to appear in every condition, making a factorial design impossible. It would be beneficial to see such effects even if only some of the conditions exist for each two-key environment. Gentner et al. (1988) uses identical four-key sequences embedded in words of varying frequencies, but in orthographic systems in which vowels are not assigned a separate letter (e.g. Arabic or Hebrew), words that contain identical four-key sequences would usually belong to the same stem or the same neighborhood. These issues can be remedied by the proposed methodology of constructing a typing-time corpus.

Building typing-time corpora

We construct the typing-time corpus in the following manner. AMT workers (or other web users) are presented with an HTML form in which they first fill in some basic details. We request our subjects to say whether they are left- or right-handed, and whether they look at the keyboard while typing. They are also requested to

type in the keyboard keys below the digits 1–6 in order to identify the keyboard layout, and to fill in the first two languages they speak, following an example in which the first language is not the language we want to investigate. In order to reduce the variance, submissions from anyone who is left-handed, looks at the keyboard, is not using the most common keyboard layout (QWERTY in the case of English) or did not fill in the language we want to investigate were not included in the analysis (but were still accepted and paid).

After the basic details are collected, the subjects move to ten open text fields. After they choose the field, text appears to the right (and in right-to-left languages, to the left) of the open text field, and the subjects are instructed to copy it. Once they move to the next field, the field they leave is locked, and they are no longer able to change it. While they type, a javascript program running in the web page collects the exact time of each key press.

The output of the collected data is then parsed and assigned additional attributes. Each keystroke is associated with the word it belongs to and the key typed in that word. Corrected text is recorded as *corrected*, and words that contain it are marked as *corrected*. Words that do not match the target text are recorded as *wrong*. Keystrokes that took more than 500ms to type are considered a *break*, and words that contain breaks past the first characters are considered *interrupted*. When a word is marked as *interrupted*, *corrected* or *wrong*, all the keystrokes that comprise it are marked as having a *interrupted*, *corrected* or *wrong* attribute, respectively.

Several tests can be performed on the collected corpus. It is possible to check in which contexts we find typing errors, which environment cause significant lags in typing time, etc. This paper concentrates on the modulation of inter-key duration, which we will call *lags*. The distribution of lags is not normal, leading us to use percentiles and medians rather than means and standard deviations. We first exclude all data from AMT workers that submitted more than five tasks, all keys that originate in *interrupted*, *corrected* or *wrong* words, all word-initial keys, and the top and bottom five percentiles of remaining lags. Following Gentner (1982) we build on the fact that the variance of keystrokes is reduced when preceding and following keys are taken into account as context. Like Weingarten et al. (2004) we use the preceding key for small corpora, but we also include the following key if at least ninety percent of every three-key sequences appear in the corpus at least five times. The median of each set of keys sequences is used as the *expected* lag of the the target key in that context. Our predicted value is the ratio between the actual lag and the expected lag, rather than the actual size of each lag. In this way, we can compare lag modulation across different words, and not limit ourselves to a specific key sequences. For ex-

ample, if the lag for the letter ‘e’ in the context ‘rea’ has an expected baseline of 220ms (based on all occurrences of the ‘rea’ in the corpus), but in a specific instance of the word ‘great’ we measure it to be 140ms long, we would like to explain why that particular ‘e’ is shorter, the value to predict being 140:220 (figure 1). Since the predicted value is the ratio, we can compare the ratios of different keystrokes, in different contexts.

key	g	↔	r	↔	e	↔	a	↔	t
actual lag		100		140		30		90	
expected lag		210		220		100		150	
ratio		0.48		0.64		0.30		0.61	

Figure 1: sample actual:expected ratios

Study 1: Lexical frequency and neighborhood density in English

In the first study, we construct a typing time corpus for English, and use it to investigate the effects of neighborhood density and frequency on the typing-time. We predict a facilitatory effect of word frequency on its typing time. Additionally, we expect to find an effect of neighborhood density.

Constructing an English typing-time corpus

The English typing-time corpus was built using AMT, using the procedure described above. Each AMT task was unique, but workers could participate in the study up to five times.

In order to choose the stimuli words to be typed, each word in the CMU Pronunciation Dictionary (Weide, 1998) was matched with its frequency and its most common letter case in the New York Times section of English Gigaword Third Edition (Graff, Kong, Chen, & Maeda, 2007): Gigaword-NYT. The corpus has two sections, which correspond to data collected using two different kinds of stimuli. Both tasks were used in order to calculate the expected lag of each keystroke in the context of one preceding and one following keystrokes.

In the first data collection task, AMT workers were requested to type in four randomly chosen words in each item. The words were independent from one another. Each word was in one of the top ten thousand lowercase words in Gigaword-NYT. A total of 475 AMT tasks were collected, and each took about two minutes to perform. No worker had to type the same word twice within the same hour.

The second data collection task required AMT workers to type in five words that form a coherent sentence, which was sampled from Gigaword-NYT. All sentences were exclusively in lowercase in the original corpus except for the first character, which was also changed into lowercase for the construction of the stimuli. The sentences were comprised only of words that are in the top

five thousand most frequent words in Gigaword-NYT. No sentence had conjunctions or WH-words. Pronouns, if they appeared at all, occurred only before the verb. Each sentence had a verb and a noun following it. A total of 190 AMT tasks were collected, and each took about two minutes to perform. No worker had to type the same sentence twice within the same hour.

Methods and materials

We investigate the effects of neighborhood density and frequency on the modulation of inter-key typing lag. A linear regression was used to estimate the predicted value, which was defined as the log ratio between a lag and its expected value. Only lags from the first section of the English typing-time corpus (words in isolation) were estimated. The key’s position in the word, the predicted lag, AMT workers’ typing rate across all items, their typing rate in the corresponding item and the logged predicted lag time were used as controls. The word frequencies used were the corresponding word counts in the NYT section of English Gigaword Third Edition (Graff et al., 2007): Gigaword-NYT. Two frequency measurement were tested. The first was the negative log unigram probability of that word: $-\log \Pr(\text{word})$. The second word frequency measurement was based on the word lemmas: $-\log \Pr(\text{lemma})$, calculated using WordNet (Miller, 1995).²

Neighborhood density was calculated using the CMU dictionary. We tested three variants of neighborhood density: the number of spelling neighbors (substitution of one letter), the number of phonological neighbors (substitution of one segment) and the number phonographic neighbors (substitution of one letter and one segment).

The linear regression model was selected using R’s (R Development Core Team, 2010) `step()` function which uses AIC (Akaike, 1974) for model selection. The model was also re-evaluated using a mixed-effect model with worker and word as random effects. No significant changes to the significance and direction of the reported coefficients were found.

Results and discussion

Both word and lemma frequency alone have a significant facilitatory effect on typing speed (words which are frequent or whose lemma is frequent are typed faster). However, in the final model only the frequency of lemma remained significant, as it masks the effect of the frequency of the word. The lemma unigram frequency has a significant ($p < 10^{-7}$) facilitatory effect and is significantly superior to word probability ($p < 0.02$).

All three neighborhood density measurements have a significant facilitatory effect on typing speed (words with a dense neighborhood are typed faster). However, in the

²If a word was ambiguous between two parts of speech, the shorter lemma was associated with the word.

final model only phonological density remains significant ($p < 0.001$). Phonological neighborhood density is not significantly better than spelling neighborhood density ($p = 0.097$) or phonographic neighborhood density ($p = 0.13$). The adjusted R^2 is 0.237

These results show that typing-time corpora are indeed sensitive to the well known effects of word frequency and neighborhood density. The fact that it is the frequency of lemmas rather than words suggests that lexicon access is active during typing, as shown in Weingarten et al. (2004). The fact that neighborhood density has a *facilitatory* effect is of particular importance, since it has been shown that in English a dense neighborhood facilitates productions whereas it inhibits comprehension (Vitevitch, 2002; Vitevitch & Luce, 1998). Therefore, although the typing task arguably involves both production and comprehension, the results suggest that this method is indeed tapping into the effects of production.

Study 2: Lexical frequency in Hebrew

In the second study, we construct a typing time corpus for Hebrew. We use it to demonstrate that this paradigm is extensible to other languages, and can be collected outside AMT. We show that Hebrew demonstrates word frequency effects on typing-time.

Constructing a Hebrew typing-time corpus

Hebrew orthography is different from that of English in several crucial aspects. It is written from right to left, it has no uppercase-lowercase distinction, and most importantly it does not incorporate most vowels. Furthermore, norms regarding the use of space are different — several very frequently occurring clitics (such as *ve* 'and') are glommed to the following word.

The Hebrew typing-time corpus was built using an online form, the results of which were collected by a web server.³ One hundred unique tasks were generated, and each task was performed no more than three times, by different subjects. Subjects could participate in the study up to five times.

In order to choose the stimuli words to be typed, we collected 1300 articles from the *Haaretz*, a Hebrew news website. We calculated the frequency of each word and used Hspell (Har'El & Kenigsberg, 2006) to stem it from possible adjoining clitics. Word-frequencies were estimated using the same data from *Haaretz*. We calculated the expected lag of each keystroke in the context of one preceding keystroke.⁴

The data collection task was similar to the isolated word section of the English corpus described in study 1. Subjects were asked to type in five randomly chosen

words in each item. The words were independent from one another. Each word was in one of the top five thousand in *Haaretz*. A total of 72 web tasks were collected, and each took about two minutes to perform. No worker had to type the same word twice.

Methods and materials

We investigate the effects of frequency on the modulation of inter-key typing lag. As in study 1, a linear regression was used to estimate the predicted value, which was defined as the log ratio between a lag and its expected value. Once again, the key's position in the word, the predicted lag, the subjects' typing rate across all items, their typing rate in the corresponding item and the logged predicted lag time were used as controls. We limited ourselves to words that had no clitics. The word frequencies used were the corresponding word counts *Haaretz*. Two frequency measurements were tested. The first was the negative log unigram probability of that word including its clitics when they occur, $-\log \Pr(\text{clitics} + \text{word})$. The second word frequency measurement was based on the stemmed words (which still include morphological inflections, but not adjoining clitics) $-\log \Pr(\text{word})$.

The linear regression model was evaluated as in Study 1. The linear regression model was selected using R's (R Development Core Team, 2010) `step()` function (Hastie & Pregibon, 1992) which uses AIC (Akaike, 1974) for model selection. The model was also re-evaluated using a mixed-effect model with worker and word as random effects. No significant changes to the significance and direction of the reported coefficients were found.

Results and Discussion

Of the two word-frequency measurements, only the frequency of the word form that included its clitics came up significant $p < 0.05$. The frequency of the bare form did not come up significant even when we excluded the frequency of the cliticized form. The adjusted R^2 is 0.1462.

These results show that even with a much smaller typing-time corpus, frequency effects can be seen.

General Discussion

The experimental results shown in both studies provide strong support of our proposal that typing time corpora can provide a simple method to investigate linguistic performance. Further investigation is required to assess the many different ways in which production is similar or different across the typed and spoken modalities.

Study 1 shows that the reduction of frequent words, an effect shown by both laboratory experiments and phonetically tagged corpora, has a corollary in typing time which can be replicated using our corpus. It also shows that a facilitatory effect of neighborhood density can be observed using our corpus, which shows that it patterns with production rather than comprehension.

³We did not use AMT because there are currently not enough native speakers of Hebrew in AMT

⁴There was not enough data to use the following key as well.

Study 2 demonstrates that this methodology can be easily extended to other, less studied languages. The results show a shortening of typing lag in more frequent words in Hebrew, as was shown for English in Study 1. This demonstrates that the method is applicable to new languages, even those with non-Roman orthographies.

Abstract

Methods for estimating people’s conceptual knowledge have the potential to be very useful to theoretical research on conceptual semantics. Traditionally, feature-based conceptual representations have been estimated using property norm data; however, computational techniques have the potential to build such representations automatically. The automatic acquisition of feature-based conceptual representations from corpora is a challenging task, given the unconstrained nature of what can constitute a semantic feature. Existing computational methods typically do not target the full range of concept-relation-feature triples occurring in human generated norms (e.g. *tiger have stripes*) but rather focus on concept-feature tuples (e.g. *tiger – stripes*) or triples involving specific relations only. We investigate the large-scale extraction of concept-relation-feature triples and the usefulness of encyclopedic, syntactic and semantic information in guiding the extraction process. Our method extracts candidate triples (e.g. *tiger have stripes*, *flute produce sound*) from parsed corpus data and ranks them on the basis of semantic information. Our investigation shows the usefulness of external knowledge in guiding feature extraction and highlights issues of methodology and evaluation which need to be addressed in developing models for this task.

Keywords: distributed conceptual representations; semantic features; corpus-based acquisition

Introduction

Concrete concepts like TIGER, APPLE and CHISEL constitute a fundamental part of people’s coherent mental representations of the world around them. A key question in cognitive science is how these semantic representations are organised and accessed. Most theories of conceptual representation assume a distributed, feature-based model of conceptual knowledge (e.g. Cree, McNorgan, & McRae, 2006; Randall, Moss, Rodd, Greer, & Tyler, 2004; Tyler, Moss, Durrant-Peatfield, & Levy, 2000). According to such theories, conceptual knowledge is distributed across a network of interconnected feature units (such as *has_eyes*, *has_ears*, *has_stripes*) with concepts’ meanings being represented as patterns of activation across these units. The relative prominence of this distributed, feature-based account of conceptual representation in the literature reflects the many perceived strengths of such a framework.

A key issue for all studies which aim to test distributed theories of concepts is the accurate estimation of the knowledge that people are likely to represent in such a system. Recent connectionist, behavioural and neuropsychological studies (e.g. Cree et al., 2006; Grondin, Lupker, & McRae, 2009; Randall et al., 2004; Tyler et al., 2000; Taylor, Salamoura, Randall, Moss, & Tyler, 2008) have relied on data derived

from property norming studies. Currently, the largest set of norms available is that collected by Ken McRae and colleagues which contains features for 541 concrete concepts (McRae, Cree, Seidenberg, & McNorgan, 2005). Participants listed features for each concept word and McRae et al. normalised them by mapping different feature descriptions with the same meaning to the same feature label.

Feature-based representations of concepts based on property-norming studies have played an important role in testing theories of conceptual knowledge. However, property norms come with several important caveats (see e.g. Murphy, 2002, for a discussion). One issue is that participants tend to under-report features which are present in many of the concepts in a category (McRae et al., 2005; Murphy, 2002, p. 32); for TIGER for example, participants list salient features like *has_teeth* but not less salient features like *has_eyes*. Thus *has_eyes* is not listed for TIGER although presumably all McRae et al.’s participants knew that tigers have eyes. Another concern is the size of the currently available property norms. Although the largest collection of norms lists features for over 500 concepts, larger sets of norms would be useful given the number of confounding variables (word length, familiarity, etc) that need to be controlled for in studies of concepts and word meaning. Unfortunately, large scale property norming studies are costly and time consuming.

In recent years, researchers have begun to develop methods which can automatically extract feature norm-like representations using corpus-based computational techniques (e.g. Almuhareb & Poesio, 2005; Barbu, 2008; Baroni, Murphy, Barbu, & Poesio, 2009). These approaches – and the approach we present in this paper – have their antecedents in early methods for extracting and organizing the semantic feature information implicit in dictionary definitions (e.g. Chodorow, Byrd, & Heidorn, 1985). The automatic approach is cost-effective and can gather large-scale frequency data from text corpora. As corpora contain words denoting concepts and their features in natural language, they provide ideal material for feature generation. However, current methods target concept-feature tuples only or are restricted to specific relations between concepts and their features. For example, Almuhareb and Poesio (2005) targeted *is-a* and *part-of* relations, whilst Barbu (2008) combined linguistic patterns with a co-occurrence based method to extract six types of features: *superordinate*, *part*, *stuff*, *location*, *quality* and *action*.

The Strudel model (Baroni et al., 2009) also uses linguis-

tic patterns, but more generally. Strudel uses “connector patterns” consisting of sequences of part-of-speech tags to look for candidate feature terms near a target concept. Properties are scored based on the number of distinct patterns connecting them to a concept, rather than on the overall number of corpus co-occurrences. When evaluated against the ESS-LLI dataset that includes 44 concepts from the McRae norms (Baroni, Evert, & Lenci, 2008), Strudel yields the precision of 23.9% – which is the best state of the art result for unconstrained acquisition of concept feature tuples.

Due to the difficulty of the task, we believe that additional linguistic and world knowledge will be required to extract more accurate representations. Moreover, Strudel has the limitation that it produces concept-feature tuples – not concept-relation-feature triples similar to those in human generated norms (although the distribution of the connector patterns for a tuple does cue information about the broad class of semantic relation that holds between concept and feature).

In this paper, we investigate the challenges that need to be met in both methodology and evaluation when aiming to move towards unconstrained, large-scale extraction of concept-relation-feature triples in corpus data. The extraction of such realistic, human-like feature norms is extremely challenging and we do not predict a high level of accuracy in these first experiments. We investigate the usefulness of three types of external knowledge in guiding feature extraction: encyclopedic, syntactic and semantic knowledge. We first compile large automatically parsed corpora from Wikipedia which contains encyclopedic information. We then introduce a novel method which extracts concept-relation-feature triples from grammatical dependences produced by a parser. We use probabilistic information about semantic classes of features and concepts to guide the acquisition process. Our investigation shows that external knowledge can be useful in guiding the extraction of human-like norms.

Extraction Method

Corpora

We chose Wikipedia as our corpus as it is a freely available and comprehensive encyclopedia that includes basic information on many everyday topics. Almost all concepts in the norms have their own Wikipedia articles, and the articles often include facts similar to those elicited in norming studies (e.g. the article *Elephant* describes how elephants are large, are mammals, and live in Africa). By using Wikipedia, we investigate the usefulness of a smaller amount of more focused (encyclopedic) corpus data for the task.

The XML dump of Wikipedia was filtered to remove non-encyclopedic articles (e.g. talk pages), article sections that are unlikely to contain parsable text (e.g. bibliography sections), and inline references (e.g. book citations). The remaining content was preprocessed with Wikiprep (Gabrilovich & Markovitch, 2007), removing tables, unparsable elements (e.g. Wikipedia infoboxes) and the WikiMedia mark-up, yielding a plaintext version of each article. Two subcorpora

were created from the resultant set of 1.84 million articles. The first of these (Wiki500) includes the Wikipedia articles that correspond to each of the McRae concepts. It contains c. 500 articles (1.1 million words). The second subcorpus consists of those articles which contain one of the McRae concept words in the title and the title is less than five words long.¹ This Wiki110K corpus includes 109,648 plaintext articles (36.5 million words).

Recoding the McRae features

We recoded a British English version of the McRae norms to a uniform representation that is more appropriate for our computational work. Each concept-feature pair in the norms (e.g. *TIGER has stripes*) was automatically recoded to a triple of the form *concept relation feature-head* where *concept* was the singular of the concept noun (e.g. ‘tiger’), *relation* was the root form of a verb (e.g. ‘have’) and *feature-head* was always a singular noun or an adjective (e.g. ‘stripe’). Feature-heads containing more complex information than could be captured with a single noun or adjective were split into two or more triples (for example, the norm feature *is a musical instrument* for ACCORDION was recoded to the two triples *accordion be instrument* and *accordion be musical*). Where “beh” and “inbeh” appeared in features in the norms (indicating behaviour features of animate and inanimate concepts; e.g. *DOG beh bark*) this was replaced with the verb “do”. Prepositions and determiners were also removed when constructing the triples. Although this recoding involves a loss of information to some extent, it also enables us to clearly distinguish between the relation and feature-head parts in each feature norm. It is triples of this form that we aim to extract with our computational method.

Candidate feature extraction

Our method for extracting concept-relation-feature triples consists of two stages: we first extract large sets of candidate feature triples for each target concept from the corpus, and then re-rank and filter the triples with the aim of retaining only those triples which are most likely to be true semantic features.

For the first stage, the corpora are parsed using the Robust Accurate Statistical Parsing (RASP) system (Briscoe, Carroll, & Watson, 2006). For each sentence in the corpora, this yields the set of grammatical relations (GRs) for the most probable analysis returned by the parser. The GR sets for each sentence containing the target concept noun are then retrieved from the corpus. We construct an undirected acyclic graph of the GRs that spans the sentence and which has the target concept word as its root node. The nodes are labelled by the words occurring in the sentence and an edge is present when a GR links those two words in the sentence. Edges can thus be labelled by the GR types. For example, the graph

¹The subset was limited to articles with titles less than five words long in order to avoid articles on very specific topics which are unlikely to contain basic information about the target concept (e.g. *Coptic Orthodox Church of Alexandria* for CHURCH.)

constructed for the sentence *Tabby tigers can often have pale stripes* contains a path connecting *tiger*, *have* and *stripe*.

Our method considers the set of paths through the tree between the target concept root node and the other nodes which are either an adjective or a noun; these adjectives and nouns are the potential feature heads in the concept-relation-feature triples. If there is a verb in the path between the target concept and the feature head, we extract the candidate triple *concept verb feature-head*. The first stage of our method extracts all possible candidate triples from the set of paths. As this method is maximally greedy, the second stage evaluates the quality of these extracted candidates using semantic information, with the aim of filtering out the poor quality features.

Re-ranking based on semantic information

The more often a triple is extracted for a concept, the more likely it is that the triple corresponds to a feature related to the concept. However, production frequency alone is an inadequate measure of the quality of the feature term because concept terms and candidate feature terms can co-occur for all sorts of reasons. For example, one of the extracted triples for TIGER is *tiger have squadron* (because of the RAF squadron called the Tigers).

The probability of a feature being part of a concept’s representation is dependent on the semantic category that the concept belongs to (*used for cutting* should have low probability for animals, for example). We conducted an analysis of the norms to quantify this type of semantic information. Our aim was to identify higher-order structure in the distribution of semantic classes for features and concepts, with the goal of investigating whether this information is useful in feature extraction. More formally, we assume that there is a 2-dimensional probability distribution over concept and feature classes, $P(C, F)$, where C is a concept class (e.g. *Animal*) and F is a feature class (e.g. *Body-Part*). Knowing this distribution gives a way of evaluating how likely it is that a candidate feature f is true for a concept c , assuming that we know that $c \in C$ and $f \in F$. We can regard the McRae norms as being a sample drawn from this distribution, provided the concept and feature terms appearing in the norms can be assigned to suitable concept and feature classes. Clustering was used to identify such classes.

Clustering Our cluster analysis used Lin’s (1998) similarity metric, which uses the WordNet ontology as the basis for calculating similarity. Such a measure is appropriate for our purposes as we are interested in generating suitable superordinate classes for which we can calculate the distributional statistics. The concepts and feature-head terms appearing in the recoded norms were each clustered independently into 50 clusters using hierarchical clustering. Table 1 presents three concept clusters and three feature clusters with five representative members of each cluster (we have given intuitive labels to the clusters for explanatory purposes). In general, semantically similar concepts and features clustered together.

We calculated the conditional probability $P(F|C)$ of a

Clusters	Example Members
<i>Concept clusters</i>	
Reptiles	alligator, crocodile, iguana, rattlesnake
Fruit/Veg	cucumber, honeydew, mushroom, plum
Vehicles	ambulance, helicopter, car, rocket, jet
<i>Feature clusters</i>	
Body Parts	ear, foot, fuzz, nose, tongue
Plant Parts	bark, berry, blade, grape, prune
Activities	cluck, drip, emergency, flow, funeral

Table 1: Example members of concept and feature clusters

	Reptiles	Fruit/Veg	Vehicles
Body Parts	0.164	0.031	0.023
Plant Parts	0.009	0.130	0.014
Activities	0.100	0.060	0.140

Table 2: $P(F|C)$ for $C \in \{\text{Reptiles, Fruit/Veg, Vehicles}\}$ and $F \in \{\text{Body Parts, Plant Parts, Activities}\}$

feature cluster given a concept cluster using the data in the McRae norms. Table 2 gives the conditional probability for each of the three feature clusters given each of the three concept clusters that were presented in Table 1. For example, $P(\text{Body Parts}|\text{Reptiles})$ is higher than $P(\text{Body Parts}|\text{Vehicles})$: given a concept in the *Reptiles* cluster the probability of a *Body Part* feature is relatively high whereas given a concept in the *Vehicle* cluster the probability of a *Body Part* feature is low. The cluster analysis therefore supports our hypothesis that the likelihood of a particular feature for a particular concept is not independent of the semantic categories that the concept and feature belong to.

Reranking We used this distributional semantic information to improve the quality of the *concept relation feature* candidate triples, by using the conditional probabilities of the appropriate feature cluster given the concept cluster as a weighting factor. To get the probabilities for a triple, we first find the clusters that the concept and the feature-head words belong to. When the feature-head word of the extracted triple appears in the norms, its cluster membership is looked up directly; when it is not in the norms we assign the feature-head to the feature cluster with which it has the highest average similarity. Given the concept and feature clusters determined for the concept and feature in the triple, we reweight the triple’s frequency by multiplying it by the conditional probability. This helps downgrade incorrect triples that occur frequently in the data and boost the evidence for correct triples.

Baseline model For the purposes of evaluation, we also implemented a co-occurrence-based model based on the “SVD” (Singular Value Decomposition) model described by Baroni et al. (2009). A word-by-word co-occurrence matrix was constructed for both our corpora, storing how often each target word co-occurred in the same sentence as each context word. Context words were defined to be the 5,000 most frequent content words in the corpora. Target words were the concept names in the recoded norms, supplemented with the 10,000

most frequent content words in the corpora (with the exception of the 10 most frequent words). The dimensionality of the co-occurrence matrix was reduced to 150 columns by singular value decomposition. Cosine similarity between pairs of target words was calculated and, for each concept word, we chose the 200 most similar target words to be the feature-head terms extracted by the model.

Experimental Evaluation

Methods of Evaluation

We considered several methods for evaluating the quality of the extracted feature triples. One method is to calculate precision and recall for the extracted triples with respect to the McRae norms “gold standard”. However, direct comparison with the recoded norms is problematic since an extracted feature which is semantically equivalent to a triple in the norms may have a different lexical form. For example, *avocado have stone* appears in the recoded norms whilst *avocado contain pit* is extracted by our method; direct comparison of these two triples results in *avocado contain pit* being incorrectly counted as an error. To deal with the fact that semantically identical features can be lexically different, we followed the approach taken in the ESSLLI 2008 Workshop on semantic models (Baroni et al., 2008). The gold standard for the ESSLLI task was the top 10 features for 44 of the McRae concepts: for each feature an expansion set was given, listing words that were synonyms of the feature term that appeared in the norms. For example, the feature *lives on water* was expanded to the set {*aquatic, lake, ocean, river, sea, water*}.

We expect to find correct features in corpus data which are not in the “gold standard” (e.g. *breathes air* is listed for WHALE but for no other animal). We therefore aim for high recall in the evaluation against the ESSLLI set (since all features in the norms should ideally be extracted) but not necessarily high precision (since extracted features that are not in the norms may still be correct; e.g. *breathes air* for TIGER). To evaluate the ability of our model to generate such novel features, we also conducted a manual evaluation of the highest ranked extracted features which did not appear in the norms. Finally, we introduce a novel evaluation method which makes no direct use of McRae norms. This is based on analysis of the extracted feature-based semantic representations in terms of conceptual structure properties. Conceptual structure statistics such as feature distinctiveness, sharedness and correlation strength have an important role to play in testing distributed theories of conceptual knowledge (e.g. see Randall et al., 2004; Taylor et al., 2008). Therefore, we were interested in the accuracy of the conceptual structure statistics that can be calculated from the extracted features. If the conceptual structure statistics calculated for the extracted features resemble those obtained from human-generated norms, it provides evidence that the extracted features capture important aspects of the semantics of concrete concepts.

Extraction set	Corpus	Prec.	Recall
SVD Baseline	Wiki500	0.0235	0.4712
	Wiki110K	0.0140	0.2798
Method - unfiltered	Wiki500	0.0239	0.5081
	Wiki110K	0.0068	0.8083
Method - top 25% unweighted	Wiki500	0.0470	0.2735
	Wiki110K	0.0179	0.6260
Method - top 25% weighted	Wiki500	0.0814	0.4167
	Wiki110K	0.0230	0.6851

Table 3: Results for the baseline model and the extraction method, when matching on features but not relations.

Precision and Recall

The *recall score* for a concept is defined as the number of extracted features for the concept that appear in the recoded norms divided by the total number of features for that concept in the norms. High recall indicates that a high proportion of the McRae features are being extracted. The *precision score* for a concept is defined as the number of extracted features for that concept that appear in the norms divided by the total number of features extracted for the concept.² As discussed above, we aim to maximize recall.

Table 3 presents the results when we evaluate using the feature-head term alone (i.e. in calculating precision and recall we disregard the relation verb and require only a match between the feature-head terms in the extracted triples and the recoded norms). Evaluating tuples (rather than triples) is how large-scale models of feature extraction have typically been evaluated in the past (e.g. Baroni et al., 2009).

Results for four sets of extractions are presented. The first set is the set of features extracted by the SVD baseline. The second set of extracted triples are the full set of triples extracted by our method, prior to the reweighting stage. “Top 25% unweighted” gives the results when all but the top 25% most frequently extracted triples for each concept are filtered out. Note that the filtering criteria here is raw extraction frequency, without reweighting by conditional probabilities. “Top 25% weighted” are the corresponding results when the features are weighted by the conditional probability factors prior to filtering; that is, using the top 25% reranked features. The effectiveness of using the semantic class-based analysis data in our method can thus be assessed by comparing the filtered results with and without feature weighting.

For the baseline implementation, the results are better using the smaller Wiki500 corpus than the larger Wiki110K corpus. This is not surprising, since the smaller corpus contains only the articles corresponding to the concepts in the norms. This smaller corpus thus minimizes sources of noise such as word polysemy that are more apparent in the larger corpus (e.g. “tiger” almost always refers to the animal in the Wiki500 corpus, but can have other meanings in larger or general cor-

²Since we define precision over the whole set of extracted features, our precision score is not comparable to Baroni et al. (2009), where the top 10 extracted features are used.

pora (the RAF squadron called the Tigers, etc)).

The results for the baseline model and the unfiltered experimental method are quite similar for the Wiki500 corpus. As our extraction method is deliberately greedy, extracting many candidate features per sentence, it is not surprising that its performance is comparable to a purely co-occurrence-based method. The innovation of our method is that it uses information about the GR-graph of the sentence to also extract the verb which appears in the path linking the concept and feature terms in the sentence, which is not possible in a purely co-occurrence-based model.

The results for the unfiltered model using the Wiki110K corpus give the maximum recall achieved by our method; 81% of the features are extracted. Precision is low (because of the large number of features being extracted) although, as discussed above, we are less interested in precision, particularly for the unfiltered model. For the results of the filtered feature sets, where all but the top 25% of features were discarded, we see the benefit of reranking, with the reranked frequencies yielding higher precision and recall scores than the method using the unweighted extracted frequencies.

We also evaluated the extracted triples using the full relation + feature-head pair (i.e. both the feature and the relation verb have to be correct). Previous researchers have typically only compared extracted features to the feature-head term; to our knowledge our work is the first to try and compare extracted features to the full relation + feature norm. Unsurprisingly, this reduces recall and precision compared to the case where only the feature-head terms need match. For example, for the Wiki110K corpus recall falls from 69% to 35% for the filtered re-ranked model. However, given that we impose no constraints on what the relation verb can be and that we do not have expanded synonym sets for verbs it is actually impressive that the verb agrees with what is in the recoded norms about 50% of the time.

Manual Evaluation Analysis

Inspection of the extracted triples reveals that some of them are correct although they do not appear in the gold standard norms. One motivation for developing NLP technology for feature extraction is the need to enrich existing models of conceptual representation with novel features. To evaluate the method’s ability to learn this type of novel data, 10 concepts were selected at random from among the McRae concepts and the top 20 extracted triples not present in the norms were selected. Two judges evaluated whether these were genuine errors or valid data missing from the norms. The judges rated each “erroneous” triple as correct, plausible, wrong, or wrong but related. The judges worked first independently and then discussed the results to reach consensus. Across the 10 concepts, 23% and 26% of the relation+feature pairs were considered correct and plausible respectively, indicating roughly half of the errors were not true errors but potentially valid triples missing from the norms. This demonstrates the potential of NLP methods in enriching existing models of conceptual representation.

Measure	Correl	<i>p</i>
Number of features	0.203	< 0.001
Number of distinctive features	0.168	< 0.001
Number of shared features	0.113	0.983
Mean distinctiveness	0.167	< 0.001
Proportion of shared features	0.155	< 0.001
Mean correlational strength	-0.118	0.014

Table 4: Evaluation in terms of CSA variables

Evaluation in terms of conceptual structure

Of particular interest to distributed, feature-based theories of conceptual knowledge is how relationships which exist between the features of concepts influence conceptual processing. Statistics capturing such relationships have proven useful in testing theories of distributed semantic representation, including the conceptual structure account (Randall et al., 2004; Tyler et al., 2000). Researchers have calculated several variables from norm data which capture various aspects of the structural organization of the semantic space (e.g. McRae et al., 2005; Randall et al., 2004). Here, we propose a novel method for evaluating feature extraction methods which is based on testing whether conceptual structure statistics calculated from the extracted features exhibit similar qualities to those calculated on the McRae norms.

Various kinds of conceptual structure variables can be calculated. The simplest is the *number of features* in the concept (i.e. the number of features with non-zero production frequency). Features can also be distinguished by whether they are shared or distinctive. Highly shared features occur in many concepts (e.g. *has_legs*); highly distinctive features occur in few concepts (e.g. *has_an_udder*). The reciprocal of the number of concepts that a feature occurs in is a measure of the feature’s *distinctiveness* (so a feature occurring in two concepts has distinctiveness of 0.5). In particular, a feature is defined to be *distinguishing* if it occurs in one or two concepts and *shared* if it occurs in more than two concepts. For each concept, we can then define the mean distinctiveness of its features, the number of shared and distinguishing features it has, and the proportion of shared features. We can also define a measure of the strength of interconnection between a pair of features. For example, *has_eyes* and *has_ears* co-occur together in concepts more often than do the features *is_gray* and *has_teeth*. The correlation strength for a pair of features is calculated as the Pearson correlation of their production frequencies across concepts. We can then calculate the *mean correlational strength* of a concept’s constituent features (using only the shared features; see Cree et al., 2006; Taylor et al., 2008). We therefore define a total of six conceptual structure variables, summarized in Table 4.

The results show a significant correlation between the norms and the extracted triples for five of the six conceptual structure variables. This is important as it indicates that the semantic representations generated from the extracted features are capturing some aspects of the conceptual structure that is present in the norms. However, the correlations are

quite weak, and we do not see expected differences between living and non-living domains that are observed in the McRae norms. What we wish to highlight here is the potential usefulness of conceptual structure statistics as a means for evaluating models: improvements to the extraction method should yield better quality conceptual structure statistics.

Discussion

The feature acquisition method that we have presented above aims to extract semantically unconstrained concept-relation-feature triples from corpus data. High accuracy extraction of such general representations from corpora is unrealistic given the state of the art. The main goal of our experiment was to investigate issues in both methodology and evaluation which need to be addressed when aiming towards higher accuracy feature extraction in the future. In particular, we examined the usefulness of three types of knowledge for guiding feature extraction: encyclopedic, syntactic, and lexical-semantic. We have also compared different approaches to evaluation: direct evaluation against existing norms, qualitative analysis, and evaluation against conceptual structure variables.

Our extraction method performs better than the co-occurrence-based baseline, demonstrating the benefits of using syntactic information for feature extraction. Using GRs also allows us to extract a relation verb for each concept-feature pair, which is not possible using a purely co-occurrence-based approach like the SVD baseline. Performance was improved further by using semantic constraints calculated from the concept and feature clusters: the re-weighting of features based on distributional data increased the rank of higher-quality features.

Our paper highlights the difficulties inherent in evaluating the quality of extracted features. Evaluation that tests against existing property norms is problematic, since participants in property norming studies list features in unsystematic ways. Furthermore, as property norms are created by normalizing participants' responses to a set of feature labels, direct lexical comparison with property norms is not necessarily meaningful. Although the ESSLLI sub-set of the norms which expands the set of features in the norms with their synonyms goes some way towards addressing the latter issue, the former issue remains: norms are not complete in the sense that there are true features which are not included in the norms.

We therefore considered other forms of evaluation. Our qualitative analysis shows that about 50% of the errors against the recoded norms are in fact correct or plausible features. Our novel evaluation in terms of the conceptual structure variables acts as a valuable task-based evaluation that avoids direct comparison with the norms, and instead compares higher-level structural properties of concepts. Future work can aim for larger-scale qualitative evaluation using multiple judges as well as investigate other task-based evaluations.

Acknowledgments

Are Random Representations Accurate Approximations of Lexical Semantics?

Abstract

A common assumption made by cognitive models is that lexical semantics can be approximated using randomly generated representations to stand in for word meaning. However, the use of random representations contains the hidden assumption that semantic similarity across randomly selected words is normally distributed. We evaluated this assumption by computing similarity distributions for randomly selected words from a number of well-known semantic measures and comparing them with the distributions from random representations commonly used in memory models.

Keywords: Memory models; semantics; episodic recognition

Introduction

A model of a cognitive phenomenon typically requires an account of both representation and process, and how the two interact (Estes, 1975). These two aspects of a model are interdependent, with the process requiring a representation on which to operate, and the representation requiring a process to simulate behavior. A common practice in cognitive modeling is to use randomly generated representations if the theorist wishes to evaluate a process mechanism, but is unsure of the correct psychological structure or features to use as a representation. This practice makes it unlikely that the representation is biased towards supporting the process model, and the process account can be later refined when further research reveals the correct representation. Over the history of computational modeling, emphasis has been placed on processing over representation.

If insufficient research exists to point towards the correct representation, random representations often provide a useful alternative or simulation of the process would be impossible. An excellent example is Hintzman's (1986) use of random representations to simulate schema abstraction using Posner and Keele's (1968) stimuli. Briefly, stimuli were random dot patterns, and exemplars of the same category were random perturbations of a prototype pattern. Without needing to account for how the human visual system represents dot patterns, Hintzman was able to create equivalent structure in his simulation by generating random prototypes and exemplars.

Random representations have been commonly used in models of episodic memory, for example, recognition, recall, and paired-associate learning. In global matching models of recognition memory (e.g., Hintzman, 1986; Murdock, 1982; Shiffrin & Steyvers, 1997) decisions are made by assessing the similarity of the probe word to the (usually noisy) study items with a particular processing and

decision mechanism. The use of random representations in these models produces a hidden assumption that the distribution of similarity across randomly selected words is symmetric and approximately Gaussian.

The distributional assumption comes from the design of a typical memory experiment in which random words are used. In these experiments, random words are selected from a word pool (e.g., Friendly, et al., 1982). Because words are randomly selected, they are assumed to have only random similarity on dimensions extraneous to the experimental manipulation (e.g., orthography, phonology, semantics, etc.); however, this assumption is unlikely to be true. Hence, it is common to explicitly control extraneous factors such as frequency. In this examination, we focus on semantics—a factor often ignored because it is difficult to quantify and control. In assuming that two randomly selected words have only a random expected semantic similarity, random representations seem appropriate.

However, the use of these representations assumes that semantic similarity is randomly distributed across all sampled words. We demonstrate in the following analysis that this is unlikely to be the case with real words, and may produce consequences for conclusions drawn from process models that have used random representations.

Analysis

To evaluate the assumption of random similarity, comparison distributions are needed. Our analysis will utilize three types of semantic similarity measures to create distributions—similarity measures computed from: 1) free association data, 2) a hand-coded lexical ontology (WordNet), and 3) corpus-based co-occurrence models.

Semantic Measures

1. Word Association Space (WAS). Steyvers, Shiffrin, and Nelson (2004) developed a method for inferring semantic representations from free association data. Steyvers et al. represented the free association data for the 5000 cue words from Nelson, McEvoy, and Schreiber's (1999) norms in a word-by-word matrix, where each entry was the probability of a cue word (the row) eliciting the response (the column). This matrix was then reduced in dimensionality using singular value decomposition so that each word was represented by an abstracted 400-dimensional vector. Steyvers et al. demonstrated that the resulting vectors are a good predictor of similarity effects in recognition, recall, and other behaviors.

2. WordNet Similarity. WordNet (Miller, 1990) is a hand-coded lexical database encoded as a network in which nodes contain one or more synonymous words. These nodes are then linked together via different types of lexical relationships (e.g. hypernymy and holonymy) and based on these relationships it is possible to build a measure of semantic similarity between two given words using network statistics. A variety of methods that have proposed to do compute similarity, but the measure that seems to best map onto human similarity ratings is the Jiang-Conrath distance measure (JCN; Maki, McKinely, & Thompson, 2004). JCN is a network distance measure that basically counts the number of nodes and edges between two concepts in the database.

3. Latent Semantic Analysis (LSA). This method (and those that follow) differs from the WAS of Steyvers, et al. (2004) in that it does not use human behavioral data to create a semantic representation but, rather, uses statistical regularities computed from a large text corpus. In LSA (Landauer & Dumais, 1997), a word-by-document matrix is created by tabulating the frequency that each word occurs in a given document, inversely weighted by the word's marginal frequency and entropy over documents. The dimensionality of this matrix is then reduced using singular value decomposition so that each word is represented by a vector containing the 300-400 dimensions with the largest eigenvalues. Words that frequently co-occur in similar documents will be represented by similar vectors.

4. BEAGLE. In the BEAGLE model of Jones and Mewhort (2007), a distributed holographic representation of a word is built through experience with a text corpus. Words are initially represented by random Gaussian vectors, and a word's semantic representation is created by summing and convolving (cf. Murdock, 1982) other words that occur in sentences with a target word. The use of convolution allows order information to be included (the sentential position of the word relative to other words), as well as the basic co-occurrence information in LSA. This associative mechanism affords inclusion of rudimentary syntactic knowledge in the vector representation of the word.

5. The COALS model. Unlike the two previous models, COALS (Rohde, Gonnerman, & Plaut, submitted) is not designed to explain human learning, but rather to create a co-occurrence metric that yields the best predictions on a variety of semantic tasks. The model creates a word-by-word matrix, with modifications to how values within the matrix are computed (i.e. correlations are used instead of pure co-occurrence count). This large, sparse matrix is subsequently reduced in dimensionality with SVD in the same way LSA reduces a co-occurrence matrix.

6. Pointwise Mutual Information (PMI). PMI uses a pure co-occurrence count across a large text corpus to create a measure of similarity between two words (e.g., Recchia & Jones, 2009). As with COALS, PMI is not meant to be a model of human learning or representation, but rather a scalar measure of similarity between two words. PMI is essentially computed by taking the probability of observing

word x and word y together and dividing by the probability of observing x and y independently. Recchia & Jones computed PMI values over a very large corpus of Wikipedia articles (approximately 400,000 articles), and found that PMI produced a significantly better fit to human rating data than LSA or other semantic similarity metrics.

Random Representations

To compare to the distributions created by the semantic measures, we explored five common types of random vectors that have been used to represent semantics in influential models of memory.

1. Random Gaussian Vectors. A word's representation is created by randomly sampling vector elements from a Gaussian distribution with a certain mean (typically zero) and variance (usually $1/N$, where N is vector dimensionality). This type of representation has been used in a variety of models of recognition (e.g. Murdock, 1982), and recall, among others. In the following analysis, vectors were created as in Murdock (1982), with a vector size of 250, a mean of 0 and an SD of $(\sqrt{1/250})$.

2. Gamma Vectors. A word vector is created by sampling integers from a gamma distribution:

$$P[V = j] = (1 - g)^{j-1} g, j = 1, \dots, \infty \quad (1)$$

Where g is a parameter between 0 and 1 that defines the environmental base rates for the different feature values. This type of representation has been used in the highly successful REM model of recognition memory (Shiffrin & Steyvers, 1997), and related models. We constructed these vectors as specified in Shiffrin & Steyvers (1997), with a length of 20, and a $g = 0.45$ (the parameter used to create high frequency words).

3. MINERVA vectors. In the influential MINERVA 2 model of memory (Hintzman, 1986), vector elements are assumed to be randomly selected from the set of $\{-1, 0, 1\}$. A value of 1 is intended to represent a positive link between the word and that feature, a -1 represents an inhibitory link, while a 0 is defined as either irrelevant or unknown for that particular word and feature. Vectors were constructed with a length of 20. Similarity for these vectors was calculated with the following equation:

$$s_i = \sum_{j=1}^D \frac{P_i \cdot T_{i,j}}{n} \quad (2)$$

Where D is the size of the vectors, P is the probe word, T is a studied memory trace and n is the number of non-zero items in P . The value is then transformed by cubing it.

4. Sparse Binary Vectors. In this type of distributed representation, the majority of entries are zero, with some entries having the value of 1 at random locations. For instance, in Plaut (1995) items in a word's semantic representation had a 10% probability of being non-zero. Sparse binary vectors have been used to model lexical priming (Plaut) and recognition memory (Dennis & Humphreys, 2001), among other domains. Similar to Plaut's

simulations we generated vectors with a length of 100 and each item having a 10% probability of being non-zero. In addition, binomial distributions (with a sparsity of 50%) will also be tested to examine the effect of sparseness on the similarity distributions.

5. Dichotomous Vectors. Another common type of representation used in connectionist modeling is a random vector composed equally of 1 or -1. These are similar to MINERVA vectors, but without any zero-valued elements. Dichotomous vectors have been used in variety of models, such as connectionist models of semantic priming (e.g., Masson, 1995). We use vectors with a length of 100 in the following simulations.

Method

To calculate similarity distributions using the semantic measures, 1000 words were selected from the Toronto word pool (Friendly, et al., 1982), and the similarity between each word in the pool was computed. Next, 50,000 of these semantic comparison values were randomly sampled to examine the distribution of similarity values. In the WAS, LSA, and BEAGLE models the similarity metric used was a vector cosine (a normalized dot-product), while in COALS Pearson's correlation was used.

For the randomly generated representations, we created a distribution of 100,000 similarity comparisons for each representation type. The distribution was constructed by randomly generating two vectors from the given representation type and computing the similarity between them. Similarity was vector cosine for all representations.

To evaluate distribution shape, two different methods of assessing normality were employed: 1) skewness, and 2) normal quantile-quantile (Q-Q) plots. Skewness is the third moment about the mean, and signals asymmetry in a distribution. Q-Q plots are used to assess the difference between an observed distribution and a theoretical (in this case Gaussian) distribution. The standardized values of the comparison distribution are plotted against the respective values for the Gaussian, and any discrepancy signals a deviation from the theoretical Gaussian distribution.

Results

The skewness values for the similarity distributions of both the semantic spaces and random representations are displayed in Figure 1. As the figure shows, all the semantic spaces create positively skewed similarity distributions. That is, there tends to be a greater number of low similarity scores and a small number of high similarity scores in a given distribution of randomly selected words. Co-occurrence models (LSA, BEAGLE, and COALS) have the lowest skew (from 1.06 for BEAGLE to 2.01 for COALS). The PMI distribution produced the largest skew, likely due to the fact that this method does not abstract across documents, but is instead a pure co-occurrence count. Even with this shortcoming, PMI has been shown to be very effective in fitting human semantic similarity ratings

Figure 1. Levels of skewness for the different distributions.

(Recchia & Jones, 2009). In the middle was the JCN measure with a skewness of 2.61 and the WAS of Steyvers, et al. (2004) with a skewness of 8.04, which signals a highly skewed distribution.

In contrast, all of the random representations produced skewness values of essentially zero (this is expected by their construction). The only distribution that is mildly positively skewed is the sparse binomial distribution with a skewness of 0.21, while the Gamma distribution is actually mildly negatively skewed with a value of -0.17.

The Q-Q plots are displayed in Figure 2 for the semantic space distributions (left panel) and the distributions computed from the random representations (right panel). Due to space limitations, only 4 graphs were included, but these are diagnostic of the remaining distributions. Again, the semantic space distributions show significant deviation from the expected Gaussian distribution. Specifically, the semantic space distributions are skewed to the right, with all of the models having lower than expected number of large similarity values. They also tend to have greater than expected low similarity values. Again, the random representation distributions produce very different results—there is little deviation from normality.

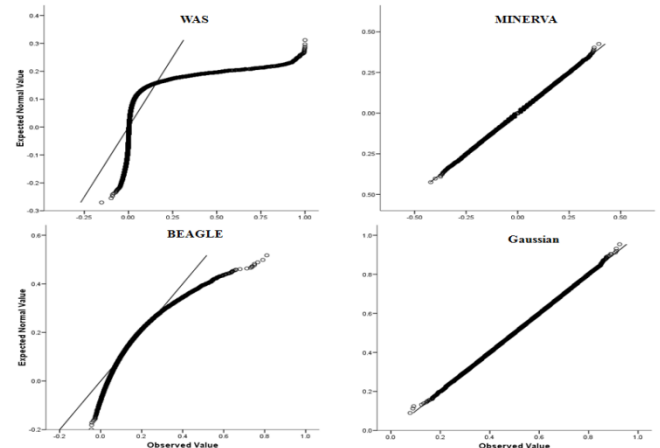

Figure 2. Q-Q plots for semantic and random vectors.

This simple analysis demonstrates that the similarity distributions created by semantic space models and randomly generated representations are considerably different. Two randomly selected words are likely to be less similar (relative to the other values in the distribution) for semantic models, than for random representations.

Demonstrations

In order to show the potential impact that the use of random representations may have, two simple demonstrations were conducted using data from recognition memory tasks.

Demonstration #1: Signal Detection Theory

The purpose of this demonstration is to show what effect skewed similarity distributions will have on a signal detection theory (SDT) based process, which is the dominant decision making process within recognition memory (Shiffrin & Steyvers, 1997; Dennis & Humphreys, 2001). In order to accomplish this, a recognition process with SDT is simulated by sampling from both skewed (semantic) similarity distributions as well as normal (random) similarity distributions. Recognition is then simulated by fitting an optimal criterion to separate old and new items, and the resulting d-prime values for the different distributions will be compared to behavioral results.

In order to compare the different similarity distributions, a normalization procedure was necessary. This was done by taking the distributions from each of the semantic metrics and random representations and normalizing them to have a range of 0 and 0.5 and a mean of 0.25. This procedure allows us to evaluate the shape of the distribution while centering the distributions on the same mean.

Evidence distributions for new and old items were simulated for lists of 20 words. The evidence for a probe was the similarity of the probe to the 20 items on the list. For ‘new’ probes, this evidence was simply the mean of 20 randomly sampled similarity values (as new probes are randomly similar to the contents of memory). For ‘old’ probes, this evidence was the average of the similarity of the item to itself and the other items on the list (simulated as the mean of 19 randomly sampled similarities and the value of 1, representing the similarity of the word to itself). This process was repeated 50,000 times for each similarity distribution.

To compare the resulting evidence values, the discriminability (measured with d-prime) was calculated for each simulation—d-prime is a measure of how distinct studied items are from non-studied items. Figure 3 displays the d-prime values for the different similarity distributions compared with the d-prime from a simple recognition experiment which used a list length of 20 (Dennis, Lee, & Kinnel, 2008). As the figure illustrates, all of the semantic distributions have higher d-prime than do the random distributions. In addition, the d-prime values for the random representations are much closer to the behavioral data from Dennis, et al. The difference in magnitude demonstrated for d-prime values for semantic and random similarity was

statistically reliable, $t(11) = 4.75$, $p < 0.001$. To evaluate the effect of skew in the similarity distributions on the resulting d-prime values, we computed the partial correlation between d-prime and skewness (controlling for kurtosis and variance) for the distributions, which resulted in a robust $r = 0.913$, $p < 0.001$.

The skewness of the similarity distribution has a large effect on the calculation of evidence distributions because the probability of sampling lower similarity values is much greater than in a symmetric distribution. Hence, with ‘true’ semantic representations an old item tends to be more distinct from other random items on the list, producing a greater difference between old and new evidence distributions. This demonstration is certainly not meant as a refutation of signal detection theory, but instead demonstrates that using realistic representations of semantics will impose significant constraint on a processing model’s ability to simulate data.

Figure 3. Levels of discriminability (d-prime) for SDT simulations; behavioral data from Dennis, et al. (2008).

Demonstration #2: MINERVA 2 and False Recognition

This demonstration was conducted in order to show that random representations provide an increase amount of freedom to fit data. The MINERVA 2 model of Hintzman (1986) has been used to successfully account for a variety of categorical false recognition effects (Arndt & Hirshman, 1998). Here, we simulate associative false recognition with the model, using both random and structured representations of semantics. Robinson and Roediger (1997) found that as the number of studied items that are related to a critical lure is increased, so is the probability of falsely recognizing that critical lure. The purpose of this demonstration is to compare the ease with which a simple process model like MINERVA is able to model this effect when using random representations versus when it is using representations that contain knowledge about the similarity structure of the actual words.

To construct MINERVA vectors that contain plausible semantic structure, we transformed the WAS representations from Steyvers et al. (2003). Typical applications of MINERVA use ternary vectors with a fairly low dimensionality. Hence, WAS vectors were collapsed from

400 to 20 dimensions by summing every 20 quadrants in the WAS vector into a single element in the reduced vector. This reduced vector was then transformed into a ternary vector with values of the set $\{-1, 0, 1\}$; the magnitude of the summed WAS values were recoded so that the highest third were assigned +1 (representing a high weighting on that feature), the middle third 0, and the lowest third -1. To ensure that the MINERVA transformed vectors still reflected the semantic structure in the original WAS vectors, we computed the word-by-word cosines between vectors in both representations, and correlated the two matrices: The original vectors and their ternary transformed versions were highly correlated, $r = .67$, $p < .001$, indicating that the transformed vectors contain an arrangement of elements that reflects the semantic structure in the original WAS vectors. Using the false recognition lists from Stadler, Roediger and McDermott, (1998) and Gallo and Roediger (2002), there was a high average similarity of the critical word's representation to the representations of the list items across the 52 word lists, $r = 0.35$, $p < .001$.

Random representations for critical words and their corresponding lists were created as in Arndt and Hirshman (1998), by using prototype and exemplar vectors. A prototype vector (representing the critical word) is first generated by randomly sampling elements from the set $\{1, 0, -1\}$ with equal probability. Each item in the word list is then created by randomly perturbing elements in the prototype vector. This process requires a distortion parameter, which determines the probability of switching elements from the prototype vector when creating a list item vector. The distortion parameter determines how similar the list items are to the critical word. The important point is that both the semantic and random representations contain the exact same elements (same number of -1, 0, and 1s). The difference is that the elements are arranged independently for the random representations, whereas they are arranged to respect the inter-word similarity structure from WAS in the semantic version.

For MINERVA with a semantic representation, the results of Robinson and Roediger (1997) were modeled by randomly selecting 3 word lists, and adding 3, 6, or 9 items from one of the lists into a study list. Because the word lists in Robinson and Roediger were longer (they also used 12 and 15 associates), 27 words selected randomly from the Toronto word pool were added into the study list. To simulate this with MINERVA using random representation, 3, 6, or 9 exemplars were created for 3 random prototypes and added into the study list. Additionally, 27 random vectors were added into the study list to make the two simulations equivalent. Decisions are based on activation levels of a probe to the studied items (echo intensity: Hintzman, 1986), calculated by summing the similarity across all items in the study list.

For the MINERVA with semantic representations, there are two free parameters: 1) a criterion to make a new-old decision based on activation levels, and 2) a forgetting parameter which determines the probability of a non-zero

element switching to zero during study. The simulation with random representations includes an additional distortion parameter (described above) to create the semantic structure. These parameters were fit to the data from Robinson & Roediger (1997) data using a Nelder-Mead simplex algorithm. The results of the simulation are displayed in Figure 4: the MINERVA model that utilizes random representations was able to reproduce the overall trend in the data. However, this was not the case with the MINERVA model that used semantic representations—this model tended to falsely recognize critical items over studied items, which is not the case with the human data. The random representation version of the model produced an excellent account of the data, $R^2 = 0.98$, $p < .001$. However, the version based on the true semantic similarity of the words used fit no better than chance, $R^2 = 0.05$, $p = .45$.

This simulation provides a simple demonstration of how a process model that has false representation assumptions may be incorrectly accepted as a plausible model. The only difference between the two models is in their representation structure—the process is identical. While the semantic version contains the “true” semantic structure for the exact words used in the experiment, the random version uses the distortion parameter to create the semantic structure that is most likely if this process account is correct. It is exclusively the incorrect inferred semantic structure that allows the process account to fit these data. If the correct representational structure were used, the process account would be rejected. The point is that random representations allow unnecessary freedom for the model to fit the data.

Figure 4. Results of false recognition simulation.

General Discussion

The use of randomly generated representations contains the assumption that semantic similarity is normally distributed over randomly selected pairs of words. This assumption was shown to be false across many different semantic metrics that have demonstrated success at accounting for human data. In experiments using words, two randomly selected words are likely to be relatively less similar (compared to the distribution of all possible pairs) than would be implied

using randomly generated representations for lexical semantics. Because similarity plays a central role in the processing mechanisms used by many memory models, the use of random representations may have consequences for conclusions drawn from simulations using these models.

As McClelland (2009) has noted, "...simplification is essential, but it comes at a cost, and real understanding depends in part on understanding the effects of simplification." (p. 18). The use of random representations in the development of cognitive models has been a necessary simplification for our understanding of cognitive processes. In doing so, researchers have made use of representations whose assumptions may not be entirely accurate, but through the use of this simplification modelers have made fundamental discoveries about how memory processes work. However without this assumption these results would not have been possible. It has only been within the last decade that researchers have had access to realistic representations of lexical semantics. The task for the future is to integrate semantic representations with processing models of memory for a fuller understanding of how they work together to produce observable behavior.

In accordance, recent models have begun to conduct this type of integration. For example, Monaco, Abbott, & Kahana (2007) have created a neural network model of the mirror effect of frequency, utilizing lexical semantic representations taken from the WAS of Steyvers, et al. (2004). Ideally, future models will combine a learning process that builds a representation through exposure to environmental information, which can then feed into a processing mechanism. For example, Johns and Jones (2009) have utilized representations built through a co-occurrence learning process to drive a processing model of both false recognition and false recall. These models suggest that it is no longer necessary to assume random representations for lexical semantics when modeling cognitive phenomena, but that item-specific semantic representations are now freely available and offer additional modeling constraints about the structure of semantic similarity that a process mechanism must operate on to produce behavior in a given task.

A Neural Model of Rule Generation in Inductive Reasoning

Centre for Theoretical Neuroscience, University of Waterloo
Waterloo, ON, Canada, N2J 3G1

Abstract

Inductive reasoning is a fundamental and complex aspect of human intelligence. In particular, how do subjects, given a set of particular examples, generate general descriptions of the rules governing that set? We present a biologically plausible method of accomplishing this task, and implement it in a spiking neuron model. We demonstrate the success of this model by applying it to the problem domain of Raven's Progressive Matrices, a widely used tool in the field of intelligence testing. The model is able to generate the rules necessary to correctly solve Raven's items, as well as recreate many of the experimental effects observed in human subjects.

Keywords: inductive reasoning; neural engineering framework; fluid intelligence; Raven's Progressive Matrices; vector symbolic architectures; cognitive modeling

Introduction

Inductive reasoning is the process of using a set of examples to infer a general rule which both describes the relationships shared by those examples and allows us to predict future items in the set. For example, if a person were watching objects in a river or lake and saw a stick, a wooden rowboat, and a telephone pole float past, they might induce the rule that "wooden things float". This rule both describes the relationship which linked those items (being wooden) and allows the person to predict future items which would also float (a wooden bookcase). Given even more examples—some non-wooden floating objects—they might infer the general rule that objects float when they displace a volume of water equal to their weight.

This type of reasoning is fundamental to our ability to make sense of the world, and represents a key facet of human intelligence. It determines our ability to be presented with a novel situation or problem and extract meaning from it. As such, it is a process which has been made central to many tests of general intelligence. One of the most widely used and well respected tools in this field is the Raven's Progressive Matrices (RPM) test (Raven, 1962). In the RPM, subjects are presented with a 3x3 matrix, in which each cell in the matrix contains various geometrical figures with the exception of the final cell which is blank (Figure 1). The subject's task is to determine which one of eight possible answers belongs in the blank cell. They accomplish this by examining the other rows and columns and inducing rules which govern the features in those cells. They can then apply those rules to the last row/column to determine which answer belongs in the blank cell.

Although there has been much experimental and theoretical effort put into understanding the mental processes involved in performing RPM-like tasks, to our knowledge there

have been no models of the inductive process of rule generation. In this paper we present a method of rule generation, and implement it in a neural model using simulated spiking neurons. This model can induce the rules necessary to solve Raven's matrices, and also displays many of the most interesting cognitive effects observed in humans: improved accuracy in rule generation over multiple trials, variable performance in repeated trials, and both quantitative and qualitative changes in individual performance.

Background

Raven's Progressive Matrices

There are several variations of the RPM; the Standard and Coloured versions are generally used to test children or adults with cognitive deficits, while the Advanced is used to differentiate average/above-average adults. In our work we focus on the Advanced version.

Figure 1 depicts an example of a simple Raven's-style matrix.¹ The matrix is shown at the top with one blank cell, and the 8 possible candidates for that blank cell are along the bottom. In order to solve this matrix the subject needs to generate three rules: 1) the number of instances of each shape increases by one across the row, 2) the orientation of the shapes within a cell is constant across the row, 3) each cell in a row contains one shape type from the set {square, triangle, circle}. Subjects can then determine which elements belong in the blank cell by applying the rules to the third row (i.e. there should be $2 + 1 = 3$ shapes, they should be arranged in the same orientation (vertically), and they should be triangles, since circle and square are already taken). Once they have

¹For copyright reasons we have created a modified matrix to present here, the model works with the true Raven's matrices.

Figure 1: A simple Raven's-style matrix

generated their hypothesis as to what the blank cell should look like, they can check for a match among the 8 possible answers. Not all subjects will explicitly generate these exact rules, and their route to the answer may be more roundabout, but they do need to extract equivalent information if they are to correctly solve the problem.

Despite the test’s broad use, the only other computational model for the RPM is that of Carpenter et al. (1990). Their model accurately recreates high-level human data, but does not reflect the flexibility and variability of individual human performance nor take into account neurological data. In addition, Carpenter et al.’s model has no ability to generate new rules; all the rules are pre-programmed. This limitation of their model reflects a general lack of explanation in the literature as to how this inductive process is performed.

The two default assumptions regarding the origin of the rules are that people are either 1) born with, or 2) learn earlier in life, a library of rules. During the RPM, these pre-existing rules are then applied to the current inductive problem. Hunt described this theory as early as 1973, and also pointed out the necessary conclusion of this explanation: if RPM performance is dependent on a library of known rules, then the RPM is testing our crystallized intelligence (our ability to acquire and use knowledge or experience) rather than fluid intelligence (our novel problem solving ability). In other words, the RPM would be a similar task to acquiring a large vocabulary and using it to communicate well. However, this is in direct contradiction to the experimental evidence, which shows the RPM strongly and consistently correlating with other measures of fluid intelligence (Marshalek et al., 1983), and psychometric/neuroimaging practice, which uses the RPM as an index of subjects’ fluid reasoning ability (Perfetti et al., 2009; Prabhakaran et al., 1997; Gray et al., 2003). A large amount of work has been informed by the assumption that the RPM measures fluid intelligence, yet the problem raised by Hunt has been largely ignored. Consequently, there is a need for a better explanation of rule induction; by providing a technique to dynamically generate rules, we remove the dependence on a past library, and thereby resolve the problem.

In contrast to the paucity of theoretical results, there has been an abundance of experimental work on the RPM. This has brought to light a number of important aspects of human performance on the test that need to be accounted for by any potential model. First, there are a number of learning effects: subjects improve with practice if given the RPM multiple times (Bors & Vigneau, 2003), and also show learning within the span of a single test (Verguts & De Boeck, 2002). Second, there are both qualitative and quantitative differences in individuals’ ability; they exhibit the expected variability in “processing power” (variously attributed to working memory, attention, learning ability, or executive functions), but also consistent differences in high-level problem-solving strategy between low-scoring and high-scoring individuals (Vigneau et al., 2006). Third, a given subject’s performance is far from deterministic; given the same test multiple times, sub-

jects will get previously correct answers wrong and vice versa (Bors & Vigneau, 2003). In the Results section we demonstrate how each of these observations is accounted for by our model.

Vector encoding

In order to represent a Raven’s matrix in neurons and work on it computationally, we need to translate the visual information into a symbolic form. Vector Symbolic Architectures (VSAs; Gayler, 2003) are one set of proposals for how to construct such representations. VSAs represent information as vectors, and implement mathematical operations to combine those vectors in meaningful ways.

To implement a VSA it is essential to define a binding operation (which ties two vectors together) and a superposition operation (which combines vectors into a set). We use circular convolution for binding, and vector addition for superposition (Plate, 2003). Circular convolution is defined as

$$C = A \otimes B$$

where

$$c_j = \sum_{k=0}^{n-1} a_k b_{j-k \bmod n} \quad (1)$$

Along with this we employ the idea of a transformation vector T between two vectors A and B , defined as

$$A \otimes T = B$$

or

$$T = A' \otimes B \quad (2)$$

where A' denotes the approximate inverse of A .

With these elements we can create a vector representation of the information in any Raven’s matrix. For example, suppose we wanted to encode the information contained in the third cell of Figure 1. The first step is to define a vocabulary, the elemental vectors which will be used as building blocks. These vectors are randomly generated, and the number of vectors that can be held in a vocabulary and still be distinguishable as unique “words” is determined by the dimensionality of those vectors (the more words in the vocabulary, the higher the dimension of the vectors needed to represent them).

Once the vocabulary has been generated it is possible to encode the structural information in the third cell. A simple method to do this is by using a set of *attribute* \otimes *value* pairs: *shape* \otimes *circle* + *number* \otimes *three* + *colour* \otimes *black* + *orientation* \otimes *horizontal* + *shading* \otimes *solid* and so on, allowing us to encode arbitrary amounts of information. As descriptions become more detailed it is necessary to use more complex encoding; however, ultimately it does not matter to the inductive system how the VSA descriptions are implemented, as long as they encode the necessary information. Thus these descriptions can be made as simple or as complex as desired without impacting the underlying model.

Figure 2: Recordings from the output population of the model, which expresses the similarity between the predicted answer and each of the 8 possible choices. On the left is the spike raster, and on the right is the decoded information from those spikes. The model correctly picks answer number one (the top line).

VSA's have a number of other advantages: vectors are easier to represent in populations of neurons than complex visual information, they are easier to manipulate mathematically, and perhaps most importantly the logical operation of the inductive system is not dependent on the details of the visual system. All that our neural model requires is that the Raven's matrices are represented in some structured vector form; the visual processing which accomplishes this, though a very difficult and interesting problem in itself (see Meo et al. 2007 for an example of the complexities involved), is beyond the scope of the current model. This helps preserve the generality of the inductive system: the techniques presented here will apply to any problem that can be represented in VSAs, not only problems sharing the visual structure of the RPM.

Neural encoding

Having described a method to represent the high-level problem in structured vectors, we now define how to represent those vectors and carry out the VSA operations in networks of simulated spiking neurons. There are several important reasons to consider a neural model. First, by tying the model to the biology we are better able to relate the results of the model to the experimental human data, both at the low level (eg. fMRI or PET) and at the high level (eg. non-deterministic performance and individual differences). Second, our goal is to model human inductive processes, so it is essential to determine whether or not a proposed solution can be realized in a neural implementation. Neuroscience has provided us with an abundance of data from the neural level that we can use to provide constraints on the system. This ensures that the end result is indeed a model of the human inductive system, not a theoretical construct with infinite capacity or power.

We use the techniques of the Neural Engineering Framework (Eliasmith & Anderson, 2003) to represent vectors and carry out the necessary mathematical operations in spiking neurons. To encode a vector $x(t)$ into the spike train of neuron a_i we define

$$a_i(x(t)) = G_i \left[\alpha_i \tilde{\phi}_i x(t) + J_i^{bias} \right] \quad (3)$$

G_i is a function representing the nonlinear neuron characteristics—essentially, how will the neuron spike given the input described within the brackets. In our model we use Leaky Integrate and Fire neurons, but the advantage of this formulation is that any neuron model can be substituted for G_i without changing the overall framework. α_i is a gain on the input, determined by the characteristics of this particular neuron. J_i^{bias} is the background current, modelling the activity in the network which is not a direct input to this neuron. $\tilde{\phi}_i$ represents the neuron's preferred stimulus, that is, which inputs will make it fire more strongly. Broadly speaking, the activity of neuron a_i is a result of its unique response (determined by its preferred stimulus) to the input $x(t)$, passed through a nonlinear neuron model in order to generate spikes.

We can then define the decoding from spike train to vector as

$$\hat{x}(t) = \sum_i h(t) * a_i(x(t)) \phi_i \quad (4)$$

where $h(t)$ is a model of the post-synaptic current generated by one spike, $a_i(x(t))$ are the spikes generated by Equation 3, and ϕ_i are the optimal linear decoders. The optimal linear decoders are calculated analytically so as to provide the best linear representation of the original input $x(t)$; they are essentially a weight on the post-synaptic current generated by each neuron (the result of summing the current generated by each spike).

We have defined how to transform a vector into neural activity and how to turn that neural activity back into a vector, but we also need to be able to carry out the VSA operations (binding and superposition) on those representations. One of the primary advantages of the NEF is that we can calculate the synaptic weights for arbitrary transformations analytically, rather than learning them. If we want to calculate a transformation of the form $z = C_1 x + C_2 y$ (C_1 and C_2 are any matrix), and x and y are represented in the a and b neural populations (we can add or remove these terms as necessary to perform operations on different numbers of variables), respectively, then we describe the activity in the output popula-

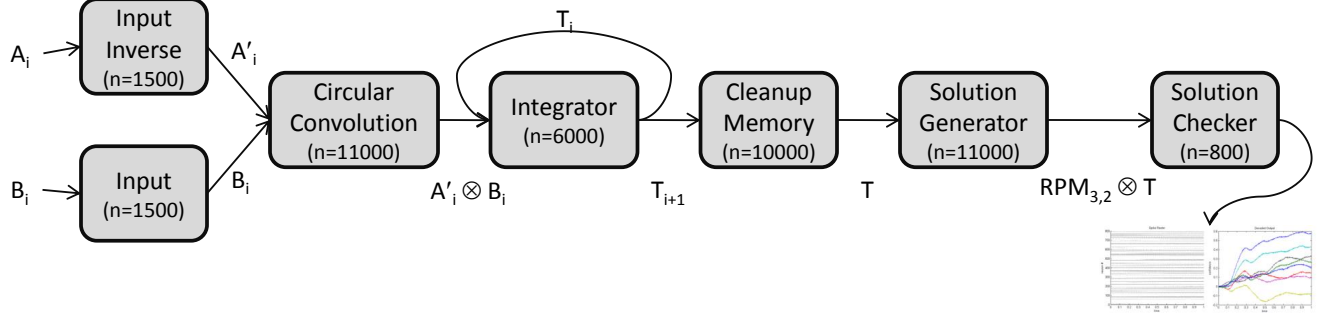

Figure 3: Schematic diagram of the rule generation section with cleanup memory, displaying the approximate number of neurons used in each submodule. The inputs (A_i and B_i) represent two adjacent cells in the matrix. The “Input Inverse” module calculates A'_i , while “Input” simply leaves B_i unchanged. The “Circular Convolution” module calculates $A'_i \otimes B_i$ (the rule for that particular pair of cells). “Integrator” is storing the calculated rule so far (based on previous pairs of adjacent cells), which we combine with the current calculation. The output of “Integrator” is the overall rule, which we pass through a cleanup memory, potentially giving us a less noisy version of that rule. Finally, “Solution Generator” generates a prediction of what should be in the blank cell by convolving the second-last cell with our calculated rule, and then “Solution Checker” calculates the similarity between that hypothesis and each of the eight possible answers given in the problem.

tion as

$$c_k(C_1x + C_2y) = G_k \left[\sum_i \omega_{ki} a_i(x) + \sum_j \omega_{kj} b_j(y) + J_k^{bias} \right]$$

where c_k , a_i , and b_j describe the activity of the k th, i th, and j th neuron in their respective populations. The ω are our synaptic weights: $\omega_{ki} = \alpha_k \langle \tilde{\phi}_k C_1 \phi_i^x \rangle_m$ and $\omega_{kj} = \alpha_k \langle \tilde{\phi}_k C_2 \phi_j^y \rangle_m$. Referring back to our descriptions of the variables in Equations 3 and 4, this means that the connection weight between neuron a_i and c_k is determined by the preferred stimulus of c_k , multiplied by the desired transformation and the decoders for a_i . To calculate different transformations all we need to do is modify the C matrices in the weight calculations, allowing us to carry out all the linear computations necessary in this model. For a more detailed description of this process, and a demonstration of implementing the nonlinear circular convolution (Equation 1), see Eliasmith (2005).

The Model and Results

Rule generation

The key to our model is the idea of the transformation vector (Equation 2). Since we have our Raven’s matrix items encoded as vectors, we can represent rules as transformations on those vectors. For example, if A is the vector representation of one square, and B is the vector representation of two squares, then the transformation vector $T = A' \otimes B$ will be analogous to the rule “number of squares increases by one”. However, we do not just want to calculate individual transformations, we want general rules for the whole matrix. To accomplish this we treat all adjacent pairs of cells as a set of A and B vectors, and extract a general transformation from that set of examples. Neumann (2001) has shown that we can

accomplish this by calculating

$$T = \frac{1}{n} \sum_{i=0}^n A'_i \otimes B_i$$

In order to perform this operation in neurons (where we cannot instantly sum over a set of examples) we translate it into the equivalent learning rule, where each pair of A and B vectors is presented sequentially:

$$T_{i+1} = T_i - w_i(T_i - A'_i \otimes B_i)$$

We implement this by combining a neural integrator (to maintain the overall value of T) with a network which calculates the T_i for the current pair of examples. We present the examples in a top-down row-wise fashion, as that is the general scanning strategy employed by humans as revealed by eye-tracking studies (Carpenter et al., 1990; Vigneau et al., 2006). Let us again take Figure 1 as an example, and examine how the model induces one of the rules necessary to solve the matrix: “number of objects increases by one”. A_0 is the vector representation of one square, and B_0 is the vector representation of two triangles (we will omit orientation in this example to keep things simple, but it is treated in exactly the same way). The network calculates $T_1 = A'_0 \otimes B_0$, which is something like the rule “number of objects increases by one and squares become triangles”, and that value is stored in the neural integrator. In the next step A_1 is two triangles and B_1 is three circles, and T_2 is “number of objects increases by one and triangles become circles”. However, when T_2 is added to the neural integrator, “number of objects increases by one” is reinforced (since it was already present) while the other information is not. This process continues with the next two rows. Thus we begin with a very noisy rule, but over time relations which are particular to individual A and B pairs are

drowned out by the relation which all the pairs have in common: “number of objects increases by one”.²

Once this process is complete we have the overall T vector, representing a general rule for the problem. Thus we have accomplished our primary goal, to provide an explanation as to how subjects can inductively generate descriptions of the rules governing a set of examples. We use these rules by applying them to the second-last cell of the Raven’s matrix $A \otimes T$ giving us B , a vector representing what our rules tell us should be in the blank cell. We then compare this hypothesis to the eight possible answers and take the most similar (determined by the dot product between the two vectors) as our final answer (see Figures 2 and 3).

Cleanup memory

In addition to being able to generate the rules to solve a matrix, the model should improve at this process given practice. We accomplish this by adding a cleanup memory, a system which stores certain values and, when given a noisy version of those values as input, outputs the clean version stored in memory. A cleanup memory can be implemented in neurons by creating a network which contains neural populations tuned to respond only to certain inputs and output the clean version of those values (Stewart et al., 2009). We implement a cleanup memory in this model by storing the past rules the system has induced. The current rule generated by the network, which will be perturbed by neural noise and the details of the particular Raven’s matrix, is passed through this cleanup memory, and if the cleanup memory contains a similar rule then that clean version of the rule is output.

The cleanup memory is improved over time by two mechanisms. First, if the cleanup memory receives an input that it does not recognize, it adds that input to its memory so that it will be recognized in the future. Second, if the cleanup memory receives an input that it does recognize, it uses that input to refine the value stored in memory, so that the stored value becomes increasingly accurate. Thus as the system encounters rules it has calculated before it will be able to draw on its past efforts to provide a more accurate output. See Figure 4 for a demonstration of how this improvement in cleanup memory can lead to improved inductive performance.

The cleanup memory not only helps account for observed learning effects, it also bridges the gap between this model of inductive rule generation and theories of a “library” of known rules. In short, we are improving on current theories by explaining where that past knowledge comes from, and why its use is a dynamic, fluid process.

Higher level processes

In addition to the inductive process of rule generation, there are high-level problem solving effects (what we might call the subject’s “strategy”) which will have a significant impact on performance. For example, how does the subject decide

²This same process will help eliminate the noise added at the neural level.

Figure 5: A demonstration of both low-level (vector dimension) and high-level (strategy) influences on accuracy (displaying 95% confidence intervals).

when and where to apply the rule generation system? When there are multiple rules to be found, how does the subject differentiate them, and how do they decide they have found all the rules? How does the subject decide whether their hypothesis is good enough to settle on as a final answer? These are important questions, but they are dependent on the particular problem the subject is solving.

We have implemented such a strategy system for the RPM (although not at the neural level) in order to collect aggregate test results and explore individual differences. Figure 5 shows an example of these results, demonstrating the model’s ability to recreate differences caused by both low-level neural processing power and high-level strategy. The low-level variable is the dimensionality of the vectors, higher dimension vectors requiring more neurons to represent. The high-level variable is how willing the model is to decide it has found a correct rule: the lower line represents a subject who has less stringent standards, and is willing to accept rules that may not be completely correct, whereas the top line represents a subject employing a more conservative strategy. These results demonstrate that both low and high level variables have a significant impact on accuracy, and reflect the quantitative and qualitative individual differences observed in human performance. Figure 5 also reveals that although the overall performance trends are clear, there is significant variability (average $\sigma = 0.13$) in any given trial, another parallel of human subjects. There are many such interesting avenues of exploration, however we will not go into the details of the strategy system here; the primary contribution of this research is the general rule-induction system described above, which is not dependent on the higher level framework within which it is used.

Figure 4: An example of the model's ability to learn over time. The model was presented with a series of matrices that appeared different but required the same underlying rules to solve; as we can see, the model is able to more quickly and definitively pick out the correct answer on later matrices.

Conclusion

We have presented a novel, neurally-based model of inductive rule generation, and we have applied this system to the particular problem of Raven's Progressive Matrices. The success of the system is demonstrated in its ability to correctly find general rules that enable it to solve these matrices, as well as in the model's ability to recreate the interesting effects observed in human subjects, such as learning over time, non-deterministic performance, and both quantitative and qualitative variability of individual differences. These results demonstrate the potential for gaining a deeper understanding of human induction by adopting a neurally plausible approach to modeling cognitive systems.

Abstract

Accounts of category-based inductive reasoning can be distinguished by the emphasis they place on structured versus unstructured knowledge. In addition, it has been claimed that certain domains of structured knowledge are more available than others. Using a speeded task paradigm, participants rated the strength of inductive arguments in which the categories were either strongly or weakly associated and shared a taxonomic or causal relation. Strongly associated categories received higher inductive strength ratings than weakly associated category pairs, regardless of the domain by which the categories were related. Strength of association was highly predictive of inductive strength ratings, but more additional variance was accounted for by beliefs about taxonomic and causal relations when people were not under time pressure. This suggests that, regardless of knowledge domain, maximizing inductive potency relies on the use of both structured and unstructured knowledge, depending on available mental resources.

Keywords: Category-Based Induction; Knowledge; Categorical Inferences; Reasoning.

Knowledge and Category-Based Induction

Category-based generalizations cover a class of inferences in which an object's category membership supports people's inferences about properties shared with other category members. For example, classifying an animal as a rabbit allows us to infer that it probably lives in a burrow. Furthermore, if we observe that the animal we have classified as a rabbit eats carrots, we are likely to infer that other rabbits and, perhaps hares, also eat carrots.

In order to understand what determines the likelihood that a property will be generalized from a known to a novel instance, we need to identify which aspects of our background knowledge are central to the induction process. Whereas some approaches view category-based induction as driven solely by associative or unstructured knowledge, such as featural overlap (Sloman, 1993), perceptual similarity (Sloutsky & Fisher, 2004) or semantic associations (Rogers & McClelland, 2004), apparently contradictory approaches place theory-based or structured knowledge at the centre of the inductive process, such as knowledge about stable category-hierarchies (Osherson, et al., 1990) and causal relations between categories (Kemp

& Tenenbaum, 2009). These contrasting types of knowledge in turn possess unique processing characteristics which differentially affect the reasoning output.

Unstructured Knowledge and Induction

Unstructured knowledge cannot be described by a higher order structure, abstract interrelationships or theories. It can include relations between entities based on contiguity, co-occurrence, similarity or associations. Several studies suggest that early category formation and induction is driven by the statistical properties inherent in the environment, such as co-occurrence and statistical distribution of perceptual features. For example, Sloutsky and Fisher's (2004) model of Similarity, Induction and Categorization (SINC) assumes that children perform categorization and inductive reasoning on the basis of perceptual similarity, in which the category label is simply treated as another feature contributing to increased similarity between different instances. These researchers also claim that there is only a gradual and developmentally late transition from exclusive reliance on similarity to the use of category membership as a basis for induction. This transition is largely seen as the product of explicit instruction and learning about general characteristics of categories (Fisher & Sloutsky, 2005).

Some proponents of associative approaches to category-based induction advocate that adult categorization and induction is also heavily influenced by similarity (Sloman, 1993) and associations in semantic memory (Rogers & McClelland, 2004). For example, Sloman's (1993) feature-based model explains generalizations purely in associative terms as the degree to which the presentation of the premise instances activates overlapping features of the conclusion instance. Arguments in which premise and conclusion categories share more features are stronger than arguments with little featural overlap between premise and conclusion. Consequently, there is no need to assume a stable category hierarchy. Sloman (1998) does not preclude the possibility that assessment of similarity can at times reflect a more effortful process which draws on knowledge about stable category hierarchies. However, he does suggest that the default mode of category-based induction reflects a predominantly intuitive thought process, requiring no processing effort or reference to class inclusion relations,

especially when people lack relevant knowledge, are under time pressure or have not been explicitly instructed to carefully consider their responses.

Structured Knowledge in Induction

An opposing approach to explaining inductive reasoning focuses on the influence of structured knowledge. The justification for assuming that structured knowledge can play an important role in category-based induction arises from several reasoning phenomena that cannot be explained exclusively by the use of unstructured or associative knowledge.

Osherson et al's (1990) Similarity-Coverage Model posits knowledge about stable taxonomic structure as an important source of information that people rely on when evaluating categorical arguments. Inductive evaluations reflect the weighted sum of two primary parameters, similarity and coverage. Similarity refers to the maximum average similarity between the premise and conclusion categories. Coverage refers to the degree to which the premise categories cover the featural space of the inclusive superordinate category and thus, calculation of coverage requires structured knowledge in the form of a stable hierarchy of categories. The coverage component of the model gives rise to the diversity effect, whereby dissimilar premise categories act as stronger evidence than similar premise categories. Although this phenomenon can be explained by Sloman's model, the developmental trajectory of the diversity effect (Lopez, Gelman, Gutheil & Smith, 1992) is more compatible with the assumption that people draw on structured knowledge about stable category hierarchies. Similarly, if sensitivity to diversity was based exclusively on unstructured associative knowledge, it would not be related to general cognitive ability (Feeney, 2007).

Approaches emphasizing the importance of unstructured knowledge also have no means of explaining effects that arise from considering underlying higher-order interrelationships between categories. Tenenbaum and Kemp (2009) and Shafto et al. (2008) have demonstrated that inductive reasoning about causal transmission can be dissociated from inductive inferences about physiological properties. Such dissociations suggest that the context or property people are reasoning about prompts them to draw on different and most relevant sources of structured knowledge. Making use of this kind of structured knowledge also gives rise to phenomena such as the causal asymmetry effect, whereby inferences about the transmission of diseases are deemed stronger from prey to predator than from predator to prey (Medin, Coley, Storms & Hayes, 2003; Shafto, et al., 2008). Again, it is hard to see how approaches relying exclusively on nondirectional unstructured knowledge might cogently explain such effects.

Processing Differences

On the surface it appears that approaches placing divergent emphasis on different types of knowledge are

incompatible. However, recent evidence suggests that both structured and unstructured types of knowledge play an important role in inductive reasoning, and that they may be a source of individual differences. One of the major distinguishing features appears to be the nature of the mental processes that mediate the use of these contrasting types of knowledge. For example, Rehder (2009) explicitly suggests that the use of structured knowledge relies on an elaborate, analytical thought processes, whereas associative knowledge influences inductive reasoning fairly automatically and without much cognitive effort. Rehder (2009) taught participants about the causal links between category features of artificial categories. In line with the assumption that people draw on extensive causal knowledge, he demonstrated various phenomena, such as a causal asymmetry effect. However, he also found that there was a substantial minority of people whose patterns of inductions did not adhere to those predicted by his causal-based generalization model. Instead, they seemed to rely more on nondirectional associations between the category features.

This suggests that selective inductive reasoning can either be driven by structured knowledge based on theoretical conceptions about relations between categories within a domain, or on unstructured knowledge based on temporal contiguity or degree of association between the categories.

Testing for Effects of Knowledge Type

To test our hypothesis that category-based induction might be driven by different types of knowledge we used a paradigm developed by Shafto, Coley & Baldwin (2007) who were interested in the effects of knowledge domain on induction. Shafto et al (2007) presented participants with arguments consisting of taxonomically or ecologically related categories and manipulated time to respond. To test our hypothesis about differential effects of knowledge type, we also included a manipulation of between-category association. As access to structured knowledge seems to require slower and more elaborate reasoning, we expected people to rely more on unstructured knowledge when under time pressure.

Our design also allowed us to attempt to replicate Shafto et al's finding that whereas people's inferences about taxonomically related categories were unaffected when under time pressure, they gave lower inductive strength ratings to ecologically related categories when they had to respond rapidly. Because Shafto et al. did not control for level of association between their category pairs, it will be of interest to examine whether processing differences between knowledge domains still emerge when degree of association is equated between domains.

Methods

Participants

40 participants took part in the study. They were volunteers from Durham University, who received course credit for their participation. Their mean age was 24.2 years (SD= 7.8 years).

Design

The experiment had a 2 (timing: speeded versus delayed) by 2 (property: cells or disease) by 2 (relation: taxonomic or causal) by 2 (level of association: high versus low) mixed design, with timing as the between-subjects variable.

Materials and Procedure

There were 20 reasoning items consisting of a base category, a causally related target category and a taxonomically related target category. Causally related pairs were always from different superordinate categories, for example, plants and animals, or mammals and reptiles. In contrast, taxonomically related pairs were always from the same superordinate taxonomic category.

For each item, there was a causal problem and a matching taxonomic induction problem, resulting in a total of 40 problems.

In order to control for level of association between the base category and its two target categories, 18 Durham University students were asked to rate how strongly pairs of words were associated on a scale from 1 (unrelated) to 9 (very strong association). Whilst no specific examples were given, when generating each rating participants were instructed to consider all kinds of possible relations, such as causal, functional, taxonomic etc, and were asked to give the first answer that came to mind. We selected only those 20 items with a similar level of association between the base and its alternative causal and taxonomic target categories. We then also derived a more objective measure of co-occurrence against which to verify our notion of association. We calculated the frequency with which the two categories co-occurred within six words on the World Wide Web by using a Google proximity search and used a formula suggested by Heylighen (2001) to calculate the conditional probability of co-occurrence:

$$Aw_1 \& w_2 = P(w_1 | w_2) = \frac{P(w_1 \& w_2)}{P(w_1)} = \frac{N(w_1 \& w_2)}{N(w_1)}$$

In this equation, $P(w_1 \& w_2)$ represents the probability that a text contains both words w_1 and w_2 , $P(w_1)$ represents the probability that it contains w_1 on its own. To calculate the conditional probability, one can simply count the number of times w_1 and w_2 co-occur and divide this by the number of times w_1 occurs by chance in the same text sample. We then took the mean of these two conditional probabilities and correlated this with our association strength ratings. These two measures were significantly correlated (Spearman's $\rho = .56$, $p < .01$) supporting our contention that we are

indeed measuring a construct of associative strength in which the activation of one leads to activation of the other, irrespective of the nature of relation between the two categories.

To explore the role that level of association plays in the availability of knowledge from different domains, a median split based on level of association was carried out on the selected items. Thus, for 10 items the association between the base and its target categories was classed as strong and for the remaining 10 items this association was classed as weak. For half the strongly and weakly associated items participants generalized diseases. For the other half, people evaluated inductive conclusions about cells, so whilst property was manipulated within-subjects, content was counterbalanced across participants in a Latin-square design.

Participants learnt that the base category had either a blank disease, such as disease 9T4, or blank cells, such as cells Lo8. They then rated the likelihood that the target category shared the disease or cells on a 9-point scale. For example, participants might be presented with the following induction problems:

Carrots have disease 3dfT.
How likely is it that Rabbits have disease 3dfT?
(causal/disease)

Carrots have disease ww3T.
How likely is it that Radishes have disease ww3T?
(taxonomic/disease)

Acorns have cells T4H.
How likely is it that Squirrels have cells T4H?
(causal/cells)

Acorns have cells eR2.
How likely is it that Walnuts have cells eR2?
(taxonomic/cells)

The induction problems were presented on a laptop. The premise and conclusions were presented simultaneously and appeared in a red font. Participants could only enter their response once the font changed to green. In the speeded condition, the font changed from green to red after one second and participants were instructed to read the problem and respond as fast as possible without sacrificing accuracy. In the delayed condition, the font only changed colour after 10 seconds and participants were instructed to carefully consider their responses. They entered their response on the key board by giving a rating between 1 and 9.

Post-Test

The post-test assessed people's beliefs about taxonomic and causal relatedness. For each of the 40 category pairs, participants were asked two questions, resulting in a total of 80 questions. One question asked them whether they believed that the two categories were from the same biological class and the other asked whether the two

categories were part of the same food chain. Participants could respond with YES, NO or DON'T KNOW, but were instructed to use the third option sparingly, as the emphasis was on their intuitions and beliefs rather than on factual correctness. The mean proportion of positive responses to the two post-test questions about biological group membership and food chain relations across the two timing conditions did not correlate with our web-based measure of co-occurrence (Spearman rho correlation coefficients ranged from -.18 to .16, all p 's > .27), nor did it correlate with our subjective measure of associative strength (Spearman rho correlation coefficients ranged from .1 to .2, all p 's > .18) suggesting that these measures did not reflect associative strength but represents beliefs based on more structured knowledge.

Results

To facilitate an initial factorial analysis of the data, mean inductive strength scores were calculated for the 5 problems representing the unique property by association by relation combination, resulting in 8 means for each participant. These were subjected to a 2 (property: disease or cell) by 2 (relation: causal or taxonomic) by association (high versus low) by 2 (timing: delayed or speeded) mixed-design ANOVA, with timing as the between-subject variable. We predicted effects of degree of association in our results. However, if association does not play an important role, we would expect to observe an interaction between timing and relation, with timing affecting causal but not taxonomic inferences, thus replicating Shafto et al's (2007) findings.

Although the effects of relation, $F_{(1, 38)} = 3.39$, $p = .073$, effect size $d = .66$, and timing, $F_{(1, 38)} = 3.18$, $p = .082$, effect size $d = .6$, were approaching significance, timing did not interact with any of the other variables. Thus, when we control for degree of association we do not replicate Shafto et al's finding.

The only large and reliable significant main effect was strength of association, $F_{(1, 38)} = 28.82$, $p < .0001$, effect size $d = 2.0$. As expected, inferences about closely associated categories ($M = 4.52$, $SE = .14$) were rated stronger than inferences about weakly associated categories ($M = 3.98$, $SE = .14$).

The only significant two-way interaction was between property and relation, $F_{(1, 38)} = 25.68$, $p < .0001$, effect size $d = 1.7$, suggesting that people showed some context-sensitive reasoning. Bonferroni posthoc tests showed that when reasoning about cells, people rated taxonomic inferences ($M = 5.01$, $SE = .2$) significantly stronger than causal inferences ($M = 3.79$, $SE = .22$, $p < .0001$, effect size $d = .9$). When reasoning about diseases, people rated causal inferences slightly higher ($M = 4.32$, $SE = .26$) than taxonomic inferences ($M = 3.89$, $SE = .17$) although this difference was not significant ($p = .16$, effect size $d = .3$). This might suggest that whereas physiological inferences are predominantly supported by taxonomic relations between categories, inferences about diseases can be made on the

basis of external mechanisms, in this case causal transmission, but also on the basis of more internal mechanisms, in this case taxonomic links and thus genetic relatedness.

None of the other higher-order interactions were significant (all p 's > .08)

Regression Analyses

To explore how structured and unstructured types of knowledge influence category-based inductions under different conditions, we calculated mean inductive strength ratings for each item separately for the two types of property and timing conditions, resulting in 4 inductive strength scores for each item. Similarly, for each item we calculated the mean proportion of positive responses to the two post-test questions about biological group membership and food chain relations across the two timing conditions.

Multiple regression analyses were carried out on the mean inductive strength scores. We make the theoretical assumption that people will be influenced by strength of association regardless of timing manipulations. Hence, we entered this variable in block 1. In a second block, we added proportion of positive responses to the biological group question and food chain question as the independent predictor variables. This enabled us to evaluate the degree to which adding variables reflecting structured knowledge accounted for additional variance above and beyond strength of association.

All four regression analyses were significant, but different relevant knowledge influenced inductive strength under different conditions. Overall, larger multiple correlation coefficients were observed in the delayed condition, suggesting that people used different types of knowledge to inform their inferences when they had time to do so, whereas under time pressure, the ability to recruit relevant knowledge seemed to be attenuated.

Inferences about Diseases

As Figure 1 shows, speeded inductive reasoning about diseases ($R = .59$) was significantly predicted by strength of association ($\beta = .45$, $t = 3.13$, $p = .003$). In the second block, knowledge about relevant causal food chain relations was also a significant predictor ($\beta = .35$, $t = 2.04$, $p = .05$), whereas taxonomic knowledge was not a significant predictor ($\beta = .08$, $t = .44$, $p = .67$). Together, adding these two structured knowledge variables accounted for a nonsignificant amount of additional variance (R^2 Change: 9.6%, $F_{(2, 36)} = 2.64$, $p = .09$).

In contrast, reasoning about diseases under delayed conditions ($R = .68$) was no longer significantly predicted by association ($\beta = .24$, $t = 1.8$, $p = .08$). However, inductive strength was strongly predicted by relevant knowledge about food chain relations ($\beta = .61$, $t = 4.34$, $p < .001$), but also by beliefs about biological relatedness ($\beta = .34$, $t = 2.33$, $p = .03$). Adding the structured knowledge predictors in a second block did account for significantly more variance in inductive strength ratings

than strength of association on its own (R^2 Change: 25.8%, $F_{(2, 36)} = 9.46, p < .001$).

Figure 1: Standardized Regression Coefficients for Predictive Relations between Taxonomic and Causal Beliefs, Strength of Association and Inductive Strength Ratings for Diseases

Inferences about Cells

Reasoning about cells showed a different pattern as shown in Figure 2. Under delayed conditions, strength of association was not a significant predictor of inductive strength (beta = .19, $t = .15, p = .14$). Inductive inferences were however predicted by beliefs about biological relatedness ($R = .72$) (beta = .48, $t = 3.48, p = .001$), and were negatively predicted by beliefs about causal relatedness (beta = -.31, $t = -2.29, p = .03$). Given that we had selected causal targets that were always from different superordinate categories, it is not surprising that causal beliefs were a negative predictor of inferences about cells.

As when reasoning about diseases, adding the structured knowledge predictors in a second block accounted for significantly more variance in inductive strength ratings than strength of association on its own when people were not under time pressure (R^2 Change: 44.2%, $F_{(2, 36)} = 16.33, p < .001$).

Speeded inductions about cells ($R = .64$) were predicted by strength of association (beta = .51, $t = 3.76, p = .001$) and were negatively predicted by beliefs about causal relatedness (beta = -.34, $t = -2.5, p = .05$). Taxonomic beliefs were not a significant predictor of speeded inductive strength ratings (beta = .11, $t = .65, p = .52$). However, adding the structured knowledge coefficients did explain some additional variance above strength of association on its own (R^2 Change: 16.7%, $F_{(2, 36)} = 5.09, p = .01$).

Discussion

Our main proposal was that knowledge effects in category-based induction can be distinguished with regards to two contrasting types of knowledge: effortlessly computable, unstructured knowledge such as strength of association (Rogers & McClelland, 2004) or similarity (Sloman 1993; Sloutsky & Fisher, 2004) on the one hand, and structured knowledge (Kemp & Tenenbaum, 2009, Shafto et al, 2008, Rehder, 2009), which requires more time and processing effort, on the other. Overall, our results strongly support this distinction between different types of knowledge that differ in their processing characteristics. The response timing paradigm used in the current experiment showed that strength of association was a stronger predictor of inductive strength ratings when people had to respond quickly. In contrast, structured causal and taxonomic knowledge became more important when people were forced to delay their response and hence had time to consider the nature of the relationship between the categories.

A secondary goal of this experiment was to explore whether differences in the accessibility of knowledge from different domains arises when level of association is controlled for. The results showed that once level of association was equated across causally and taxonomically related category pairs, the previously observed advantage for taxonomic knowledge (e.g. Shafto et al., 2007) was no longer observed. This suggests that no domain of knowledge is more privileged than any other.

With regards to our main proposal, there are several benefits of being able to draw on two types of knowledge that differ in their processing characteristics. The potency of inductive inferences can be maximized by recruiting structured knowledge, making inferences more sensitive to

contextual factors and relational constraints. It is difficult to see how connectionist models, whose hallmark processes are instantiated by nondirectional and automatic spreading activation, could explain how additional sources of knowledge, such as causal and taxonomic knowledge, selectively influence people's inferences about diseases when people have time but not when they have to respond rapidly.

However, people may not always have the time and available mental resources to try and draw on elaborate background knowledge. Thus, unstructured knowledge acquired through associations, temporal contiguity, or co-occurrence provides a rich source of ecologically valid information at little or no processing cost (Evans, 2008; Smith & DeCoster, 2000). As demonstrated by Rogers & McClelland's (2004) PDP model, it is conceivable that frequently co-occurring categories would lead to a gradual adjustment of their semantic representations in memory, so that activation of one would either 'prime' or partially activate the representation of strongly associated categories.

Conclusion

We provide support for the claim that category-based inductive reasoning is influenced by two types of knowledge, structured and unstructured knowledge, which are mediated by two contrasting mental processes (Rehder, 2009). Use of unstructured knowledge, such as nondirectional associative strength (Sloman, 1993; Rogers & McClelland, 2004) seems to reflect a relatively effortless process, in which inductions are proportional to the degree to which activation of the premise and conclusion category representations in semantic memory overlap. However, this can be supplemented by the use of more elaborate structured knowledge (Kemp & Tenenbaum, 2009; Shafto et al., 2008). Structured knowledge encodes intuitive theories about the structural relationships between categories, such as knowledge about taxonomic connections or causal interactions. Use of this type of knowledge is constrained by cognitive resources but can maximize inductive potency of inferences beyond mere associative strength between categories.

Learning hypothesis spaces and dimensions through concept learning

Joseph L. Austerweil (Joseph.Austerweil@gmail.com)

Department of Psychology, University of California, Berkeley, Berkeley, CA 94720-1650 USA

Abstract

Generalizing a property from a set of objects to a new object is a fundamental problem faced by the human cognitive system, and a long-standing topic of investigation in psychology. Classic analyses suggest that the probability with which people generalize a property from one stimulus to another depends on the distance between those stimuli in psychological space. This raises the question of how people identify an appropriate metric for determining the distance between novel stimuli. In particular, how do people determine if two dimensions should be treated as separable, with distance measured along each dimension independently (as in an L_1 metric), or integral, supporting Euclidean distance (as in an L_2 metric)? We build on an existing Bayesian model of generalization to show that learning a metric can be formalized as a problem of learning a hypothesis space for generalization, and that both ideal and human learners can learn appropriate hypothesis spaces for a novel domain by learning concepts expressed in that domain.

Keywords: generalization; categorization; Bayesian modeling; similarity; integral and separable dimensions

Introduction

Almost every two objects, events, or situations (or the sensory data for the *same* object at two different moments) that we encounter are unique. Despite this fact, when people (and animals) learn that one stimulus has a property, they reliably and systematically believe certain other stimuli have that property and others do not (Shepard, 1987). For example, if you learn a dark, large circle is a *gnarble*, how likely is a dark, slightly smaller circle or a dark very small circle to be a *gnarble*? This is the problem of *generalization*, which is pervasive across cognitive science. It occurs in many forms from higher-level cognition (e.g., concept learning, Tenenbaum, 2000) to linguistics (e.g., word learning, Xu & Tenenbaum, 2007) to perception (e.g., color categorization, Kay & McDaniell, 1978). How should an ideal learner generalize a property from a group of stimuli observed to have the property to other stimuli?

One of the most celebrated theoretical results of cognitive psychology provides a deceptively simple answer to this question, indicating that we should generalize a property from one object to another object when the two objects are similar, or equivalently, close in some psychological space (Shepard, 1987). However, this establishes a new problem: How should the distance between objects be measured? More formally, the problem is one of identifying a *metric* on a space, a basic challenge that also arises when using machine learning methods that rely on computing distances, such as nearest-neighbor classification (Xing, Ng, Jordan, & Russell, 2002; Davis, Kulis, Jain, Sra, & Dhillon, 2007). Cognitive psychologists have determined that people use two different kinds of metrics when forming generalizations about multi-dimensional stimuli: *separable* dimensions are associated

with “city-block” distance or the L_1 metric, while *integral* dimensions are associated with Euclidean distance or the L_2 metric (Garner, 1974). These different metrics also have consequences beyond generalization behavior, influencing how people categorize objects varying along different dimensions (Handel & Imai, 1972) and whether people can selectively attend to each dimension (Garner & Felfoldy, 1970).

Analyses of human generalization have tended to treat the metric as a fixed property of stimuli. However, determining the appropriate metric on a psychological space is an important step towards developing an appropriate representation for the properties of novel objects. If two dimensions are separable, then those dimensions form privileged axes for representing locations in the psychological space, and it is easier to learn categories defined by rules that align with those axes (Kruschke, 1993). This is qualitatively different from an integral representation, in which there are no natural axes for representing the space. Identifying whether dimensions should be separable or integral is thus just as basic a step towards forming a representation for a novel domain as determining the number of dimensions, or the locations of each stimulus in the resulting space.

In this paper, we consider how a learner could identify the appropriate metric for representing a novel domain, comparing an ideal Bayesian learner with human judgments. The starting point for this investigation is an existing Bayesian model of generalization, introduced by Shepard (1987) and extended by Tenenbaum and Griffiths (2001). In this model, the property of interest is possessed by all stimuli within an unknown region of psychological space, and the probability of generalizing to a new stimulus is computed by summing over all candidate regions containing the new stimulus and the previous stimuli observed to have some property, weighted by the posterior probability of that region. The difference between separable and integral dimensions emerges as the result of probabilistic inference with different hypothesis spaces of regions (Shepard, 1987, 1991; Davidenko & Tenenbaum, 2001). The hypothesis spaces that produce generalization corresponding to separable and integral dimensions consist of axis-aligned and axis-indifferent regions in the space, respectively (see Figure 1). Axis-aligned regions produce stronger generalization along the axes, while axis-indifferent regions produce generalization that depends only on the Euclidean distance between stimuli.

This analysis of separable and integral dimensions lays the groundwork for our account of how people learn an appropriate metric for a novel space. Learning a metric thus becomes a matter of inferring an appropriate hypothesis space on which to base generalization. We define a hierarchical

Bayesian model that makes this inference from a set of observed concepts. We demonstrate that this model infers a city-block or Euclidean generalization metric when given axis-aligned or axis-indifferent concepts, respectively, and that people infer a hypothesis space for generalization based on the concepts they learn in a way that is consistent with this ideal observer analysis. This extends previous results by Goldstone (1994) who changed dimensions from being integral to separable via repeated training of a single concept.

The plan of the paper is as follows. The next section provides the theoretical background for our approach, summarizing the basic generalization model, revisiting some of the literature on separable and integral dimensions, and laying out our approach to hypothesis space learning. We then present a test of the predictions of this model with human learners. Finally, we conclude the paper with a discussion of our results and possible future directions.

Theoretical Framework

Our theoretical framework builds directly on the Bayesian generalization model introduced in Shepard (1987) and Tenenbaum and Griffiths (2001), so we begin by summarizing the key ideas behind this approach. We then show how this approach produces separable and integral generalization, and how it can be extended to allow an ideal learner to infer an appropriate representation for novel stimuli.

The Bayesian Generalization Model

Let X be the stimulus space and \mathcal{H} be the hypothesis space, where $h \in \mathcal{H}$ is a hypothesis as to which objects have and do not have the property of interest (i.e., a hypothesis is a set of $x \in X$). After observing that a set of stimuli $X = \{x_1, \dots, x_n\}$, $x_i \in X$, stimuli have some property, how should you update your belief in: (1) which property it is and (2) which other stimuli have that property? Assuming that stimuli are generated uniformly and independently under the true hypothesis at random for the property ($p(X|h) = \prod_i p(x_i|h) = |h|^{-n}$ for a hypothesis containing all stimuli in the given set; $p(X|h) = 0$ otherwise) and taking some prior over hypotheses $p(h)$, the posterior probability that a hypothesis h is the property that n given stimuli share is

$$p(h|X) = \frac{p(h) \prod_{i=1}^n p(x_i|h)}{\sum_{h' \in \mathcal{H}} p(h') \prod_{i=1}^n p(x_i|h')} \quad (1)$$

which is simply Bayes' rule. Using Equation 1, we can derive the probability of generalizing from X to some other stimulus y as the sum over the posterior probability of hypotheses containing y

$$p(y|X) = \sum_{h: y \in h} p(h|X) \quad (2)$$

which constitutes a form of *hypothesis averaging* (Robert, 2007). The predictions of the model depends intimately on the nature of the hypotheses under consideration, with different hypothesis spaces leading to different generalization patterns.

Separable and Integral Dimensions

Psychological explorations of human similarity metrics of multidimensional stimuli discovered two different ways in which people use these dimensions: separable and integral (Shepard, 1987). Separable dimensions can be interpreted independently and form natural axes for representing a space, while integral dimensions are difficult to perceive independently. The dimensional structure of stimuli affects many aspects of human information processing, including the ease of categorizing objects into groups and perceived distance between objects (Garner, 1974). For example, Garner and Felfoldy (1970) found that categorization time was facilitated for objects with integral dimensions (e.g., saturation and lightness of a color) into groups where the values of the dimensions of the objects in each group are correlated (light and desaturated vs. dark and saturated). However, there was interference for objects categorized into groups of objects where the values of the dimensions are orthogonal (light and saturated vs. dark and desaturated). Conversely, there were no major differences in categorization time for these types of categorization structures when the dimensions were separable.

Dimensional structure also affects the perceived distances between objects (Shepard, 1991). The perceived distance metric for objects with separable dimensions is the “city-block” distance, also known as the L_1 metric, with the distance between two stimuli x_i and x_j being $d(x_i, x_j) = \sum_k |x_{ik} - x_{jk}|$, where k ranges over dimensions and x_k is the value of stimulus x on dimension k . The perceived distance metric for objects with integral dimensions is the Euclidean distance, or L_2 metric, with $d(x_i, x_j) = \sqrt{\sum_k (x_{ik} - x_{jk})^2}$. The use of these different distance metrics is consistent with the different properties of separable and integral dimensions: city-block distance sums the distance along each axis separately for all points in the space, while Euclidean distance is insensitive to whether a point is located along an axis, and is thus invariant to changes in the axes used to represent the space. Recent extensions of classic multidimensional scaling techniques bear out these results, and provide a way to identify whether people seem to use separable or integral dimensions in their representation of a set of stimuli (Lee, 2008).

In the Bayesian generalization model introduced in the previous section, the difference between integral and separable dimensions emerges from using two different hypothesis spaces (Shepard, 1987). Using a hypothesis space in which regions are aligned with the axes results in behavior consistent with separable dimensions, while a hypothesis space in which regions are indifferent to the axes results in behavior consistent with integral dimensions. Figure 1 shows a schematic of two such hypothesis spaces, restricted to rectangular regions in two dimensions, together with the generalization gradient for a single exemplar concept in each space.¹

¹We calculated the generalization gradients by sampling from the prior distribution over hypotheses for the axis-aligned and axis-indifferent hypothesis spaces, then weighting each hypothesis by the likelihood given the single exemplar $E5$. The gradients were evaluated on a discretized 9×9 grid.

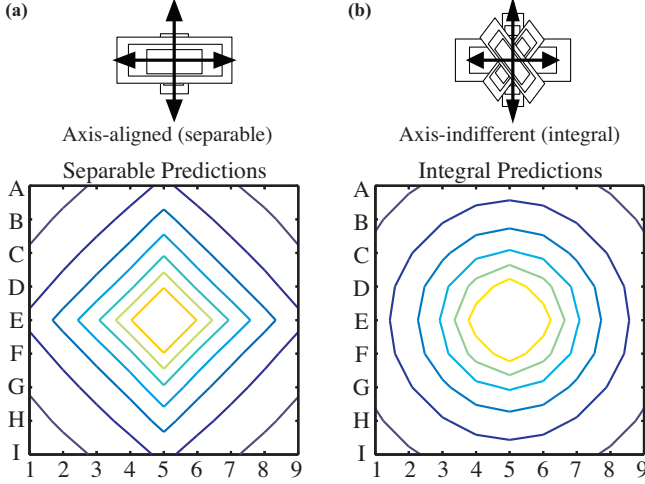

Figure 1: Hypothesis spaces and generalization gradients. (a) Axis-aligned (separable) and axis-indifferent (integral) hypothesis spaces. (b) Resulting generalization gradients for each hypothesis space given a single exemplar of a concept.

The generalization gradient resulting from the axis-aligned hypothesis space given a single exemplar of a concept decreases with distance under a city-block metric, while the gradient resulting from the axis-indifferent hypothesis space decreases with Euclidean distance. Models using the appropriate hypothesis spaces capture generalization judgments well for concept learning tasks using separable and integral dimensions for both single and multiple exemplars (Davidenko & Tenenbaum, 2001; Tenenbaum, 1999).

Learning a Hypothesis Space

The Bayesian generalization framework naturally extends to learning an appropriate hypothesis space by introducing the hypothesis space itself as a higher-level random variable in a hierarchical Bayesian model. Given an enumerable set of hypothesis spaces $\mathcal{M} = \{\mathcal{H}_1, \dots, \mathcal{H}_M\}$, the probability that an ideal observer generalizes to a new stimulus y given a set of stimuli X have a property and a set of previously observed concepts \mathcal{C} (where each concept itself is a set of stimuli) is

$$P(y|X, \mathcal{C}) = \sum_{m=1}^M P(y|\mathcal{H}_m, X) P(\mathcal{H}_m|\mathcal{C}, X) \quad (3)$$

where the first term is the probability of generalizing from X to y under hypothesis space \mathcal{H}_m (as specified by Equation 2), and the second term is the posterior probability of hypothesis space \mathcal{H}_m given the previous concepts \mathcal{C} and the observed stimuli of the current concept of interest. This posterior probability can be computed by applying Bayes' rule

$$P(\mathcal{H}_m|\mathcal{C}, X) = \frac{P(\mathcal{C}, X|\mathcal{H}_m)P(\mathcal{H}_m)}{\sum_{m=1}^M P(\mathcal{C}, X|\mathcal{H}_m)P(\mathcal{H}_m)} \quad (4)$$

where $P(\mathcal{C}, X|\mathcal{H}_m)$ is the probability of observing a set of concepts \mathcal{C} and the currently observed stimuli under hypothesis

space \mathcal{H}_m and $P(\mathcal{H}_m)$ is the prior probability of hypothesis space \mathcal{H}_m . The probability of concepts \mathcal{C} and current stimuli X under hypothesis space \mathcal{H}_m is

$$P(\mathcal{C}, X|\mathcal{H}_m) = \prod_{C \in (\mathcal{C} \cup X)} \sum_{h \in \mathcal{H}_m} P(h|\mathcal{H}_m) \prod_{x \in C} P(x|h) \quad (5)$$

where \mathcal{C} plays the same role as X , but for the previously observed concepts.

Intuitively, the model can be thought as being composed of m Bayesian generalization “submodels” (each with their own hypothesis space). The model’s generalization judgments are made by averaging over the generalizations made by the individual submodels (given the current stimulus X) weighted by how well the submodel explains the previously and currently observed stimuli. Thus, the model “learns” to use hypothesis spaces that explain the observed concepts well.

Human Learning of Hypothesis Spaces

The model presented in the previous section predicts that a learner should be able to infer whether dimensions are integral or separable for a novel domain after seeing some examples of concepts expressed in that domain. Preliminary support for this idea is provided by the results of Goldstone (1994), who showed that teaching people a novel axis-aligned concept could affect generalization along that axis in both integral and separable spaces. However, shifting a representation all the way towards integral or separable dimensions will require learning more than one concept. To test whether human learners behaved in this way, we conducted an experiment in which we examined how the generalization judgments that people produce depend on the concepts they have learned. We used rectangles varying in width and height as our set of stimuli, and participants learned 20 concepts that were either aligned with or orthogonal to these dimensions (rectangles with the same aspect ratio or area). The key prediction was that participants observing axis-aligned concepts should show a generalization gradient consistent with a city-block metric, whereas participants observing concepts indifferent to these axes should show a generalization gradient consistent with a Euclidean metric. This prediction results from the different hypothesis spaces the two groups of participants should infer are appropriate for these domains.

Stimuli and Methods

The stimuli for this experiment were rectangles where the two manipulated dimensions were the width and height (ranging from 13 to 115 pixels in increments of approximately 25 pixels). The stimulus set is shown in Figure 2. We chose rectangles because it is easy to think of concepts on our two manipulated dimensions (same width or height) and the diagonals of the dimensions (same aspect ratio or area). Previously, Krantz and Tversky (1975) found people weakly favor using area and aspect ratio as separable dimensions (the diagonals of separable dimension space). However, people can use any of the four potential dimensions for generalization depending on the context rectangles are in. This natural flexibility

Figure 2: Stimuli used in our experiment (not to scale).

makes rectangles an ideal candidate for training participants to represent rectangles using different dimensional structures.

There were two phases to the experiment: training and test. For the training phase, there were two between-subjects conditions: the *separable* condition ($n = 15$), in which people observed axis-aligned concepts, and the *integral* condition ($n = 18$)² in which people observed axis-indifferent concepts. The test phase was the same for all participants. The cover story for the experiment was:

On a small island in the Pacific Ocean, scientists found the ancient ruins of a small civilization. While excavating the ruins, they discovered objects on the doors of particular houses. They believe that the objects carry information about the people in the houses. Some of the objects the scientists found had names written under them.

Stimuli were then presented as objects with names, and people guessed what other objects would share the same name.

The 20 concepts shown to the training groups are shown in Figure 3 (each concept is a straight line picking out several points, corresponding to stimuli). The concepts for the two conditions were chosen such that each condition saw each object an equal number of times, there were two to four objects in each concept, and the concepts spanned the space of objects. The 20 concepts were presented to participants in a random order as examples of objects that were called different nonsense names randomly chosen from a standardized list. While the objects in each concept were on the screen, participants were asked whether or not they thought every object in $\{A, C, E, G, I\} \times \{1, 3, 5, 7, 9\}$ shown individually below the objects in the concept could be called that name.

The test phase of the experiment was identical to the first phase except participants' generalizations were tested for

²The different number of participants in each group was due to the computer crashing mid-experiment.

Figure 3: The 20 concepts for each training condition. Each concept is the collection of objects on a straight line on the grid. The separable concepts are axis aligned and the integral concepts are indifferent to axes.

concepts consisting of single objects ($\{B2, B8, E5, H2, H8\}$ were tested) over the total 9×9 set of objects.

Results

Figure 4 shows averaged results for single exemplar generalization for the test phase in the two conditions. The single exemplar concept results were re-aligned to $\{E, 5\}$ and then averaged over the five concepts per participant and over participants. We then took the difference between the generalization gradients for the two conditions, and compared them with the difference between the generalization gradients produced by the Bayesian model. The integral group generalizes more on the diagonals and less on the axes than the separable group as predicted if the integral and separable groups used Euclidean and city-block distance metrics respectively.

To test quantitatively that the two groups learn integral and separable dimensions, we found that the integral training group generalized significantly more often on diagonals than axes (averaging over $\{C, D, F, G\} \times \{3, 4, 6, 7\}$ vs. $C5, D5, F5, G5$, $t(32) = 3.23$, $p < 0.005$). Within the separable group, the generalization judgments on the axes were significantly greater than the diagonals ($t(34) = 2.66$, $p < 0.05$); however, the integral group did not differentiate between changes on the axes and the diagonals ($t(30) = 0.43$, $p = 0.43$). Interestingly, both groups of participants treated the positive diagonal ($F3, F4, G3, G4, C6, C7, D6, D7$) differently than the negative diagonal ($C3, C4, D3, D4, F6, F7, G6, G7$) ($t(34) = 2.58$, $p < 0.05$ for separable and $t(30) = 2.63$, $p < 0.05$ for integral). This replicates Krantz and Tversky (1975)'s finding that people tend to generalize rectangles based on constant aspect ratio. This is not surprising as constant aspect ratio is an important invariance of an object's projection on the retina as it changes in depth (keeping the viewpoint orientation constant) due to perspective projection (Palmer, 1999).

Finally, we calculated a mixed effect 2×2 ANOVA that corroborates the conclusions of our other statistical tests. It identified a main effect of generalizing on the diagonal vs. the

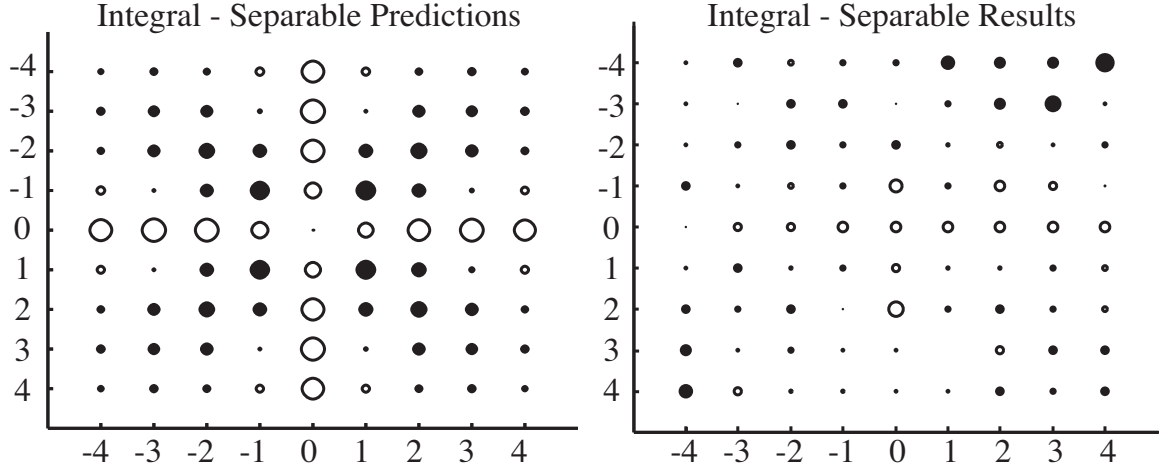

Figure 4: Predictions of the difference between the two Bayesian models formed by model averaging given the separable and integral concepts, and difference between the human generalization results from the two conditions. The results are presented as bubble plots where the size of the bubble represents the degree of generalization. Solid and open bubbles represent positive and negative values respectively. Each single exemplar concept results were re-aligned to *E5* and then averaged over the five concepts per participant and over participants. Notice how the differences on the axes aligned with the given stimulus (*E5*) are negative and the differences on the diagonals are positive.

axes ($F(1,32) = 44.258, p < 0.001$) and an interaction between generalizing on the diagonal vs. the axes and the training group ($F(1,32) = 10.453, p < 0.005$). This suggests that in the future we should include a hypothesis space into our hierarchy that includes regions varying on the axes and the positive diagonal (but not the negative diagonal).

Discussion

Generalization is an essential problem that basically every cognitive system needs to solve in virtually every domain. Previous analyses of the generalization problem (Shepard, 1987; Tenenbaum & Griffiths, 2001) indicated how an ideal learner should act assuming that an appropriate representation of the stimuli and hypothesis space for generalizations is known. However, how people arrive at a representation and hypothesis space has been left as an open question. As it seems unlikely that people would be born with the appropriate representation and hypothesis space for all possible domains, people need to be able to infer this information from their observations of the properties of stimuli. Using the problem of learning a metric as an example, our analysis shows how an ideal learner would go about inferring such hypothesis spaces, and our experimental results suggest that people do so in a way that is consistent with this model.

To our knowledge, our results provide the first behavioral evidence that people can learn whether stimuli should be represented with separable or integral dimensions. Our results also provide compelling support for the idea that the difference between separable and integral dimensions can be thought of as the result of different hypothesis spaces for generalization, building on (Shepard, 1987, 1991; Davidenko & Tenenbaum, 2001). In future work, it would be interesting to

further test this account of separable and integral dimensions by exploring if after training participants show other consequences of having separable or integral dimensions, such as classification and attentional effects. Additionally, this would address a potential confound that the training affects the attention participants pay to each dimension. Fortunately, our larger conclusion that people use the concepts they are given to learn the appropriate hypothesis space for a domain holds regardless of the potential confound (as this conclusion is agnostic to the exact mechanism affecting generalization).

One attractive aspect of this analysis (over using a different solution, like model selection) is that it provides a way to explain why the empirical literature suggests that integrality has been found to be a fuzzy rather than a binary distinction (Garner, 1974). Such fuzzy boundaries emerge as a consequence of Bayesian inference when there is uncertainty to which hypothesis space is appropriate for generalization. We would predict that the “integrality” of natural dimensions are a consequence of how real world objects are categorized along those dimensions. For example, the reason why the saturation and brightness of a color are integral is because in our environment we do not make distinctions between colors at different saturations and brightnesses. “Light” green is a typical color word; however, “saturated” green is an esoteric word, reserved only for artists, designers, and perceptual psychologists. In fact, Goldstone (1994) and Burns and Shepp (1988) found that these dimensions are separable in people who regularly distinguish between the two (color experts and participants trained to distinguish between the two), which implies that they have concepts aligned with the axes of brightness and saturation.

Another important implication of our results is that humans learn the metric appropriate for generalization in a particular domain from the concepts they observe. It would be interesting to compare how metric learning algorithms developed in machine learning (e.g., Xing et al., 2002; Davis et al., 2007) compare to human metric learning on this task, and after learning other types of concepts. This could pave the way towards new machine learning algorithms that automatically infer dimensions intuitive to people from a given set of concepts. Dimensionality reduction techniques like multi-dimensional scaling and principal component analysis are some of the most widely used tools for scientific data analysis, but only produce the equivalent of integral dimensions. An algorithm that determines whether a space is better represented by separable or integral dimensions, and produces interpretable separable dimensions, would be a valuable addition to any data analysis toolkit.

Though Bayesian models have become very popular and successful at explaining different cognitive phenomena (Chater, Tenenbaum, & Yuille, 2006), the hypothesis spaces used in the models are handpicked by the modeler and usually specific to the particular investigated phenomenon. This leaves open the question of how people choose the hypotheses for a set of observed stimuli. Our framework presents an answer to this problem – a hypothesis space is used for a set of observed stimuli depending on how well it explains the observed stimuli and its prior probability. We provide behavioral evidence for our framework in the case study of learning whether or not two dimensions should be separable or integral. Furthermore, this introduces an interesting equivalence between learning the structure of dimensions used to represent stimuli and the set of candidate hypotheses for generalization, which we plan to investigate in future research.

Acknowledgments. We thank Rob Goldstone, Stephen Palmer, Karen Schloss, Tania Lombrozo, and the Berkeley Computational Cognitive Science Lab for insightful discussions, and Shubin Li, Brian Tang, and David Belford for help with experiment construction, running participants, and data analysis and four anonymous reviewers and Nick Chater for their comments on a previous draft of the paper. The Role of “Explaining Away” in Human Abstract Rule Induction

Abstract

Of great interest to cognitive science is how human learning is constrained to avoid spurious generalizations. While many constraints must be relatively experience-independent, past experience provides a rich source of guidance for subsequent learning. If a learner discovers some structure in part of the environment, this can inform her future hypotheses about that domain. If a general structure parsimoniously accounts for particular sub-patterns, a rational learner should not stipulate separate explanations for each detail without additional evidence, as the general structure has “explained away” the original evidence. In a grammar-learning experiment using tone sequences, manipulating learners’ prior exposure to a tone environment affects their sensitivity to the grammar-defining feature, in this case consecutive repeated tones. Grammar-learning performance is worse if context melodies are “smooth”, that is, if small intervals occur more often than large ones, as this smoothness is a general property that accounts for a high rate of repetition.

Keywords: statistical learning; artificial grammar; Bayesian inference; language acquisition; music cognition

Introduction

In traditional theories of learning, the relationship between knowledge¹ and learning is fairly static. Some initial knowledge is provided by experience-invariant biology to constrain learning. Within these *a priori* constraints, learning builds one’s body of knowledge. An area that has been explored relatively little is the dynamic interplay between learning and knowledge: namely, (how) can the results of learning actually change how subsequent learning proceeds? If this feedback loop is ignored, observed constraints on learning may be incorrectly attributed to initial biologically provided knowledge instead of to learning that has already taken place.

Untangling the relative contributions of experience-independent biology and prior learning has been particularly important in the study of infant cognition, not least infant language acquisition. If an adult can learn one pattern and not another in the absence of *a priori* differences in difficulty, there are often ready explanations in terms of her years of experience in the world. In contrast, if a young infant exhibits the same discrepancy, it is tempting to

attribute it to biology. This conclusion would be premature without further examination, however.

Indeed, previous research suggests that infants reorganize their domain knowledge within the first year of life, and even within the laboratory. In language, infants reorganize their phonetic categories (Werker & Tees, 1984; Bosch and Sebastian-Galles, 2003; Maye, Werker, & Gerken, 2002) and even exhibit shifts in what features a stress rule can reference (Gerken and Boltt, 2008). In music, attention shifts from absolute pitches to relative intervals (Saffran and Griepentrog, 2001; Saffran, 2003), and infants’ tonal and rhythmic categories change as a function of cultural context (Hannon and Trehub, 2005; Lynch and Eilers, 1992).

Marcus, et al. (1999) and Marcus, Fernandes and Johnson (2007) found that 7-month-old infants can learn an AAB or ABB pattern in three-element sequences, provided the elements are syllables. Infants at the same age failed at the same task when the elements were non-linguistic events such as musical tones or animal noises. It was suggested that the child’s initial endowment may tell her that speech can be structured by abstract, relational properties, but other auditory stimuli cannot.

While this is possible, subsequent research has revealed AAB-style learning in infants with other stimuli, such as pictures of dogs (Saffran, et al., 2007), and simple shapes (Johnson, et al., in press). Murphy, Mondragon and Murphy (2008) found that even rats can learn such generalizations from both speech and tones. These results cast doubt on the notion that language is privileged for abstract pattern-learning.

“Explaining Away” Details With Generalities

Dawson and Gerken (2009) found that while 7-month-olds fail at learning AAB and ABA patterns with tones, 4-month-olds succeed given the same input. They suggested that 7-month-olds’ failure may be due to their having learned certain general properties about music. In particular, if they have learned that (a) melodies tend to move in small intervals from pitch to pitch, and (b) individual melodies tend to use only a restricted set of pitches (Temperley, 2008), the presence of a large number of repetitions would become much less surprising, and hence less informative about the abstract structure in the AAB-style task. This change in informativeness is an example of a phenomenon known as “explaining away”, central to several cognitive models in a variety of areas

¹ Here, “knowledge” is meant in a broad sense – roughly, “information about the environment”. This can be anything that affects behavior, or, critically, the interpretation of experiences.

including visual inference (Kersten, Mamassian and Yuille, 2004), linguistic processing (Ciaramita and Johnson, 2000), and infant causal reasoning (Xu and Garcia, 2008; Gergely and Csibra, 2003).

The basic idea is as follows. When an observed pattern could arise from multiple hidden causes, the causes “compete” with each other over the evidence contained in the data, even when the underlying hypotheses do not conflict with each other a priori. For example, suppose during a card game you peek at the dealer’s hand, and you notice that on one hand, she has three aces, and on the next she has the nine through king of hearts. If you assume the game is poker, this unusually lucky sequence might raise suspicion that the dealer has stacked the deck to give herself a favorable hand. However, if you later learn that the players are engaged in a friendly pinochle match, in which only the cards nine through Ace are used, the dealer’s hands are less surprising given a fair deal. Although the dealer may still be stacking the deck, the evidence for this hypothesis must be discounted, or “explained away”.

In a musical context, repetition is an ambiguous event. On the one hand, it constitutes a “sameness” relation between two tones. At the same time, it is also an interval of magnitude zero between successive pitches. If one assumes that melodies are random, and that any tone is equally likely at any point (i.e., the tone distribution is uniform), hearing every melody begin with two repeated notes would be quite surprising, and evidence for a “sameness” interpretation would be strong. If, however, one knows that tones nearby in time also tend to be nearby in pitch (i.e., melodies are usually “smooth”), repetition becomes a more common event (*qua* interval of distance zero), and it should take more evidence to conclude that repetition is special. Similarly, as the set of tones shrinks, the probability of chance repetitions increases (as with the three aces in the Pinochle hand), and the evidentiary bar for learning a repetition grammar should be raised.

The present experiment provides a test of the first of these two predictions with human adults. Participants are first placed in one of three melodic environments: one where every tone is equally likely at any point (the Uniform condition); one in which small intervals are more common than large intervals (the Smooth condition); and one in which repetition alone is more frequent than other intervals (the Repetition condition). Following this exposure, participants are given a grammar-induction task where the “grammatical” melodies have either an AABCD or DCBAA structure. If learners model the interval distribution in the larger environment, the Smooth context should lead them to represent repetition as the result of a general constraint on melodies, and not as a specific grammatical feature. Hence, learners should exhibit decreased sensitivity to positional repetition, as well as decreased grammar-learning performance.

In contrast, in the Repetition environment, the only way to explain the high rate of repeated tones is to represent it explicitly. This unexplained repetition may even *increase*

learners’ attention to that feature, improving their performance relative to the Uniform group.

Methods

Participants

One hundred and twenty University of Arizona undergraduates participated in the study for course credit. An additional eighteen participated but were excluded from analysis due to their failure to score above chance on a melodic-discrimination screening task.

Materials and Procedures

The experiment consists of a “context” phase and a grammar-learning phase. The latter contains four blocks, each with a training component and a test component. All “sentences” consist of five tones generated using the FM Synthesizer in the MIDI Toolbox for MATLAB (Eerola & Toivainen, 2004), which produces a horn-like sound. The first four notes are 250 msec each, with 50 msec gaps after each one. The last note is 500 msec. In music terms, the melodies contain four eighth notes followed by a quarter note, played at 200 beats per minute.

Procedures: Context Phase The context phase consists of two blocks of 100 sentences, in random order. Ten are “probe” sentences, after which either the same sentence is repeated or one of the other ten probe sentences is played. On the probe trials, participants have 3 seconds to press the “1” or “0” key on the keyboard to register “same” or “different” sentence pairs. The absence of a response is coded as incorrect. Each block lasts about five minutes. Data from participants who did not perform above chance on this discrimination task (15 or more out of 20 correct) was discarded, as these participants presumably either could not distinguish differences among melodies, or were not attempting to succeed.

During context exposure, all participants see a group of eight cartoon “aliens” (Folstein, Van Petten and Rose, 2007). Half are “star-chested” and half are “brick-chested”.

Materials: Context Phase Participants are assigned to one of three context conditions: Uniform ($n = 24$), Smooth ($n = 48$) or Repetition ($n = 48$). The Smooth and Repetition conditions are further divided into High Variance (HV) and Low Variance (LV) sub-conditions. In all cases, context melodies are drawn from a “vocabulary” of six tones: A3, A#3, C#4, E4, G4 and G#4 (MIDI values 57, 58, 61, 64, 67 and 68).

In the Uniform condition, each tone is equally likely and independent of the last. As such, the probability of a repetition at any given point is 1/6 (in the 200 generated melodies, the empirical rate was 18.1%). The resulting distribution of intervals is shown in Fig. 1a.

In the Smooth condition, melodies are generated as follows. The first tone is chosen from a uniform distribution over the six tones. For each subsequent tone, a

sample is generated from a normal distribution, truncated between 0.5 and 6.5. The mean of the distribution is an integer corresponding to the previous tone (the lowest tone is 1; the highest tone 6). The standard deviation is 2 in the HV condition and 1.2 in the LV condition. The sampled value is rounded to the nearest integer to generate the tone. The resulting distribution reflects the bias toward small intervals in typical folk music (Dawson, 2007). The rate of repetition across the 200 melodies is 39.3% of all intervals in the LV condition (Fig. 1b), and 26.3% in the HV condition (Fig. 1c).

The Repetition conditions control for the actual rate of repetition, while removing the overall “smoothness” constraint. Here, the HV and LV conditions (Fig. 1d-e) are matched to their Smooth counterparts for the number of repetitions, but unlike in the Smooth cases, the remaining notes are equiprobable. Here, the high rate of repetition cannot be explained by a general bias for small intervals; instead, a learner modeling the tone distribution must encode repetitions separately to achieve a good fit.

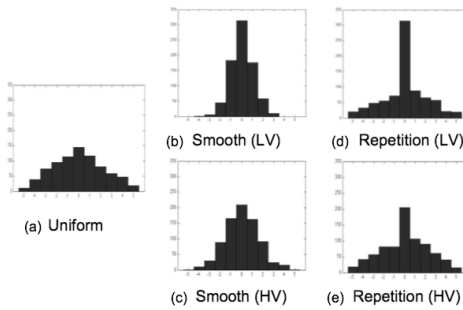

Figure 1(a-e): Interval Counts in the Context Phase²

Procedures: Grammar-Learning Phase After the context phase, participants move on to the grammar-learning phase. They are asked to detect “spies” attempting to infiltrate the “Qixian” colony, and are told that they can distinguish Qixians from spies by the grammaticality or ungrammaticality of their speech.

In each training block, participants hear thirty “grammatical” sentences in random order while an image of four star-chested aliens is displayed.

After each training block, participants hear twenty-four test sentences, half grammatical. After each sentence, participants make a continuous grammaticality judgment by clicking on a line (Fig. 2), where the left pole represents “definitely grammatical”, the right pole represents “definitely ungrammatical”, and every gradient response in between is possible. There is no time limit. The computer records a binary response, based on whether the participant

clicks left or right of center, and a continuous “discrimination score” calculated by subtracting from 100 the percentage of the line lying between the response and the correct pole. Participants experience four training-test cycles on the same grammar.

Figure 2: Test Prompt

Materials: Grammar-Learning Phase The “Qixian” and “spy” sentences are again five tones in length. Each participant is trained using one of two five-tone vocabularies. The first (V1) contains the tones A3, C4, D#4, F#4 and G4 (MIDI 57, 60, 63, 66 and 67); the second (V2) contains the tones A#3, B3, D4, F4 and G#4 (MIDI 58, 59, 62, 65 and 68). Each set shares two tones with the context vocabulary.

For half of participants, the “grammatical” sentences follow an AABCD pattern (with a repetition at the beginning and nowhere else), while the “ungrammatical” sentences have a DCBAA pattern. For the other half of participants, the labels are reversed.

Of the 120 sentences possible in each grammar, 60 are used as training items, and 24 as test items. The chosen items were balanced for pitch contour: $\frac{1}{4}$ in each section had a rising segment followed by a falling segment (in addition to the repetition), $\frac{1}{4}$ had the reverse; $\frac{1}{4}$ had a rise-fall-rise pattern and $\frac{1}{4}$ a fall-rise-fall pattern.

Thirty training sentences are used in the first two learning blocks; the other thirty in the last two blocks. On odd-numbered test blocks, participants are tested with items from the training vocabulary; on even blocks they hear items from the opposite vocabulary. Both vocabularies were used to test whether the context manipulation has an effect on the level of abstraction at which participants learn the grammar. The training vocabulary always comes first, as the vocabulary switch could provide a clue to the nature of the grammar (i.e., that it was vocabulary-independent), and if the new vocabulary came first, participants could not demonstrate mastery independent of this “hint”.

Results

Of primary interest is whether prior exposure to the Smooth distribution will impair participants’ detection of the repetition pattern. If so, this will suggest that learners are establishing a higher baseline for repetition, which (partially) explains away the training pattern. The key comparison is between the Smooth and Repetition conditions, as these are matched for number of repetitions,

² Here, 0 is a repetition, +1 is a step to the next-highest note, etc. The distributions are combined across all pitches. The truncation of the pitch range results in more small intervals across all conditions. If the interval distributions were separated by preceding pitch, those for the Uniform and Repetition conditions would each be flat, except for the peak at 0 in the Repetition case.

differing only in the presence or absence of a larger-scale regularity that accounts for that frequency.

A secondary question is whether the presence of an *inexplicably* high rate of repetitions will encourage learners to encode discrete “same” and “different” relations at the expense of the continuous relations among frequencies, thereby increasing the proportion of attention allocated to repetition and hence increasing performance in grammar-learning. If so, the Repetition group should outperform the Uniform group.

Pilot data revealed that many participants performed near ceiling at discriminating grammatical and ungrammatical sentences, while another large set performed at chance overall. For many of these, presumably only a fairly strong manipulation would observably shift performance. As such, the particular values of the scores received by these participants are mostly uninformative, and contribute noise that could obscure effects of the manipulations.

To address this issue, participants were separated into quartiles within each context condition based on their combined number of correct responses throughout the four test blocks, and two sets of analyses were conducted. The first used all of the data; the second discarded the highest- and lowest-performing quartiles in each condition, thereby greatly reducing the proportion of participants performing either at floor or ceiling. When “floor” is defined as producing fewer than 57 correct binary responses out of 96 (the one-tailed $p < 0.05$ cutoff under coin-flip guessing), and “ceiling” is defined as 88 or more correct (i.e., the same distance from 100% as floor is from 50%), then of the 60 participants in the trimmed sample, only 9 were still at floor, and 7 at ceiling. Of the 30 participants excluded for low performance, all but 2 were at floor, and of the 30 excluded for high performance, all but 4 were at ceiling.

Full Sample Analysis

Both the binary and continuous responses were analyzed, yielding qualitatively similar results. In the interest of concision, we report only the latter here. Mean scores were computed for each participant at each block and entered into an ANOVA with between-subjects factor Context Condition (five levels: Uniform, Smooth (High Variance), Smooth (Low Variance), Repetition (High Variance) and Repetition (Low Variance)), and within-subjects factor Block (1 through 4). Four planned contrasts were used for the Context factor: the first three concerned the Repetition and Smooth groups, corresponding to main effects of (1) distribution type and (2) variance, and (3) the interaction between distribution and variance; the last comparison contrasted the two Repetition groups with the Uniform group.

Figure 3: Mean Discrimination Scores by Context Condition and Block, Full Sample

The main effect of Block was significant ($F(3, 345) = 30.59, p < 10^{-15}$) but the Block X Context interaction was nonsignificant ($F(12, 345) = 0.55, n.s.$). Of the contrasts among context conditions, only the contrast between the Repetition and Smooth groups reached significance ($F(1, 115) = 5.63, p < 0.02$). The contrast between the Repetition group and the Uniform group was nonsignificant ($F(1, 115) = 0.03, n.s.$), as were the contrast between the High and Low Variance groups ($F(1, 115) = 1.08, n.s.$) and the Distribution X Variance interaction ($F(1, 115) = 0.12, n.s.$). Means and standard errors for each block and each group (collapsing the High and Low Variance groups) are displayed in Fig. 3.

Trimmed-Sample Analysis

The above analysis was repeated using only those participants in the second and third quartiles within each context group, as determined by total number correct collapsed across blocks. The effect of Block was significant ($F(3, 165) = 26.89, p < 10^{-13}$), but the Block X Context interaction was not ($F(12, 165) = 1.12, n.s.$). Of the contrasts among context conditions, only the contrast between the Repetition group and the Smooth group reached significance ($F(1, 55) = 16.16, p < 0.001$). The contrast between the Repetition group and the Uniform group was nonsignificant ($F(1, 55) = 0.41, n.s.$), as were the contrast between the High and Low Variance groups ($F(1, 55) = 1.58, n.s.$) and the Distribution X Variance interaction ($F(1, 55) = 0.004, n.s.$). Means and standard errors for this trimmed sample are displayed in Fig. 4.

Discussion

The present experiment set out to investigate the contribution of rational, generative “explaining away” to induction of an abstract repetition rule over a set of tone sequences. In the context of sequences of musical tones, repetition has a dual nature, first as an identity relation between two consecutive events, and second as an interval of magnitude zero between two tones on a continuum. Hence when a repetition occurs, it is ambiguous which of these two descriptions should be attached to it. The central finding was that adult humans appear to take into account a global “smoothness constraint” on melodies, which have a statistical tendency to move in small intervals, to set a baseline expectation for the rate of repetitions. This reduces the informational value of a repeated tone as a cue to an abstract rule.

The secondary prediction was that participants in the Repetition condition (in which repetitions are uniquely frequent and cannot be explained except by representing them explicitly) would be inclined to downplay the ordinal relations among tones in their representation of the environment, focusing instead on abstract, “discrete” relations like “same” and “different”. Since these are precisely the relations needed to learn the repetition grammar, participants in this group were expected to learn the rule more easily than those in the Uniform group. Support for this prediction is tenuous at best: although scores in the Repetition group were numerically higher than those in the Uniform group, this difference failed to reach significance. Exploratory analyses suggested that an advantage for the Repetition group may be present in the early blocks, disappearing later, but the difference was only marginally significant, and in any case the analysis was *post hoc*. It may be that a larger sample is needed to detect a difference if one indeed exists.

At first glance, the presence of differences in participants’ use of information resembles situations in which learners come to focus on features that are predictive of a relevant task outcome, filtering out redundant information (Haider and French, 1996; Pellegrino, Doane, Fischer and Alderton, 1991; Doane, Sohn and Schrieber, 1999). Although many of the same mechanisms may be involved here, the nature of the learning is somewhat different. Whereas in the preceding experiments participants were engaged in a specific task all along, in the present experiment the key manipulation occurs before participants become aware of what it is they will be asked to learn. As such, it is not simply a matter of repetition being predictive of a particular response (or even of other stimulus features); rather this result suggests that learners in this experiment are creating an *explanatory* model of the alien environment, and forming hypotheses about how their input is being generated.

Although ultimately the value of explanation may be connected to the future ability to make predictions, the absence of explicit behavioral demands frees learners to pursue a general goal of understanding the underlying nature of the environment. Here, in the Smooth environment repetitions do not appear to be an essential component of the environment at all, whereas in the Repetition environment it is necessary to represent them in order to understand the distribution of intervals. This concept of the learning process as rational hypothesis testing fits nicely into the wealth of recent literature using Bayesian models to capture aspects of cognitive functioning (see, e.g., Tenenbaum, Griffiths and Kemp (2006), for a review).

The present set of findings is of great relevance to the rule-learning literature initiated by Marcus, et al. (1999), and is particularly supportive of the conjecture by Dawson and Gerken (2009) that 7.5-month-olds may have “learned to fail” at learning AAB rules due to the acquisition of knowledge about tonality and the smoothness of natural melodies. We are currently carrying out a version of the present experiment adapted to infants to determine whether the explaining away process observed here in adults comes into play in infancy as well. If so, it will add a new explanatory tool to be applied to the puzzle of why formally analogous rules are easier to learn in some contexts than others. More generally, the sort of “metalearning” observed here may play an important role in the formation of apparently domain-specific biases and constraints. In general, when a potential role for differential experience exists, caution should be exercised before proposing innate biases.

Finally, in order to explain away, learners must be explaining in the first place. The present findings add to a growing body of evidence (Gopnik, 1998; Schulz and Bonawitz, 2007; Xu and Garcia, 2008; Gerken, 2010) that learning is a lot like science: in addition to making specific predictions, an important role of cognition is to build explanatory models of the environment, and to construct and test hypotheses about why the world works the way it does.

An Analysis of the Working Memory Capacity Paradox

Eddy J. Davelaar (e.davelaar@bbk.ac.uk)

Department of Psychological Sciences, Birkbeck College
London, WC1E 7HX United Kingdom

Abstract

In the literature on working memory (WM), a paradox exists according to which very similar memory tasks provide support for very different estimates of working memory capacity. The current paper analyses the conflicting estimates of a capacity of 4 ± 1 with a capacity of 1. To this end a dynamic process model of short-term recognition is used to generate data to which exponential speed-accuracy trade-off functions are fitted. The results show that even though the process model has a capacity larger than one, the exponential SAT functions indicate a one-chunk hypothesis. Further nested modeling reveals, counter to the dominant belief, that retrieval rate is insensitive to differences in WM capacity. The resolution of the WM capacity paradox lies in the choice of dependent measure.

Keywords: working memory capacity; speed-accuracy tradeoff; memory retrieval; model comparison.

Introduction

The last ten years have seen increased efforts in elucidating various aspects of working memory. Currently, there are several theories of working memory (see the chapters in Miyake & Shah, 1999) giving different explanations of behavioural data. Although many similarities exist among the theories, there are also important differences. In this paper, I will address the paradox of different estimates of working memory capacity and contrast the view that working memory can hold about 4 ± 1 chunks (Cowan, 2001) with the view that the focus of attention is limited to 1 chunk (McElree, 2006). The paradox lies in the fact that the behavioural paradigms that provided different estimates are very similar – presentation of a sequence of words – whereas the dependent measure differs. I will use an activation-based model of working memory that has been applied to the list presentation paradigm (Davelaar, et al., 2005, 2006) and assess whether the model can reconcile the different views. Stated differently, is it possible that the estimate of 4 ± 1 is compatible with the estimate of 1, when the paradigm-specific feature, i.e., the dependent measure, is taken into account?

The starting point is the paper by Nelson Cowan (2001) in which he reviewed a wide literature on attention and memory and concluded that the capacity limit or the focus of attention is around four chunks. Such a limit was suggested previously in a review by Donald Broadbent (1975) based on similar analyses of the literature. Furthermore, computational analyses using models such as the Search of Associative Memory (SAM; Raaijmakers & Shiffrin, 1980) supported the estimate of around four (Raaijmakers, 1982).

The commentaries based on Cowan's target article included empirical arguments supporting the view that the focus of attention is limited to one chunk (McElree & Doshier, 2001). This particular empirical argument focuses on the speed of retrieval from working memory and is central to the current paper. McElree and Doshier (2001) based their argument on data obtained using the response-signal speed-accuracy tradeoff (SAT) procedure. In this procedure, participants are presented with a sequence of words and receive a test probe after the final item. The participant has to indicate whether the test probe is one of the items in the just-presented sequence. Instead of freely responding, the participant makes a response as soon as a signal (e.g., a beep) is given. The profile of retrieval can be mapped out by employing a wide range of response signal delays. With very short delays, the participant is unlikely to have processed the test probe and performance is at chance. With a longer delay, performance rises above chance and with very long delays, performance asymptotes. The function that is traced by this procedure is called the speed-accuracy tradeoff function and can be described by or fitted with Equation 1 that involves three parameters: the intercept (T_0), the rate (s), and the asymptote (d'_{asy}).

$$d' = d'_{asy} (1 - e^{-s(t-T_0)}) \quad \text{for } t > T_0, 0 \text{ otherwise (1)}$$

The argument favouring the one-chunk hypothesis is as follows. Assume that the representation can either be in or outside the focus of attention. When it is in the focus of attention it is more readily accessible and should therefore lead to a faster rate of retrieval. This is measured by the rate parameter of the SAT function. Empirical studies consistently show (e.g., McElree, 1996; McElree & Doshier, 1989; Wickelgren, Corbett & Doshier, 1980) that the SAT function for the very last item has a faster rate than the SAT functions of the other items. In addition, the retrieval speeds for all pre-final items are equal. This suggests that the very last item is in the focus of attention, while the other items are not and thus that the capacity is limited to one item – the very last presented (or the very last processed McElree, 1998) item.

Initially, one would comment that it is possible that the most recent item is consistently in working memory, whereas the pre-final items reside in working memory with a lower probability. Therefore the estimated retrieval speeds for those items is a mixture of the fast and slow speeds, where the slow speed correspond with retrieval of presented items that are displaced from working memory (Cowan,

2001). The implied assumption underlying this view is that the probability of residing in working memory is a constant factor. Two objections to this assumption can be articulated. First, if a fixed-capacity buffer is used to encode a *sequence* of words, the probability of being in the buffer is highest for the most recent item. Thus theoretically, there is recency gradient *within* the buffer. Second, empirical observations show a recency gradient over the last four items for accuracy and reaction times (e.g., McElree & Doshier, 1989; McKone, 1995; Ratcliff, 1978), suggesting that if these items are in the buffer, a recency gradient must exist within the buffer.

To appreciate the complexities of these findings, consider that the encoding phase in the paradigms used by Raaijmakers (1982) and McElree and Doshier (1989) is identical but that the test phase differs. In addition, whereas Raaijmakers (1982) and Cowan (2001) focused on memory accuracy, McElree and Doshier (2001) focused on retrieval rate, which they argue provides direct evidence for distinct representational states. It should be said that the asymptotic accuracy of the SAT functions show a typical recency gradient. Therefore the paradox might be recast as a difference in opinion about what constitutes a proper dependent measure. This might well be the critical factor that prevents resolution of this central feature of working memory. The proposed way forward is to use a computational model with a capacity larger than one and produce the SAT functions. This requires (1) a *process* model of recognition memory that (2) implements a dynamic buffer, and (3) is capable of producing retrieval dynamics that can produce SAT functions. Several process models of recognition memory exist (Gillund & Shiffrin, 1986; Hintzman, 1984; Hockley & Murdock, 1987; McClelland & Chappell, 1998; Norman & O'Reilly, 2003; Shiffrin & Steyvers, 1997), but only a subset have been applied to SAT functions (Diller, Nobel & Shiffrin, 2001). Instead of readjusting the models to also include a dynamic buffer, the research strategy followed here is to extend a dynamic buffer model (Davelaar, et al., 2005; Haarmann & Usher, 2001) with a matching process that allows for a yes/no-recognition decision. This involves combining the dynamic buffer model with Ratcliff's (1978) diffusion model.

Model Description

The dynamic buffer model is based on the view that the content of working memory is the active part of long-term memory. More precisely, representations in consolidated memory, such as semantic long-term memory, phonological long-term memory (Baddeley, Gathercole & Papagno, 1997), and other modalities in long-term memory, are activated through sensory information. This activation is short-lived and would decay to baseline activation if there was not an active process that counteracts this decay. This process of active maintenance is a function of working memory (Baddeley, 1996) and has been called primary memory (Norman, 1968). The consequence of this process

is that more than one representation can be activated simultaneously, albeit at different levels of activation. Previous work has shown that this model, which has many points of contact with Cowan's embedded processes framework (1995, 2001), is able to capture several observations in list memory paradigms. The core aspect of the model is the differential Equation 2 that governs the change of activation for every representation in long-term memory per timestep,

$$\frac{dx_i}{dt} = -x_i + \alpha F(x_i) - \beta \sum_{j \neq i}^N F(x_j) + I_i + \Phi(0, \sigma) \quad (2)$$

where x_i is the internal activation of representation i , $F = 1/(1+x)$ is the output activation function, α captures the process of active maintenance. When $\alpha = 0$, the model reduces to system with a capacity of one and is indistinguishable from theoretical models that purport to assume that only one representation can be active at any one moment (Brown, Neath & Chater, 2007; Howard & Kahana, 2002)¹. All representations compete with each other through the inhibition parameter, $\beta = 0.2$, which governs the maximum capacity. Each representation receives activation, $I_i = 0.33$, from sensory processing levels. The activation dynamics is supplemented with zero-mean Gaussian noise with standard deviation, $\sigma = 1.0$. Representations that are active above a fixed threshold $\theta = 0.2$ interact with other aspects of the cognitive system. This includes episodic memory encoding and probe matching.

The diffusion model as used by Ratcliff (1978) is in essence a dynamic signal detection model and includes the mean drift rate, ξ , which represents the amount of match between the probe and the memory item. From trial to trial the amount of match varies and this variability is captured by the standard deviation, η , of the drift rate. When applying the diffusion model to behavioural tasks, the effective drift rate for a given trial is drawn from a normal distribution with mean ν and standard deviation η . For each unit of time, zero-mean Gaussian noise with standard deviation 0.1 is added to the mean drift rate causing the total amount of evidence indicating a match or mismatch to drift towards a boundary. When a match boundary is reached, system responds with a yes-response. When a non-match boundary is reached, a no-response is emitted. The original diffusion model has many more parameters and has been applied to a wide range of reaction time paradigms. Relevant to the current discussion is that the diffusion model has been

¹ So-called single-store models include some form of relative strength calculation. When reimplementing those models in a connectionist form in order to allow direct comparison, these models require a stage where multiple representations are active to allow for the ratio-rule type of calculation. An extreme version of this is where only one representation is allowed to be active during encoding, while multiple representations are active during retrieval (Sederberg, et al., 2008).

applied to the response-signal speed-accuracy tradeoff procedure (McElree & Doshier, 1989; Ratcliff, 1978, 2006).

The diffusion model takes the value for the drift rate from the dynamic buffer model. Specifically, the drift rate on each trial is the above-threshold activation for that representation. To produce SAT functions, the following two situations need to be explicated. First, when the response-signal appears and the diffusion process has not reached any boundary, the response is based on whether the process is moving towards the yes- or no-boundary. This represents making decisions based on partial information (see for discussion, Ratcliff, 2006). Second, when a boundary has been reached before the response-signal, the corresponding decision will be given at the time of the response-signal. The resulting decision probabilities are converted into d' scores and the full SAT functions are fitted with two version of Equation 1. In version 1, all parameters are free to vary across conditions, yielding 18 free parameters. In version 2, the reduced model that is supported by the empirical literature is used. This model has a fixed T_0 for all conditions and two different rates, yielding 9 free parameters.

The process model as described above was applied to a sequence of six words. Each of six representations was activated sequentially for 1,000 iterations. Then one of the six positions was probed and a SAT function created for that serial position by using response-signals at 100, 200, 300, 400, 500, 750, 1,000, 1,500, 2,000, and 3,000 iterations. Each serial position was probed 1,000 times at each of the ten response-signal delays. The effective capacity of the model is easily assessed by counting the number of representations that are active above threshold at $t = 6,000$ iterations. In order to address the possibility that different parameters obtained from the exponential SAT function are sensitive to different working memory capacities, the simulations are repeated for $\alpha = 0$ (no buffer), $\alpha = 1.8$ (small capacity), and $\alpha = 2.0$ (large capacity).

Simulation Results

Figure 1 shows a noise-less simulation of a sequence (with $\alpha = 2.0$). At time = 6,000, the very last item is the most active and activation levels decrease with the temporal distance of presentation. Figure 2 shows the frequency distribution of the activations for each of the items in Figure 1 at $t = 6,000$ iterations. As can be seen, items that are still in the activation buffer at time of test show a step-like function, with the very last item being more active than all other active items, which in turn have similar activation levels. The reason for this is immediately apparent when taking a closer look at Equation 2. Assume that at time of test, the activation level does not change and is above threshold. The resulting $F(x_i)$ is governed by α and β , leading to convergence of the activations. Only the very last item still receives external input, leading to a higher activation.

Figure 1. A noise-less simulation of 12 sequentially activated items. The x-axis indicates time in iterations. The y-axis indicates activation level, $F(x_i)$.

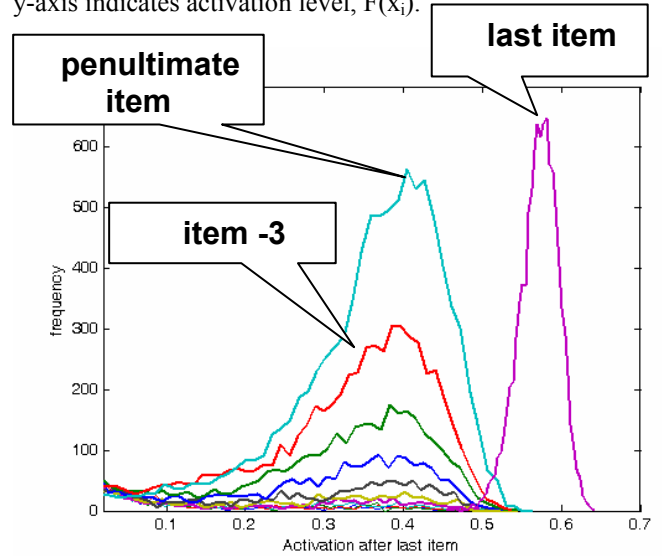

Figure 2. Frequency distributions of the activation levels of the 12 items in Figure 1 at $t = 6,000$ iterations.

The simulated data and corresponding best-fitting SAT functions for the simulation of $\alpha = 2.0$ are presented in Figure 3. Table 1 shows the parameter values of the best-fitting reduced model for each of the values of α . The models were fit by maximising the adjusted R^2 .

Although the reduced model fits the data less well compared to the saturated model, the change in goodness of fit, ΔR^2 , is negligible given the amount of variability present in real data. This supports the findings in the empirical literature that led to the one-chunk hypothesis. However, the model maintains multiple items at the time of test, as seen by the capacities. The capacity at $\alpha = 2.0$ is higher than at $\alpha = 1.8$.

Figure 3. Simulation data and best-fitting reduced model for the simulation with $\alpha = 2.0$.

Table 1: Parameter estimates for the 9-parameter exponential SAT function and the estimates of buffer capacity.

parameters	Serial position	simulation		
		$\alpha = 0$	$\alpha = 1.8$	$\alpha = 2.0$
d'_{asy}	1	0.015	0.014	0.173
d'_{asy}	2	0.028	0.031	0.261
d'_{asy}	3	0.000	0.107	0.509
d'_{asy}	4	0.025	0.632	0.910
d'_{asy}	5	0.018	1.966	1.652
d'_{asy}	6	1.208	3.760	2.471
T_0	1-6	279.56	338.12	33.92
s	1-5	0.0005	0.0068	0.0102
s	6	0.0019	0.0088	0.0129
R^2 -adjusted		.996	.999	.999
ΔR^2		0	.001	0.0002
capacity		1	2.64	3.38

Note: the capacity was estimated by counting the number of above-threshold representations at $t = 6,000$ iterations.

The parameter values for the d'_{asy} are well-fitted by an exponential function, allowing the 6 free parameters to be reduced to 2 free parameters. In addition, s could be fitted with a function with only 1 parameter. Therefore, the best-fitting 9-parameter model could be further reduced to a 4-parameter model. This further parameter reduction allowed an examination of model fit as a function of differences in buffer capacity. To do this the data from the simulations

with $\alpha = 1.8$ and $\alpha = 2.0$ were compared. This resulted in a “full” model having 8 free parameters with 4 parameters for each α -level. The 8-parameter model, $[2F(d'_{asy}) - 2G(s) - 2H(T_0)]$, $(F(x)$ has 2 parameters) and all nested models were fit to 120 datapoints by maximizing the adjusted R^2 . Of special interest was the identification of parameters that reduce the fit and thus carry the difference in buffer capacity. The results are shown in Table 2 and are clear-cut. The goodness of fit is largely unaffected when $G(s)$ or $H(T_0)$ is fixed between the two levels of α . However, a 5% decrease in fit is observed when $F(d'_{asy})$ is fixed. The interpretation of this finding is that differences in buffer capacity are only picked up in the differences in *gradient* of the d'_{asy} function. The rate parameter seems insensitive to variation in buffer capacity and is therefore only useful to assess which item or one-chunk was the most-recently processed.

Table 2: Results of nested modeling fits on the data from the two different WM capacity simulations. The number of free parameters are given between brackets after each model.

Model	Degrees of freedom	adjusted R^2
Full model (8)	112	.989
F-fixed (6)	114	.942
G-fixed (7)	113	.988
H-fixed (7)	113	.989
F/G-fixed (5)	115	.942
F/H-fixed (5)	115	.943
G/H-fixed (6)	114	.987
All fixed (4)	116	.943

Discussion

This paper focused on the paradox that different estimates of working memory capacity are estimated based on very similar tasks. Using a dynamic model of short-term recognition, data were generated and fitted by exponential SAT functions. Contrary to what was previously thought, the results show that the rate of retrieval from WM is insensitive to the WM capacity and instead is most sensitive to the recency of cognitive processing. The asymptotic accuracy is found to be the only parameter that is sensitive to WM capacity. The resolution of the WM paradox lies in the choice of dependent measure, with accuracy being the preferred measure for estimating WM capacity and retrieval rate being the preferred measure for identifying the most recently processed chunk in WM.

The process model predicts that items that are not in WM will lead to misses. Therefore for items that were presented a very long time ago, only misses should happen. This is partially correct. One would, however, expect that deactivated items require an additional process of episodic retrieval to allow for contextual matching. This is likely to result in slower retrieval dynamics and quite likely to a larger intercept. The problem is that in order to assess this possibility, trials would have to be separated into those in which the probe matches with a deactivated item and trials in which the probe matches a pre-recency active item. This is not possible experimentally and thus differences in intercept for pre-recency items are always mixtures. The same holds for the retrieval speeds. With long lists, very early items could be probed and used to check if they do have the slowest retrieval speed and the largest intercept. The difficulty here is that performance is close to chance (Wickelgren, Corbett & Doshier, 1980). Wickelgren et al. used a 16-word list and measured the SAT of the list item -12 (position 4). In some of the participants, the intercept for the item -12 was larger than all other items. Although this might suggest that the intercept is the preferred parameter to assess whether items are retrieved from WM or from long-term memory, a thorough empirical investigation waits.

What does the reinterpretation of the exponential SAT-parameters mean for the use of the exponential SAT-procedure? Several authors have commented that exponential and diffusion SAT are too similar to be distinguished (McElree & Doshier, 1989; Ratcliff, 2006). Others have argued that diffusion SAT should be used as it is based on an actual theory of memory retrieval (Ratcliff, 2006), whereas the exponential SAT is not based on a theory and therefore only of statistically-descriptive use. Despite the finding that exponential SAT can not be used to address capacity estimates, it is able to identify the last processed item (McElree, 1998). This utility depends heavily on the assumption that across many trials, participants process the stimuli in identical ways. Whether the SAT-procedure is robust against violation of the identical-processing assumption remains for future analyses. What does all this mean for WM capacity? The analyses presented here suggest that WM can hold multiple items in

an active state to varying degrees, but that the very last processes item is in a highly accessible state. The work also demonstrates more generally the importance of using explicit formal analyses to verify the interpretations based on statistical tests.

Working Memory Load Affects Device-Specific but Not Task-Specific Error Rates

Abstract

Human error in routine procedural tasks is often attributed to momentary failures to remember what step to perform. We argue that task-specific steps, which can be defined as actions required to achieve a particular goal across a variety of different devices, are far less prone to error than device-specific steps, which can be defined as actions that are required for the operation of the device but do not directly contribute to the goal. An experiment is reported that supports this distinction, showing that device-specific steps are more error prone than task-specific steps. Moreover, we argue that these errors reflect a failure of memory because the error rate for device-specific steps was sensitive to increased working memory load, while the error rate for task-specific steps was not. The current work demonstrates that a distinction between device- and task-specific steps can be effective in explaining error patterns observed on a specific task.

Keywords: human error; device-specific error; working memory load.

Introduction

While routine procedural errors occur only occasionally, they are persistent. A growing body of empirical work has studied these errors in the laboratory. Most of them have focussed on the post-completion error (PCE) (e.g. Byrne & Bovair, 1997; Chung & Byrne, 2008; Li, Blandford, Cairns, & Young, 2008), a cognitive slip that occurs when the final step in a task is omitted after the main goal has already been completed.

The PCE is theoretically well understood. An influential account is the *memory-for-goals* model developed by Altmann and Trafton (2002). This account assumes that goals are declarative memory representations (chunks) with an associated activation level. The interference level is defined as the 'collective effect of distractor goals'. In order to direct behaviour, the relevant goal needs to be above the interference level. In order to overcome the interference level, the activation of goals must be strengthened. A goal that is retrieved more often or the most recently retrieved subgoal will have a higher activation value than others with less history. Associative links between goals allow activation to spread to other goals. The PC step is usually

remembered because it receives associative activation from the step preceding it. Moreover, Byrne and Bovair (1997) have argued that upon completion of the main goal, the sources of activation for the PC subgoal are reduced, leading to lower activation on the PC subgoal, often to a point where it cannot be retrieved.

Another step that is associated with a relatively high error rate is the device-initialisation (DI) step. A device initialisation step is an action that must be executed before the main task steps can be completed (e.g. pressing a 'mode' key before setting the alarm on a digital watch). Li et al. (2008) and Hiltz, Back & Blandford (2010) found relatively high error rates on both the post-completion and the device-initialisation steps. However, this error is less well understood, and it is not clear how the *memory-for-goals* model would account for it. For this error, the main goal has not yet been completed, so should still provide activation for the device-initialisation step.

A common factor that the PC step and the DI step share is that they are both device-specific (Cox & Young, 2000). This means that they do not make a direct contribution towards the main goal, but are only required for the correct operation of the device. Task-specific steps, on the other hand, do make a direct contribution towards the main goal and are required regardless of the type of device they are carried out on. Consider the example of using a state-of-the-art induction hob. A typical task-specific step may be to increase or decrease the power output by pressing the '+' or '-' button, whereas a device-specific step may be to press the selector button to cycle through the different hobs until you have selected the one for which you want to adjust the power. While a number of previous studies have discussed concepts similar to device- and task-specific steps (e.g. Cox & Young, 2000; Kirschenbaum, Gray, Ehret, & Miller, 1996; Gray, 2000), this is a novel approach to explaining routine procedural errors.

In this paper, we propose that the distinction between task-specific and device-specific steps can explain why some steps in a procedure appear to be more error prone than others. Our account relies on the user having a task model (how to do the task) and a device model (how to do the task using a particular device), two concepts widely used

in the field of human-computer interaction research (Young, 1983). Device-specific steps are only represented in the device model, whereas task-specific steps are represented in both. Using an activation-based approach, the current work hypothesises that device-specific steps have lower activation levels, because they have only one source of activation (the device model), whereas task-specific steps receive activation from two sources (the device model and the task model). These lower activation levels make it more likely that device-specific steps fall below the interference level, resulting in a slip. Ament, Blandford & Cox (2009) describe an experiment in which device-specific error rates on the ‘Spy task’ were significantly higher than those on task-specific steps, as predicted.

There are two aims to this paper. First, we seek to provide empirical evidence to support the idea that error rates are higher on device-specific steps than on task-specific steps. Second, we investigate the effect that varying working memory load has on these two classes of steps. We argue there is good reason to believe that device-specific steps are more susceptible to the deleterious effects of increased working memory load than task-specific steps.

Byrne and Bovair (1997) argued that post-completion errors are memory-based failures. Therefore, they investigated how working memory load affects the PCE. They found that the frequency of the PCE increased under a high working memory load. Byrne and Bovair (1997) argued that a higher working memory load leads to the scaling back of activation on all items in memory. This means that the decay rate is higher, and items are displaced from memory faster. If the source of activation for an item is lost, such as on the post-completion step, it is more likely

that that step will not reach the threshold necessary to be executed and a post-completion error will be likely.

However, this account does not explain how working memory load would affect other device-specific errors, since their source of activation is not lost like that of the PC step. In the *memory-for-goals* model (Altmann & Trafton, 2002), higher working memory load is represented by an increased interference level. While no direct predictions about the effect of this are made, it seems clear that an increased interference level makes it more likely that the activation level for a given action falls below it, leading to an error. We therefore hypothesise that device-specific errors should be particularly affected by an increase in working memory load, because a higher interference level makes it even more difficult for device-specific steps to overcome this. Conversely, task-specific steps are expected to be affected less, because their higher activation levels make them more robust to increases in the interference level.

We investigate the effect of working memory load on device-specific and task-specific error rates, by means of a secondary load task. It is expected that in low memory load conditions, participants will make fewer errors overall compared to high load conditions. Critically, it is expected that, under high load, there will be proportionally more errors on device-specific steps than on task-specific steps.

Method

Participants

Forty participants were recruited from a dedicated psychology subject database. They were aged between 18

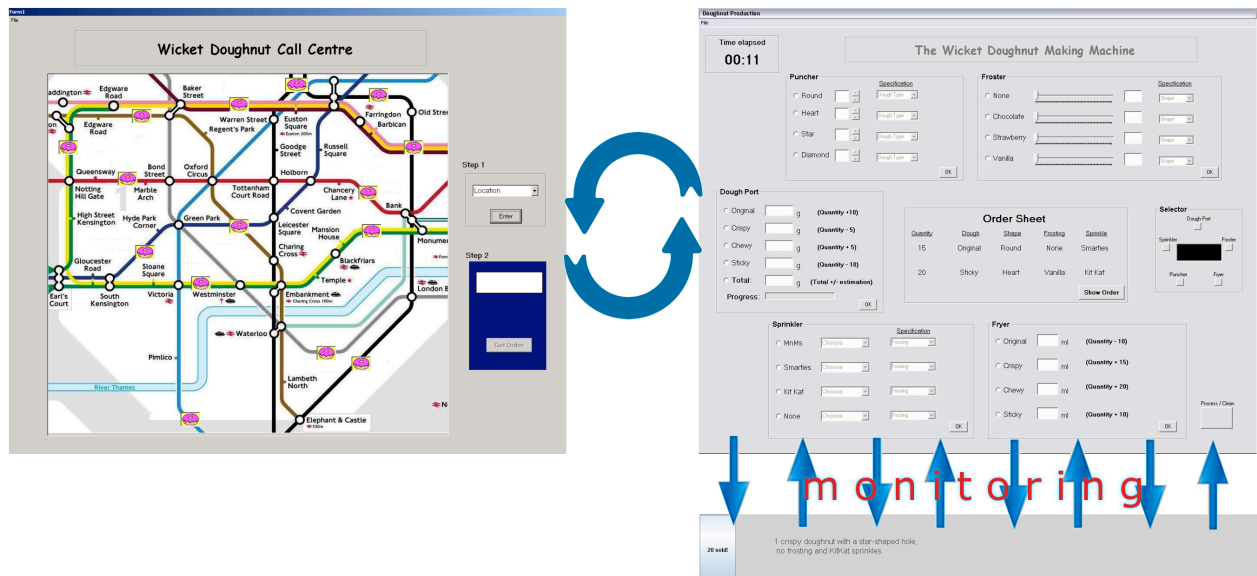

Figure 1: Diagrammatic representation of the Doughnut task. On the top right is the main Doughnut task interface. While making the doughnuts, participants monitor the Doughnut Live Feed, displayed directly underneath the main Doughnut task interface. In between doughnut making trials, participants answer a call at the Call Centre, displayed on the left.

Figure 2: Hierarchical task analysis of the doughnut task. Step 2.2.1.1.1 is the device-initialisation/device-specific step, whereas step 2.4.1 is the post-completion step; both are shaded. Note that the ‘Operate Puncher’, ‘Operate Froster’, ‘Operate Sprinkler’ and ‘Operate Fryer’ subgoals are not defined further to save space; they are identical in structure to ‘Operate Doughport’ and as such also contain a device-specific step at the beginning.

and 33 with a mean age of 22.0, and 27 were female. The majority of participants were students, and they were paid £6 for their time.

Materials

The Wicket Doughnut task (Li, 2006), a routine procedural task in which participants have to follow a defined procedure to make virtual doughnuts, was used. Figure 1 shows the components of the doughnut task: the main doughnut interface, the call centre (both developed by Li (2006)), and the live feed (developed for the current study). Figure 2 shows a hierarchical task analysis of the doughnut and call centre tasks. The main task consists of two subtasks (represented as ovals), which are further subdivided into smaller subgoals. The square boxes represent the lowest-level goals and correspond to discrete actions. Device-specific steps are shaded. While only two are shown in the figure to save space, the task contained a total of 6 device-specific steps; the steps that are not shown are the initial selector steps on the Puncher, Froster, Sprinkler and Fryer subtasks.

A trial starts with taking a call at the call centre to get the next order, done on a separate computer terminal. It involves selecting the correct doughnut shop from a list, and finding it on a map. After confirming, the order is then ‘transferred’ to the Doughnut task interface on another computer terminal.

The main doughnut task consists of five compartments, or widgets, in which participants have to enter information from the order sheet. These need to be operated in the order: Dough Port → Puncher → Froster → Sprinkler → Fryer. Before data can be entered, a widget needs to be activated by clicking the appropriate selector button on the selector panel on the right-hand side. Clicking the Ok button then confirms the entry for that widget. Once all widgets have been completed, the order needs to be processed by clicking the ‘Process’ button. A pop-up screen then indicates the completion of the trial, and the number of doughnuts made.

At the end of the trial, the machine must be cleaned by clicking the ‘Clean’ button. While Li et al. (2008) used interruptions at certain points during the task, the current experiment did not.

To vary working memory load, a monitoring task was added in which participants had to count the number of doughnuts sold in the shops. The Doughnut Live Feed was shown at the bottom of the screen, where occasionally a description of a doughnut was shown. Participants had to attend to a specific characteristic of the doughnut (such as dough type, hole shape or frosting) and keep count of how many with that characteristic were sold. In the low working memory load condition, participants were asked to attend to and keep track of doughnuts with a specific dough type, for instance Crispy. In the high working memory load condition, participants were asked to attend to and separately keep track of doughnuts with a specific dough type and those with a specific hole shape. In both conditions, once a participant had counted 20 doughnuts of

Figure 3: the doughnut live feed. A cycle starts out completely white (a). The background then quickly fades to grey, while the item fades from white to black (b). Halfway through the cycle, the background and the item are at its darkest, and the item is clearly visible (c). At the end of the cycle, the background fades to white again while the item may either stay visible or fade as well (d).

the specified type, they had to click the button on the left of the live feed and start counting from zero again. This allowed the experimenter to assess whether a participant was successfully monitoring the live feed.

To ensure effective monitoring, new items on the live feed did not capture visual attention. This was achieved by using a background that changed from grey to white and back in continuous cycles. Each doughnut description faded in on top of that from white to black, and faded out again after a random number of cycles. Figure 3 shows the progression through one cycle. Each cycle took three seconds, and items remained visible for between 2 and 4 cycles. This randomness made it impossible for participants to predict when a new doughnut description would be shown. The monitoring task and primary tasks were carried out simultaneously.

A number of device-specific steps were present in the doughnut task. Selecting the first compartment, the dough port, was a device-initialisation step. The other selecting steps were counted as other device-specific steps. The last step in the procedure, cleaning the machine, was a post-completion step. A false completion signal was given in the form of a pop-up screen indicating that the doughnuts were ready. In addition, a flashing message notifying the participant of the next call provided a competing signal for the post-completion step. After dismissing this pop-up, the post-completion step took place.

Two separate computer terminals were used; one for the call centre and one for the doughnut making task and live feed. Both screens were operating at a resolution of 1280 x 1024 pixels.

Design

A mixed design was used, with two levels for each independent variable. The first independent variable was working memory load; this was varied between participants. This variable had two levels: low load and high load. The second independent variable was the type of step; this was varied within participant. This variable had two main levels, device-specific and task-specific.

The dependent variable was the error rate. Errors were counted systematically according to the required steps. An error is defined as any action that deviates from the required action at a certain step. To ensure only inappropriate actions

are counted and not each individual inappropriate click, only one error could be made on each step.

Procedure

Participants carried out the experiment individually. During the training phase, participants were given an instruction sheet that explained in detail what their task was, and all the procedures necessary to complete the task. After reading the instruction sheet, they observed the experimenter doing the task once, after which they were allowed to practice it twice. Any errors made during the training trials were pointed out immediately using the default Windows XP notification sound and were required to be corrected before the participant was allowed to move on. After each practice trial, the experimenter asked the participant how many doughnuts they had counted on the live feed, and encouraged more accurate performance if necessary.

Participants were instructed to complete the doughnut task as quickly and as accurately as possible. A timer was displayed on the screen throughout the experiment to encourage swift performance; it was reset after each trial. After processing the doughnuts, a pop-up screen notified the participant of the number of doughnuts made. Participants were also told to count the doughnuts in the live feed as accurately as possible; this was further encouraged by the '20 doughnuts' button. Participants were not aware that errors were being studied.

During the experimental phase, the participants completed 11 trials, with the opportunity of a short break after 6 trials. Any errors were pointed out immediately and had to be corrected before the participant was allowed to carry on. The total duration of the experiment was approximately 60 minutes.

Results

Data from 12 participants was excluded from the analysis. The reasons for excluding participants varied. Three participants were excluded because they failed to follow the instructions to monitor the live feed correctly. One participant's data sheet was lost. Eight participants were excluded because they made omission errors at any step on more than 65% of trials. The reason for excluding these error-prone participants is that such high error rates likely

Type of Step	Error count (Opportunity)	Mean error rate (SD), in %
Total	292 (5852)	4.99 (2.51)
Task-specific	57 (4004)	1.42 (0.96)
Device-specific	235 (1848)	12.7 (7.44)
<i>Device-initialisation</i>	84 (308)	27.27 (20.55)
<i>Post-completion</i>	66 (308)	21.43 (21.60)
<i>Other device-specific</i>	85 (1232)	6.90 (6.47)

Table 1: Total error counts and mean error rates across all participants and conditions for the different types of steps.

indicate that the participant has not correctly learnt how to perform the task. We present analysis of error-rate for the remaining twenty-eight participants.

Due to the failure of so many participants to perform the task to criterion, we first examine whether error rate decreased as participants gained more experience at performing the task. There was no evidence of a learning effect over consecutive trials; that is, there was no relationship between number of errors per trial and trial number ($r = -0.26$, $p = 0.27$). This suggests that those included in the analysis had been effectively trained before conducting the study.

We were primarily interested in error rates at device-specific and task-specific steps. Error rates were calculated for each participant for the relevant step types. Only one error was possible on each of the steps. Step 19 (dismissing the pop-up screen) was removed from further discussion, because no error was possible on this step, since the pop-up screen blocked action on the main screen. Thus, a total of 19 errors could be made on a single trial. Each participant did 11 trials, and data from 28 participants was analysed, giving a total opportunity for errors of $19 \times 11 \times 28 = 5852$. Across all participants, a total of 292 errors were made, giving an overall error rate of 4.99%.

It was hypothesised that error rates were higher on device- than on task-specific steps. Table 1 shows the average error rates across all participants on the different types of steps. A repeated-measures ANOVA, comparing error rates on task-specific, device-initialisation, post-completion and other device-specific steps, showed a significant difference between the types of steps, $F(3,81) = 19.46$, $p = 0.000$, with Greenhouse-Geisser correction. A post-hoc comparison showed that task-specific steps had

significantly lower error rates than all device-specific steps. Looking more specifically at the different types of device-specific steps, it becomes clear that the error rates on DI and PC steps are higher than on the other steps. Post-hoc tests confirm that PC and DI steps have significantly higher error rates than both task-specific steps and other device-specific steps, although there is no significant difference between PC and DI steps.

Working memory load was also manipulated on two levels, low load and high load. Figure 4 shows the error rates on the different working memory load levels, for both device- and task-specific steps. Error rates on task-specific steps remained stable across all conditions, while error rates on device-specific steps increased under high working memory load. A 2×2 mixed-design ANOVA with type of step as the within-subjects variable and working memory load as the between-subjects variable revealed a main effect of working memory load, $F(1,26) = 8.10$, $p = 0.009$. An interaction effect was also found, $F(1,26) = 6.68$, $p = 0.016$. A main effect of type of step was also found to be significant, $F(1,26) = 81.90$, $p = 0.000$. Simple effects analysis showed that there was no simple effect of working memory load on task-specific steps, $F(1,26) = 0.95$, $p = 0.339$. There was a simple effect of working memory load on device-specific steps, $F(1,26) = 7.53$, $p = 0.011$.

Discussion

The current experiment investigated the hypothesis that error rates on device-specific steps are higher than on task-specific steps, and that working memory load has a differential influence on them. The results of this study show that the error rates observed at device-specific steps is greater than the error rates observed at task-specific steps. Also, a high working memory load resulted in higher error rates overall. In addition, an interaction effect of working memory load and type of step was found. This supports our predictions.

It can be argued that the finding that error rates are higher on device-specific than on task-specific steps is mainly due to the high error rates on device-initialisation and post-completion steps. However, it should be noted that the error rate on the 'other device-specific steps' was also found to be higher than that on task-specific steps. This indicates that device-specific steps are indeed associated with higher error rates than task-specific steps. Nevertheless, the relatively high error rates on the PC and DI steps may indicate that other factors play a role as well.

Byrne and Bovair (1997) found that only low-capacity individuals were affected by a high working memory load. Although we did not administer working memory capacity tests to participants, the fact that working memory load had a significant effect without dividing participants into low and high capacity groups suggests that this is unlikely to have adversely affected the results.

As expected, working memory load increases the overall error rates. The significant interaction indicated that this

Figure 4: Error rates across working memory load and type of step conditions. Error bars represent the standard error of the mean.

effect is much stronger on device-specific than on task-specific steps. This confirms our predictions.

The current work has implications for theoretical models of error. We hypothesised that device-specific steps have lower activation levels, and are therefore more likely to fall below the interference level. The higher error rates on device-specific steps are in line with this explanation. In addition, the differential influence of working memory load on the two types of steps further supports our theory. It is not clear how the *memory-for-goals* model would account for the lower activation on device-specific steps, highlighting a possible limitation of the model.

Apart from higher error rates and a greater influence of working memory load, these lower activation levels make a number of further predictions. First, reaction times should be longer on device-specific steps. A lower activation level on such steps means that more time is needed for the activation level to increase above the interference level, in order to execute the associated step. Due to the nature of the steps within the doughnut task, it is not appropriate to conduct this analysis on the data from the experiment reported in this paper. Future studies should use a more suitable task to investigate the differences in reaction times on device- and task-specific steps.

Second, device-specific errors should be qualitatively different from task-specific errors. It is more difficult for device-specific steps to overcome the interference level, making it more likely that the step's activation inadvertently falls below the interference level. When this happens, it is likely that the next step has the highest activation level and directs behaviour: an omission error occurs. On the other hand, the higher activation levels on task-specific steps make it less likely that the step accidentally falls below the interference level. Instead, other errors such as incorrect sequence errors (i.e. performing a different task-specific step that is out of sequence) may be more common.

The current work also has implications for the design of interactive systems by going beyond the well-studied PCE. While PC steps are relatively rare, device-specific steps occur on many devices. The current results have demonstrated that device-specific steps are more prone to errors than their task-specific counterparts, and therefore these steps should be avoided in task design where possible.

Conclusion

The current study demonstrated that people are more likely to make errors on device-specific steps than on task-specific steps, providing support for the claim that this distinction can be effective in explaining observed error patterns. Moreover, working memory load was found to have a greater effect on device-specific error rates than on task-specific ones, providing support for our hypothesis that device-specific steps have lower activation levels. Future studies can look more closely at the mechanisms underlying device- and task-specific steps, and investigate how these can lead to different activation levels.

Abstract

There has been much debate in recent years as to whether recognition memory is best described using a single or dual process model. State-trace analysis provides an atheoretical approach to determining the number of underlying psychological variables, or processes, that mediate the effect of one or more independent variables on the measured dependent variables. Recently, state-trace analysis has shown strong support for a single process interpretation of the behavioral results from recognition memory experiments. In this paper, we demonstrate, using state-trace analysis, that both the behavioral and electrophysiological results from recognition memory experiments are also supportive of a single process interpretation. **Keywords:** recognition memory; event-related potentials; single process models; dual process models

The study of recognition memory aims to determine the process(es) underlying how one recognizes something, or someone, as having been previously encountered (Mandler, 1980). In a typical recognition experiment, participants study a list of items, and at test are asked to discriminate between both studied (old) and unstudied (new) items. Two measures are obtained: the hit rate (proportion of old items correctly identified as being old) and the false alarm rate (the proportion of new items incorrectly identified as being old). The hit and false alarm rates can be combined to indicate an overall level of accuracy¹.

A number of mathematical models have been proposed attempting to describe the basis of recognition memory. These models can be grouped into two main frameworks: single and dual process models. This paper will attempt to assess the validity of these two classes of models by testing their basic assumptions using electrophysiological data from a recognition memory experiment. First these two frameworks will be described as well as some of the supporting behavioral, imaging and electrophysiological evidence. Next, an atheoretical method that can be used to test the basic assumptions of these two classes of models will be described. Following which, the results from an

experiment, designed to test these underlying assumptions are presented.

Models of Recognition Memory

It has long been debated whether recognition memory decisions are performed on the basis of a single memory process, referred to as either strength, familiarity, or matching, or whether a recall-like component is also involved (Clark, 1999). The first dual process models were developed in the 1970s (e.g., Atkinson & Juola, 1974), but were overtaken in popularity when single process, global memory/matching models, were developed in the 1980s. Dual process models regained popularity in the early 1990s and as such the debate as to which type of model best describes memory is ongoing.

Single Process Models

Single process theories are based on the signal detection framework (Green & Swets, 1967). In its simplest form, signal detection theory considers two basic aspects of detection: the underlying representations, which are interpreted as psychological distributions, and a decision aspect, which involves the use of decision criteria to arrive at a response (DeCarlo, 2002). Signal detection theory can be applied in any task in which participants are required to discriminate between two or more classes of stimuli (Stanislaw & Todorov, 1999).

Signal detection memory models assume that when a participant is presented with a test stimulus it is directly matched to multiple memory representations in parallel and the fit of these matches is used to calculate a familiarity value (Clark, 1999). Familiarity is thought to be based on associative information and information about other items in memory, as well as on stored item-specific information about the test item. In a recognition memory experiment, stimuli presented in the study phase have familiarity values drawn from the 'old' normal distribution, while the familiarity values for new items are drawn from the 'new' normal distribution. The mean of the old distribution is assumed to be higher than the mean for the

¹ For example, d' is calculated by subtracting the z-transformed false alarm rate from the z-transformed hit rate.

new distribution. Each old and new condition has its own response distribution and the criterion is placed at a point chosen by the participant that determines whether an old or new response is made.

There are a number of specific single process theories that have been developed to account for findings in recognition memory. Although each of these models is considered to contain a single process, they vary quite substantially in their focus. For example, Attention-Likelihood Theory (ALT, Glanzer & Adams, 1990) is based on the idea of feature marking first proposed by Glanzer and Bowles (1976). Retrieving Effectively from Memory (REM, Shiffrin & Steyvers, 1997) is centered around item noise, while at the other end of the spectrum, the Bind Cue Decide Model of Episodic Memory (BCDMEM, Dennis & Humphreys, 2001) is focused on context noise.

Dual Process Models

Dual process models assume that recognition is based on two memory processes: familiarity and recollection, which are assumed to make independent contributions to recognition (Clark, 1999). Familiarity is assumed to be a fast process and is equivalent to the signal detection process described by single process theories. On the other hand, recollection is assumed to be a slow, deliberate, and relatively accurate search process whereby information about the study episode is retrieved (Arndt & Reder, 2002; Yonelinas, 1999). Generally, dual process theorists propose that the hit rate in a recognition experiment is driven by recollection and the false alarm rate is driven by familiarity (e.g., Joordens & Hockley, 2000).

Yonelinas (2002) presented a high-threshold dual process model of recognition memory. He proposed that recollection and familiarity are independent parallel processes that differ in the type of information they provide and the extent to which they influence a person's confidence. Familiarity reflects the assessment of quantitative memory strength information in the same manner as signal detection theory used in single process theories. The variable strength of familiarity leads to a wide range of confidence ratings. Recollection reflects a threshold retrieval process in which qualitative information about a previous event is retrieved, producing a high level of confidence.

A number of pieces of evidence have been put forward in support of the dual process models of recognition memory. The most dominant of these behavioral, imaging and electrophysiological findings are presented in the following section.

Behavioral, Imaging and Electrophysiological Evidence

The Remember-Know paradigm (Tulving, 1985) has been used to add support to the claim that recognition memory is best described using a dual process model. This procedure

requires participants to indicate whether their 'old' responses in a recognition memory test are based upon familiarity alone (Know) or whether they recollect seeing the item in the study list (Remember). Some researchers (e.g., Gardiner & Java, 1990) have suggested that the mere finding that participants are able to distinguish between these two types of responses is evidence that both familiarity and recollection contribute to the recognition memory task. However, experiments finding dissociations between remember and know responses provide much more compelling arguments. For example, Gardiner (1988) reported a dissociation between remember and know responses such that deeper levels of processing at study led to more remember responses at test, but did not affect know responses. Since this early finding, numerous studies have been reported finding dissociations between remember and know responses (e.g., Gardiner & Java, 1990, 1991; Glanc & Greene, 2007; Joordens & Hockley, 2000; Park, Reder, & Dickison, 2005; Rajaram, 1993).

Although these dissociations between remember and know responses are often taken as evidence for dual process models (e.g., Jacoby, Yonelinas, & Jennings, 1997), a number of single process advocates have argued that remember and know responses are simply classifications of different levels of confidence, and as such can also be accounted for by single process models (e.g., Donaldson, 1996). Dunn (2004) put forward a compelling argument for remember and know responses representing higher and lower levels of confidence, respectively. In an analysis of 72 studies, Dunn showed that the arguments against remember-know data being described by a signal detection, single process framework could not be ruled out, and provided an equally plausible account of the data.

Since it appears that behavioral data can be well explained using single process models, researchers have recently started looking at the neurological basis of recognition memory, in order to determine if there is any biological evidence for familiarity and recollection playing a role in the decision process. Despite evidence that the remember-know procedure does not necessarily separate recollection and familiarity, it has been widely used in imaging and electrophysiological studies. Here the aim is to find either separate brain regions (in fMRI studies), or distinct event-related potentials (ERPs) related to remember and know responses, which are then interpreted as being related to recollection and familiarity, respectively.

Recently, Yonelinas, Otten, Shaw and Rugg (2005) suggested that they had found a neural signature of recollection that was distinct from familiarity. Because past researchers (e.g., Dunn, 2004) had suggested that remember responses simply reflect a subject's high level of confidence, Yonelinas et al. had their subjects respond 'remember' if they could remember something specific about the study episode, otherwise they were asked to give

a confidence rating that the item was studied using a four-point scale (sure old / sure new). Yonelinas et al. found different neural signatures for remember and high confidence familiar responses, which led them to the conclusion that recollection and familiarity are two distinct processes (but see Dunn & Dennis, submitted, for a conflicting interpretation of these results).

Curran (1999, 2004) and colleagues (e.g., Curran & Dien, 2003; Curran, DeBuse, Woroch, & Hirshman, 2006; Curran, Tepe, & Piatt, 2006; Curran, DeBuse, & Leynes, 2007) have focused on differentiating recollection and familiarity using ERPs. Two time periods of interest have been identified. The first, occurring 300-500ms after stimulus onset is commonly referred to as the FN400 as it is a frontal negative peak. The second, occurring 400-800ms after stimulus onset has received numerous names, but the most common is the LPC, or late positive component, and is more dominant in the parietal brain region. Curran et al. have argued that the FN400 is an old/new decision component related to item familiarity, while the LPC is related to the recollection process. Evidence for this distinction also comes from studies using the remember-know procedure. Studies have shown that studied items produce a more negative FN400 than unstudied items, and that 'remembered' items produce a more positive LPC than 'known' items (e.g., Rugg et al., 1998; Rugg & Curran, 2007; Rugg & Yonelinas, 2003). However, as Finnigan, Humphreys, Dennis, and Geffen (2002) have demonstrated, these findings can be easily fit by a single process model whereby the FN400 reflects an individual's old/new decision, and the LPC reflects their confidence.

Obviously there is much controversy as to how both the behavioral and neurological data should be interpreted. The following section outlines a technique that can be used to determine the number of processes that are needed to account for a given data set, without making any assumptions about single or dual process models.

State-Trace Analysis

State-trace analysis (Bamber, 1979) is based on the premise that two dependent variables will covary with each other to the extent that they are affected by the same independent variable. By producing a plot of one dependent variable as a function of another dependent variable, one can determine the number of intervening psychological variables, or processes, that mediate the effect of one or more independent variables on the measured dependent variables. If the resulting scatter plot is one dimensional, that is all the data points lie on a single monotonically increasing (or decreasing) curve, then it can be assumed that the two dependent variables are functions of the same latent variable.

Dunn (2008) performed a state-trace analysis on the data from 37 remember-know studies. When the old/new hit rate was plotted as a function of the remember (or high

confidence) hit rate, a predominately one dimensional curve was found, suggesting that the remember-know task is best described by a single process model. Further, when the z-transform of the state-trace was computed, a straight line with a slope of one was obtained. This finding is also in accordance with an unequal variance, signal detection, or single process model.

Experiment

The aim of the present research is to examine the ERP correlates of recognition memory. To do this, state-trace analyses will be applied to behavioral and ERP data obtained from an experiment that manipulates two independent variables identified by Yonelinas (2002) to affect either familiarity or recollection. The behavioral state-trace will plot the low confidence hit rate (LCHR) as a function of the high confidence hit rate (HCHR) and the ERP state-trace will plot the FN400 as a function of the LPC. If the HCHR/LPC reflects recollection, the state-trace plots should show two lines, separated on the dimension outlined by Yonelinas to reflect recollection. However, if the state-trace plots show a one dimensional curve, this will be indicative of a single process underlying recognition memory, and will provide strong evidence in favor of single process models.

Specifically, in our experiment the number of study repetitions (1/2/4) and attention at study (focused/divided) were manipulated. According to Yonelinas (2002), the attention manipulation should affect recollection, but not familiarity, and the study repetition manipulation should affect both familiarity and recollection. If the dual process interpretation of recognition memory is accurate, the state-trace plots should show two monotonic functions, separated by the attention manipulation. Specifically, the LCHR/FN400 should become more positive as the number of study repetitions increases, and the focused attention condition should be shifted to the right (i.e., a more positive HCHR/LPC) compared to the divided attention condition. However, if the resulting state-trace plot is one-dimensional, this will indicate that both the number of study repetitions, and attention at study are related to the same latent variable, or memory process, indicating that a single process interpretation of the data is accurate.

Method

Participants

54 students from the Ohio State University participated in return for course credit.

Stimuli

The stimuli consisted of 240 high frequency words with a mean frequency of 155 (ratings taken from the Celex

database, Baayen, Piepenbrock, & van Rijn, 1993). Words were 4-8 letters in length (mean 4.6). Words were randomly divided into 5 lists for each participant and items within each list were randomly allocated to old/new, focused/divided attention, and repetition conditions.

Design

The experiment was a 2x3 design, with attention at study (focused/divided) and number of study repetitions (1/2/4) manipulated within-subjects.

Procedure

Participants were first briefed on the requirements of the study, signed a consent form and were fitted with the Geodesic Electrode Net.

Each study list consisted of 24 words. Half the words were presented alone on the screen (focused attention condition) while the other half were presented flanked by two numbers (divided attention condition). In the divided attention condition, the flankers appeared for 200ms and were then covered by a mask. The numbers differed in both their numerical value, and their font size. After the target word was removed from the screen, the participants were asked to report which number (left or right) was larger in either value or size by pressing the appropriate key on the keyboard. One third of the study items were presented once, one third were presented twice, and one third were presented four times during the study phase to give a total of 56 study trials. Repeated words were always repeated within the same attention condition. Words were presented for three seconds followed by a one second interstimulus interval (isi). Following the study phase, participants completed several math problems for a period of approximately three minutes.

The test lists consisted of 48 words, with an equal number of old and new items. Each word was presented for two seconds followed by a response cue, at which time the participant was required to give their response by pressing the appropriate key on the keyboard using a six-point confidence rating scale (sure old/sure new). Participants were instructed to wait for the cue before responding, to stay as still as possible, and to minimize eye blinks.

Each study/test cycle took approximately 20 minutes to complete. After each cycle, the Electrode Net was checked to ensure that impedances remained below 50k Ω . Participants completed as many study/test cycles as possible during the two hour time period, with most completing an average of four cycles.

EEG Recording

Scalp voltages were collected using a 128-channel Electrical Geodesics Sensor Net connected to a high impedance amplifier (300k Ω Net AmpsTM, Electrical Geodesics Inc, Eugene, OR, USA). Amplified analog voltages (0.1-100Hz bandpass, -3dB) were digitized at 500Hz. Individual sensors were adjusted until each reached

an impedance of less than 50k Ω . The EEG was digitally low-pass filtered at 40Hz.

Results

Trials were discarded from the analysis if they contained eye movements (EOG over 70 μ V), or more than 20% of channels were bad (average amplitude over 200 μ V or transit amplitude over 100ms). Individual bad channels were replaced on a trial-by-trial basis with a spherical spline algorithm (Srinivasan, Nunez, Silberstein, Tucker, & Cadusch, 1996). Consistently bad channels for a given subject were replaced throughout that subject's entire dataset (bad channels per subject: median = mode = 1, range = 0 - 3). EEG was measured with respect to a vertex reference (Cz), but an average-reference transformation was used to minimize the effects of reference-site activity and accurately estimate the scalp topography of the measured electrical fields (Dien, 1998; Picton, Lins, & Scherg, 1995). Average-reference ERPs were computed for each channel as the voltage difference between that channel and the average of all channels. The average reference was corrected for the polar average reference effect (Junghofer, Elbert, Tucker, & Braun, 1999). ERPs were baseline-corrected with respect to a 100ms prestimulus recording interval.

Figure one shows the state-trace plot obtained by plotting the mean LPC against the mean FN400 for each attention by repetition condition. Both the FN400 and the LPC were found to increase (i.e., become more positive) with increasing study repetitions. Additionally, there is no significant differentiation between the focused and divided attention conditions.

The behavioral state-trace plot, also shown in Figure one, shows that both high and low confidence hit rates increase with increasing study repetitions. Further, there is no differentiation between the attention conditions.

Figure 1: State-trace plots of the behavioral (left) and ERP (right) results for each of the attention by repetition conditions.

Discussion

The state-trace plots produced from the analysis of our experiment are clearly one-dimensional and thus provide very little evidence in support of the dual process interpretation of recognition memory. Rather, our findings

show strong support for a single process interpretation of recognition memory.

Numerous previous recognition memory studies looking at ERPs have assumed that the LPC is reflective of recollection (e.g. Curran, 2004; Curran, Tepe, & Piatt, 2006). These studies have rejected a single process interpretation of the FN400 and LPC because it “does not explain the double-dissociation between mid-frontal and parietal effects observed by Woodruff et al.” (Rugg & Curran, 2007, p.264). In the study which Rugg and Curran (2007) refer to, participants were asked to respond using a variation of the remember-know procedure, in which they either made a graded, confidence-based familiarity judgment on a 4-point scale, or a remember/recollection response. The authors report differing ERP patterns for the FN400 and the LPC and suggest that the ordering of the waveforms ($1 < 2 < 3 < 4 = R$ and $1 = 2 = 3 < 4 < R$, respectively) are evidence that the FN400 represents familiarity, and the LPC represents recollection. However, as explained by Dunn and Kirsner (2003), this is actually a classic non-double-dissociation. The error is that the authors implicitly assume that changes in volts (a physical variable) are linearly related to memory strength (a psychological variable). If on the other hand, one assumes that this relationship is at best monotonic and different for frontal and parietal, the underlying assumption of state-trace analysis, then there is no dissociation. At both sites, the underlying pattern of memory strength is $1 < 2 < 3 < 4 < R$ but mapped onto frontal and parietal volts by different functions. By using state-trace analysis to interpret our research findings, we have not only avoided this common error, but have also shown strong support for a single, rather than dual, process interpretation of ERP results.

Additionally, the results from our experiment add weight to the suggestion by Finnigan et al. (2002) that the LPC is not reflective of recollection. Finnigan et al. suggested that the LPC may instead be related to confidence. Although not specifically addressed in this analysis, our research methods provided an opportunity for testing this idea in the future.

Yonelinas (2002) suggested that dividing attention at study would affect recollection at test, such that items in the focused attention condition would have higher levels of recollection than items in the divided attention condition. The analysis of our behavioral data produced a single monotonic state-trace curve (see also Dunn, Heathcote, Dennis, & deZubicary, in preparation). Our ERP findings extend these behavioral findings, supporting a single process interpretation of recognition memory.

Combined, these findings suggest that not only is the LPC not reflective of recollection as suggested by Curran and colleagues, but they also suggest that the notion of recollection itself may be flawed, further supporting the predictions of single process models of recognition memory.

Abstract

One of the key memory tests in the clinical assessment and diagnosis of Alzheimer's Disease (AD) is the recognition memory task. Models developed in cognitive psychology have previously been applied to help understand clinical data. In particular, Signal Detection Theory (SDT) models have been used, to separate people's memory capabilities from their decision-making strategies. An important finding in this literature is that people with AD change their decision strategy in response to memory impairment, applying a more liberal criterion than people without AD. In this paper, we analyze clinical data that measures the progression of AD in a detailed way, using a theoretically motivated version of SDT, and applying hierarchical Bayesian methods to model individual differences. Our results corroborate many of the previous findings, but provide a more detailed focus on recognition performance with AD progression.

Keywords: Alzheimer's disease; Cognitive psychometrics; Hierarchical Bayesian modeling; Human recognition memory; Signal detection theory

Introduction

The clinical assessment and diagnosis of Alzheimer's disease (AD) routinely involves the administration of memory tests that are familiar to cognitive scientists who study human memory. In particular, recognition, immediate free recall, and delayed free recall are large sub-components of assessment tools such as the MCIS and the ADAS-Cog (e.g., Morris, Heyman, & Mohs, 1989). This link means there is an important role for theories and models of memory, as developed in the cognitive sciences (for an overview, see Norman Detre, & Polyn, 2008), in helping understand AD. In particular, memory models can provide quantitative measurement tools that allow for patient behavior to be interpreted in terms of psychologically meaningful latent parameters (e.g., Riefer, Knapp, Batchelder, Bamber, & Manifold, 2002).

A good example of the potential for applying memory models to clinical data is provided by a literature that uses equal-variance Signal Detection Theory (SDT) models (e.g., MacMillan & Creelman, 2004). SDT is widely-used as a basic model of the recognition memory task, and has the theoretical attraction of separating memory capabilities from decision processes when explaining people's behavior (e.g., Budson Wolk, Chong,

& Waring, 2006; Snodgrass & Corwin, 1988). This is a very important capability, because there is considerable evidence that AD patients do have different decision-making strategies in tasks like recognition memory.

The recent review by Budson et al. (2006) notes that the application of SDT models to clinical data has repeatedly shown that patients with AD use a more liberal criterion in identifying previously studied words. This strategy is usually interpreted as a response to awareness of diminishing memory capabilities. Additionally, Budson et al. (2006) report the results of an experiment which addressed several potential confounds in the existing experiments, including unequal numbers of old and new words and semantic and/or perceptual relatedness of the old and new words. Again, AD patients were found to have abnormally liberal response biases compared to non-AD patients.

In this paper, we extend the application of SDT models to clinical recognition memory data. We do this in a number of ways. First, we use a large new clinical database, which has the advantage of measuring the progression of AD in some detail. This lets us conduct a finer-grained analysis of how recognition memory changes as AD progresses. Second, we use a simple variant of the standard SDT model that builds in an unequal-variance assumption. This is theoretically preferable, given empirical evidence that there is more variability in people's memory for studied than non-studied words. Third, we embed our SDT analyses with a hierarchical Bayesian framework for statistical inference. This lets us provide a coherent model-based account of variation, at both the level of individual patients, and the level of clinical sub-populations.

The plan of the paper is as follows. We begin by describing the clinical data, and then the unequal-variance SDT model we use. We show that the model provides a good account of the data, and show how inference about the model's parameters gives an interpretable account of changes in recognition memory with the progression of AD. We then extend the modeling to account explicitly for changes in decision bias, and conclude by discussing how our findings relate to the existing literature.

Clinical Data

Our data come from two neurology clinics where 1350 patients completed a standard old/new recognition mem-

ory test. The patient was shown a study list of 10 words to memorize, and was then tested on their ability to recognize the 10 studied *old* words from 10 unstudied *new* words. This means there are 20 test trials, on each of which the patient was shown a word and simply asked to decide whether or not the word was on the study list. Consequently, the patient's behavior on each trial naturally falls into one of the standard SDT classes of hits, misses, false alarms, and correct rejections. The words themselves were selected from the CERAD (Consortium to Establish a Registry for Alzheimer's Disease) word list (Shankle, Mangrola, Chan, & Hara, 2009).

Independent of patient performance on the recognition memory tests, a trained neurologist used the Functional Assessment Staging Test (FAST) to assess the severity of each patient's AD. The FAST (Reisberg, 1988) is a well-validated diagnostic tool used by clinicians to classify patients into one of the seven *stages* of AD, each of which corresponds to a level of functional impairment. Specifically, stage 1 corresponds to 'normal aging', stage 2 to 'possible mild cognitive impairment', stage 3 to 'mild cognitive impairment', stage 4 to 'mild dementia', stage 5 to 'moderate dementia', stage 6 to 'moderately severe dementia' and stage 7 to 'severe dementia'. We focus on only FAST Stages 1–5, because patients diagnosed into Stages 6 and 7 have very limited functional capabilities, and cannot necessarily understand and complete memory tasks. In our sample of 1350 patients, 288 were classified as Stage 1, 308 as Stage 2, 129 as Stage 3, 436 as Stage 4, and 189 as Stage 5.

Hierarchical SDT Model

In this section, we describe the hierarchical SDT model we use to analyze the clinical data. We start with a standard SDT model, and then describe how our hierarchical extensions add the capability to model individual differences and changes in bias. We then implement the model as a graphical model to allow Bayesian inference.

Signal Detection Theory

The basic SDT model shown in Figure 1 assumes that, on each trial, the presented word evokes some memory strength. The memory strengths of both old and new words are assumed to have Gaussian distributions, with the mean of the new distribution separated from the mean of the old distribution by a distance $d' > 0$. In this way, d' measures the *discriminability* of the old from the new words, and so represents the acuity of memory for the words.

Due to the assumed overlap of the old and new distributions, an individual needs a decision strategy for relating memory strength to responses in a recognition test. SDT models assume this is done using a criterion level of memory strength k below which the individual will respond studied and above which the individual will respond non-studied. The area h under the old distribution above the criterion corresponds to the hit rate, and the area f under the new distribution above the criterion corresponds to the false-alarm rate.

Figure 1: The unequal-variance SDT model and parameters.

The distance c between this criterion and unbiased responding is commonly used as a measure of *response bias* due to its purported independence from d' (Snodgrass & Corwin, 1988). The response bias measures the tendency of an individual to give one response rather than another.

Extension for Unequal Variance

Most SDT modeling in psychology assumes that the standard deviations of the old and new distributions are equal, with $\sigma_{\text{old}} = \sigma_{\text{new}} = 1$ for convenience. Results of recognition memory experiments (e.g., Mickes, Wixted, & Wais, 2007), however, support a version of SDT in which the standard deviation of the old distribution is 25% larger than the standard deviation of the new distribution, so that $\sigma_{\text{new}}/\sigma_{\text{old}} = 0.8$. This finding is usually interpreted as coming from variability in the encoding of studied words. Our SDT model adopts an unequal-variance assumption, using the approach developed by Dennis, Lee, & Kinnell (2008).

Extension for Individual Differences

Most previous applications of SDT models to the recognition memory data of Alzheimer's patients have also ignored the issue of individual differences. To address this shortcoming, we apply hierarchical methods to extend the standard SDT model (e.g., Dennis, Lee, & Kinnell, 2008; Rouder & Lu, 2005). The basic idea is to introduce sub-populations at a group-level that allow for different parameter values for different levels of severity in AD. An individual patient's discriminability and response bias parameters are then drawn from the appropriate group-level distribution for their level of severity. In this way, the model allows freedom for different individuals to have different parameters, but still maintain a

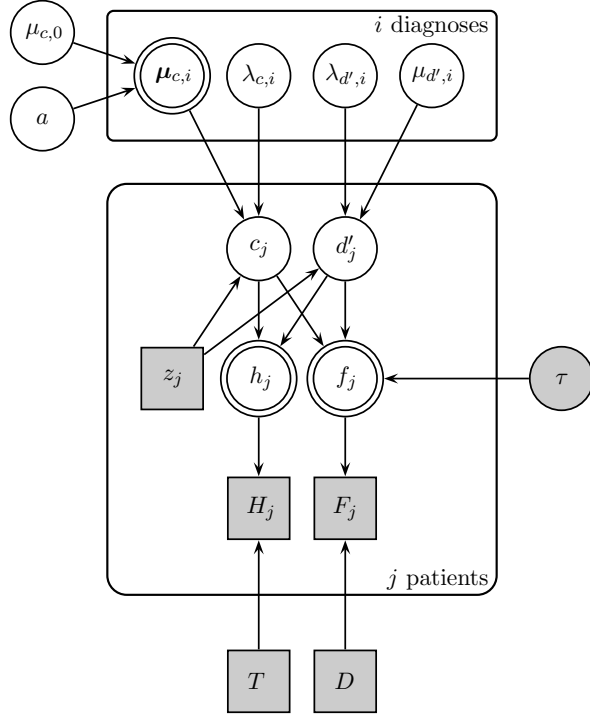

Figure 2: Graphical model implementation of the hierarchical SDT model.

similarity to other patients with a similar level of cognitive impairment.

Extension for Modeling Change

Most previous analyses focusing on changes in response bias with AD progression have taken a purely statistical approach. Typically, they have tested for significant differences in bias or criterion parameters, as inferred separately from AD and non-AD patients. We adopt a different approach based on cognitive modeling, building assumptions about how bias changes into the model itself. This is consistent with the basic idea of *generative* models, which try to provide formal accounts of how latent parameters produce and co-vary with observed behavior, and can be contrasted with the *discriminative* philosophy of post-hoc statistical tests. In the generative approach, a model of change is incorporated into the SDT model, with the goal of providing a complete and integrated account of how the criterion changes with the progression of AD.

Graphical Model Implementation

We implemented our hierarchical SDT model in the form of a Bayesian graphical model, a formalism widely used in statistics and computer science (e.g., Jordan, 2004). In graphical models, nodes correspond to variables, and their interdependencies show the causal relationships between the variables. In particular, graphical models

show how unobserved variables (i.e., parameters) generate observed variables (i.e., data). Details and tutorials aimed at cognitive scientists are provided by Lee (2008) and Shiffrin, Lee, Kim, and Wagenmakers (2008). The practical advantage of graphical models is that sophisticated and relatively general-purpose Markov Chain Monte Carlo (MCMC) algorithms exist that can sample from the full joint posterior distribution of the parameters conditional on the observed data.

It is easiest to understand the graphical model in Figure 2 by starting with the d'_j and c_j nodes, which are the discriminability and bias parameters for the j th patient. These parameters can be used to generate the hit and false-alarm rates for that patient, according to the SDT model. The hit rate is $h_j = \Phi(d'_j/2 - c_j)$ and the false alarm rate is $f_j = \Phi(-(d'_j/2 + c_j)/\tau)$, where $\tau = 0.8$ gives the unequal-variance model advocated by Mickes, Wixted, and Wais (2007). Based on these hit and false alarm rates and the $O = 10$ old and $N = 10$ new words presented to all patients during the recognition tests, the j th patient produces $H_j \sim \text{Binomial}(h_j, T)$ hits and $F_j \sim \text{Binomial}(f_j, D)$ false-alarms.

The distributions of discriminability and bias for different AD diagnoses, at the group or sub-population level, are controlled by the mean μ and precision λ variables. There is a Gaussian group distribution for each group. If, for example, we use FAST stage diagnoses to define groups, and the j th patient belongs to stage z_j , then $d'_j \sim \text{Gaussian}(\mu_{d',z_j}, \lambda_{d',z_j})$ and $c_j \sim \text{Gaussian}(\mu_{c,z_j}, \lambda_{c,z_j})$.

Finally, the graphical model in Figure 2 implements a basic model of change for response bias. Following previous analyses (e.g., Snodgrass & Corwin, 1988), we just consider the change from non-AD to AD patients. The parameter $\mu_{c,0}$ measures the non-AD response bias, and a quantifies the change, so that $\mu_{c,1}, \mu_{c,2} = \mu_{c,0}$ and $\mu_{c,3}, \dots, \mu_{c,5} = \mu_{c,0} + a$.

Modeling Results

In order to perform Bayesian inference, we implemented the graphical models in WinBUGS (Spiegelhalter, Thomas, & Best, 2004). This software uses a range of MCMC computational methods to obtain samples from the posterior distributions of the relevant parameters (e.g., Mackay, 2003). All of our analyses are based on 10,000 posterior samples collected following a burn-in of 1000 samples, using multiple chains to check convergence.

Assessing Model Fit

Posterior predictive distributions provide an intuitive and principled way to assess the descriptive adequacy of a Bayesian model (Gelman, Carlin, Stern, & Rubin, 2004, pp. 165–172). A posterior prediction corresponds to the data the model expects, based on the parameter values it has inferred, and naturally takes into account uncertainty in those parameter estimates.

Figure 3 shows a posterior predictive analysis for the

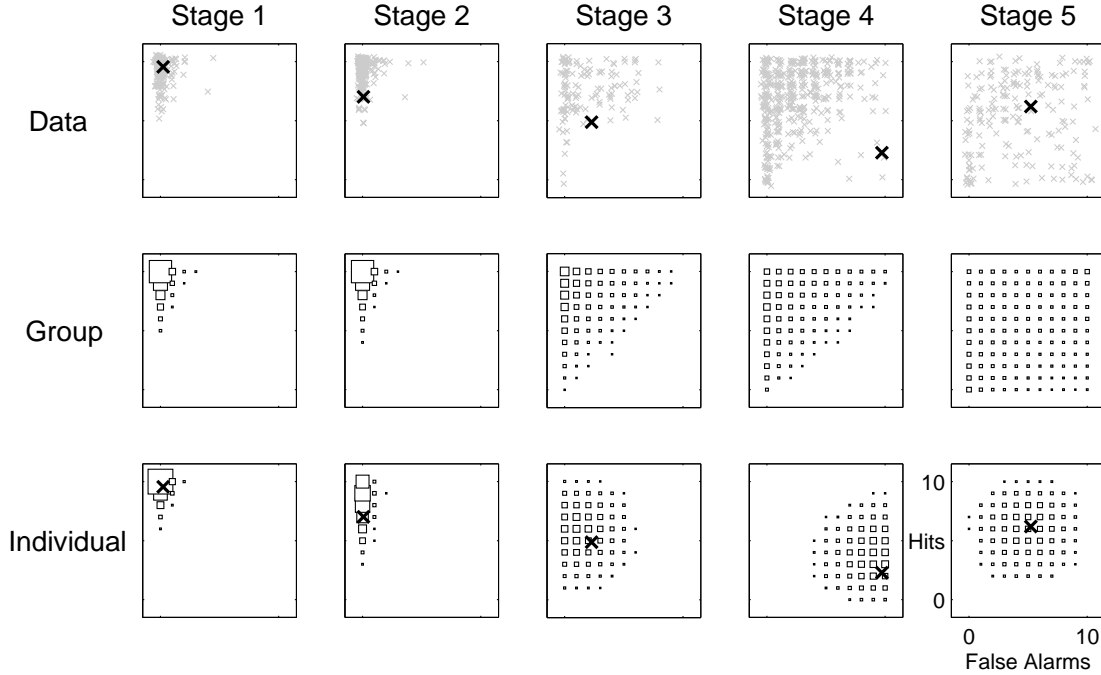

Figure 3: Posterior predictive assessment of the fit of the hierarchical SDT model. The first row shows the hit and false-alarm counts for each patient, according to their FAST stage, with the counts for a randomly selected patient shown in bold. The second and third rows show the corresponding posterior predictive distributions for hit and false alarm counts for the group data and for the individual patient data. In the posterior predictive panels, the box sizes are proportional to the mass of the posterior predictive distribution for that combination of hits and false alarms.

hierarchical SDT model. The first row corresponds to the behavioral data, the second row to the group-level inferences of the model, and the third-level to the individual-level inferences of the model. The columns correspond to the five FAST stages. Each panel shows the distribution of data or predicted data in terms of hit and false-alarm counts, as in standard Receiver Operation Characteristic (ROC) analysis (e.g., MacMillan Creelman, 2004).

The observed data for all patients are shown as gray crosses, except for one highlighted individual—selected out to test the individual-level predictions of the model—shown by a black cross. For the group level, the model’s posterior predictions are shown by squares, with areas proportional to predictive mass. It is clear that the group-level predictions match the data, and show a degradation in performance, with fewer hits and more false-alarms, as the severity of AD progresses. In this sense, the model provides an accurate description of the similarities and differences between clinical sub-populations. In the individual-level model predictions, the area of the squares again correspond to predictive mass, and provide accurate fits to the observed data. We note that several of the individuals were deliberately chosen to be outliers within their clinical sub-population. The ability of the model for describe these individuals well, while si-

multaneously describing group-level performance, highlights the advantages of the hierarchical approach we have taken to modeling individual differences.

Assessing Discriminability and Bias

Figure 4 shows the joint and marginal posterior distributions for both discriminability and bias, at the level of the FAST stage groups. The main panel shows samples from the joint distribution for each of the five FAST stages. The side panels show the marginal distributions for both discriminability and bias.

As would be expected, discriminability decreases as AD severity progresses, starting around $d' = 4$ for non-AD patients in the first two stages, and decreasing to $d' < 1$ for patients in stage 5. The pattern change in recognition bias across the stages is more revealing. Patients in the non-AD stages start with a conservative bias, with $c > 0$, meaning they are more likely to fail to recognize studied words than to false-alarm to non-studied words. This bias changes significantly for the AD patients, and becomes much more liberal, shifting to a position almost consistent with unbiased responding at $c = 0$.

Assessing Change in Recognition Criterion

Figure 4 shows that the change in criterion is sudden and sustained. At FAST stage 3—which is the first AD

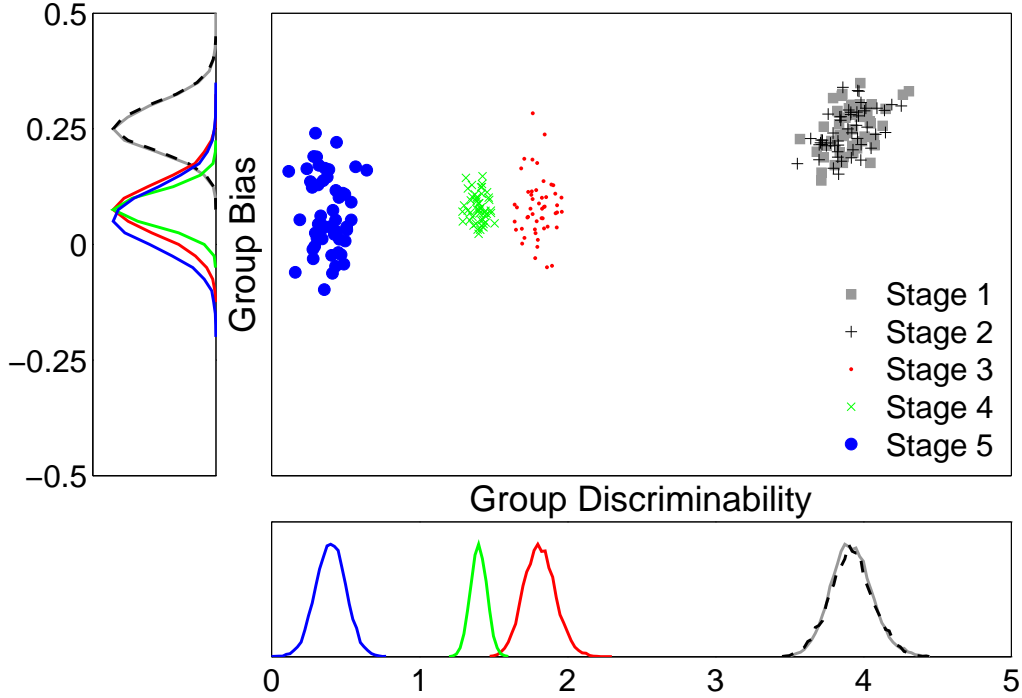

Figure 4: Joint and marginal posterior distributions for the group-level discriminability and bias parameters, for each of the five FAST stages.

stage—the distribution of individual response bias moves to a smaller value, and it sustains approximately the same distribution over subsequent progression through stages 4 and 5.

Our generative model of change allows an immediate inference about the significance of these apparent change in response bias, via the posterior distribution of the α parameter. This is the parameter that control the step-change in response bias between AD and non-AD diagnoses. Its posterior distribution is shown in Figure 5, and is clearly negative, and does not include zero, confirming the liberal change in bias at the onset of AD.

Discussion

Our results are largely consistent with previous findings, but are not identical. We have corroborated the most important existing finding, which is that the onset of AD leads to a liberalization in response bias in recognition memory tasks. Our results, however, extend the previous understanding of the change in response bias, through using a clinical data set with more FAST stage information about AD progression. Using this more detailed measure we found, perhaps surprisingly, that the change in response bias seems to involve a sudden shift at the onset of AD, rather than gradual change over its progression.

Unlike most previous studies, we found non-AD patients starting from a conservative criterion setting—being more likely to miss than to false-alarm—and so the liberalization actually leads to more unbiased decision-

making in the AD patients. There are many possible reasons for this difference, which are worth further investigation. One possibility involves methodological issues, including details of the assessment tasks, such as differences in the word lists used. Another possibility relates to more fundamental theoretical and modeling differences in our analysis. We have introduced a number of innovations, any (or all) of which might lead to different findings from more standard analyses.

We think the modeling approach we have used has some clear advantages over previous work. As AD progresses, memory capabilities and decision strategies change in important and interpretable ways. But there remains variability in the characteristics of individual patients, even though they can appropriately be classified within groups like FAST stages. Our hierarchical approach naturally incorporates this interplay between clinical sub-populations and individual patients, making it suitable for both broad characterization of AD progression and for individual diagnosis.

Throughout our modeling, we used a simple extension of the standard SDT model to allow for unequal-variances between studied and non-studied words. We think this theoretically preferable, although we did not observe very different results when we repeated the current analyses with equal-variance SDT. Perhaps the most striking difference was that the posterior for the response bias parameter in Figure 5 showed a much stronger change in bias for the non-AD versus AD comparison.

Figure 5: Posterior distribution for the a parameter, which controls the change in response bias from non-AD to AD patients.

It may be that equal-variance SDT overstates the change in decision strategies.

We believe the framework for modeling change we have introduced also has great potential, but realize we have only taken the smallest first step. The key idea is that group-level parameters like discriminability and bias can now be inter-related across diagnoses or classifications like FAST stages. We used a simple step function between non-AD and AD patients, but much more sophisticated functional relationships could be modeled, expressing a theory of how key psychological variables change throughout AD progression. Even more generally, graphical models provide a natural vehicle for modeling and evaluating changes in these variables due to external factors like treatments in clinical trials, or for expressing these variables in terms of causal or co-variate information like demographic or other properties of people. These sorts of extended possibilities highlight the potential of using cognitive models like SDT and hierarchical Bayesian analysis to understand Alzheimer's Disease.

Context, Syntactic Priming, and Referential Form in an Interactive Dialogue Task: Implications for Models of Alignment

Abstract

Two experiments examined how context and syntactic priming interact to determine interlocutors' choice of referential form. Pairs of naïve participants took turns producing descriptions of target pictures from a set of alternatives. The first experiment established that a contrast picture in the display (e.g. a striped cat in a display where a spotted cat was the target) primarily determined whether an adjective was used. Priming with an adjective had a only small, secondary effect on adjective use. However, when an adjective was used, it was more likely to occur in the prime-congruent structure than the alternative structure. Experiment 2 compared the effects of a prime produced by the dialogue partner with the effects of a pre-recorded prime played through headphones. Syntactic priming was significant only for the dialogue prime trials, indicating that priming may be stronger in dialogue than outside of dialogue, as previous work has suggested. However, even in dialogue, the primary factor that determined referential form was the set of alternatives. Our results begin to clarify the role of syntactic priming in dialogue, suggesting that it has at most a small effect on message formulation.

Keywords: dialogue; language production; referential form; syntactic priming; alignment; message formulation.

Introduction

How does a speaker choose the content and form of a referring expression? In addition to being a classic question in the philosophy of language, it is an important problem for language generation systems. Such systems aim to approximate the types of utterances that a speaker would produce in a task-oriented dialogue, and thus provide important data for evaluating models of dialogue developed within psycholinguistics.

Work on reference production in the Gricean tradition assumes that a speaker will provide sufficient information for her addressee to identify an intended referent, taking into account the purpose of the conversation (Grice, 1975). Speakers should be specific enough for the addressee to identify the intended referent, without being overly specific by providing unnecessary information. For example, a speaker might say “the cat” when referring to a single cat among several other animals, but refer to the same animal as “the striped cat” when there are multiple cats present.

A more striking observation in language production research is that interlocutors not only converge on the same referring expressions (Clark & Wilkes-Gibbs, 1986), but also begin to use the same syntactic forms. This effect is

often referred to as structural persistence, syntactic persistence, structural priming, or – as we will call it in this paper – syntactic priming (Bock, 1986; Ferreira & Bock, 2006; Pickering & Ferreira, 2008). Some research suggests that syntactic priming might be stronger in dialogue settings than in other types of experimental tasks (Branigan, Pickering, McLean, & Cleland, 2007; Branigan, Pickering, & Cleland, 2000). Pickering & Garrod account for this trend by suggesting that “a major reason why priming effects occur is to facilitate alignment, and therefore they are likely to be particularly strong during natural language interactions” (p. 174, 2004).

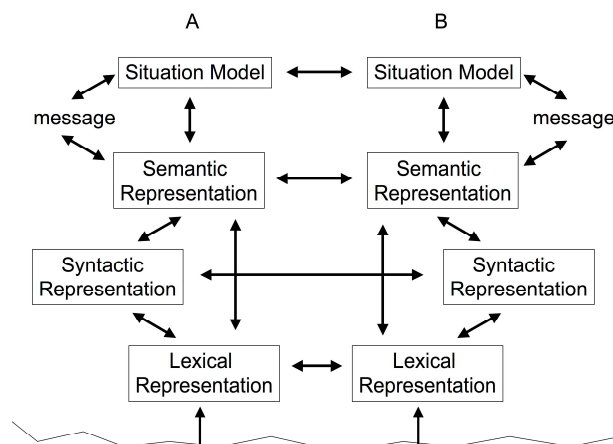

Figure 1: The Interactive Alignment Model (based on Pickering and Garrod, 2004); the mental representations of hypothetical interlocutors, A and B, are shown.

As a first step toward extending this idea and integrating it with a broader model of language production in dialogue, Pickering & Garrod (2004) proposed the Interactive Alignment Model, illustrated in Figure 1. The model assigns a central role to syntactic priming, casting it as a mechanism that aligns interlocutors' representations at multiple levels. Alignment at one level affects alignment at higher and lower levels of representation, making the model interactive.

Notably, the model assumes that the process through which interlocutors come to have the same representation of a situation is unconscious and automatic. Alignment at the syntactic level – that is, syntactic priming – is treated as an important factor that allows for communicative success, by increasing alignment at these other levels (Pickering &

Garrod, 2004, 2006). The model treats syntactic priming as a mechanism for alignment at other levels, which in turn explains how interlocutors are able to communicate successfully. In this way, syntactic priming has played a major empirical and theoretical role in the development of alignment models of dialogue. However, few, if any, investigations have attempted to examine how and when syntactic priming might affect representations and processes at various levels of representation in dialogue. We focus on two levels of representation that are typically distinguished in models of language production: message formulation and building the syntactic form of the utterances (see Bock & Levelt, 1994, for a classic language production model that makes this distinction).

According to Bock & Levelt, the message formulation level “captures features of the speaker’s intended meaning and provides the raw material for the processes of grammatical encoding” (p. 946, 1994). In other words, the message formulation stage involves planning the information to be communicated at a pre-grammatical level. Bock & Levelt present this as a stage that occurs before grammatical encoding begins. However, the Interactive Alignment Model is compatible with the possibility that grammatical encoding, such as syntactic category selection, could indirectly affect the message (refer to Figure 1 for a general idea of how this would work in that model). While message selection is most naturally affected by Gricean processes, like including the appropriate amount of information in an utterance, it is possible that the availability of syntactic structures could have some influence on the message that is formed.

Optional adjective use within a noun phrase is ideal for investigating this possibility. Adjectives are often used in referential expressions, even when the context does not require it from a Gricean perspective. Speakers are prone to over-informative adjective use when describing objects, including adjectives in their descriptions unnecessarily up to 46% of the time (Belke, 2006; Sedivy, 2003). This makes noun phrases that can optionally contain adjectives (e.g. *the [striped] cat*) ideal for an investigation of how syntactic priming and message formulation interact. Syntactic priming with an adjective-containing structure might increase the likelihood that the subsequent message will include information associated with an adjective, so that the primed syntactic structure can be used again. This structure provides a special opportunity to observe any potential effects of priming on message content, since speakers are free to use adjectives, even when the context does not require it. In addition, previous work has indicated that noun phrase structures containing adjectives are susceptible to syntactic priming effects (Branigan, McLean, & Jones, 2005). This structure should therefore allow us to observe any possible effects of syntactic priming on message formulation.

The hypothesis is that the message selection level of representation could be subtly affected by the increased availability of a primed syntactic representation. We

compare two conditions: one in which syntactic priming could affect message formulation by increasing the likelihood of subsequent adjective use, and another where no increase in adjective use would be expected. For example, will a speaker be more likely to refer to a single cat, among other potential referents, as “the striped cat,” if their interlocutor had used an adjective-containing noun phrase construction on the previous trial?

Our design also allows us to explore the claim that syntactic priming effects are stronger in dialogue than in non-dialogue situations. Although some previous research has suggested that syntactic priming effects are stronger in dialogue, this conclusion has been primarily based on post-hoc comparisons of priming effects between experiments that use different methods (but see Branigan, et. al., 2000, 2007 for exceptions). This creates the potential for confounds which could mimic a difference between dialogue and non-dialogue, and makes it difficult to determine whether differences are significant.

In addition, the few experiments (Branigan, et. al., 2000, 2007) that directly examine syntactic priming effects in dialogue are scripted confederate studies, in which a participant takes part in a highly controlled task with a trained assistant. In this setting, many factors that would normally affect what is said – such as referential context and lexical availability – are highly controlled by the situation, and unlikely to have a strong effect. This is a problem, since syntactic priming effects may appear to be larger when other influences on a referential expression are minimized. It is unclear whether the magnitude of priming effects in such a setting can be considered evidence that priming is a special mechanism that causes language production to occur differently in dialogue than in other experimental settings.

We report two experiments that investigate how syntactic priming affects referential form in an unscripted dialogue task. The first experiment examined the effects of syntactic priming on message formulation during dialogue. The second experiment compared priming effects in dialogue with priming effects outside the dialogue, in an otherwise identical task. Both experiments allowed us to explore how referential constraints interact with syntactic priming to determine referential form, and to address the relationship between syntactic priming and successful communication.

Experiment 1

Experiment 1 was a first step towards examining how syntactic priming in dialogue affects other levels of representation. Specifically, does priming affect alignment at the level of message formulation, as one interpretation of the Interactive Alignment Model suggests? Or, does syntactic priming exert an effect on language production only after the message to be communicated has been fully planned, as the Bock & Levelt (1994) model predicts?

Materials and Methods

Participants Fifteen pairs of friends from the University of Rochester were paid to participate. All were native English speakers and naïve to the purpose of the experiment.

Experimental Setup Individual participants sat at separate computers on either side of a large cardboard barrier, so that they could not see each other or each other's computer screens. To ensure that they could clearly hear each other, participants wore headphones and spoke into microphones. This setup facilitated audio recording of the entire session. To initiate each trial, one participant clicked a central fixation cross. The same set of four clip-art pictures then appeared on both screens. To discourage participants from using expressions like "the top left picture," picture locations were pseudo-randomized. After a 2-second delay, Participant 1 saw a circle appear around the target picture. Her task was to instruct her partner to click on that picture, using any description she chose. The trial ended when Participant 2 clicked the target picture. The overall error rate was less than 1%, and participants were given no feedback about their performance. Participants alternated between giving and responding to instructions, and found the task very easy and natural (see Figure 2).

Figure 2: The experimental setup.

The order of prime target pairs was pseudo-randomized so that different participant pairs saw the displays in different counter-balanced orders. The experiment was divided into blocks, so that participants had 5 breaks throughout the experiment.

Experimental Items There were two types of displays that occurred in pairs: *prime displays* and *response displays*. Half of the prime displays were *adjective primes*, designed to elicit descriptions that included either a pre- or post-nominal adjective; for example, "click the striped cat" or "click the cat with stripes." This was achieved using a contrast set, including the target and a picture that differed from the target in only one adjectival property (e.g. a striped cat vs. a spotted cat). This required participants to use an adjective in their description in order to uniquely identify

the target.¹ The *no adjective prime* displays contained a target picture with no related pictures in the display, allowing participants to successfully describe the target without an adjective.

Each prime display was followed by a response display. The referential context of the response displays was manipulated so that the target was part of a contrast set half the time, and appeared with unrelated pictures only half the time. When there was *contrast* in the display, an adjective was required for a felicitous referential expression, and when there was *no contrast* an adjective was unnecessary. This 3 x 2 design allowed us to test the effects of prime type (no-adjective, prenominal, postnominal) and contrast (present or absent) on the referential expression produced in a response display.

Coding and Analysis The entire interaction was digitally recorded. Participants' descriptions of the pictures were later transcribed word-by-word, and coded by the second author according to the syntactic structure had been used (e.g. prenominal, postnominal, noun only, etc.). Task-irrelevant utterances were not included in the analysis. All statistical comparisons were made using mixed-effects regression models,² which were computed using the R data analysis software, version 2.6.1 (2007).

Results and Discussion

We wanted to answer two questions: was there a basic syntactic priming effect, and if so, did priming affect message formulation by increasing adjective use? Looking first at the subset of data where an adjective *was* used in the description of the response display, we asked whether prenominal and postnominal primes types had an impact on the syntactic structure of the description. If syntactic priming effects in dialogue are strong, then we would expect to see a strong syntactic priming effect: participants should produce more prenominal structures following prenominal primes, and more postnominal structures following postnominal primes. When the property associated with an adjective was already included in the message, we expected that the prime type would affect the structure in which the adjective appeared. Two separate mixed-effects regression models, with subject pair and item as random effects, were

¹ Norming data allowed us to classify prime displays as being likely to generate prenominal or postnominal descriptions, and the experiment included half of each display type. This prompted participants to use a prenominal adjective on 47% of prime descriptions, and a postnominal adjective on 43% of prime descriptions, even though no limitations were placed on what participants could say.

² Mixed-effects regression models were more appropriate for our dataset than ANOVAs, since the unscripted nature of the task led to unequal numbers and variances in each cell of the design. For a discussion of why this choice was appropriate, see Jaeger (2008).

used to test for significance of prenominal and postnominal priming.³

This analysis revealed that the use of a prenominal prime significantly predicted the use of a prenominal adjective in the subsequent response description ($B = 0.45$, $SE = 0.20$, $p = 0.05$). Similarly, the use of a postnominal prime significantly predicted the use of a postnominal response description ($B = 0.46$, $SE = 0.21$, $p < 0.05$). As shown by the coefficients, the magnitude of the effect was approximately equal for pre- and postnominal primes. On average, participants produced a prime-congruent response (i.e. a response that contained the same structure as the prime) 61% of the time, and an incongruent response 39% of the time. This 22% difference is similar to what has been found in classic priming studies not involving dialogue (e.g. the alternating dative priming effect shown by Bock, 1986).

Having established a syntactic priming effect when the message includes an adjective, we evaluated the extent to which priming affected message content. Figure 3 shows the rate of adjective use for response descriptions following each prime type. The pre- and postnominal prime types did not produce different effects, and so they were collapsed into one “adjective prime” type for the purposes of analysis. A mixed-effects regression model with subject pair and item as random effects tested the significance of three predictor variables: Display Type, Trial Order, and Prime Type. The coefficient and significance level for each of these factors is shown in Table 1.

Table 1: The effects of contrast, trial order, and prime type on adjective use.

Predictor	Coefficient (SE)	Significance
Contrast in Display	4.53 (0.43)	$p < 0.001$
No Adjective Prime	0.60 (0.61)	n.s.
Trial Order	-0.0004 (0.002)	n.s.
No Adjective Prime x Contrast in Display	-2.06 (0.88)	$p < 0.05$
No Adjective Prime x Trial Order	-0.0015 (0.005)	n.s.
Contrast in Display x Trial Order	-0.0011 (0.0038)	n.s.
Contrast x Trial Order x No Adjective Prime	-0.0040 (0.0074)	n.s.

There was no effect of trial order, indicating that participants did not prime each other more as the experiment unfolded. Instead, the degree of syntactic priming remained constant over the course of the experiment. This is not what would be expected if syntactic priming was associated with

³ We tested for prenominal and postnominal priming separately, to determine whether one structure caused stronger priming than the other, and to rule out the possibility that the overall priming effect was driven by only one of these structures. Since priming effects were comparable for both structures, subsequent analyses treat prenominal and postnominal priming together.

successful dialogue, as participants became faster and better at this communication task as the experiment unfolded.

As shown in Table 1, adjective use in response display descriptions was predicted only by a main effect of contrast and an interaction between prime type and contrast.

The primary determiner of whether the message included an adjective was the referential context. When a contrast was present in the display, there was a small additional increase in adjective use when the preceding prime had contained an adjective (see Figure 3). However, there was no main effect of adjective prime indicating a complex relationship between priming and adjective use. This was true even though the message could have been modified to include more information based on the presence of an adjective in the preceding prime without any negative consequences for communication.

Figure 3: Mean (standard error) adjective inclusion rates in response descriptions following three prime types, for contrast and no-contrast displays.

The only suggestion of an effect of syntactic priming on message content was the slightly higher rate of adjective use following adjective primes. Priming appeared to increase the rate of adjective use only when a contrast was present. An alternative interpretation is that adjective use following no-adjective primes was artificially low. This may have occurred because some of no-adjective primes involved single words that were coded as nouns, but that could also have been considered adjectives (e.g. *wood* for a tree branch or *fluffy* for a Persian cat). This small subset of the data may have increased the likelihood that an alternative adjective-containing structure would be used again, thereby reducing the rate of pre- and postnominal adjective use following no-adjective primes. This is a viable alternative explanation for the lower rate of adjective use following no-adjective primes in this study, which will need to be carefully explored in future work.

Experiment 2

Experiment 2 was designed to extend the results of Experiment 1, by directly comparing the effects of dialogue and non-dialogue primes using a within-subjects design. If

syntactic priming is stronger in an unscripted dialogue setting than in a non-dialogue setting, participants should be more likely to reuse a syntactic structure generated by the conversation partner than a description that had been pre-recorded by a speaker not participating in the dialogue.

Materials and Methods

Participants Seventeen pairs of friends from the University of Rochester were paid to participate. All were native English speakers who had not taken part in the first experiment.

Experimental Setup and Items The setup was the same as for the first experiment, with a few notable changes. First, primes were now divided into two new categories, depending on dialogue status. Dialogue primes involved one participant describing a prime display to her partner; this was followed by the other participant describing a response display. For one third of trials, non-dialogue primes that had been pre-recorded by a trained female speaker were played through headphones to the participant who was the listener on that trial. The other participant, who would normally be generating the prime description, did not hear the prime, and instead completed an unrelated task (clicking a dot that appeared in an unpredictable location). This prevented the pre-recorded prime from becoming part of the participants' shared knowledge about the situation, or become introduced to the dialogue in any another way. All the response descriptions were participant-generated, regardless of prime status. In order to include enough trials in each condition to support the comparison between dialogue and non-dialogue, the no-adjective primes were eliminated. Thus, we manipulated *prime type* (prenominal or postnominal) and *prime status* (dialogue or non-dialogue) independently.

Results and Discussion

If syntactic priming in dialogue is truly stronger than outside of dialogue, then participants should be more likely to re-use the syntactic structure just used by an interlocutor than a structure just produced by a prerecorded voice. The results of our second experiment supported this prediction. When all the descriptions that included adjectives were considered together, we saw a small but significant priming effect for both prenominal and postnominal primes ($p < 0.05$), just as in experiment 1. However, when these response descriptions were examined separately by prime status, participant-generated primes had a greater impact on the subsequent descriptions than pre-recorded primes (see Figure 4).

A mixed effects regression model with participant pair and item as random effects was used to test for significance. Whether a response description was syntactically congruent or incongruent with the preceding prime was predicted from the prime status. When only trials containing adjectives were considered, incongruent responses were significantly more likely following pre-recorded primes than following dialogue primes ($B = 0.58$, $SE = 0.16$, $p < 0.001$). The

observation of priming effects in this paradigm depended on dialogue, since syntactic priming was not observed with the pre-recorded primes.

Figure 4: The proportion (standard error) of prime-congruent and prime-incongruent response descriptions following dialogue and non-dialogue primes, when only trials containing an adjective are considered.

Next, we wanted to address the hypothesis that syntactic priming effects in dialogue are instrumental in successful communication, as has been suggested by Pickering and Garrod (2006). One way to test this hypothesis is to examine priming over the course of the experiment. As the experiment unfolded, participants become better at the task, making fewer mistakes, and completing the trials more quickly. If syntactic priming promotes successful communication by increasing alignment at other levels, then we might expect that increased levels of priming should be correlated with this improvement at the task. However, this was not the case: syntactic priming did not significantly increase or decrease over the course of the experiment. Moreover, the degree of syntactic alignment, that is, the proportion of trials where participants re-used the primed structure, was not correlated with a pair completing the task more quickly (Spearman's $\rho = -0.197$, $n.s.$). This was true both for the subset of trials where the response description included an adjective and for all of the trials.

When examined as part of a larger system of language production in dialogue, syntactic priming appeared to play only a small part in determining referential forms. There was no evidence from this experiment to support the idea that syntactic priming contributed to task success. This suggests that syntactic priming and successful communication are not necessarily related.

General Discussion and Conclusions

In Experiment 1, we examined how referential context and syntactic priming interact to affect referential form. At the level of message formulation, where a speaker makes decisions about what information to include in an utterance, content was determined primarily by referential context.

One hypothesis was that syntactic priming would increase the likelihood that a speaker would include an adjectival property in the message, in order to re-use the structure that had just been primed. When the context strongly supported including an adjective in the message, priming with structures containing an adjective had a small additional effect on adjective use. However, when the context did not support adjective inclusion, priming had no affect on message content. This rules out the possibility that syntactic priming has a strong affect on message formulation independent of other factors. Our results are compatible with a model in which context constrains message content, and syntactic priming exerts a small additional affect. However, it is also possible that syntactic priming affected the message structure, but not the content; the rate of adjective use following no-adjective primes might have been lower due to adjective-like content being incorporated into the message in other ways.

In Experiment 2, we compared syntactic priming in dialogue and non-dialogue trials during an unscripted interaction between two naive participants. We found that syntactic priming depended on a prime that was generated by the conversation partner, as the Interactive Alignment Model suggests. This is in line with the trends that have been observed in previous experiments: syntactic priming effects are greater in dialogue than in response to a non-dialogue prime. We did not, however, find a relationship between syntactic alignment and task success. These results, taken together with the findings of previous work, raise questions about whether priming facilitates communication by aligning interlocutors' mental representations. In future research it will be important to address the relationship between priming and task success more directly. This could involve using more complex tasks, where there is a greater likelihood of differences in how well participants perform in a task-oriented dialogue.

These experiments shed light on how syntactic priming affects the selection of referential forms in dialogue, suggesting that while priming occurs, it is secondary to contextual factors that more strongly constrain what is said. This represents an initial step toward more carefully evaluating if and how syntactic priming impacts other levels of representation in dialogue. It also highlights the importance of using experimental designs where potential priming can be observed in interaction with other variables affecting message formulation. Experimental situations in which speakers have a larger range of options, (e.g. Gómez Gallo, Jaeger & Smyth, 2008), will allow priming to be examined in conjunction with such variables in single utterances and pairs of utterances. Situations like these are also ideal for future investigations because they closely approximating natural dialogue settings.

Acknowledgments

We thank Dana Subik for years of assistance with data collection, and current and former members of the Tanenhaus lab for helpful comments on this project. These

experiments were supported by the NIH grant HD-27026 to Michael Tanenhaus.

Abstract

Interlocutors sometimes repeat each other's representational hand gestures. We investigated if this is a case of direct mimicry of form, or whether perceiving a gesture gives rise to a semantic representation, which subsequently informs gesture production. For this we used an interactive route description task, in which a confederate's gestures indicated the route in either the vertical or the horizontal plane and either with one or four fingers extended as an index. We found that perceiving vertical gestures led to an increase not only in participants' production of vertical gestures, but also in their use of one finger as an index, suggesting that seeing vertical gestures caused participants to think of the route as on a map, which led them to point with one finger (as is common on a map) rather than four. Our results support the notion that repetition of meaningful gesture forms results from converging semantic representations.

Keywords: Gesture; Adaptation, Lexical Entrainment.

Introduction

It is well established that when people interact in dialogue, they tend to adapt to each other in many ways (for an overview, see Pickering & Garrod, 2004). For example, interlocutors reuse each other's (referring) expressions (e.g. Brennan & Clark, 1996) and syntactic constructions (e.g. Branigan, Pickering, & Cleland, 2000). In one study, Levelt and Kelter (1982) found that if shop keepers were asked in Dutch "(At) what time does your shop close?", their answer tended to match the question in surface form, either including or omitting 'at'. Similarly, repetitions of form across interlocutors have also been found for co-speech hand gestures (e.g. De Fornel, 1992). Such gestures are spontaneous movements of the hands and arms during speech, which can convey information, or emphasize certain parts of speech (e.g. McNeill, 1992). Elements of a gesture's physical form (*articulators*), like the shape and orientation of the hand, the direction and size of the movement, and where it is performed relative to the speaker can be repeated in subsequent gestures by the same or another speaker.

Some scholars believe that speech and gesture jointly express a speaker's ideas (McNeill, 1992), or that speech and gesture are both part of a speaker's communicative effort (Kendon, 2004). From this perspective, it seems likely that repetition of each other's gesture forms would resemble

repetition of each other's (other) linguistic forms. On the other hand, repetitions in physical behavior are found in many species, and need not be tied to speech (Parrill & Kimbara, 2006). In this paper, we focus on gestures that depict some of the content a speaker is conveying, which are known as *illustrators* (Ekman & Friesen, 1969) or *representational gestures* (McNeill, 1992). We compare the repetition across speakers of certain articulators of such gestures to the repetition of meaningful units in speech, specifically *lexical entrainment*, as well as to non-linguistic forms of behavioral mimicry. We first explain a difference between direct behavioral mimicry and lexical entrainment. We then describe some empirical results on the repetition of gesture forms across speakers. This will lead to our research question: Is the repetition of meaningful gesture forms across interlocutors a consequence of converging semantic representations, or is there a more direct link between perceiving a form and producing a form?

Mimicry and Adaptation

Mimicry is defined as one person repeating the behavior of another person (Bock, 1986). Some forms of mimicry enable the transfer of important functional behaviors (Tomasello, Savage-Rumbaugh, & Kruger, 1993). It has also been found that repeating others can have social benefits. Van Baaren et al. (2003) found that a waitress received higher tips when repeating her customers' orders literally, than when signaling in some other way that she understood the order. Yet for some repetitions of behavior, the functional or social purpose is less clear (Chartrand & Bargh, 1999). For example, if one person starts yawning, oftentimes those around will start yawning as well. Chartrand and Bargh explain this type of behavior in terms of the *perception-behavior link*, meaning "the mere perception of another's behavior automatically increases the likelihood of engaging in that behavior oneself", p. 893. Notably, they state that although such mimicry may act as a kind of 'social glue', intent or conscious effort are not required for it to occur. We will subsequently use the term 'mimicry' to refer to such automated repetitions of behavior.

Pickering and Garrod (2004) propose that similar automatic priming underlies the repetition of linguistic

behaviors across interlocutors, a form of adaptation which they call *alignment*. They state that at each linguistic level, “the activation of a representation in one interlocutor leads to the activation of the matching representation in the other interlocutor directly”, p. 177. These representations are thought to be used in both language production and processing (parity of representation). Thus, if a certain lexical or semantic representation has just been constructed as a result of hearing an utterance, it can subsequently be used for production. In addition to this direct source of alignment across interlocutors, alignment at one level can also enhance alignment at certain other levels within a speaker, because of bidirectional connections between the representations at different levels. Thus, if a lexical representation is connected to a semantic one, activation of that semantic representation may subsequently activate the lexical one.

Let us focus on one particular case of converging linguistic behavior: the repetition of referring expressions across speakers, known as *lexical entrainment* (Brennan & Clark, 1996). Brennan and Clark propose that interlocutors use the same words to refer to the same objects, because they use similar conceptualizations of that object. For example, suppose a particular object could be thought of as a document, a picture, or a map. When a speaker refers to it with ‘the map’, she conceptualizes the object for the current purpose as such. If the addressee agrees with this conceptualization and a *conceptual pact* is formed, both interlocutors can subsequently use ‘the map’ as a reference to both the object and the particular conceptualization of it. In this view, the repetition of references across interlocutors results from the establishment of conceptual pacts.

In both the model by Pickering and Garrod and the model by Brennan and Clark, lexical representations and semantic representations are linked. This is where lexical entrainment seems to differ from some instances of direct behavioral mimicry. In mimicry, we may repeat forms without being aware of their meaning. In other words, the perception of a form directly leads to the production of that form. In lexical entrainment on the other hand, there seems to be an intermediate stage: meaning. A form that is perceived is coupled with a certain meaning. Only when that meaning is activated again is the same form a likely candidate for repetition.

Repetition of Gesture Form

Is meaning also involved in the repetition of gesture forms across interlocutors? Kimbara (2008) observed interlocutors while they were discussing an animated cartoon. She found that their gestures looked more similar if they could see each other, compared to when they were separated by an opaque screen. Thus, it seems that adaptation occurs in gesture like it does in speech. Yet if these similarities in gesture form resulted from similarities in semantic representations, one could argue that they would also occur when interlocutors cannot see each other, since similarities in semantic representations can also be arrived at through

Figure 1: Part of a scene used in the experiment, note the route starting at the bottom-center.

speech. Therefore, it may be the case that the repetitions of gesture form resulted from the automatic across-speaker path of alignment (direct copying of form), rather than from connections between gesture forms and semantic representations, or the establishment of conceptual pacts.

In a previous study, we have investigated how relevant the semantic context was for certain gestures to be repeated across interlocutors (Mol, Krahmer, & Swerts, 2009). Gestures were either performed with speech matching the gesture’s form in meaning (e.g. a speaker moved his arms as though running, while talking about running), or with speech that expressed a very different meaning (e.g. the same gesture performed while describing looking through binoculars). We found that repetition did not occur when a gesture was shown in a non-matching semantic context. This suggests that repetition of form in gesture may result from the coupling of a certain form to a certain meaning, rather than from direct copying of form. However, since the mismatches were designed to be very clear in this study, the non-matching gestures may not have been processed very deeply to begin with, or participants may simply be less likely to adapt to a less coherent speaker. We thus need to investigate further whether repetition of gesture forms across interlocutors results from converging meanings.

Present Study

In this study we investigate whether a perceived gesture form can influence the construction of meaning (whether it be any semantic representation or a conceptual pact), which subsequently influences gesture production (also see Cassell, McNeill, & McCullough, 1998). Suppose that certain articulators of a perceived gesture give rise to the construction of meaning. Then when this meaning is subsequently expressed in gesture, all articulators of the gesture produced will likely be consistent with this meaning. Therefore, we would expect that articulators of the perceived gesture that are inconsistent with the meaning constructed would not be repeated as frequently. On the other hand, if repetition of gesture form happens without the

semantic level being involved, any combination of perceived articulators could be repeated in gesture production. In this case, whether an articulator matches the constructed meaning will not affect how frequently it is repeated.

To test this we use a task in which a confederate and a participant give each other route directions repeatedly. We present participants with bird's view drawings of a city scene, with a short route indicated on them (see Figure 1 for an example). These scenes are neither presented vertically nor horizontally, but at an angle. Therefore, the production task can be thought of as either describing a route on a vertically oriented map, *or* as describing a route through an actual (horizontal) city.

In each condition, the confederate expresses only one of these conceptualizations in her gesturing. While speech is kept constant, she gestures either as though moving along a route in a horizontal city, or as though indicating the route on a vertical map. This is done using two articulators: the plane in which the gesture is produced (either horizontal or vertical) and hand orientation (with fingers moving along with the route, or pointing forward as though on a map).

It is interesting in itself to see whether participants adapt to the confederate's perspective in their gesturing. Yet this alone would not tell us whether this is based on direct mimicry of form, or on the convergence of semantic representations. Therefore, we manipulate a third articulator (hand shape) independently. Gestures are produced either with one finger, or four fingers extended as an index. Now if it is the case that gesture form is perceived and reproduced directly, without mediation of meaning, both the confederate's perspective and her hand shape could be repeated independently by participants in their own gesturing. There may be a difference in how frequently each aspect is repeated, but what we would not expect based on this view, is for the confederate's perspective to influence participants' hand shapes or for the confederate's hand shape to influence participants' perspective.

On the other hand, if meaning does form an intermediate stage between the perception and production of gesture forms, we would expect such cross-effects to occur. For example, it is more common to point at a map using a single finger, than it is to point at a map using four fingers at once. Therefore, if the confederate's vertical perspective would lead participants to think of the communication task as describing a route on a map, then their gestures may be produced more frequently with only one finger as an index (even if the confederate uses more than one finger). This would mean there is an effect of the confederate's gestures' perspective on the hand shape of participants' gestures. This effect may also be found in the opposite direction: the confederate's use of more fingers as an index may lead participants to think of the route as through an actual city rather than on a map, causing them to gesture horizontally more frequently.

Figure 2: Partial view of the experimental set-up. Participants were seated on the right.

Method

Participants

48 Native Dutch speakers, all students of Tilburg University took part in this study. The data of eight participants could not be used for analysis (six participants did not produce any relevant gestures). The remaining 40 participants (33 female) had a mean age of 20.5, range 18 – 25.

Procedure

The participant and the confederate came to the lab and were introduced by the experimenter. They each received a written instruction and were seated across from each other. The instruction explained the communication task, and stated that the couple with most correct responses could win a book voucher (in reality there was a random draw). To their side (right to the participant) was a table, on which there was a flip chart for each of them. In between these flip charts was a screen, such as to keep information private. The screen did not keep the interlocutors from seeing each other, see Figure 2. Both behind the confederate and the participant was a camera capturing the other interlocutor.

After reading the instruction, both 'participants' were allowed to ask questions. The confederate always asked one question, after which the experimenter quickly went over the task again. Then the experimenter turned on the cameras and left the room.

The confederate started by studying a little map and memorizing the route on it. Each route had one turn, see Figure 1 for an example. She then turned the page of her flip chart and described the route to the participant, for example: "Je begint bij de rondvaartboot, dan ga je langs het voetbalstadion en dan rechts een winkelstraat in tot ongeveer halverwege." ("You start at the tour boat, then you go along the soccer stadium and then into a shopping street on the right until about halfway.") The confederate's speech always followed the same script. Gestures were timed naturally with speech and gazed at by the confederate.

Figure 3: The confederate's path gestures. a: Hand/ Route; b: Finger/ Route; c: Hand/ Map; d: Finger/ Map.

After the confederate's description, the participant turned a page and was to choose which route had just been described, selecting from four alternatives by pronouncing the corresponding letter. No feedback was provided. Then it was the participant's turn to study a route. This route was always on the same scene that the confederate's route had been on. After turning the page (rendering a blank page) the participant described the route to the confederate, who then turned a page and selected one of the four alternatives. This ended one cycle of the experiment. In total each participant perceived and produced five route descriptions.

Afterward, both the confederate and the participant filled out a questionnaire, which included questions on the presumed purpose of the experiment and whether the participant noticed anything peculiar, as well as some questions on how they liked their interaction partner. It ended with the question whether the participant was left or right handed. When the participant was done filling out the forms, the confederate revealed herself and asked the participant's consent for the use of the data. Participants were also asked if they had suspected any deception. Two participants were excluded from our analysis, because they indicated having been suspicious about either the goal of the experiment or the role of the confederate.

Design, Coding and Analysis

We used a 2 x 2 between subjects design. The independent variables were the hand shape (one or four fingers extended) and perspective (route or map) of the confederate's path gestures. In the route perspective, gestures were performed with the index in the direction of the hand movement and movement was in the horizontal plane, as though following a virtual route (Figure 3a, 3b). In the map perspective, gestures were performed in the vertical plane and the index was always pointing forward, as though pointing on a virtual map (Figure 3c, 3d).

The confederate gestured with her right hand. The first direction of a route was always straight, which was depicted with either a forward or an upward movement. These movements were of comparable size. The gesture for the second direction (to the side) was placed relative to the first gesture; it started where the first gesture had ended.

Figure 4: Examples of participants' path gestures (published with permission of the people depicted).

a: Hand/ Vertical Map; b: Finger/ Vertical Map; c: Hand/ Route; d: Finger/ Horizontal Map.

We coded all *path gestures* participants produced, that is, all gestures in which one or more fingers were extended as an index, there was hand movement along some virtual path, and the co-occurring speech mentioned a direction to take. Within the stroke phase of each path gesture, we coded hand shape and perspective. The labels for hand shape were *Finger*, when one finger was extended as an index, and *Hand*, if more than one finger was extended. The label for perspective was based on three articulators: location in the gesture space, hand orientation, and movement (direction and size). It turned out that in addition to the two perspectives the confederate had used, participants occasionally used an alternative one, as though pointing on a horizontal map. Therefore, we chose from three labels: *Route*, *Vertical Map*, and *Horizontal Map*. A gesture in the route perspective would typically have horizontal movement in front of and to the side of the speaker, with the fingers pointing in the direction of the hand movement (Figure 4c). Vertical Map gestures on the other hand would typically have vertical movement, with relative sizes mapping onto distances on the map, fingers pointing forward and the location in the gestures space corresponding to the location on the map (Figure 4a, 4b). Horizontal Map gestures (Figure 4d) differ from Route gestures in their hand orientation (fingers pointing down), and their relative size and location. The label that could explain most of the articulators was assigned to each gesture. Figure 4 shows some examples of participants' path gestures and our coding.

Each of the confederate's verbal descriptions contained two target landmarks, which also appeared along the participant's route. For each of these landmarks it was

determined whether the participant referred to it, and if so whether it was a *literal repetition*, an elaboration or shortening of the confederate's reference (both counted as *partial match*) or a complete *mismatch*. For example, if the confederate said "hoog gebouw" (tall building), "gebouw" (building) and "hoog grijs gebouw" (tall grey building) would be labeled as *partial match* whereas "flat" (apartment building) would be a *mismatch*.

The data of 6 participants were excluded because these participants did not produce any path gestures. This left 40 participants, 10 in each cell. Analysis was done using ANOVA, with factors perspective (levels: Route & Map) and hand shape (levels: Finger & Hand) of the confederate's gestures. The significance threshold was .05 and we used partial eta squared as a measure of effect size.

Results

Neither the confederate's hand shape nor her perspective significantly influenced the total number of path gestures participants produced ($M = 5.5$, $SD = 3.9$) and there was no interaction between these factors. We did not find a significant effect of gender, or left or right handedness on the amount or type of path gestures produced. Analysis of the answers to the questionnaire showed no significant effect of condition on how the participants perceived the confederate.

Verbal Alignment

Neither the confederate's perspective ($p = .63$), nor her hand shape ($p = .81$) had a significant effect on the number of target nouns repeated by participants ($M = 6.2$, $SD = 1.3$), or on the number of partial matches or mismatches.

Effects of the Confederates' Perspective

The confederate's perspective influenced participants' perspective. When the confederate gestured as though on a map, the mean proportion of participants' path gestures in the vertical map perspective was higher ($M = .46$, $SD = .35$) than when she gestured as though following a route ($M = .11$, $SD = .20$), $F(1, 36) = 14.88$, $p < .001$, $\eta^2 = .29$. Similarly, when the confederate gestured as though following a route, participants produced a higher proportion of gestures with the route perspective ($M = .77$, $SD = .32$) than when she gestured as though on a map ($M = .52$, $SD = .39$), $F(1, 36) = 12.35$, $p < .001$, $\eta^2 = .14$, see Table 1.

The confederate's gestures' perspective also influenced the hand shape used by participants, $F(1, 36) = 5.00$, $p < .05$, $\eta^2 = .12$. The proportion of gestures with more than one finger extended was higher when the confederate used the route perspective ($M = .78$, $SD = .37$) than when she used the map perspective ($M = .52$, $SD = .39$), whereas the proportion of gestures with one finger extended was higher when she used the map perspective ($M = .48$, $SD = .39$), compared to when she used the route perspective ($M = .22$, $SD = .37$), see Table 2.

Table 1: Means and standard deviations of the proportion of path gestures participants produced from each perspective.

Confederate's Perspective	Prop. Route	Prop. Vertical Map	Prop. Hor. Map
Route	0.77 (.32)	0.11 (.20)	0.12 (.26)
Map	0.43 (.31)	0.46 (.35)	0.11 (.25)

Table 2: Means and standard deviations of the proportion of path gestures participants produced with each hand shape.

Confederate's Perspective	Prop. Hand	Prop. Finger
Route	.78 (.37)	.22 (.37)
Map	.52 (.39)	.48 (.39)

Effects of the Confederates' Hand Shape

We did not find that the confederate's hand shape influenced participants' hand shape $F(1, 36) = .04$, $p = .85$, nor that her hand shape influenced the proportion of gestures in the map, $F(1, 36) = .38$, $p = .54$, or route perspective, $F(1, 36) = .030$, $p = .86$.

Discussion

We found some of the cross-effects we expected if perceiving gestures would lead to the construction of meaning, which in turn would influence gesture production. The perspective of the confederate's gestures influenced the hand shape of participants' gestures: participants more frequently pointed with one finger if the confederate gestured as though on a vertical map. This can be explained by the confederate's vertical gestures leading participants to think of the route as on a map, which caused them to point with their finger more frequently.

Gestures, like speech, seem to allow for the convergence of representations of meaning across interlocutors. This leads to the question of whether the same representations underlie adaptation in both gesture and speech, and whether these representations can also be influenced by both gesture and speech.

Adaptation in Gesture through Speech

The results of an additional study indeed point in this direction. In this study, the confederate gestured with one finger extended and in the map perspective. Thus, all articulators in gesture suggested a vertically oriented map. Yet we added a condition ($N = 10$) to the previous study, in which speech also matched this perspective. Rather than using horizontal terms like "rechtdoor" (straight), the confederate now used vertical terms like "naar boven" (up) instead. Note that the first direction was always straight/ up.

When comparing this condition to the Finger/ Map condition with horizontal speech, we found that the perspective of the confederate's speech had an additional effect on the perspective of participants' gestures. With

vertical terms, participants produced a lower rate of gestures with the route perspective ($M = .17$, $SD = .25$) than with horizontal terms ($M = .54$, $SD = .36$), $F(1, 18) = 7.21$, $p < .02$, $\eta^2 = .29$. This supports the notion that semantic representations were converging across interlocutors, rather than surface forms. In addition, it suggests that these representations may be shared between speech and gesture.

Future Work

A limitation of our studies is that the confederate always acted according to a script, and thus was not exactly like a spontaneous partner in forming a conceptual pact. Whereas this usually can be thought of as an interactive process between both interlocutors, the confederate always stuck to her own initial proposal. It would be interesting to see how spontaneous interaction is similar to or differs from this partly staged interaction.

Overall, perspective was repeated more than hand shape. This may be because perspective was expressed in two articulators, whereas hand shape is only one. Thus, the one articulator not matching the constructed meaning may have been adapted to the two matching ones. Another explanation would be that in this task, perspective carried a more important meaning than did hand shape. A vertical gesture cannot possibly depict a route one can walk (at least not in the Netherlands), whereas the distinctions between the different hand shapes are probably far subtler. Therefore, the perspective of gestures may have influenced the construction of meaning more readily than their hand shape. Apparently, in this task, hand shape was not a likely candidate for the type of direct alignment at one level between interlocutors that Pickering and Garrod (2004) proposed. However, in other settings it may very well be. It would be interesting to investigate whether adaptation in hand shape depends on to what extent hand shape carries meaning, and similarly for other articulators. Additionally, other types of gestures (especially non representational gestures) need to be looked at, since they may carry meaning in a way different from the path gestures we studied, and may or may not be linked to semantic representations.

Conclusion

In the adaptation of one interlocutor to another, some hand gestures seem to behave truly like linguistic forms. Whether they are repeated across interlocutors depends on whether their form corresponds to the semantic context (Mol et al., 2009), and the repetition of forms is mediated by mental representations of meaning, rather than being based on a direct perception-action link.

Abstract

This study examines the temporal and directional characteristics of child-adult vocal exchanges in day-long naturalistic recordings of autism and typical control groups. In both populations, adults responded frequently (on average about 40% of responses) within 1s or less, a time thought to be conducive for contingency learning by the child. However, the time to adult response tended to be longer for the autism population. In the autism group, children also tended to follow more and lead less relative to the control group, as measured by differences in diagonal recurrence profiles computed based on cross recurrence plots. The results inform on the dynamics of naturalistic communicative interaction in normal development and therefore on the social context in which language develops. They also illustrate how large datasets and modern interaction analyses can expand our understanding of differences in children with autism, a population with both social and language deficits.

Keywords: Social interaction; autism; temporal dynamics; cross recurrence; language development; naturalistic recording; response time; social contingency

Introduction

In this paper, we examine fundamental issues related to the fine-grained temporal organization of vocal interaction between children and their social environment, primarily, caregivers. Recent years have seen an abundance of interest in joint action and coordinative processes in both children and adults (Galantucci & Sebanz, 2009). In the current study, we make use of latency response measures as well as the technique of cross recurrence analysis to identify leading and following patterns in the vocal exchanges between children and adults. We find a distinct signature of leading in normal children and find that a distinct breakdown of this signature is identifiable in children with autism. These results show that analysis of naturalistic recordings may reveal socio-dynamic indicators of at-risk children. We conclude with a brief discussion of the relevance of our findings to models of language acquisition in normal and disordered individuals.

Interaction and Contingency in Language Development

The fact that language learning occurs in a dynamic and interactive social context is becoming increasingly appreciated. Children are not passive information processors nor do they learn language purely on the basis of contingent reinforcement. They are, rather, actively engaged in perceptual learning and responding to communicative acts produced by others as well as being engaged in behavioral and motor exploration for which they at least sometimes receive feedback in the form of communicative response by adults and other children in their environment.

For example, in a video-recording study performed in the participants' homes, Keller et al. (1999) found that mothers often respond within one second to their three-month-old infants' communicative acts. Relating this to the fact that one second had been previously shown to be about the amount of time within which a contingent response must occur in order for the infant to detect that contingency, the authors concluded that mothers' communicative responses to their infants' communicative attempts tend to occur within the necessary window of time for the infant to perceive them as contingent. In other words, their results support the notion that caregivers' responses to their children support infant communicative development by serving as contingent reinforcers for the infant's own communicative acts.

In a more recent study, Gros-Louis et al. (2006) observed naturalistic interactions in a laboratory setting and found that mothers responded contingently to their infant's vocalizations over 70% of the time and that the type of response they gave depended on the phonological characteristics of the infant's vocalizations. Furthermore, Goldstein, King, and West (2003) and Goldstein and Schwade (2008) have found experimentally that mothers' contingent responses do appear to shape the infant's speech-

related vocal development as measured through follow-up tests.

Recently, cross recurrence analysis of time series has allowed for additional quantitative measures of interactive contingency to be measured in naturalistic child-caregiver interaction. For example, patterns of leading and following by interlocuters can be examined at multiple timescales concurrently. Dale and Spivey (2006) examined diagonal cross recurrence profiles calculated on syntactic patterns (specifically, part of speech bigrams) for three well-known child-caregiver conversation corpora. They found individual differences among the three children in their tendency to lead versus follow their caregiver. Abe (Kuczaj, 1976), who had the most advanced language out of the three children also had the greatest tendency to lead rather than follow the caregiver. This work lays foundations for application of cross recurrence analysis to other vocal interaction phenomena, to larger naturalistic datasets, and, as carried out here, to the study of populations with autism.

Autism Spectrum Disorders (ASD)

Impaired social interaction and language learning are two components of the DSM autism diagnostic criteria. With regard to social interaction, children with ASD have exhibited differences in initiation, turn-taking, imitation, and joint attention behaviors.

In recent years, technology has become available to permit day-long naturalistic recording of infant's acoustic environments, including their own vocalizations and the speech and other environmental sounds in the infant's vicinity. Warren et al. (2009) evaluated social interaction in all-day recordings (5,256 hours over 438 sessions) in ASD and control groups. The authors discovered differences between typically developing and autistic children in the frequencies of both conversational turns and child vocalizations. These results, based on summary measures, encourage analysis at a more fine-grained level of temporal detail in order to address such issues as the directionality of the conversational exchanges and temporal characteristics of adult-child interactions. Both latency to response and diagonal cross recurrence profiles can be automatically calculated, making them suitable for application to large-scale naturalistic recordings.

This Study

In the present study, we first looked at response latencies in a way that was similar to Keller et al. (1999). However, we evaluated much more data and used more naturalistic recordings (collected at home, daycare, and therapy as opposed to only at home in a single post-sleep, post-feeding context with experimenters present and videotaping). Other differences are that we looked at the vocal modality only, and that we evaluated age, autism, gender, and maternal education as predictive factors. We also applied cross recurrence analysis to the data and investigate leading and following tendencies in the recordings. The application of this method with large-scale recordings of adult-child

speech is unique as is its application to the autism population.

Method

Participants

The participant recruitment, recordings and the automated labeling of them were conducted as part of previous studies. Warren et al. (2009) provide more detailed information on the procedures. The present study includes data from 26 children between 16-48 months who have been diagnosed under the classic autism subtype except for two who received Pervasive Developmental Disorder-Not Otherwise Specified subtype diagnoses; documentation of ASD diagnoses by trained professionals was provided by the children's parents. No child was reported to have a diagnosis that included echolalia (pathological repetition of previously heard speech). The study also includes data from 78 typically developing (TD) children who were selected from a larger normative database such that for each child with ASD there were three TD controls of the same gender and socioeconomic status (SES), as measured by the mother's education level, and collectively across the three controls spanning the same range of ages as the ASD child.

Recording

Recordings were made using LENA digital language processor devices. These recorders fit into a pocket sewn into the front of custom-designed clothing and record a single channel of audio for up to 16 hours at a time. The device records the child's voice as well as other sounds within approximately a 6-10' radius of the child. Parents were mailed the devices and were instructed to begin recording when the child awoke in the morning and left the recorder on throughout the day. Recordings contexts included the home, preschool, and speech-language therapy. There were 438 recordings in total, each lasting at least 12 hours. The present study is thus based on over 5,256 hours of naturalistic recording.

Automated Labeling

Each recording was processed using the professional version of the LENA analysis software. The software analyzes and time segments the entire recording according to the likely source of the signal, e.g., the child wearing the recorder, another child, an adult, a television or radio, silence; every part of the recording is given a label. Within child segments it also labels some sub-segments (termed *vocalizations* by the system) as speech-like or as cry/vegetative/fixed. Reliability for the automated labeling compared to human raters on TD child recordings is approximately 82% correct for adult speaker, 76% correct for key child, 75% correct for child speech-like, and 84% for child cry/vegetative/fixed (Xu et al., 2009). The software allows for exporting these sound source and child vocalization type segmentations along with other information in XML format.

We developed a set of Perl scripts to extract the specific information of interest for this study from the XML files (exported as *.its* files by the LENA software). Specifically, we extracted the start and end times of each segment labeled with relatively high confidence as coming from the child wearing the recorder (*child near*, *CHN*, segments, labeled as such because they fell near the maximum of the Gaussian mixture model that gave the likelihood that a segment was produced by the child) and of each segment labeled as coming from an adult with relatively high confidence (*female adult near*, *FAN*, or *male adult near*, *MAN*). Note that loudness and nearness to the child increase the confidence of segment coding and therefore increase the likelihood of a sound being included in the present study. Also, there were minimum duration thresholds for each segment label type; thus, a long string of vocalization by the same speaker could only be split if there was an intervening silence, TV, or other-speaker vocalization meeting the minimum duration requirement. We also identified child segments that contained only speech-like sub-segments as well as those that contained only cry/vegetative sub-segments. All the subsequent response time and cross recurrence calculations were made using only those child segments that contained no cry/vegetative sub-segments and at least one speech-like sub-segment.

Response Time Analysis

We developed a set of programs written in Perl and R that automatically extracted and calculated response time information from the speaker labels. First, adult response times were calculated according to the following procedure. For each child segment, we determined whether an adult segment followed without any child segment intervening. Other sound source labels were permitted to intervene between the child segment and the subsequent adult segment. Then the time between the offset of the child segment and the onset of the adult segment was calculated. Child response times were calculated in exactly the same manner, except with the speaker labels reversed. Based on these response times, the median adult response time and the median child response time were calculated as well as the proportion of adult responses occurring within 1s and the proportion of child responses occurring within 1s.

Cross Recurrence Analysis

Cross Recurrence Plots Cross recurrence plots (Marwan et al., 2007; Richardson et al., 2007) are matrices that indicate correspondence or lack of correspondence for every possible combination of events or times in one event time series and the events or times in another series. In our case, the vertical dimension of the matrix corresponds to the presence and absence of child segments and the horizontal dimension of the matrix corresponds to the presence and absence of adult segments (Fig. 1). Each element in the plot matrix is assigned a value of 1 (marked in black in the figure) if there is a child segment at the row corresponding to the element's

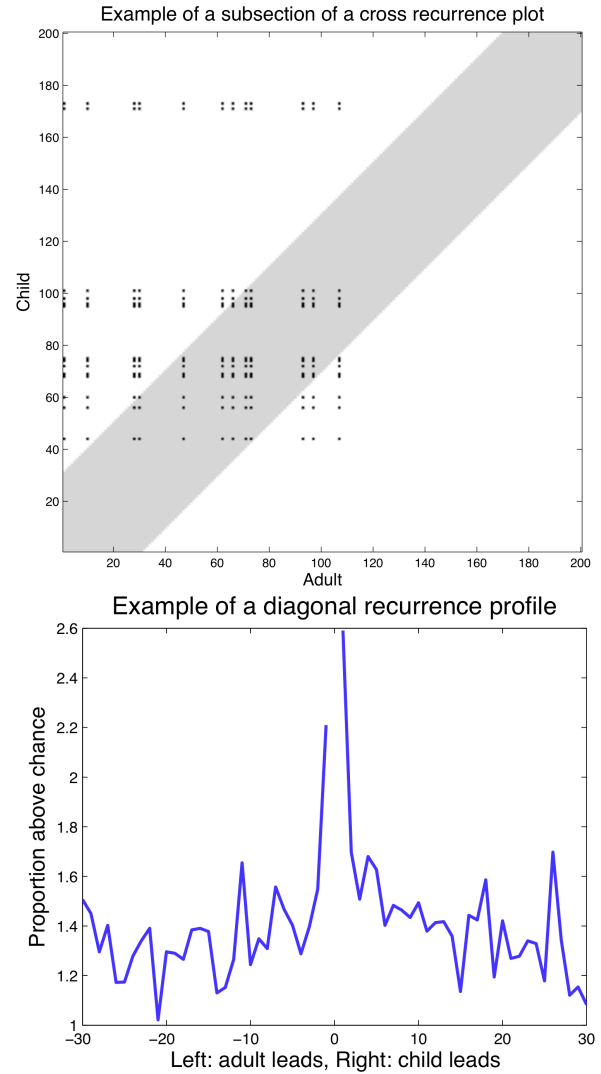

Figure 1: On the top is the cross recurrence plot for the first 200s of one of the recordings. The gray region indicates the portion from which the diagonal recurrence profile is calculated. On the bottom is the diagonal recurrence profile for the entire recording.

row number as well as an adult segment at the segment corresponding to the element's column number.

The time series that were used for making these charts were broken into 1s chunks. When either the child or an adult was speaking, a 1s chunk was coded as 1 in the speaker's series and as null value in the non-speaker's series. Regardless of the actual length of the segment, it was coded as lasting 1s so that long speaker segments would not be treated as having long lags to segments by the other speaker. When neither child nor adult were speaking, both time series were coded as null values for the duration of the no-speaker time, rounded down to the nearest second. The recurrence plot is square since both the vertical and the horizontal dimensions have length equal to the total number of 1s chunks in the recording.

Diagonal Cross Recurrence Profiles A number of measures, such as recurrence rate, determinism, etc. can be extracted directly from the cross recurrence plot (Marwan et al., 2007). However, in this study we focused on measures that were extracted from the plot's diagonal recurrence profile (explained below) after it had been derived from the recurrence plot. In the physical sciences, this is sometimes referred to as the recurrence probability or the recurrence spectrum (Marwan et al., 2007). Richardson and Dale (2005) and Richardson et al. (2007) have used this measure in analyses of linguistic coordination. It can be interpreted as a lag profile that reflects co-occurrence patterns between utterances at varying relative lags. We provide some further description here.

The diagonal on the recurrence plot running from the origin to the final event on both axes reflects when the child and caregiver are speaking at the same time. Sometimes this main line is referred to as the "line of synchronization," since any points on this line reflect matching on/off states for the child and the adult(s). However, since the automatic labeling procedure does not allow overlapping speaker labels, there will never be a match along this diagonal.

The next diagonal line just below-right of the primary diagonal contains the matches between the child's on/off states and those of the adult series one step into the future. In other words, the elements of this adjacent below-right diagonal are given a point on the plot when a given child segment was immediately followed by an adult segment (i.e., the adult spoke one time step later during the interaction). Conversely, the elements of the adjacent above-left diagonal line have a point when a given adult segment was immediately followed by a child segment. Moving to diagonals further below-right or above-left give indication of when the adult followed the child at larger lags and when the child followed the adult at larger lags, respectively.

For each diagonal line parallel to the primary diagonal, the number of 1's can be added and divided by the total number of elements in that diagonal to give the proportion cross recurrence for the speaker order and lag amount corresponding to that diagonal. These proportions can then be plotted to create a diagonal recurrence profile (Fig. 1). By randomly shuffling the speaker labels and recalculating the diagonal recurrence profile, and by repeatedly doing this and averaging across the shuffled label profiles, one can obtain a bootstrapped estimate of the baseline diagonal recurrence profile that would be expected if there were no systematic leading-following relationship between the speakers. Dividing the actual diagonal recurrence profile by the baseline estimate gives a normalized diagonal recurrence profile that represents proportion above chance leading/following tendencies.

In this study, we measured three characteristics of the normalized diagonal recurrence profile for a given recording. The first was the height of the profile at the point immediately right from center. This gives an indication of how often the adult vocalized immediately after a child vocalization. The second was the height at the point

immediately left of center; it tells how often the child's vocalizations immediately followed the adult's. The third measure is the ratio of the sum of values on the right side of the profile (which is higher when the adult tended to follow the child) to the sum of values on the left side of the profile (higher when the child tended to follow the adult). This gives a measure of the general balance between leading and following across the two speakers.

Results

Response Time Results

The adult response times and child response times for the ASD and control groups are plotted as averaged histograms in Figure 2.

For each of the four response time independent measures (adult median response time, adult proportion within 1s, child median response time, and child proportion within 1 s) we ran a mixed model regression with participant ID as a random effect and ASD status, age in weeks, gender, and mother's education level (a measure of the family's socioeconomic status) as fixed effects.

Adult median response time was significantly longer for children with ASD ($M = 2.32s$, $SD = 1.22$) than for the controls ($M = 1.65s$, $SD = 0.78$), $p < 0.001$, $\beta = 0.331$, and was significantly shorter as maternal education increased, $p < 0.001$, $\beta = -0.234$. Adult proportion of responses within 1s was significantly smaller for children with ASD ($M = 0.37$, $SD = 0.10$) than for the controls ($M = 0.43$, $SD = 0.08$), $p < 0.001$, $\beta = -0.348$, and was significantly larger as maternal education increased ($p < 0.001$, $\beta = 0.284$).

Child median response time was longer for children with ASD ($M = 2.70s$, $SD = 1.38$) than for the controls ($M = 2.37s$, $SD = 0.92$) though this did not reach statistical significance, $p = 0.063$, $\beta = 0.161$, and was significantly shorter as maternal education increased, $p = 0.016$, $\beta = -0.153$. Child proportion of responses within 1s was significantly larger as maternal education increased, $p = 0.010$, $\beta = 0.174$.

Age and gender did not significantly predict any of the four independent variables.

Cross Recurrence Results

The averaged diagonal recurrence profiles for the ASD and control groups are plotted in Figure 3. As with the response time measures, each of the three dependent variables (height immediately right of center, height immediately left of center, and ratio of right side to left side) was regressed on participant ID as a random effect and ASD status, age in weeks, gender, and mother's education level as fixed effects.

The height at the point immediately right of center was only significantly predicted by age, decreasing as age increased, $p < 0.001$, $\beta = -0.228$.

The height at the point immediately left of center, which represents the frequency with which the child immediately

Figure 2: Histograms of adult response latencies for children with and without ASD.

followed the adult, was significantly higher for the ASD group ($M = 1.73$, $SD = 0.91$) than for the control group ($M = 1.53$, $SD = 1.09$), $p < 0.001$, $\beta = 0.207$. The height at this point was also significantly lower as maternal education increased, $p = 0.017$, $\beta = -0.183$, and was lower as age increased, $p = 0.002$, $\beta = -0.214$.

The ratio of the right side (from lag 1 through lag 10) to the left side (from lag 1 through lag 10) of the diagonal cross recurrence profile was smaller for the ASD group ($M = 1.06$, $SD = 0.18$) than for the TD group ($M = 1.25$, $SD = 0.30$), $p < 0.001$, $\beta = -0.398$, indicating that the general tendency for the child to lead and for the adult to follow was lessened in the autism group. A small but significant increase was accounted for by age, $p = 0.01$, $\beta = 0.136$.

Figure 3: Diagonal recurrence profiles averaged across all recordings in the TD group (top) and all recordings in the ASD group (bottom). In each profile, the red line indicates the mean values across recordings. Blue lines indicate 95% confidence intervals. Displacement from diagonal is in seconds.

Discussion

This study provides new information from automated analysis over large naturalistic recordings in support of the idea that social interaction is impaired in ASD. Interestingly, the strongest trend concerned the adult's responses to the child rather than the child's responses to the adult. There were differences in both the dynamics and the directionality of adult-child interaction in ASD. The length of time before an adult responded to an ASD child's speech or speech-like vocalization was larger in ASD than for TD children with a smaller percentage of responses occurring within the 1s window considered ideal for contingency detection. In addition, ASD children's speech and speech-like vocalizations were more of a tendency to follow the adult vocalizations than TD children's.

The shift of the balance toward child following (and adults leading) and increased latency of adult responses to the child when they did occur could be due to less initiation of communication on the part of the ASD children and/or to

reduced communicative content or other deficiencies in the vocalizations of children with ASD. It could also be due to adults' reduced attentiveness to the vocalizations of children with the disorder. This pattern of following vs. being followed may have feedback effects on the child's language development, reducing the quality of the contingency-based input available to the child with ASD as they acquire speech, language, and other communication skills. At present, there are very few computational models that attempt to capture the interplay among cognitive agents in a realistic way (one exception may be language evolutionary models; see Cangelosi & Parisi, 2002, for examples). The dynamic interplay between cognitive agents during development, such as speech-contingency patterns, may produce feedback loops that substantially impact learning within an individual system.

The present work is relevant to theoretical, including computational, modeling of speech-language development. Language learning occurs in the context of social interactions during which the child hears what other speakers say but also receives contingent reinforcement for their own vocalizations. Understanding the typical dynamics of these interactions may help guide the development of models that take into account the dynamic interactive social context of language learning. They may also help inform models of autism. Some of the deficits present in autism may be the result of a negative feedback loop in which children with autism produce fewer or lower-quality conversation initiations, leading to adults' responding with lower frequency and more latency, which in turn leads to poorer learning of language and communication-related skills by the child.

From a practical standpoint, measures of conversational dynamics, both at short and long timescales could potentially be applied for early identification of autism or other communicative disorders. Being a disorder that involves profound social and cognitive impairments, differences in patterns of communicative interaction, such as in leading-following and elicitation of quick responses, might indicate risk for autism. For example, automatically computed interaction-based measures (such as the ones used in the present study) could supplement the acoustic measures used in an existing autism screening tool (Xu et al., 2009)

Abstract

Why do people accommodate to each other's linguistic behavior? Studies of natural interactions (Giles, Taylor & Bourhis, 1973) suggest that speakers accommodate to achieve interactional goals, influencing what their interlocutor thinks or feels about them. But is this the only reason speakers accommodate? In real-world conversations, interactional motivations are ubiquitous, making it difficult to assess the extent to which they drive accommodation. Do speakers still accommodate even when interactional goals cannot be achieved, for instance, when their interlocutor cannot interpret their accommodation behavior? To find out, we asked participants to enter an immersive virtual reality (VR) environment and to converse with a virtual interlocutor. Participants accommodated to the speech rate of their virtual interlocutor even though he could not interpret their linguistic behavior, and thus accommodation could not possibly help them to achieve interactional goals. Results show that accommodation does not require explicit interactional goals, and suggest other social motivations for accommodation.

Keywords: Conversation; interaction; accommodation; alignment; virtual reality.

Introduction

Why do people accommodate to each other's linguistic behavior? Studies of multi-party interactions both in the laboratory and in natural conversation have suggested that two or more speakers in a conversation tend to align their linguistic behavior along several dimensions: lexical choice (Barr & Keysar, 2002; Bortfeld & Brennan, 1997; Niederhoffer & Pennebaker, 2002), phonetics (Alim, 2004; Pardo, 2006), and syntactic constructions (Gries, 2005), among others. The fact that accommodation occurs is well accepted, but the motivations for this convergence between speakers have been a matter of debate.

Studies of natural conversational interactions have identified social/interactional factors that influence how much speakers accommodate (Giles, Taylor & Bourhis, 1973). Based on these studies, it appears that a speaker accommodates towards or away from their interlocutor to achieve interactional goals: to make one's interlocutor do, think, or feel things. This can involve conveying social information, such as information about their social stances toward their interlocutor or toward a group that their interlocutor belongs to (Coupland, 1985). Accommodation could also help to coordinate joint actions being negotiated through conversation (Brennan & Clark, 1996).

But are immediate social motivations necessary to make speakers accommodate? Or might speakers accommodate even in the absence of a desire to achieve direct interactional goals? Mechanistic theories of dialogue (Pickering & Garrod, 2004) offer one possible alternative. Automatic alignment processes could account for convergence in linguistic behavior. That is, speakers might use similar linguistic forms to those used by their interlocutors because these forms are highly active and thus have an advantage over alternatives in the selection process.

On another alternative, accommodation could be a consequence of a speaker's attempt to achieve longer-term social goals: accommodation could be part of how speakers develop the linguistic styles that they use to communicate social information about themselves to others and to indicate their membership in social groups. This could occur in tandem with or independent of interaction-specific social goals.

Distinguishing these alternatives is difficult because in real-world conversations, interactional motivations are ubiquitous; in any conversation between two real people, the interlocutors may have social goals and relationships that could be influencing their linguistic behavior. Experimenters have attempted to deal with this complexity in a few ways. Experiments using pre-recorded speech in repetition paradigms have uncovered alignment between a speaker and a recording (Babel, 2009). However, because these experiments do not involve conversation, it's difficult to know whether the same mechanisms underlie speakers' production in these tasks and their accommodation in conversations.

In other experimental paradigms, the conversational setting is retained by using a confederate (Hannah & Murachver, 1999). However, no human confederate can entirely prevent his or her speech from being influenced by the naïve participant's speech. Introducing a confederate means losing experimental control over precisely those social and linguistic variables that might matter the most. This makes it difficult to assess the extent to which accommodation on the part of the participant depends upon their own interactional motivations, and to what extent it is a response to their interlocutor's behavior.

Virtual Reality (VR) provides an opportunity to engage participants in a conversational interaction with an interlocutor whose speech is not influenced by their speech, and can be varied systematically along a single dimension.

Moreover, a virtual interlocutor cannot feel or think at all, so participants cannot hope to influence the thoughts or feelings of the virtual interlocutor by accommodating to him. What happens in a conversational situation where interactional goals cannot be achieved? Do speakers still accommodate when their interlocutor cannot interpret their accommodation behavior? And if so, are they motivated by other, longer-term social goals, or is it a fully automatic process that is independent of social factors?

To find out whether speakers accommodate in a conversation with someone who cannot interpret their accommodation, we asked participants to enter an immersive VR environment and to converse with a virtual interlocutor, VIRTUO. While accommodation could theoretically occur along many dimensions at once, this experiment focused on the single dimension of speech rate, because this was easily manipulated in the virtual interlocutor. We varied VIRTUO's speech rate between participants to see whether participants would adjust their own speech rate to better match the rate at which their virtual conversational partner was speaking.

If immediate interactional goals motivate accommodation, then speakers in a conversation with VIRTUO should not accommodate to his speech rate, because they cannot hope to influence his thoughts, feelings or behavior by accommodating to him. If speakers *do* accommodate to VIRTUO by adjusting their speech rate towards his, there are two possible explanations: either accommodation occurs entirely automatically, or it can be motivated by social goals with a locus outside the current interaction (i.e., long-term social goals). To distinguish between these possibilities, we administered a post-experiment questionnaire investigating how participants judged VIRTUO on relevant social dimensions. If participants' judgments of VIRTUO correlate with their degree of accommodation to him, then this suggests that social goals beyond the level of the individual conversation influence accommodation.

Methods

Participants

Members of the Radboud University community (N=62, 30 male) participated in exchange for payment. Participants were all native speakers of Dutch between the ages of 17 and 28.

Materials

VIRTUO's speech was pre-recorded by a male native Dutch speaker reading in a conversational tone from a script of statements and questions designed to simulate a conversation about products in a grocery store. The speed of the original recordings was manipulated without changing the pitch of the recordings using the "change speed" function in the audio manipulation software package Audacity, which removes or replicates short intervals of the acoustic signal in order to extend or shorten the overall length of a sound clip. Participants in the FAST condition

heard these recordings sped up by 12%, and those in the SLOW condition heard them slowed down by 12%. Both sets of recordings remained within the range of possible speaking rates of a Dutch speaker, but the two rates were noticeably different.

The virtual environment (VE) was a supermarket, which was custom-designed for this experiment using Adobe 3ds Max 4. The virtual supermarket consisted of a single long aisle with shelves on both sides, stocked with products, providing a variety of items for VIRTUO to inquire about.

The experiment was programmed and run using WorldViz's Vizard software. Participants wore an NVIS nVisor SX60 head-mounted display (HMD), which presented the VE at 1280x1024 resolution with a 60 degree monocular field of view. Mounted on the HMD was a set of 8 reflective markers linked to a passive infrared DTrack 2 motion tracking system from ART Tracking, the data from which was used to update the participant's viewpoint as he moved his head. Sounds in the VE, including the voice of the avatar, were rendered with a 24-channel WorldViz Ambisonic Auralizer System. The sound system was supplemented by 4 floor shakers mounted on a raised platform. These produced vibrations that contributed to an illusion of motion as participants were driven through the supermarket by VIRTUO in a specially modified virtual golf cart.

VIRTUO was represented by a stock avatar produced by WorldViz. The avatar's appearance suggested that he was a Caucasian male in his mid-twenties (the average age guessed by participants in debriefing was 26 years old), which matched the age of the Dutch speaker who recorded his speech.

Figure 1. VIRTUO in the virtual supermarket, from the perspective of a participant. The arrow indicates the next item that VIRTUO and the participants should discuss (here, ketchup). The steering wheel of the virtual golf cart is visible in the bottom left corner.

Procedure

Prior to entering the VE, participants were told that they would be having a conversation with VIRTUO, a virtual

agent who wanted to learn more about the human world. They entered the VE by putting on the HMD, which showed them a virtual supermarket. When participants moved their heads, the display changed, so they could explore the virtual world by looking around. Participants remained seated on a chair throughout the experiment. They traveled through the virtual supermarket in a virtual golf cart with VIRTUO in the drivers' seat, so there was no need for participants to walk in order to move down the aisle of the grocery store.

Participants were randomly assigned to the Fast or Slow speech condition automatically by the experiment program, so that the experimenter was not aware of which condition participants would be in until the experiment had begun. This minimized the possibility of experimenter expectancy effects influencing participants' speech rate before they spoke with VIRTUO. Once the experiment began, all instructions were written; therefore participants did not have any verbal interaction with the experimenter, which could have influenced their speech rate.

The experiment consisted of a Baseline block of trials followed by a Conversation block. During the Baseline trials, participants were alone in the VE, and had an opportunity to get accustomed to their surroundings. We collected a sample of speech during this time to use as a Baseline speech rate. To elicit speech, we gave participants written instructions (via the HMD) to look at 4 of the products on the shelves in front of them, one at a time, and describe each product briefly.

After the four Baseline trials, participants met VIRTUO, who introduced himself in a few sentences. VIRTUO then took participants on a tour of the grocery store, stopping at six products (bananas, ketchup, light bulbs, toothpaste, cat food, and beer) to ask them three or four questions about each one. Participants responded with information about the identity of the products, what they were made of, how they are used in the human world, etc. Participants' speech was recorded through a microphone suspended from the HMD.

VIRTUO's speech behavior created a conversational setting, but he did not have the ability to understand or flexibly respond to participants' utterances. The experimenter listened to participants' responses from a control booth, and pressed a button to advance VIRTUO to the next utterance in his script. VIRTUO's speech began after a random delay between 150 and 400 ms, so that the experimenter's button-pressing (i.e., turn-taking behavior) could not directly influence the speech rate of the participant. If the next item in VIRTUO's script did not constitute a sensible response to something a participant said, the experimenter pressed a button that caused VIRTUO to say that he did not understand, and that they should move on.

Speech rate (in words per second) was calculated by transcribing participants' speech and marking the boundaries of their utterances as intervals in the audio and video transcription and coding software ELAN, then dividing the number of words transcribed by the number of seconds in the interval. Each participant's speech rate during

the Conversation block was compared to their own Baseline rate.

Results and Discussion

Participants were assigned randomly to the two speed conditions, resulting in 33 participants in the Fast condition and 29 participants in the Slow condition. Mean speech rates during Baseline and Conversation periods are shown for participants assigned to the Fast and Slow conditions in Figure 2. Results indicate that VIRTUO's speech rate influenced how fast the participants spoke during their Conversation with him. Participants in the Fast condition spoke significantly faster during their Conversation with VIRTUO than during their Baseline measurement ($t(1,32)=4.02$, $p=.0003$), and significantly faster than participants in the SLOW condition ($t(1,60)=2.24$, $p=.03$), whose Conversational speech rate did not differ from their Baseline rate ($t<1$). This resulted in the predicted interaction between Condition (Fast, Slow) and Measurement (Baseline, Conversation; $F(1,60)=4.36$, $p=.04$; Figure 2).

Figure 2. Experimental results. Speech rate differed between the Fast and Slow conditions during the Conversation period but not during the Baseline period.

The fact that the Baseline speech rate did not differ between conditions confirms that speaking with the experimenter prior to the experiment did not differently influence the speech of the Fast and Slow groups; rather, the differences that appeared in the Conversation period were a result of speaking to VIRTUO.

Participants in the SLOW condition did not speed up significantly, but there was a trend toward speaking faster in the Conversation condition than in the Baseline condition among these participants. This occurred despite the fact that their virtual interlocutor spoke slower than even their Baseline rate on average throughout their Conversation (VIRTUO spoke at 3.31 words per second on average in the Slow condition, and 4.20 words per second in the Fast condition). The slight increase in speed from Baseline to Conversation even among participants in the Slow condition suggests that while participants were influenced by VIRTUO's speech rate, they also may have been influenced

by other factors, such as increasing “immersion” in the virtual world (Heeter, 1992). This may have counteracted the effects of VIRTUO’s speech rate on participants in the Slow condition. Importantly, the critical interaction between Condition and Measurement indicates that VIRTUO’s speech rate affected participants’ speech rate above and beyond any unexpected task-related effects.

To find out how early in the Conversation period accommodation could be detected, we first conducted an analysis comparing participants’ speech rate in the Baseline period to their speech rate during their responses to VIRTUO’s questions about the first item they discussed in their Conversation.

Results of this analysis suggest that speech rate can be adjusted quite quickly; a comparison of the Baseline speech rate with participants’ speech in just the first item yields a significant interaction between Measurement and Condition ($F(1,58)=4.82$, $p=.03$), indicating that speakers in the Fast condition had already sped up more than speakers in the Slow condition over the course of the first 4 question-answer pairs. These results suggest that accommodation occurred rapidly and did not develop slowly over the course of the experiment.

This might seem surprising given the widespread assumption that accommodation is a process that occurs gradually over time. However, there are many respects in which speakers adjust to their interlocutors in the beginning of a conversation quite immediately; for example, when a Spanish-English bilingual speaker is approached by a stranger who begins to speak English to them, they are very likely to speak English in response immediately. There is no period of gradual adjustment in choice of language. Similarly, if someone begins a conversation with a friend in a sorrowful tone of voice, the friend is unlikely to respond back in a chipper tone; they will adjust to the emotional tone of the conversation immediately, without requiring a period of gradual change.

Participants’ speech rate in response to VIRTUO’s questions did not relate to the position in the experiment where the question appeared. This is consistent with rapid change immediately after meeting VIRTUO; perhaps speech rate accommodation does not occur gradually over time, but instead happens early in a conversation and is maintained fairly consistently throughout the interaction. However, the fact that accommodation did not increase over time in this experiment must be interpreted with caution, because the order of VIRTUO’s questions was fixed rather than counterbalanced across subjects. Differences in content between the questions might have influenced participants’ speech rate, which could have obscured any possible effects of the passing of time.

According to the questionnaire participants filled out after they finished the VR portion of the experiment, speakers accommodated more to VIRTUO when they judged themselves to be more similar to him ($r=.25$, $p=.05$). This correlation suggests that in addition to whatever automatic mechanisms might cause accommodation, people

accommodate more to an interlocutor they identify with for longer-term social reasons (a point we will return to below).

General Discussion

The results of this experiment indicate that participants accommodated to the speech rate of their virtual interlocutor. Participants who spoke to a fast-talking VIRTUO sped up significantly from their Baseline speech rate, and spoke significantly faster than their counterparts in the Slow condition. This was true even though VIRTUO could not interpret participants’ linguistic behavior, and thus accommodation could not possibly help them to influence VIRTUO’s thoughts or behavior. Why, then, did participants accommodate to VIRTUO?

On one possibility, participants accommodated to VIRTUO through fully automatic mechanisms, without any social component. This would be consistent with studies showing alignment between a speaker and non-conversational speech (Babel, 2009; Goldinger, 1998), and might suggest that social motivations are unnecessary to cause accommodation in conversation.

However, results of the post-test support the idea that long-term social goals may be a factor that drives accommodation. Speakers may have social goals that extended beyond their current interaction. For example, some participants may have been motivated to accommodate to VIRTUO by a general tendency to speak similarly to other speakers, especially those that they can identify with to some extent.

Accommodation to certain interlocutors may be one of the mechanisms by which speakers develop a coherent linguistic style over a longer time scale, perhaps even playing a critical role in sound change (Niedzielski & Giles, 1996; Auer & Hinskens, 2005). Selective accommodation, to people with the right social characteristics, may help speakers speak in a way that reflects the way their in-group members speak.

The tendency to speak more like someone who one identifies with is fundamental to the organization of linguistic variation. Linguistic behavior at many levels, including phonetics, word choice, and choice of syntactic constructions, is subject to variation – there are many possible ways for a speaker to communicate approximately the same thing. Although this variation can seem random, these choices can often be predicted by a speaker’s membership in various social groups. These groups can correspond to macrosociological categories (e.g. gender, age, ethnicity), or they can be locally defined (e.g. communities of practice) (Eckert & McConnell-Ginet, 1992). But how do these relationships between social group membership and linguistic behavior get established?

Individuals’ linguistic behavior must be influenced by the behavior of others whom they consider to be in-group members in order for social groups to become correlated with linguistic behavior. The mechanisms underlying this process of sociolinguistic differentiation and identification are not entirely well-understood; however, they must

operate on the level of actual language use, i.e. individual conversations.

There is another way that social motivations could have influenced accommodation even in a virtual interaction. Perhaps people accommodated to VIRTUO because participants were somehow confused into thinking that he can interpret their social behaviors. VIRTUO does, after all, resemble a human interlocutor in many ways; perhaps speakers do not realize his limitations? It seems unlikely that participants were truly confused about this, given the restrictions in how VIRTUO could respond to them in this experiment. However, the principle that humans might interact with VIRTUO as though he were a real human even though he is not could still explain their accommodation behavior.

Some social behaviors seem to be so automatic that they do not disappear in human-computer interaction even when they are totally illogical in these scenarios. For example, humans have been shown to exhibit politeness and reciprocity to computers (Nass & Moon, 2004), in what Nass and colleagues have called “overlearned social behaviors.” If accommodation is such an overlearned social behavior, then people might accommodate to VIRTUO not because they think that they will influence his beliefs about them or behavior toward them, but because this behavior is applied automatically regardless of its applicability in a specific situation.

If this is in fact the reason why speakers accommodate to VIRTUO, then it suggests a reinterpretation of the accommodation we see in natural conversation as well. That is, interactional motivations may underlie linguistic accommodation, but in an automatic, overlearned way. If so, then speakers may not have specific intentions about the interaction they are engaged in, and they may have very little control over their accommodation behavior. This is consistent with the idea that accommodation can be motivated by general social goals, even in the absence of short-term social motivations.

Conclusions

In real-world conversations, accommodation may often be motivated by efforts to achieve interactional goals: people accommodate to make others do, think and feel things. But the present data show that this is not the only reason that people accommodate. Since people accommodate to a virtual interlocutor, we can conclude that accommodation is not necessarily driven by immediate attempts to influence social relationships or convey social messages. Yet, social motivations at a broader level may motivate accommodation, which may be a tool by which people develop linguistic styles, over the long term. The finding that the degree to which people accommodate correlates with how much they identify with their interlocutor suggests that accommodation is not merely a reflex. However, these results do not rule out some role for alignment processes that are engaged automatically. In real conversations, social

and interactional factors may combine with automatic factors to produce linguistic accommodation.

Acknowledgments

Abstract

Learning about ecosystems is challenging because, like any complex system, they are simultaneously multidimensional and dynamic. Often, learners engage only with the visible components of an ecosystem and draw either single or linear causal connections between components. In this study, we explored how using a Structure-Behavior-Function framework supported middle school students' conceptual and complex reasoning about the visible and invisible components of an ecosystem. Research shows that learners often engage only with the visible components of an ecosystem and draw linear/single causal connections between the components of the ecosystem. Our findings suggest that a combination of using structure, behavior, and function approach along with a set of carefully designed technology tools can push the students toward a better understanding of the ecosystem functioning. The results show that along with the visible components of the ecosystem, students have started to identify the invisible components of the ecosystem.

Keywords: Ecosystems learning, SBF, complex systems, Science education

Introduction

Given the urgent need to empower the future generation with knowledge to help them make informed decisions about their ecosystems and environment, both national and local science standards have a growing focus on ecosystems learning (e.g., National Research Council, 1996; New Jersey Department of Education, 2006). Developing ecosystems understanding is challenging, because it requires learners to understand how different aspects of an ecosystem are interconnected, and the processes that occur within such systems (Anderson, 2008; Covitt & Gunckel, 2008; Jordan et al., 2009).

Ecosystem processes are challenging for learners, because these are complex systems that transcend spatial, temporal and cognitive boundaries (Pickett, et al 1997). Similar to other complex systems, ecosystems are also characterized by multidimensional processes that connect visible and invisible components of the system to one another (Hmelo-Silver & Azevedo, 2006). These visible and invisible components within the ecosystem are interdependent. The components have their own behavior patterns and any

change in the patterns, affects not only other components, but also overall functioning of the system (Jordan, et al 2009). The dynamic and multifaceted nature of an ecosystem makes it difficult for learners to grasp the associations and interactions among system components (Gallegos et al 1994).

Learners find it challenging to think beyond the linear relationships and visible components of an ecosystem (e.g., food chains: Reiner & Eilam, 2001; aquaria: Hmelo-Silver, Marathe, & Liu, 2007; systems: Hogan, 2000, food webs/nutrient cycles: Hogan & Fisherkeller, 1996, energy flow: Leach et al. 1996; water cycle: Covitt & Gunkel, 2008). When asked to draw or name components of an ecosystem, learners often focus on the visible components of the ecosystem (Gellert, 1962; Hmelo, Holton, & Kolodner, 2000). Expert-novice studies suggest that it is hard for young learners to conceptualize the invisible components within an ecosystem such as: oxygen, nitrogen, and bacteria, (Hmelo-Silver, Marathe, & Liu, 2007). It is also challenging for students to think beyond single causality and linear connections between ecosystem components (Grotzer & Basca 2003).

In this paper, we present the results of a technology-intensive classroom intervention designed to teach middle schools students about aquatic ecosystems. The goals of our intervention are to help learners develop deep understanding of ecosystems and to use tools that make the invisible visible and the interconnections explicit.

Aquariums as Models for Learning

To help students understand complex systems, we implemented a two-week aquarium unit that was designed by a team of learning scientists, middle school classroom teachers, and ecologists. The technology consisted of a suite of tools: a function-oriented hypermedia (Liu & Hmelo-Silver, 2009), simulations of macro- and micro-level processes (Liu & Hmelo-Silver, 2008; Gray et al. 2008), and the Aquarium Construction Kit (ACT; Goel, Rugaber, & Vattam, 2009). The unit was grounded in the structure behavior and function approach.

Our approach to instruction is grounded in the structure-

behavior-function theory (Goel et al., 2009). The structure behavior function (SBF) approach is useful to explain dynamic systems with multiple components and levels (Goel et al., 2009; Liu & Hmelo-Silver, 2009). We view SBF theory as providing a conceptual representation with canonical explanations in biological systems, as well as, being consistent with expert understanding (Bechtel & Abrahamson, 2005; Hmelo-Silver et al., 2007). In addition to helping students organize their system knowledge the SBF representation also provides a scaffold for overall knowledge organization. The approach helps the learner to breakdown and distinguish individual parts of the complex system.

In a biological system, structure refers to components of an ecosystem that have form. Structures can be macro (e.g. Fish, plants) or micro (e.g. bacteria, fungi) in nature. Behavior represents the process of how structures achieve their functions, and, finally, functions are roles the structures play in an ecosystem.

Technology Support for Learning about Complex System

It is difficult for learners to understand many aspects of ecosystems because they have not had opportunities to engage with those processes that are dynamic and outside their perceptual understanding. In addition to helping students organize their system knowledge, the SBF representation also provides a scaffold for overall knowledge organization because it helps learners consider the relationships among form and function as well as the causal behaviors. We make SBF explicit through the use of hypermedia, organized in terms of SBF, and through the Aquarium Construction Toolkit (ACT) (Figure 1a and 1b).

Figure 1a. ACT: A space to create models

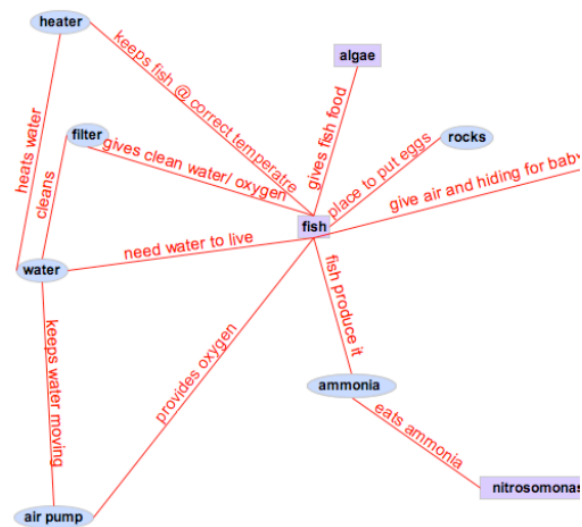

Figure 1b. ACT: Example of model created by a student.

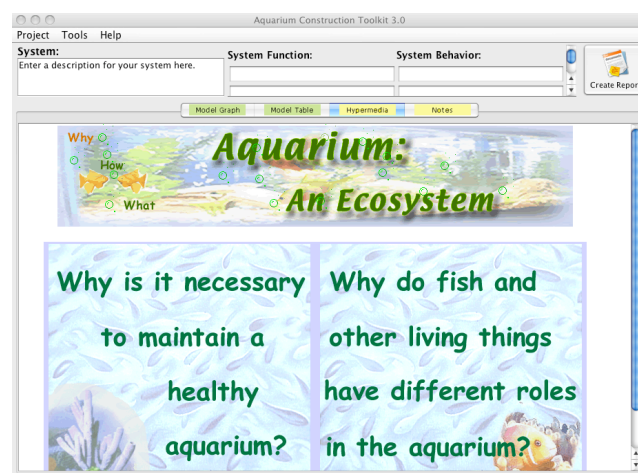

Figure 2. SBF is used to organize the hypermedia

Along with the hypermedia and ACT tools students also used NetLogo simulations to learn about behaviors and functions within an ecosystem (Wilensky & Reisman, 2006). Using these simulations, (Figure 3) students learned about how to keep an ecosystem 'healthy.' For example, the macro fishspawn simulation allowed students to manipulate different aspects of the ecosystem such as initial population, spawning, filtrations, and amount of food. Thus if the students overfed the fish then the increasing ammonia (due to fish waste) within the water would affect water quality and the fish would die. This helps problematize water quality, which is a black box in the macro simulation. This creates the need for students to identify some of the invisible components within an ecosystem, and students also start to see the importance of these invisible components. For example, the students can observe how crucial nitrification cycle is for the overall health of an ecosystem. They also can learn that many components of the ecosystem involved in the nitrification process are invisible. These

behaviors and functions can then be observed in the micro level simulation.

Figure 3: NetLogo simulation

Classroom Instruction

The science teacher introduced the unit by asking students to articulate their thoughts about ecosystems functions. This allowed the teacher to gauge the students' prior knowledge. The teacher then moved on to the ACT modeling tool and asked the students to represent their thoughts about ecosystems as structures behaviors and functions. The students recorded their ideas in a table within the ACT tool (Figure 4).

Figure 4: ACT table where students record ideas as structure, behavior, and function

The teacher also encouraged the students to use the hypermedia to sharpen their existing ideas about the ecosystems. The teacher then proceeded to the modeling activity using NetLogo simulations. In the NetLogo simulations students manipulated various ecosystem components (number of fish, amount of food, etc) in order to maintain a healthy ecosystem. The students worked in groups and were given the freedom to continuously refine

their models. Finally at the end of the two-week period the students presented their models in front of the entire classroom.

Methods

Participants

Fifty-four seventh grade students from a suburban public middle school in the northeast United States participated in this study during their regular science instruction time. Two of the participants reported having an aquarium at home and most had been to a public aquarium. Many had also been on excursions to the beach or on fishing trips with adults in their families.

Data Sources

The students were given pre and post-tests before and after the intervention. In the pre and post-test students were asked to draw components of an aquatic ecosystem, and show relationships between them. They were also asked to label all of the components and relationships between those components.

Coding for pre and post tests

There were three parts to the coding. The first part of the coding scheme involved counting the number of visible and invisible ecosystem components that were drawn by the students. The second part of the coding scheme involved counting the number of relationships that the students observed between the components in their drawing. Care was taken to make sure that the relationships were scientifically plausible. We coded the connections on a three-point scale. We gave a connection one point if students made implausible connections between components of the ecosystem. A connection was assigned two points if students made plausible connections within the same level of an ecosystem (e.g. visible component to visible component; invisible to invisible). One example of this is a connection that shows fish eat plants. Here both fish and plants are visible components of the ecosystem. A connection was assigned three points if students were able to make plausible connections between the visible and invisible components of the ecosystem. An example of this would be a connection showing that fish breathe oxygen (Figure 5). Here fish is the visible component of the ecosystem and oxygen is the invisible component of the ecosystem.

The third part of the coding scheme was designed to find out the type of connections the students made between the different components of the ecosystem. As components within an ecosystem function nonlinearly, it was important to find out whether student understanding of ecosystem functioning went beyond linear-single cause relationships. The coding scheme for the third part (types of connections) was adapted from Grotzer & Basca (2003).

This part of the coding scheme was also coded on a three-point scale. A connection was assigned a point if students made a 'simple linear' connection between the components of the ecosystem. A simple linear connection was observed as a connection that was linear, one directional and

indicating single cause and effect. For example, fish eat plants is a linear connection because it indicates that only fish benefit from the plants. A connection was given two points if the students made a 'complex linear' connection between the components of the ecosystem.

A complex linear connection was defined as a linear connection that had more than one cause and effect. For example, plants get energy from the sun, fish eat plants and thus fish get energy from the plants is a complex linear relationship because it shows one directional relationship between more than two components of the ecosystem. This code was also used when students represented symbiotic relationships/mutually beneficial relationships.

Finally a connection was given three points if the connection was observed to connect more than two components in a mutually benefiting relationship. The connection was called 'cyclic' (Figure 5). For example, fish waste produces ammonia, a form of nitrogen that is then transformed by different bacteria into new forms of nitrogen that support plant growth, which in turn benefit the fish.

Figure 5: Connecting the visible (fish) to invisible (ammonia). Also, an example of a cyclic connection.

Reliability was calculated by having three independent raters code the entire sample. The overall reliability was 98% agreement.

Results

We expected the students to start identifying invisible components within an ecosystem. Since the intervention provided them with an opportunity to learn about the system in depth the results show that the students have identified more invisible components (Table 1). However, the students did not show any significant change in identifying the visible components (Table 1).

Table 1: Components coding (N=54).

	Visible	Invisible
Pretest Mean (SD)	8.50 (3.34)	0.28 (0.49)
Posttest Mean (SD)	7.61 (3.21)	2.87 (2.17)
Sample Size	54	54
T (53)	1.90	8.86*
Effect Size	0.13	0.64

* $p < 0.05$

We also expected the students to make more plausible connections between the components because the instruction was designed to scaffold students' understanding of how ecosystem components are connected to each other. The results, shown in Table 2, demonstrate that students made significant progress in making plausible connections within levels (visible to visible and invisible to invisible) and between levels (visible to invisible).

Table 2: Plausible connections made between ecosystems components (N=54)

	Plausible connections made within level	Plausible connections made between levels:
Pretest Mean (SD)	3.81 (2.15)	0.17 (0.61)
Posttest Mean (SD)	4.87 (2.91)	1.43 (1.53)
Sample Size	54	54
T (53)	2.55*	7.09*
Effect Size	0.21	0.47

* $p < 0.05$

Finally we investigated whether the types of plausible connections students were making were demonstrating the complexity of ecosystem functions. It was not clear whether students were able to move beyond making linear connections or complex linear connections. We found that the number of students making simple linear connections increased from pre to post. However, there was no significant change in the number of students making complex linear connections. Finally there was a significant change in the number of students making cyclic connections. Although, the results clearly showed that only a small number of students made a leap to making more complex connections between the ecosystem components (Table 3).

Table 3: Types of connections made by students

	Linear Relationships	Linear Complex relationships	Cyclic
Pretest Mean (SD)	1.85 (1.87)	0.52 (0.91)	0.02 (0.14)
Posttest Mean (SD)	2.80 (2.33)	0.74 (0.96)	0.15 (0.36)
T (53)	2.76*	1.73	2.81*
Effect Size	0.21	0.11	0.09

* $p < 0.05$

Discussion and Conclusion

Our results show that students find it challenging to conceptualize the role of invisible components within an ecosystem. Consistent with other research, students initially focus on the interactions between the visible components of the ecosystem (e.g., Hmelo-Silver et al., 2007). For example, most students represented the fish eating fish (prey predator) relationship as the primary relationship within an ecosystem. However the study also shows that students are on a trajectory of conceptual change and began to consider invisible components of the ecosystem and how they connect to what is visible.

Our findings suggest that a combination of using structure, behavior, and function approach along with a set of carefully designed technology tools can push the students toward a better understanding of the ecosystem. Another study (Goel et al. 2010) that looks at how the ACT tool helps students construct SBF models of complex ecosystem processes is a part of the proceedings.

The results show that along with the visible components of the ecosystem, students have started to identify the invisible components of the ecosystem. They are still not completely making a sophisticated model that includes the visible and invisible components connected to each other, but this is the first step. Moving students to a more robust and rich understanding of complex systems requires more than a two week intervention. In our ongoing research, we are exploring how SBF thinking can provide a tool for students to understand complex biological systems that are pervasive in the world in which they live and are key components of helping students become scientifically and environmentally literate citizens.

Abstract

Patterns of incorrect answering or “misconception-like” responses to scientific concept questions have been well documented. Here we investigate both response choices and response times to gain insight into the nature of misconception-like responses. In a series of experiments involving questions on graphs in which participants must compare the slopes of two points, we find that students answering with misconception-like responses, namely comparing heights rather than the slopes, do so consistently and more rapidly than those answering correctly. We also find in a speeded experiment, that all students are able to compare slopes and heights, but comparing heights requires less time than comparing slopes. Finally, by imposing a delay in responding that is long enough for the responder to process both slopes and heights, we find a reduction in misconception-like responses. Thus the misconception-like responses can be explained in terms of speed-accuracy trade-off models in which responders place high priority on answering quickly.

Keywords: Scientific misconceptions, graphs, response time, speed-accuracy tradeoff, physics education.

Introduction

It is well documented in science education that students often respond to scientific concept questions in regular and persistent patterns of errors (Pfundt & Duit, 2000). For example, when presented with qualitative questions about the time of flight of a projectile with various trajectories, many students will incorrectly answer that both range and height of the trajectory influence the time of flight, when in fact only the height determines the time of flight. For convenience, we will refer to such patterns of incorrect answers as *misconception-like* responses, as we do not know whether they stem from coherent and explicit “misconceptions” of the students or some other mechanism.

While past studies of student difficulties with answering science concept questions have examined the patterns of response choices, in this study we investigated the response *times* as well as the response choices in order to address two main questions. First, are there interesting patterns of response times when comparing correct and misconception-like responses? Second, does response time data shed any

light on the processes involved in choosing correct or misconception-like answers?

A number of investigators have examined response times on standardized tests. These studies use both response time and response accuracy in order, for example, to eliminate the effect of guessing and thus improve the accuracy of the tests (e.g., Schnipke & Scrams, 1997; van der Linden, 2008), or to detect cheating (van der Linden & van Krimpen-Stoop, 2003). In this study we investigate questions that evoke misconception-like responses. As we will see in Experiment 1, these incorrect responses are not guesses but rather a coherent pattern of answering.

In addition to studies on standardized tests, a long history of response time studies in a wide range of tasks has revealed the well-known phenomenon of the speed-accuracy tradeoff, namely that there often exists a monotonically increasing relation between response time and response accuracy (Wickelgren, 1977). There are two classes of models used to explain the speed-accuracy tradeoff curve. The first is the *fast-guess* model which proposes that students use a mixture of guesses, which are fast, and non-guesses, which are slow. As mentioned earlier, since there is very little guessing in the responses in this study, we will not consider this class of models.

The second class of models postulates that response choices are a result of *decision criteria* applied to evidence that accumulates over time. As time increases, the amount of information increases, thus increasing accuracy, which explains the speed-accuracy tradeoff curve (e.g., Ratcliff, 1978; Smith & Vickers, 1988).

Let us consider the decision-criteria model with respect to response times on scientific concept questions that often evoke misconception-like responses. If correct answers and misconception-like answers require different solution paths, then it is possible that the response times of the two paths will be different. For example, if the time needed for the process involved in obtaining the misconception-like answer is inherently shorter than the process for obtaining the correct answer, then one would expect the misconception-like response times to be shorter.

In addition to expecting different response times for correct and misconception-like responses, in this model the

actual response time also depends on decision criteria. For example, there may be a minimum amount of information needed before a decision can be made. On the other hand, there may also be a maximum amount of time allotted for the decision. Therefore, misconception-like responses may be a result of implicit decision criteria rather than the responder's absolute ability to determine the correct answer.

This study proceeds as follows. In the first experiment, we established that our example science concept question evokes misconception-like responses, and we characterized the difference in the response times of the correct and misconception-like responses. In Experiment 2, we measured and characterized the response times needed to process the main underlying tasks required for obtaining the correct and misconception-like responses. In Experiment 3, we impose a minimum time to respond in order to determine whether this will affect the response choices.

Experiment 1

The first experiment investigates a well-known student difficulty with interpreting graphs commonly used in math and physics courses at the high school and introductory university level. Specifically, when a variable of interest corresponds to the slope of a line at a given point, students instead often attend to the value (i.e. the height) of the point on the line rather than the slope. For example, When students are presented with a position versus time graphs for an object (see Figure 1) and asked “at which point does the object have a higher speed?”, many incorrectly answer according to the higher point rather than the greater slope (McDermott, Rosenquist, & van Zee, 1987).

Experiment 1 was designed to achieve three goals. The first goal was to replicate the misconception-like response pattern indicating a tendency to attend to values (heights) of points on a line rather than slopes at those points. The second was to determine whether this pattern was due to students' fundamental inability to compare the slopes of points on a line, or if it was instead a function of familiarity with the question context. Finally the third goal was to compare the response times of students answering correctly vs. those answering incorrectly to determine if there was a pattern in response times corresponding to answer choice.

Experiment 1 used a between-subjects design employing three conditions: math graphs, kinematic graphs, and electric potential graphs (see Figure 1). Each condition presented a series of graphs and participants were asked to compare two points on a curved (or straight) line on the graph. Figure 1 presents examples of the graphs in the three conditions, including the question posed for each graph.

In addition to the fact that the series of graphs in the three conditions were identical (except for the labels on the axes), the questions posed for each graph are also conceptually analogous. In particular, the math graph condition asked for a comparison of the slopes at two points (magnitude of slope = $|dx/dt|$), and the other two conditions also effectively asked for a comparison of slopes since *speed* is the slope for the position-time (kinematic) graph (speed = $|dx/dt|$), and

the magnitude of *electric field* is the slope of the electric potential (V)-position (x) graph (magnitude of electric field = $|dV/dx|$).

The three graph conditions were also at differing levels of familiarity for the participants. The math graphs were the most familiar, as they are introduced in standard curricula before and throughout high school. The kinematic graphs were the next most familiar. They are typically introduced in high school physics or physical science courses, and used frequently in the university level physics course that was a prerequisite to the physics course in which the participants were enrolled at the time of the study. Finally, the electric potential graphs were the least familiar, as they are not part of standard pre-university curriculum and most participants saw them for the first time in physics course in which they were enrolled at the time of the study.

Figure 1. Examples of the graphs and questions used in the three conditions in Experiment 1. The answer choices for all three were: “A”, “B”, or “the same at A and B”.

Method

Participants Participants were enrolled in one of two undergraduate calculus-based introductory physics courses. The first course covered the topic of classical mechanics and the topic of the second course covered electromagnetism. The courses are part of a three-course introductory physics series, and are typically populated with engineering majors. Participants received partial course credit for participation, and the participation rate for both courses was > 95% of all students enrolled in course.

Participants were randomly chosen to be placed in each condition. For the math graphs condition, 28 participants were chosen from the mechanics course and 49 were chosen from the electromagnetism course, for a total of 77 participants. For the kinematics graphs condition, 94 participants were chosen from the mechanics class. For the electric potential graphs condition, 38 students were chosen from the electromagnetism course.

Procedure, materials and design All testing was presented to individual participants on a computer screen in a quiet room. They proceeded through testing at their own pace, and their response choices and response times were electronically recorded.

In each condition students were presented with a series of graphs and asked to compare relevant values at two points on each graph. Participants were given no feedback as to the correctness of their answers. See Figure 1 for examples of graphs and specific questions asked.

Testing consisted of a comparison of two points on 14 graphs (presently serially) with various curve shapes: 8 graphs in which the higher point had a lower slope (these are the difficult “target” questions), 2 graphs in which the higher point had a higher slope, 2 graphs in which both points had the same slope, and 2 graphs in which the two points had the same height but different slopes. The graphs types were placed in a fixed random order, and this sequence was presented to all participants in all conditions. Thus the graphs were mixed such that the correct response was not always “A”, and not always the lower or higher point. Our previous pilots studies did not reveal any significant effects of order of graph type on answering. Furthermore, Experiment 3 uses a design to counterbalance for order, with similar results to Experiment 1. Therefore we are confident that the results here are not an artifact of question order.

Results

Analysis of response choices We first report on the performance on the “target” questions, namely those graphs in which the higher point has a lower slope (see Figure 1 for examples). These type of questions are important for investigating graph difficulties, since the correct answer choice (the point with the greater slope, but with a lower height on the graph) is opposite of the common “misconception” that, for example, “the higher point has greater speed”.

Figure 2 presents the average scores for the target questions for each condition. The averages depended strongly on the graph type, with scores of 94% for the Math graphs, 72% for the Kinematic graphs and 47% for the Electric Potential graphs (One-way ANOVA with Bonferroni adjusted post-hoc comparisons, $p_s < 0.0001$). Thus the less familiar the graph context, the lower the score.

Figure 2. Experiment 1, mean scores for the Math graphs, the Kinematic graphs, and the Electric potential graphs conditions. Scores are shown for target questions in which one of the points has a higher slope but lower value, for “aligned” questions in which one of the points has a higher slope and higher value. Error bars are 1 S.E.M.

Figure 3. Distribution of scores on target questions for the Electric Potential graph questions. Rather than a random binomial distribution, this distribution is bimodal, indicating that most participants are not guessing.

The patterns of specific answer choices also revealed that answering was not random, and those choosing incorrect answers consistently choose the main misconception-like answer. There are two kinds of evidence to support this. First, Figure 3 presents the score distributions for students

answering the electric potential graph questions. If the answering were random, one would expect a binomial distribution of scores. Instead Figure 3 shows a strong bimodal distribution, with most students either answering all questions correctly or answering all questions incorrectly. Note that over 95% of the incorrect answers were the main misconception-like distracter, namely the point with the higher value; few incorrect answerers chose that the points had the same electric field.

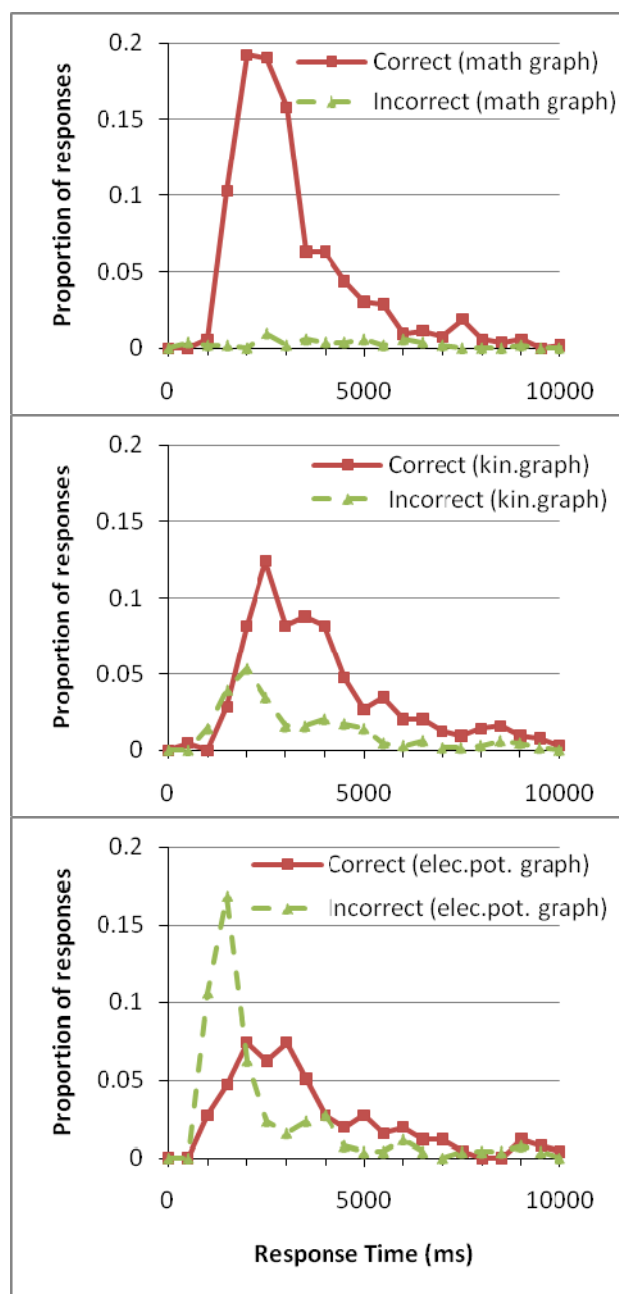

Figure 4: Experiment 1 distribution of response times on target questions in the math (top), kinematic (middle), and electric potential (bottom) graphs conditions. The area under the curves represents the total proportion of correct or incorrect (misconception-like) responses for each condition.

The second kind of evidence to support the fact that students answering incorrectly consistently chose the misconception-like distracter comes from the non-target type of questions. For example, Figure 2 shows the score for the questions for which the point with the highest values was also the point with the highest slope. In all three conditions, participants scored higher on these “aligned” questions in which the slope and values were both greater compared to the target questions in which the point with the higher slope had the lower value (paired t -tests, $ps < 0.003$).

Analysis of response times Figure 4 presents the distribution of response times for each question in each condition, separated out by all questions answered correctly and those answered incorrectly. Note that the response times for all students were pooled together, so this graph represents both between student and within student data mixed together.

There are two main points about the data presented in Figure 4. First, for the kinematic and electric potential graphs conditions, the response times are shorter for the incorrect answers than the correct answers (Mann-Whitney U test used because of long tails in distribution, $ps < 0.0001$). The peaks of the distribution for the incorrect answers are about 500 ms earlier than for the correct answers. There are so few incorrect responses for the math graphs that no reliable comparisons can be made for that case. Second, the peaks of correct answers for all three conditions are at the same place (about 2000 ms) for all three conditions.

At first glance, the fact that the response times for the incorrect responses are shorter than the correct responses may not be a surprise: the speed-accuracy tradeoff is a well known phenomenon. However, as discussed earlier, the incorrect answers are not random guesses, so one cannot conclude that the shorter response times are due to fast guessing. Rather, there is a pattern to the guessing.

This leads us to the question of whether there is an inherent difference in time required to perform the two different response modes, which in Experiment 1 translate to systematically correct vs. “incorrect” (misconception-like) responses. The underlying task to determine the correct answer is to compare the slopes at the two points and the underlying task to determine the misconception-like answer is to compare the heights of the two points. Therefore, in Experiment 2 we determine the time required to perform these two basic tasks.

Experiment 2

The goal of Experiment 2 is to compare the response times for the tasks of comparing the heights of two points vs. comparing the slopes at two points.

Method

Participants Eighteen undergraduate students participated, receiving partial credit for a calculus-based introductory physics course.

Procedure, materials and design The procedure was similar to Experiment 1. Participants were presented with examples depicting various position time curves for a car (see Figure 1 for an example). For each graph, two points on the curve were marked, indicating the position and time of the car at two different times. In a within-subject design, participants were asked to determine as quickly as they can without making a mistake either which point was higher, or at which point the slope was greater. The test was administered in blocks of 9 questions of the same type (compare height or compare slope). Question type blocks were presented in an alternating sequence, with 2 blocks for each question type, for a total of 4 blocks (36 questions).

Results

The mean score for both the compare height questions and the compare slope questions was >97%. Because the response times in the first two blocks were initially relatively high and decayed to an asymptote within 3-4 questions, and the times were near a steady asymptote in the second two blocks, we only compared the response times in the second two blocks (third and fourth block). The response times in the first two blocks showed the same trend. Figure 5 presents the distributions of response times for the height and slope comparison tasks. The mean response time was significantly lower for the comparison of height questions (788 ms) versus the comparison of slope questions (1216 ms), (paired-sample $t(17) = 7.04$, $p < 0.001$, $d = 1.28$).

Figure 5: Distribution of response times for the height comparison and slope comparison tasks in Experiment 2.

Figure 5 is similar to the results from the electric potential graphs in Figure 4, with the participants choosing the point with the greater height answering significantly faster than those choosing the point with the greater slope. The main difference is that the peaks in Experiment 2 are earlier and the widths are narrower. One possibility for the difference is that in Experiment 2, the participants were asked to answer

as quickly as possible. Therefore the time to peak represents a typical minimum time needed to perform the task.

These results suggest that the difference in response times between the correct answer (comparing slopes) and misconception-like answer (comparing heights) is due to these answers employing different procedures to complete, and these two procedures require different amounts of time.

Experiment 3

The results of Experiments 1 and 2 demonstrate that response times of misconception-like responses are shorter than those of correct responses, and the underlying task necessary for determining the misconception-like response (comparing heights) takes less time than the task necessary for determining the correct response (comparing slopes). Considering the decision-criteria model discussed earlier, one way to help explain misconception-like responses on these questions is to propose that students self-imposed a decision criterion that gave high priority to answering quickly. In this case, then students may have tended to choose the information that was processed first, namely information about the relative heights of the points, and this lead to an incorrect response. The information about the relative slopes would lead to the correct answer but took longer to process, so it was excluded from the decision.

Experiment 3 aims to test this idea by imposing a minimum time delay before responding. That is, participants are shown the question and may answer only after a short delay. If the delay is long enough to allow for the processing of both faster solution (comparing heights) and slower solution (comparing slopes), then they would have both kinds of information available. This could then result in participants with the delay answering more frequently with the response consistent with the slower process compared to participants who had no delay imposed. The delay was set to 3 seconds, since the majority of participants who answered correctly in Experiment 1 did so within this time.

Method

Participants A total of 72 undergraduates enrolled in a calculus-based introductory physics courses in electromagnetism participated, receiving partial course credit for participation. Participants were randomly assigned to one of two conditions: 37 in the delay condition and 35 in the control condition.

Procedure, materials and design The procedure was similar to Experiment 1. Participants in the control condition were presented with the same graphs as in the electric potential graph condition in Experiment 1. Participants in the delay condition were presented with the same graphs. However, before the questions began they were presented a screen with the following message: “On each slide, you will see the question with a message at the bottom of the screen. At first the message will read: ‘Take a moment to carefully consider your answer.’ While this message is displayed, you will not be able to answer the question. After a couple of seconds, the message will

change and prompt you for an answer. Please press the key that corresponds to your answer at that time.” They were then given a simple math-fractions problem as an example of the delay, then they proceeded to the graph questions.

Therefore the students in the delay condition were required to wait 3 seconds before responding. The only other difference in Experiment 3 was to randomly assign students within each condition into one of two question-order conditions, to counterbalance for any question order effects. Note that there were no significant differences in performance between the control in Experiment 3 compared to the electric potential graphs condition in Experiment 1.

Results

As shown in Figure 6, participants in the Delay condition score significantly higher than those in the control condition (70% vs. 49%, $t(70) = 2.07$, $p = .04$, $d = .5$).

Figure 6: Results of Experiment 3. Error bars are 1 S.E.M.

Discussion and Conclusion

There are three main results of this paper. First, in Experiment 1 we found a clear difference in the pattern of response times for correct vs. misconception-like responses. This cannot be explained by correct vs. guessing responses because the misconception-like responses are not guesses, rather a consistent pattern of answering. For the particular example used in this study, we found that students will often compare heights of points on a graph, even in cases when they are supposed to compare the slopes. The participants answering with the misconception-like response tend to respond more quickly than those answering correctly.

Second we found in Experiment 2 that participants were able to compare heights and slopes with near-perfect accuracy, and it takes longer to compare slopes than heights. This response-time pattern is consistent with Experiment 1.

Third, when a delay for responding is imposed on the participants, they tend to answer correctly more frequently. This suggests that participants are able to arrive at the correct answers for these kinds of questions, but there is another factor influencing their responses.

The basic structure of the decision-criterion model may at least qualitatively provide an explanation for these results.

The key feature of the model is that there exists a set of criteria for responding. Let us hypothesize two criteria that can explain the results. The first criterion is the need for information about the comparison of the two points that is *plausibly relevant*. The second criterion is the need for rapid responding. If the information on the comparison of heights is plausible enough, the responder who is free to respond at any time may tend to use *only* the height information since it is obtained quickly, and thus respond consistently and incorrectly. If, on the other hand, a time delay were imposed that was long enough to allow the responder to process both height and slope comparison information, then the response choice will be based on *both* height and slope information (and an additional decision is made on which is more relevant). This could naturally result in an increase in respondents choosing the correct answer.

Therefore, these results suggest that for the graphs questions studied here, an implicit tendency to answer rapidly coupled with the fact that an incorrect answer with sufficient plausibility is arrived at rapidly may be at least partially responsible for the misconception-like answers. The respondents are capable of answering correctly, but instead they tend to answer quickly. This prevents them from processing additional relevant information and considering alternative possibilities that may be more valid.

Abstract

The effect of problem format on problem solving strategy selection is investigated within the early algebra domain of functional thinking. Functional Thinking is a type of algebraic reasoning appropriate for elementary students, in which a relationship exists between two sets of values. Three function table problems were given to students in grades two through six ($N=232$) in three different problem contexts. Problem context affected student strategy selection. Presenting the problem with non-indexical X values elicited the most correct strategy use, whereas the format with indexical X values elicited the most naïve and incorrect strategy use. Presenting the problem in a story context did not help correct strategy selection, but it decreased incorrect strategy use. Findings highlight factors influencing strategy selection, and have implication for instructional design and problem solving.

Keywords: Problem Solving; Context; Strategy Use; Mathematics; Functional Thinking; Algebra.

Problem Format and Problem Solving

The format a problem is presented in can affect how well a student understands the underlying concepts and skills the item is tapping (Collins & Ferguson, 1993; Day, 1988; Kirshner, 1989; Zhang, 1997). One problem context is a story context. Teachers and researchers often believe that story problems are harder for students than symbolic problems (Nathan & Koedinger, 2000; Nathan, Long, Alibali, 2002). National assessment data support this notion. Elementary student performance on story problems is generally worse than symbolic problems in the US (Carpenter, Corbitt, Kepner & Reys, 1980; Koba, Carpenter & Swafford, 1989). However, linguistic difficulties seem to account for younger children's poor performance on arithmetic story problems rather than inadequate knowledge of mathematics (Briars & Larkin, 1984; Cummins et al., 1988; de Corte, Verschaffel, & de Win, 1985; Hudson, 1983; Kintsch & Greeno, 1985; Riley et al. 1983).

Once students have proficient linguistic skills, story contexts can have an advantage. In high school students, a verbal advantage of story problems has been found with in algebra and arithmetic. The advantage of story problems was not only a consequence of situated world knowledge facilitating understanding. This advantage was also due to difficulties comprehending the formal symbolic representations of the symbolic problem formats (Koedinger & Nathan, 2004). The effect of problem context was further clarified in college students. A story context was advantageous when the underlying problem was simple, but a symbolic context was best when the problem was

complex, presumably because these students had expertise interpreting the symbolic notation (Koedinger, Alibali & Nathan, 2008). Based on these findings, the ideal problem context seems to be dependent on the student's relative familiarity with linguistic and mathematic symbol systems.

When introducing early algebra concepts to elementary school students, mathematics education researchers stress the importance of rich and intuitive background contexts. These are thought to ground students' understanding of the new mathematic concepts they are learning (Carraher, Martinez, & Schliemann, 2008). Story contexts were found to help third grade students solving arithmetic problems over comparable symbolic contexts (Baranes, Perry, & Stigler, 1989). These ideas are in line with learning theories that have emphasized the role of contextual knowledge in supporting the development of symbolic knowledge (e.g., Greeno, Collins, & Resnick, 1996; Vygotsky, 1978).

Problem context can be varied in ways other than adding a story. The presentation of numeric information can be changed in ways which might alter how much attention is given to surface features versus the deep structure of the problem (Bassok, 1996). Having an understanding of the deep structure of a problem is important for fully understanding and correctly solving a problem.

This study investigates the effect of problem context on problem solving strategy within functional thinking, a type of early algebraic reasoning. Functional thinking tasks are appropriate for students that range in age from early elementary, where story context has been shown to hurt, to early middle, where story context has been shown to help. Giving the same task to students in this age range will help elucidate the effect of problem context on problem solving strategy use.

Functional Thinking

Functional Thinking is a type of mathematical thinking which focuses on the relationship between two (or more) varying quantities, specifically the kinds of thinking that lead from specific relationships to generalizations of that relationship across instances (Smith, 2008). The understanding of functions is also one of the core strands of the National Council of Teachers of Mathematics expectations for mathematics curriculum. At the heart of functional thinking is a relationship between two particular quantities that can be described by a *rule of correspondence* (Blanton & Kaput, 2005). This rule of correspondence can

be used to find other sets of particular quantities that adhere to the same rule.

Functional Thinking encapsulates some of the most important core components of early algebraic reasoning, such as generalization and covariation, and provides a developmentally appropriate way to scaffold these ways of thought through elementary mathematics education.

X	1	2	3	4	5
Y	5	6	7	8	9

Figure 1: Function Table ($Y = X + 4$).

Difficulties in Functional Thinking

A critical aspect of functional thinking is understanding the functional relationship between XY pairs. Functional thinking problems can be represented in a *function table* (Figure 1). A function table has an X and a Y column, filled with values that are all related by a function (e.g., $Y = X + 4$). This is the functional relationship of the table (Carraher et al., 2008). An understanding the functional relationship requires considering the relationship across the columns; between the X and Y values. However, the table can be interpreted another way, by only looking at the relationships within one column, such as between Y_1 and Y_2 . This is the recursive relationship within the table (Carraher et al., 2008). Considering this recursive relationship is often temping, particularly when the X values are arranged indexically, with regular intervals, and therefore there are also regular intervals between the Y values. When the problem is presented in this format, to find later Y values in the function table, all one would have to do is extend the pattern within the Y values. However, this relationship is only useful when the X values increase at a constant rate. Additionally, this relationship cannot be efficiently used to predict a Y value for new X value.

Children tend to begin with this recursive strategy, particularly when they are unfamiliar with problems of this type (Carrahar et al., 2008). Broadly speaking, the power of functions is in the functional relationship between X and Y values, so a focus on the recursive relationship is misguided.

Mathematics educators have suggested different problem presentation contexts to help students get out of using the recursive strategy and into using the functional XY strategy. One way is to present the function table with an X axis that has irregular intervals between values (Carraher & Earnest, 2003; Warren & Cooper, 2005), or even clearly defined visual breaks in the table structure itself (Carraher et al., 2008; Schliemann, Carraher, & Brizuela, 2001). These break up the regular pattern in the Y values, thus discouraging children’s strategy of simply looking to only the pattern in the Y values to determine the missing Y values later in the table.

Another way this can be overcome is to present the function problem with a story context, so the student can have an intuitive understanding of the underlying functional relationship. A story context can help ensure that students

are considering the relationship between multiple input and output values (Schliemann et al., 2001). In this way, students are less likely to utilize a shallow recursive strategy. These instructional techniques help guide students away from the initial recursive strategy and into the correct functional strategy.

There is much writing as to which problem contexts are best for learning, but no systematic investigation for elementary level functional thinking problems. This study investigates the effect of problem context on strategy use within function table problems.

X	Y	X	Y	Cost of Present	Cost of Present with Gift Wrapping

Story Context: At a gift shop, you can pay extra to have your present gift-wrapped, as shown in the table below. What is the *total cost of the present with gift-wrapping* if the *cost of the present* is \$6? \$14? What about \$41? If the *total cost of a present with gift-wrapping* is \$36, what was the *cost of the present itself*?

Figure 2: Function Table Formats. Indexical, Non-Indexical, and Story Context.

Method

An assessment on functional thinking was given to students in grades two through six. Three function table items were included, which asked the students to fill in missing Y values in a function table, and to find the rule of correspondence. The underlying functions for these items were additive ($Y = X + 4$), multiplicative ($Y = 3X$), and a combination ($Y = 3X + 2$). These three items were presented in three contexts: a function table with indexically increasing X values and no story context (*indexical*), a function table with non-indexically increasing X values and no story context (*non-indexical*), and a story problems with indexically increasing X values (*story*) (see Figure 2). The items in these three conditions were kept as similar as possible, with the only differences being the factors that we were manipulating. The story contexts were about the cost of having a present gift-wrapped, saving money for a bicycle, and how many people could be seating at different arrangements of dinner tables. These story contexts were adapted from instructional materials created by math education researchers (e.g. Schliemann et al., 2001). The rule was not articulated in the story context and had to be deduced from the function table values. Each individual assessment contained the additive, multiplicative, and combination function table problems in the same context condition. All problems on a given assessment were in the

same format, therefore there were three versions of the assessment; indexical, non-indexical, and story.

The assessments were randomly distributed to 232 2nd through 6th grade students in a middle class suburban elementary and middle school in the southeastern United States. The general instructions for the assessment were read aloud to the second grade students, but they read the individual problems themselves.

Coding The students' work was coded for strategy use. The student's strategy was determined from the values they wrote in the function tables. Students' strategy use was coded as *correct* if they used the correct functional strategy, *recursive* if they used a recursive strategy, and *other*. If the student gave the correct entries, regardless of a correctly written rule of correspondence, or gave an incorrect entry for one blank, but gave a correct rule of correspondence, they were coded as *correct*. Students were given a *recursive* code if they had filled in the table by looking at the pattern in one column, instead of the relationship between the two columns. Students often used *other* strategies, such as an incorrect functional strategy, a mix of a functional and recursive strategy, an indiscernible strategy, or if the student left the table blank. There were no systematic differences in other strategy use of these types between conditions, and so they were collapsed in all further analyses. See Table 1 for a breakdown of strategy use by condition. Only correct and recursive strategy use was considered in this analysis.

Strategy	Description	Sample Student Response	Frequency		
			Index	Story	Non Index
Correct	Used correct functional rule to fill in table	Y = 3X X: 2 3 4 5 6 12 52 Y: 6 9 12 15 18 36 156	39.1%	39.4%	48.3%
Recursive	Filled in table following Y pattern, instead of between X and Y	Y2 = Y1 + 3 X: 2 3 4 5 6 12 52 Y: 6 9 12 15 18 21 24	16.4%	9.1%	6.25%
Other	Incorrect Functional, Mixed Functional and Recursive, Unclear, and Blank		44.5%	51.5%	45.5%

Coded as strategy even if one entry in the table was incorrect or blank

Table 1: Strategy Use Percentages by Condition

Results

We compared the effect of problem context (indexical, non-indexical, and story) on strategy use (correct or recursive). There was an overall effect of problem format on both correct and recursive strategy use.

Correct Strategy Use

The correct strategy was utilized the most overall, with it being used 39% of the time in both the indexical and story context, and 48% of the time in the non-indexical context

(See Figure 3). The effect of problem context on correct strategy use was evaluated through a series of ANCOVAs with correct strategy use as a dependent variable, condition and grade as between subjects factors and a grade by condition interaction term. Grade was treated as a continuous variable. The initial model tested for a grade by condition interaction, which was not significant, and therefore the interaction term was dropped from all further analyses. Problem context had a significant effect on correct strategy use, $F(2, 225) = 3.23$, $p = .042$, $\eta^2 = .028$. A post hoc analysis of correct strategy use revealed that differences between conditions were significant when comparing the *non-indexical* and *story problem* contexts, $F(1,151) = 5.74$, $p = .018$, $\eta^2 = .037$. The difference between the *indexical* and *non-indexical* was marginal, $F(1,149) = 2.778$, $p = .098$, $\eta^2 = .018$. There was no difference in correct strategy use in the *indexical* and *story* contexts $F(1,146) = .523$, $p = .47$, $\eta^2 = .004$. This pattern of results was the same when students were split into younger (2nd and 3rd) and older (4th through 6th) groups, showing that this effect was not dependent on grade. Average accuracy performance was similar within these groupings, and so were collapsed for summative analyses. The younger students used the correct strategy in the *non-indexical* condition the most (29.1%), and less in the *indexical* and *story* contexts (15.5% and 11.6%). The older students used it 66.7% in the *non-indexical* context, and 55.8% and 61.2% in the *indexical* and *story* contexts. Overall, the *non-indexical* context was the most conducive to the correct problem solving strategy, and there was no difference in strategy use in the *indexical* and *story* contexts.

Recursive Strategy Use

The recursive strategy was utilized less often, with it being used 16% of the time in the *indexical* context, 6% of the time in the *non-indexical* context, and 9% of the time in the *story* context. Problem context had a significant effect on recursive strategy use $F(2, 225) = 3.49$, $p = .032$, $\eta^2 = .03$. There was a significant difference in strategy use between the *indexical* and *non-indexical* contexts $F(1,149) = 6.217$, $p = .014$, $\eta^2 = .04$. There was no significant difference when directly contrasting the other conditions (*story* vs. *non-indexical*, $F(1,151) = 1.003$, $p = .318$, $\eta^2 = .007$; *story* vs. *indexical*, $F(1,146) = 2.28$, $p = .133$, $\eta^2 = .015$). Again, this pattern of results was the same when students were split into younger (2nd and 3rd) and older (4th through 6th) groups. The younger students used the recursive strategy in the *indexical* condition the most (28.2%), and less in the *non-indexical* and *story* contexts (13.6% and 13.6%). The older students used it 6.2% in the *indexical* context, and 2.3% and 5.4% in the *non-indexical* and *story* contexts. This effect was not dependent on grade. Interestingly, there was a trend towards a stronger effect of problem context on recursive strategy use when the type of underlying function (i.e., multiplicative) was difficult for the student. The *indexical* context elicited the most recursive strategy use, and there was no difference in strategy use in the *non-indexical* and *story* contexts.

Discussion

Problem context had an effect on problem solving strategy use. Particularly, the *non-indexical* context encouraged the use of the correct strategy relative to other formats, and the *indexical* context encouraged the use of the recursive strategy relative to other formats. Interestingly, the *story* context discouraged use of the recursive strategy, but it did not encourage use of the correct strategy.

These findings have direct implications for the teaching and learning of function tables. In pedagogical contexts, function table problems should be presented with non-indexical X values to facilitate student understanding.

Figure 3: Problem Solving Strategy Use by Problem Context.

The indexicality of the X values had a large effect on student strategy use. Particularly, the *indexical* context encouraged the use of the naïve and incorrect recursive strategy. This could be the case because the students may have utilized the surface feature of the constant pattern in the Y values, and found it sufficient to determine the missing values. Specific aspects of content, context, and phrasing of a problem often play a crucial role in helping people determine the structure of a problem. Because of this, different structures may be abstracted from formally isomorphic problems that have different surface features (Bassok, 1996). The differences in surface features between function tables with indexical and non-indexical X values seemed to have been enough to invoke different structural interpretations in students. By arranging surface features of a problem, the learner's attention can be directed in more or less efficient manner to the underlying structure.

The story context did reduce the use of the naïve recursive strategy, but it did not support use of the correct strategy. Previous research suggests that the benefits of story contexts are dependent on the learner's relative familiarity with the linguistic and mathematic symbol systems (Koedinger, Alibali & Nathan, 2008; Rittle-Johnson & Koedinger, 2005). Our population included a range of students whose reading ability varied from novice to proficient, allowing us to address the effect of story context on students with different reading skill. The second and third grade students read the story context to themselves, yet the pattern of results between conditions was the same as

those of the older students. This suggests that reading difficulties were not an issue, and that there was no verbal disadvantage for younger students. Standardized state test data was available for a subset of the 3rd through 6th grade students, and performance on our whole functional thinking assessment did not highly correlated with reading scores ($r(89) = .613, p < .01$). The story context seemed to reduce the tendency to focus on the Y_1Y_2 recursive relationship. This may be because the familiar and semantic information contained in the story helped form the students' understanding of the underlying problem structure. However, this story context was not enough to encourage correct strategy use, by considering the XY relationship. This effect of story context may be different from previous research findings, as the domain of functional thinking does not, at this elementary level, involve any mathematic symbolic notation. The problems only contain whole numbers, and the new concept is the focus on the XY relationship. As such, story contexts might not have as great a benefit as they do in arithmetic and algebra.

In this study, we wanted to isolate the effects of indexicality of the X values and a story context. How the two problem presentation features would interact was an open question. Given the results of this study, it is clear that future investigations should include story contexts with non-indexical X values. Perhaps the combination of both the real world context and numeric values without tempting surface patterns will be the most powerful in facilitating correct functional strategy use.

This study shows that seemingly small changes in problem context can affect the strategies a learner uses to solve a problem.

Abstract

The goal of this study was to test a foreign language teaching method inspired by Newport (1990)'s Less is More hypothesis. Computerized French language lessons were presented to 112 adults over two one-hour sessions. Learning trials were presented either in full sentences to resemble the adult learning environment, or in small phrases that incrementally increased in length to full sentences, resembling the steadily expanding processing capabilities of children. Trials were also ordered randomly or blocked such that multiple examples of the same objects and verbs were presented consecutively, in order to promote attention to individual words within those sentences. Language proficiency tests of vocabulary and grammar were administered after the lessons. The incremental and blocked conditions outperformed the randomly ordered full sentence conditions on the grammar measure. This outcome suggests that a teaching method based on Newport's Less is More hypothesis can be advantageous in learning a foreign language.

Keywords: adult language acquisition; constraints; starting small

Introduction

For many years, second language acquisition researchers and educators have been trying to sidestep the age effect problem in foreign language acquisition to help older children and adults reach a near native level of proficiency. Findings from this research demonstrate that (a) language is better learned at an earlier age, (b) despite numerous methods of explicit language instruction, older children and adult learners do not reach a native level of language proficiency, and (c) adults generally learn the word order and semantic aspects of language more quickly than children but usually never master the grammatical aspects (Newport, 1990). The demand for a solution to the age effect problem is essential to our multicultural society. A first step to solving this issue may be to investigate why young children are better language learners.

We suggest that second language educators may benefit from exploring developmental theories of language acquisition that (a) explain the robust findings of child-adult differences in language proficiency and (b) provide insight for methods of instruction to the second language teaching community. Developmental psychologists propose that the mind of a young child is more suitable for certain complex learning processes like language acquisition than is that of an older child or adult (Newport, 1990; Turkewitz & Kenny,

1982). Newport's Less is More theory explains that in the beginning stages of language learning, limited input helps children learn language (Newport, 1990). Young children's limited processing capacity and working memory only allow them to take in a small amount of the language heard around them, and as a result, they attend to limited language input such as individual words or morphemes. When learning a language, children must learn to map morphemes to specific meanings, and then combine those morphemes in original ways to create new sentences. Initial limited input may create the opportunity for children to analyze simple morphemes and create a small number of linguistic form-to-meaning mappings. When children's cognitive processes develop (working memory and processing capacity increase), they are then able to process more complex input, allowing them to learn the rules for combining morphemes in grammatical production. These cognitive processes fully develop around puberty (Newport, 1990).

The Less is More theory also explains why older children and adults do not learn language as well as young children. When older children and adults begin to learn language, they use their fully developed working memories and processing capacity to attend to complex sentences that contain multiple morphemes. From processing the complex input, adults (a) tend not to analyze individual morphemes but learn "frozen" combinations of multiple morphemes and (b) create many form-to-meaning mappings that are susceptible to noise. Out of the many possible morpheme mappings, only a few are correct, resulting in inconsistent and often incorrect language production. Therefore, adults do not learn the same morphological structure of a language as children.

Newport's research shows that late learners of ASL were more inclined to produce variable ungrammatical signs (Newport, 1990). Her theoretical explanation for these findings is the late learners immediately processed complex whole signs as units rather than analyzing the individual morphemes that make up a sign, encouraging the use of imitative unanalyzed signs. In contrast, the native and early learners of ASL used their developing cognitive abilities to process small parts of signs, enabling them to learn the individual morphemes and eventually produce original grammatically correct combinations of the morphemes.

Previous language learning studies found that initial limited exposure can be beneficial in learning the morphological structure of the language. Goldowsky &

Newport (1993) show that a computational model that has a filter restricting the amount of input when exposed to linguistic form-to-meaning mappings learns the correct mappings better than one without restrictions. Cochran, McDonald, & Parault (1999) demonstrate that restricting adults' language input by having them attend to an external working memory task or encouraging them to concentrate on small parts while being exposed to complex ASL morphology led to more consistent ASL production than did attending to the full complexity of the language. Kersten & Earles (2001) found that adults who were presented with an artificial language in small phrases that gradually increased in complexity performed better on vocabulary and morphology measures than did adults who were immediately presented with the full complexity of the language. These studies suggest that starting with limited input of language can facilitate learning.

Other research demonstrates learning benefits of a different approach to starting small. In particular, research on category learning has revealed that manipulating the order of learning trials, such that multiple examples of the same category are presented sequentially before exposing learners to the full range of variability in category exemplars, results in superior ultimate learning. For example, Sandhofer & Doumas (2008) show that manipulating the order of presentation so that children are presented with multiple examples of the same color category before introducing a new color led to better learning than did random presentation.

Additionally, Elio & Anderson (1981) introduced adults to two categories that differed on multiple attributes. The exemplars of each category were presented in either random or blocked order, in which multiple examples of the same category were presented before moving onto the next category. They found that learning the attributes of each category and generalizing new examples to the correct category were better in the blocked condition than the random condition.

These results suggest that blocking manipulations may function similarly to incremental presentation, encouraging learners to focus on the commonalities among members of an individual category and to ignore the variability associated with other, orthogonally-varying categories. Once learners acquire a basic vocabulary of individual categories, they may be in a better position to learn the more complex rules for combining those categories. Thus, teaching methods that encourage attention to simple information, and then gradually encouraging attention to more complex material, may be beneficial in learning the categories, and ultimately the structure, of language.

Present Research and Predictions

The present research tests the applicability of the Less is More hypothesis to second language learning by attempting to teach adults a foreign language using teaching approaches inspired by the theory. Adults participated in an unsupervised experiment consisting of two sessions of

French language lessons in which they watched short videos and heard French descriptions. Two different methods were used to encourage participants to initially focus on individual French phrases before attempting to learn the complex grammar of entire French sentences. First, consistent with the method used by Kersten & Earles (2001), some participants were initially presented with individual phrases that gradually increased in complexity as learning progressed, whereas others were immediately presented with entire sentences. Second, consistent with the methods of Sandhofer & Doumas (2008) and Elio & Anderson (1981), some participants were presented with learning examples in a blocked order that encouraged the acquisition of individual words within the sentences that accompanied the videos, whereas others were presented with learning examples in a random order. Crossing these two factors led to four between-subjects conditions.

The incremental random (IR) condition presented a set of French lessons initially in individual phrases that gradually increased to full-length sentences. First, participants viewed a set of videos and heard only the direct object that corresponded to the video in the French language. In the second phase, participants viewed similar videos but heard entire phrases (including the verb and direct object). In the final phase, participants viewed the same videos from the previous phases but heard the full complex sentences that consisted of subject, verb and direct object. The trials within each learning phase were presented in random order. We predicted that initially presenting the descriptions in individual phrases would promote the learning of individual words and their meanings. As longer phrases were presented, participants were expected to learn additional words as well as the rules for combining those words.

The incremental blocked (IB) condition presented participants with the French language in incrementally larger phrases as in the IR condition, but the order of presentation within each learning phase was blocked by similarity of object and verb. Similar to methods used in category learning, a block consisted of presenting two examples of the same object or verb sequentially before presenting a new object or verb. In the first learning phase, trials were blocked by similarity of object so that participants were presented with two trials containing the same object before moving onto a new object. In the second and third learning phases, in which participants heard verb phrases and full sentences, respectively, trials were blocked by similarity of verb meaning. The intention of blocking trials was to encourage acquisition of individual words within the speech stream. We predicted that both incremental and blocking manipulations would ultimately produce advantages in grammar acquisition.

The sentence blocked (SB) condition immediately presented the language in full sentences but in a blocked order similar to the IB condition. Even though these participants were not initially exposed to individual phrases, we expected that the blocked order of presentation would still encourage attention to individual words within the

speech stream, leading to better learning of those words and ultimately giving a grammar learning advantage to this group.

Emulating the adult learning experience, the sentence random (SR) or control condition was immediately exposed to the foreign language without restrictions. The SR condition viewed videos accompanied by full sentences in random order. Therefore, we did not expect these participants to focus on learning the individual morphemes or structure and do as well on the morphology measure as the other conditions.

Following the lessons were test trials assessing language acquisition. The measures of acquisition were vocabulary and grammar (word order and morphology) from the presented foreign sentences, as well as tests of inductive grammar, measuring the ability to extract grammatical rules and apply them to novel sentences. Although word order is a component of grammar, in this study it was measured separately from grammatical morphology. Performance on the vocabulary and word-order measures was predicted to be similar among all groups, as vocabulary and word order are generally acquired without difficulty in both adults and children. However, a disparity was expected in performance among conditions on both grammar measures that test participants' knowledge of morphology. The three experimental conditions (IR, IB, and SB) were expected to outperform the control condition (SR) in the measures of morphology.

Method

Participants

One hundred twelve native English speakers from Florida Atlantic University participated in this experiment. Only participants who reported in a language background questionnaire that they did not speak a Romance language and knew fewer than 30% of the French words on the vocabulary pre-test were included in the data analysis. The average age of the participants was 22.2 (SD = 4.6) years. Each participant was randomly assigned to one of the four conditions of the experiment.

Stimuli

French Language The stimuli included sentences of active and reflexive verb forms made up of high frequency French words. The French active sentences in the stimuli share similar structure to the English language. Each active sentence consists of a subject, action verb, and object. However, English and French languages have grammatical distinctions when conveying a reflexive action. In English, possessive pronouns are used to express a reflexive action, but in French, reflexive pronouns are used. The pronoun "se" is added and placed in front of the verb and definite articles describe the object rather than possessive pronouns. For example, a man brushing his hair is described as "L'homme se brosse les cheveux". If the "se" is omitted from the sentence, the statement changes the meaning to "The man brushes the hair," implying the hair of an object.

The word order of the French language is similar to English. Lesson and test trials were in French and only the instructions and examples of the tasks were in English.

Trials All trials were programmed into Superlab Pro 4.0 and displayed on computers. Each trial consisted of a video playing on the screen and a corresponding French description presented audibly through headphones. French text was not available. Each video consisted of an actor performing a specific action on him/herself or on an object. Six different actors performed the same actions in different contexts. A female native French speaker recited French descriptions into a recorder and the recordings were linked to correspond with the videos. Each trial was approximately 3 seconds in length.

Learning Trials Learning trials were designed to teach participants the semantics and grammatical structure of sentences using 8 verbs and 16 nouns. Lessons were made up of three learning phases. Each learning phase consisted of 32 trials that presented 4 examples of each verb (2 in the active and 2 in the reflexive form) and 2 examples of each noun. In the IR condition, phase 1 comprised 32 trials of videos accompanied by only the direct object description from the corresponding sentences, phase 2 consisted of 32 trials accompanied by the verb and direct object, and phase 3 comprised 32 trials with full sentence descriptions. The IB condition presented the same trials from the IR condition in blocked order. Phase 1 consisted of videos and direct object descriptions, ordered such that the trials with the same direct objects were presented one after the other. Phases 2 and 3 involved the exact trials from the IR condition, but ordered such that trials involving the same verb were presented one after the other, first in the active form then in the reflexive form. The SB condition consisted of three phases of trials with full sentence descriptions, but presented in blocked order similar to the IB condition. Participants in the control condition (SR) were exposed to trials with full sentence descriptions in random order identical to the last phase of the IR condition for all learning phases. See Table 1 for an illustration of the presentation of two learning trials between the groups.

Test Trials To measure participants' knowledge of the French vocabulary, a judgment task of 16 trials of videos and corresponding French sentences were presented. The correct trial included the appropriate object and verb description of the video, whereas the incorrect trial contained an incorrect noun or verb. The incorrect French sentences were taken from the learning trials but linked to an incorrect video from the learning trials entailing a different object or action.

As one test of participants' knowledge of French grammar, a word order forced-choice task for the active and reflexive sentences was administered. The word order task consisted of 8 trials. The correct trials resembled the learning trials, whereas the incorrect trials included videos

Table 1: Illustration of two learning trials for each condition.

Experimental Condition	Learning Phase 1		Learning Phases 2 & 3		
	Video	Audio	Video for 2 & 3	Audio Phase 2	Audio Phase 3
Incremental Random	woman sprays car	“la voiture”	Same as phase 1	“asperge la voiture”	“La femme asperge la voiture.”
	woman shakes bottle	“la bouteille”		“secoue la bouteille”	“La femme secoue la bouteille.”
Incremental Blocked	woman sprays car	“la voiture”	woman sprays car	“asperge la voiture”	“La femme asperge la voiture.”
	woman washes car	“la voiture”	woman sprays her face	“s’asperge le visage”	“La femme s’asperge le visage.”
Sentence Blocked	woman sprays car	“La femme asperge la voiture.”	woman sprays car	Same as Learning phase1	
	woman washes car	“La femme lave la voiture.”	woman sprays her face	“La femme s’asperge le visage.”	
Sentence Random	woman brushes her hair	“La femme se brosse les cheveux.”	Same as phase 1	Same as Learning phase1	
	woman cuts the ticket	“La femme coupe le billet.”			

from the learning trials linked to French sentences with incorrect word order.

The grammar forced-choice task assessed participants’ understanding of the morphological structure underlying the active and reflexive sentence forms. This task comprised 16 test trials. The goal of this task was to determine if the participants could correctly identify, discriminate, and link the active and reflexive sentence forms to the appropriate video. In other words, would participants learn to understand that reflexive actions are linked to reflexive sentences with the “se” pronoun and that active sentences (without the reflexive pronoun) are used to express actions on objects rather than to self? The correct choices consisted of videos with the correct corresponding French sentences resembling the learning trials. The incorrect choices included videos with incorrect grammatical French sentences of the active or reflexive forms.

The purpose of the inductive task was to assess participants’ ability to apply the learned French grammatical rules to new stimuli. First, there was a learning phase of 8 videos and sentences (4 active and 4 reflexive sentences), each presented twice. The intention of the learning phase was to introduce participants to new vocabulary. The testing phase consisted of a forced-choice task of 8 trials (4 reflexive and 4 active). The videos and French descriptions in the test trials were novel. In particular, a verb presented only in the active form during learning was presented in the reflexive form in testing. To succeed in the inductive task, participants had to use the grammar rules of verb forms extracted from the lessons to fit the video and description of the task. Since this was a forced-choice task, participants did not have to produce the verb; however, they had to decide which one of the provided sentences contained the correct verb form.

Procedure

The experiment consisted of two one-hour sessions. The first session entailed lessons and a vocabulary test. During the lessons portion, participants were instructed to view each video and listen to the French description. They were told to repeat the description after each trial. Participants viewed learning trials from each phase twice before moving on to the next phase, totaling 192 trials. Every participant was issued one-minute breaks after every 32 trials. Once the learning trials were all presented and another break was given, participants took the word-meaning test.

Two days later, the participants returned for the second session. First, participants viewed lessons identical to the third learning phase in session one, totaling 64 trials. After a break, participants completed the word meaning, grammar and word order measures. Following a final break, participants completed the inductive task, and then a short questionnaire on prior knowledge of the French language, concluding the procedure of the experiment.

Results

The results of this experiment are presented in Table 2. Each measure was scored as the percentage of the total correct acceptances and rejections out of the total number of test trials for each task. Analyses of the word meaning judgment task were split into two separate measures of verbs and nouns. A 2(noun vs. verb) X 2(1st session vs. 2nd session) X 2(incremental vs. sentence) X 2(block vs. random order) repeated measures ANOVA was conducted to investigate within and between group differences on word meaning measures. The results revealed a significant within-group difference between noun and verb learning, $F(1, 107) = 146.765, p < .001, MSE = 3.752$. Participants scored higher on the noun items than verb items of the vocabulary measures. However, there were no significant increment, blocking, or interaction effects on vocabulary (all $ps > .05$).

Table 2: Means (Standard Deviations) for Groups

Language Measures	Incremental Random n = 31	Incremental Blocked n = 25	Sentence Blocked n = 27	Sentence Random n = 29
Vocabulary				
1 st session nouns	.742(.21)	.613(.19)	.785(.18)	.830(.13)
2 nd session nouns	.811(.13)	.825(.16)	.810(.18)	.806(.20)
1 st session verbs	.612(.19)	.567(.18)	.638(.20)	.625(.24)
2 nd session verbs	.641(.16)	.610(.18)	.690(.18)	.586(.21)
Word order	.879(.14)	.930(.09)	.912(.12)	.897(.12)
Grammar (based on trials from lessons)	.621(.14)	.655(.13)	.683(.18)	.586(.13)
Inductive grammar (based on trials from inductive task)	.605(.20)	.640(.18)	.644(.25)	.543(.24)

A two way ANOVA was conducted on performance that tested participants' knowledge of word order for the active and reflexive French sentences. The results revealed no significant main or interaction effects on word order performance (all $ps > .05$).

Analysis of the grammar measures was conducted using three planned orthogonal contrasts. The first contrast compared the control participants (SR) to the three experimental conditions, examining whether manipulations that promote attention to low-level sentence elements promote acquisition of French grammar. The second contrast compared the IB condition to the IR and SB conditions, examining whether receiving both manipulations yields better knowledge of French grammar than receiving just one. The third contrast compared the incremental IR condition to the SB condition, examining whether one manipulation promoting attention to low-level sentence elements yielded better knowledge of French grammar than the other.

The first of these three contrasts was significant, indicating that the three experimental conditions scored significantly higher on the grammar tasks than did the control condition ($p = .023$). However, the other two contrasts were not significant (both $ps > .05$). These results suggest that the increment or blocking methods produced better performance than the sentence random method on the grammar tasks, but having both the increment and blocked methods did not facilitate performance any better than having one of the two methods.

Discussion

The goal of this study was to investigate the usefulness of language teaching methods that were based on the Less is More hypothesis. The results suggest that presenting the language lessons in increments, or in a blocked order does not lead to better performance on the word meaning and word order measures. However, the results of the other grammar measures suggest that these teaching methods can be advantageous in grammar acquisition.

The generally high levels of performance on the vocabulary measures suggest that participants had little difficulty learning the meanings of the words. All groups learned more nouns than verbs. This finding is consistent

with the notion that concrete count nouns are easier to learn than verbs, and with findings that children learn the names of objects more quickly than verbs (Gentner & Boroditsky, 2001). It can be said that the lessons promoted noun learning because the nouns were concrete, consistent and appeared at the end of each phrase.

The intent of the word order measure was not to test the effects of incremental presentation or order of the lessons but to confirm that the participants comprehended the lessons. All groups performed at similarly high levels near ceiling on the word order measure.

The crux of the experiment was the outcome of the grammar measures. Generally, adults have difficulty mastering the grammar of foreign languages. In this experiment, French language lessons inspired by the Less is More hypothesis were presented to adults as an attempt to overcome this challenge. The results revealed that learning strategies that encouraged the learning of language in small pieces by incremental presentation or blocked order of presentation facilitated learning the rules of grammar, with the three experimental groups performing better than the control group on these measures. Further analysis revealed that groups that used either incremental or blocked presentation, performed just as well as the condition that received both of these manipulations. These results suggest that either incremental presentation or blocking was sufficient to encourage attention to lower-level sentence elements and thus to ultimately yield better grammatical acquisition. The results of the study thus support our predictions that teaching methods inspired by the Less is More hypothesis may be fruitful in facilitating the acquisition of the grammar of a second language.

Limitations

The results of the experiment are consistent with Newport's Less is More theory, but there remain several limitations of the study that must be remedied before fully endorsing this theory. First, the grammar task involved only a single, relatively simple grammatical alternation. Despite this simplicity, the participants in the study still had difficulty learning the grammatical rule, performing only slightly above floor on the grammar measures. This difficulty likely reflects the limited amount of exposure to the language, involving only two one-hour lessons, and the

high demands of the task. High demands include auditory rather than visual presentation and a lack of explicit grammar instruction. Previous studies found that grammar performance is better in adults when using visual modes of instruction and testing and when using methods that encourage explicit rule learning instead of implicit learning (Conway et al., 2003, Dekeyser & Larson-Hall, 2001). The acquisition of more complex grammatical rules may require much longer, more varied training. However, this study provides a good steppingstone for further experiments.

Second, we designed our method with the assumption that children with limited cognitive processes preferentially attend to the ends of sentences, reflecting a recency effect in working memory. For that reason, the lessons in the incremental condition were presented in small increments starting with the last word of each sentence. This design gave participants simple and consistent lessons. However, the Less is More hypothesis does not state that children always attend to the last word or part of a sentence. If children do not always attend to the last word of a sentence but rather are equally likely to attend to any part of a sentence, then the incremental condition is not fully representative of children's language learning strategies. Changing the incremental condition to involve presenting randomly-chosen pieces of sentences would make the incremental condition less consistent, and as a result, language learning would likely be more difficult for adults.

Lastly, one may argue that the lessons resemble infant-directed talk (IDT). Studies suggest that IDT plays a role in language acquisition and can facilitate adult foreign vocabulary acquisition (Baldwin & Meyer, 2007; Golinkoff & Alioto, 1995). Though the Less is More hypothesis and IDT could potentially coexist in explaining children's language learning, further experimentation would be needed to investigate separate effects of IDT and incremental presentation on adults.

Implications

To address the challenge of learning foreign language grammar in adulthood, this study shows that foreign language educators may profit from incorporating teaching methods based on developmental theories. Presenting a foreign language in increments or in blocked order that promotes the learning of small pieces during the initial stages of language learning are alternative approaches for adults to learn the vocabulary and grammatical structure of a foreign language. Widely-used language teaching methods such as immersion programs or explicit instruction that heavily emphasize focus on semantics in the initial stages of foreign language learning tend to fall short of getting adults to the native level of proficiency in grammar (Harley, 1998). Although our proposal counters these established methods of adult foreign language instruction, it would be worthwhile for the foreign language community to further explore the potential of developmental theories such as Newport's Less is More hypothesis that can offer insightful new methods for foreign language learning.

Abstract

Sequential decision-making tasks are commonplace in our everyday lives. We report the results of an experiment in which human subjects were trained to perform a perceptual matching task, an instance of a sequential decision-making task. We use two benchmarks to evaluate the quality of subjects' learning. One benchmark is based on optimal performance as defined by a dynamic programming procedure. The other is based on an adaptive computational agent that uses a reinforcement learning method known as Q-learning to learn to perform the task. Our analyses suggest that subjects learned to perform the perceptual matching task in a near-optimal manner at the end of training. Subjects were able to achieve near-optimal performance because they learned, at least partially, the causal structure underlying the task. Subjects' learning curves were broadly consistent with those of model-based reinforcement-learning agents that built and used internal models of how their actions influenced the external environment. We hypothesize that, in general, people will achieve near-optimal performances on sequential decision-making tasks when they can detect the effects of their actions on the environment, and when they can represent and reason about these effects using an internal mental model.

Keywords: sequential decision making; optimal performance; dynamic programming; reinforcement learning

Introduction

Tasks requiring people to make a sequence of decisions to reach a goal are commonplace in our lives. When playing chess, a person must choose a sequence of chess moves to capture an opponent's king. When driving to work, a person must choose a sequence of left and right turns to arrive at work in a timely manner. And when pursuing financial goals, a person must choose a sequence of saving and spending options to achieve a financial target. Interest in sequential decision-making tasks among cognitive scientists has increased dramatically in recent years (e.g., Busemeyer, 2002; Chhabra & Jacobs, 2006; Fu & Anderson, 2006; Gibson, Fichman, & Plaut, 1997; Gureckis & Love, 2009; Lee, 2006; Sutton & Barto, 1998; Shanks, Tunney, & McCarthy, 2002).

Here, we are interested in whether people are successful at learning to perform sequential decision-making tasks. There are at least two ways in which the quality of learning can be evaluated. These ways differ in terms of the benchmark to which the performances of a learner are compared. One way uses a benchmark of optimal performance on a task. Analyses based on optimal performance are referred to as ideal observer analyses, ideal actor analyses, or rational analyses in the literatures on perception, motor control, and cognition, respectively. At each moment during training with a task, a

learner's performance can be compared to the optimal performance for that task. If a learner achieves near-optimal performance at the end of training, then it can be claimed that the learner has been successful.

A second way of evaluating a learner is to compare the learner's performances with those of an adaptive computational agent that is trained to perform the same task. We consider here an agent that learns via "reinforcement learning" methods developed by researchers interested in artificial intelligence (Sutton & Barto, 1998). Cognitive scientists have begun to use reinforcement learning methods to develop new theories of biological learning (e.g., Busemeyer & Pleskac, 2009; Daw & Touretzky, 2002; Schultz, Dayan, & Montague, 1997; Fu & Anderson, 2006). To date, however, there are few comparisons of the learning curves of people and agents based on reinforcement learning methods. Because reinforcement learning is regarded as effective and well-understood from an engineering perspective, and as plausible from psychological and neurophysiological perspectives, the performances of agents based on this form of learning can provide useful benchmarks for evaluating a person's learning. If a person's performance during training improves at the same rate as that of a reinforcement-learning agent, then it can be argued that the person is a successful learner. If a person's performance improves at a slower rate, then the person is not learning as much from experience as he or she could learn. Experimentation is often required to identify the cognitive "bottlenecks" preventing the person from learning faster. Lastly, if a person's performance improves at a faster rate, then this suggests that the person is using information sources or information processing operations that are not available to the agent. A new, more complex agent should be considered in this case.

We report the results of an experiment in which human subjects were trained to perform a perceptual matching task. This task was designed to contain a number of desirable features. Importantly, the perceptual matching task is an instance of a sequential decision-making task. Subjects made a sequence of decisions (or, equivalently, took a sequence of actions) to modify an environmental state to a goal state. In addition, efficient performance on the perceptual matching task required knowledge of how different properties of an environment interacted with each other. In many everyday tasks, people are required to understand the interactions, or "causal relations", among multiple components (Busemeyer, 2002; Gopnik &

Shulz, 2007). For example, when reaching for a coffee mug, a person must understand that forces exerted at the shoulder also influence the positions and velocities of the elbow, wrist, and fingers. To make an efficient movement, a person must use this knowledge of the causal interactions among motor components to design an effective motor plan.

Subjects' performances on the perceptual matching task were evaluated via two benchmarks. Using an optimization technique known as dynamic programming, optimal performance on this task was calculated. In addition, computer simulations of an adaptive agent were conducted in which the agent was trained to perform the perceptual matching task using a reinforcement learning method known as Q-learning (Sutton & Barto, 1998; Watkins, 1989). Comparisons of subjects' performances during training with optimal performance and with those of the adaptive agent suggest that: (i) subjects learned to perform the perceptual matching task in a near-optimal manner at the end of training; (ii) subjects learned, at least partially, the causal structure underlying the task; (iii) subjects' learning curves were consistent with those of model-based reinforcement-learning agents; and (iv) subjects may have learned by building and using mental models of how their actions influenced the external environment. Additional details and results are reported in Yakushijin & Jacobs (2010).

Experiment

Methods: Twenty-four undergraduate students at the University of Rochester participated in the experiment. Subjects were paid \$10 for their participation. All subjects had normal or corrected-to-normal vision. Subjects were randomly assigned to one of six experimental conditions. Each condition included both training and test trials. Only the results of training trials are discussed here due to space limitations.

On a training trial, subjects performed a perceptual matching task which used visual objects from a class of parameterized objects known as "supershapes" (highly realistic but unfamiliar shapes; see Gielis, 2003). The parameters were latent (hidden) variables whose values determined the shapes of the objects. On each trial, subjects viewed a target object, a comparison object, and a set of six buttons (see left panel of Figure 1). Buttons were organized into three pairs, and each pair could be used to decrease or increase the value of an action variable. By pressing the buttons, subjects could change the values of the action variables which, in turn, changed the values of the parameters underlying the comparison object's shape which, in turn, changed the shape of the comparison object. Subjects' task was to press one or more buttons (i.e., to change the values of the action variables) to modify the shape of the comparison object until it matched the shape of the target object using as few button presses as possible.

An experimental condition was characterized by a specific set of causal relations among the latent shape parameters. For example, one such set is schematically illustrated in the right panel of Figure 1. Here, the three action variables are denoted A , B , and C . These variables are observable in the sense that

subjects could directly and easily control their values through the use of the buttons. The values of the action variables determined the values of the shape parameters, denoted X , Y , and Z . Note that there are causal relations among the shape parameters. According to the network in Figure 1, if the value of X is changed, then this leads to a modification of Y which, in turn, leads to a modification of Z . The shape parameters determine the shape of the comparison object, whose perceptual features are denoted f_1, f_2, f_3, f_4, f_5 , and f_6 . The perceptual features used by a subject to assess the similarity of target and comparison object shapes may only be implicitly known by a subject, and may differ between subjects.

Importantly, to efficiently convert the comparison object's shape to the target object's shape (i.e., with the fewest number of button presses) often requires an understanding of the causal relations among the shape parameters. For instance, if the values of parameters X , Y , and Z all need to be modified, a person who does not understand the causal relations among shape parameters may decide to change the value of action variable C (thereby changing shape parameter Z), then the value of action variable B (thereby changing Y and Z), and finally the value of action variable A (thereby changing X , Y , and Z). In many cases, this will be an inefficient strategy. A person with good knowledge of the causal relations among the shape parameters knows that he or she can change the values of X , Y , and Z with a single button press that decreases or increases the value of action variable A . Thus, a good understanding of the causal relations among the shape parameters will lead to efficient task performance, whereas a poor understanding of the causal relations will lead to many more button presses than necessary.

The six experimental conditions differed in the causal relations among the latent shape parameters X , Y , and Z . Two of the causal relations were "linear" structures (one parameter had a direct causal influence on a second parameter which, in turn, had a direct causal influence on a third parameter; e.g., $X \rightarrow Y \rightarrow Z$ or $Y \rightarrow X \rightarrow Z$), two of the relations were "common cause" structures (one parameter had direct causal influences on the two remaining parameters; e.g., $Y \leftarrow X \rightarrow Z$ or $X \leftarrow Y \rightarrow Z$), and two of the relations were "common effect" structures (two parameters had direct causal influences on a third parameter; e.g., $X \rightarrow Y \leftarrow Z$ or $Y \rightarrow X \leftarrow Z$).

An experimental session consisted of 7 blocks of trials where a block contained a set of training trials followed by a set of test trials. (Test trials evaluated subjects' one-step look-ahead knowledge; on a test trial, a subject decided if a comparison object could be converted to a target object using a single button press, and the subject did not receive feedback. Again, test trials are not discussed here.) Each set contained 26 trials, one trial for each possible perturbation of a target object shape to form an initial comparison object shape.

Results: Task Performances: As a benchmark for evaluating subjects' performances on training trials, we computed optimal performances on these trials using an optimization method known as dynamic programming (Bellman, 1957).

Figure 1: Left: Example of an experimental display. Right: Bayesian network representing the causal relations (in one of the experimental conditions) among the action variables, shape parameters, and perceptual features. For simplicity, the network does not represent the fact that subjects’ button presses determined the values of the action variables.

In brief, dynamic programming is a technique for computing optimal solutions to multi-stage decision tasks. That is, dynamic programming finds the shortest sequences of actions that move a system from an initial state to a goal state when all states are fully observable. In the context of a training trial, the initial state corresponds to the initial values of the shape parameters X , Y , and Z for the comparison object, and the goal state corresponds to the values of the shape parameters for the target object. The dynamic programming algorithm is provided with full state information. This means that the algorithm knows the values of the comparison object’s shape parameters at every time step. It also knows the state transition dynamics, meaning that it knows the causal relations among the shape parameters and, thus, knows how any button press will change the values of the shape parameters. Relative to our subjects, the dynamic programming algorithm is at an advantage. At the start of the experiment, our subjects did not know the values of the shape parameters or the causal relations among the parameters. Consequently, it would be impressive if subjects learned to perform the task as well as the dynamic programming algorithm.

We determined the optimal performances in the six experimental conditions via dynamic programming. Our analysis revealed that the range (1-5 steps or button presses) and the average length (2.54 steps) of the optimal action sequences were identical for all conditions. Thus, the conditions were well balanced in terms of their intrinsic difficulties.

Figure 2 shows subjects’ learning curves on training trials in the two experimental conditions with linear causal structures among shape parameters. Due to space limitations, we do not show results for conditions with common-cause and common-effect structures, though subjects in these conditions showed very similar results to subjects in linear structure conditions (Yakushijin & Jacobs, 2010). Eight subjects participated in linear structure conditions and, thus, the figure contains eight graphs. The horizontal axis of each graph gives the block number, and the vertical axis gives the average difference between the number of steps (i.e., button presses) used by a subject during a trial and the optimal number of steps for that trial as computed by the dynamic programming procedure. These graphs show a number of interesting features. Many subjects found the task to be difficult toward the start

of the experiment and, thus, their performances were highly sub-optimal during this time period. However, every subject learned during the course of the experiment. Importantly, every subject achieved near-optimal performance at the end of training: The average difference between a subject’s performance and the optimal performance at the end of training is less than 1/2 of a step (mean = 0.434; standard deviation = 0.324).

Results: Causal Learning: The data from the training trials show that subjects achieved near-optimal performances. These results are consistent with the idea that subjects learned about the causal relations among the latent shape parameters. Additional analyses of training and test trials, not described here due to space limitations, confirm that subjects did indeed learn (at least partially) about these causal relations, and that this knowledge played a role in their task performances. Details can be found in Yakushijin & Jacobs (2010).

Reinforcement Learning Agents

Above, our analysis of subjects’ data used a benchmark of optimal performance based on dynamic programming. Although very useful, this analysis does not allow us to evaluate the quality of subjects’ rates of learning. To do so, we use a different benchmark based on an adaptive computational agent that uses a reinforcement learning method known as Q-learning to learn to perform the perceptual matching task (Sutton & Barto, 1998; Watkins, 1989). Without going into the mathematical details, the reader should note that Q-learning is an approximate dynamic programming method (Si et al., 2004). It is easy to show that, under mild conditions, the sequence of decisions found by an agent using Q-learning is guaranteed to converge to an optimal sequence found by dynamic programming (Watkins & Dayan, 1992). Hence, the benchmarks based on dynamic programming and on Q-learning are related.

In a reinforcement learning framework, it is assumed that an agent attempts to choose actions so as to receive the most reward possible. The agent explores its environment by assessing its current state and choosing an action. After executing this action, the agent will be in a new state, and will receive a reward (possibly zero) associated with this new state.

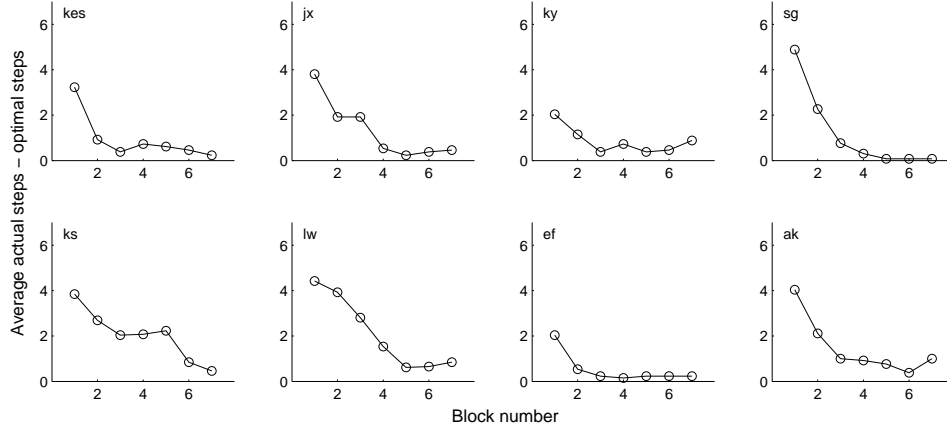

Figure 2: Subjects’ learning performances on training trials in the two experimental conditions with linear causal structures among shape parameters (top row: $X \rightarrow Y \rightarrow Z$; bottom row: $Y \rightarrow X \rightarrow Z$).

The agent adapts its behavior in a trial-by-trial manner by noticing which actions tend to be followed by future rewards and which actions are not. To choose good actions, the agent needs to estimate the long-term reward values of selecting possible actions from possible states. Ideally, the value of selecting action a_t in state s_t at time t , denoted $Q(s_t, a_t)$, should equal the sum of rewards that the agent can expect to receive in the future if it takes action a_t in state s_t : $Q(s_t, a_t) = E[\sum_{k=0}^{\infty} \gamma^k r_{t+k+1}]$ where t is the current time step, k is an index over future time steps, r_{t+k+1} is the reward received at time $t+k+1$, and γ ($0 < \gamma \leq 1$) is a term that serves to discount rewards that occur in the far future more than rewards that occur in the near future. An agent can learn accurate estimates of these ideal values on the basis of experience if it updates its estimates at each time step using the equation:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha[r_{t+1} + \gamma \max_a Q(s_{t+1}, a) - Q(s_t, a_t)]$$

where the agent makes action a_t in state s_t and receives reward r_{t+1} , and α is a step size or learning rate parameter (Sutton & Barto, 1998; Watkins, 1989).

In our first set of simulations in which a reinforcement-learning agent was trained to perform the perceptual matching task, all “Q-values” were initialized to zero, the discount rate γ was set to 0.7, and the learning rate α was set to 0.45. In preliminary simulations, these values were found to be best in the sense that they led to performances that most closely matched human performances. At each time step, the state of the agent represented the difference in shape between the comparison and target objects. It was a three-dimensional vector whose elements were set to the values of the shape parameters for the comparison object minus the values of these parameters for the target object. Six possible actions were available to the agent corresponding to the six buttons that a subject could press to modify the action variables. The agent chose an action using an ϵ -greedy strategy, meaning that the agent chose the action a that maximized $Q(s_t, a)$ with probability $1 - \epsilon$ (ties were broken at random), and chose a random

action with probability ϵ . The value of ϵ was initialized to one, and then it was slowly decreased during the course of a simulation. As a result, the agent tended to “explore” a wide range of actions toward the beginning of a simulation, and tended to “exploit” its current estimates of the best action to take toward the middle and end of a simulation. If the agent chose an action that caused the comparison object to have the same shape as the target object, the agent received a reward of 100. Otherwise, it received a reward of -1. The agent performed the training trials of the experiment in the same manner as our human subjects—it performed 7 blocks of training trials with 26 trials per block. To accurately estimate the agent’s performances during training, the agent was simulated 1000 times.

The results for experimental conditions using linear causal structures are shown in the left graph of Figure 3 (results for other conditions were similar). The horizontal axis plots the block number, and the vertical axis plots the average difference between the number of steps (i.e., actions or button presses) used by the agent or by human subjects during a trial and the optimal number of steps for that trial as computed by the dynamic programming procedure (as in Figure 2; the error bars in Figure 3 indicate the standard deviations). The solid line shows the data for the simulated agent, and the dotted line shows the data for our human subjects. Interestingly, the learning curves of the simulated agent and of the human subjects have similar shapes, though subjects learned faster than the agent at nearly all stages of training in all experimental conditions. Modifications of the agent by either using different values for the agent’s parameters or by adding “eligibility traces” did not significantly alter this basic finding.

Why did subjects show better learning performances than the simulated agent? In the machine learning literature, a distinction is made between model-free versus model-based reinforcement learning agents. The agent described above is an instance of a model-free agent. Although model-free agents are more common in the literature, we hypothesized

Figure 3: Left: Learning curves for the simulated agent trained via Q-learning (solid line) and for the human subjects (dotted line) in experimental conditions using linear causal structures (error bars plot standard deviations). Right: Identical to the left graph except that the simulated agent learned a model of how actions influenced the environment, and used this model to reason about good actions to take at each time step.

that a model-based reinforcement learning agent may provide a better account of our subjects' performances. Model-based agents typically learn faster than model-free agents, albeit with greater computational expense. Based on real-world experiences, a model-based agent learns an internal model of how its actions influence the environment. The agent updates its Q-values from both real-world experiences with the environment and from simulated experiences with the model (see Sutton and Barto, 1998, for details).

In our simulations, the model was an artificial neural network. Its six input units corresponded to the six possible actions or key presses (an action variable could either increase or decrease in value, and there were three action variables). Its nine output units corresponded to the nine possible influences on the comparison objects' shape parameters (a shape parameter could either increase in value, decrease in value, or maintain the same value, and there were three shape parameters). The network did not contain any hidden units.

When updating its Q-values, the model-based agent used 'prioritized sweeping' (Moore & Atkeson, 1993). This is an efficient method for focusing Q-value updates to state-action pairs associated with large changes in expected reward. Large changes occur, for example, when the current state is a non-goal state and the agent discovers a previously unfamiliar action that leads to a goal state. Large changes also occur when the current state is a non-goal state, and the agent discovers a new action that leads to a new non-goal state known to lie on a path toward a goal state.

In brief, our simulations used prioritized sweeping as follows. At each moment in time, the model-based agent maintained a queue of state-action pairs whose Q-values would change based on either real or simulated experiences. For each update based on a real experience, there were up to N updates based on simulated experiences. The items on the

queue were prioritized by the absolute amount that their Q-values would be modified. For example, suppose that at some moment in time, state-action pair (s^*, a^*) had the highest priority. Then $Q(s^*, a^*)$ would be updated. If performing this update on the basis of simulated experience, the agent used the model to predict the resulting new state. In addition, the agent also used the model to examine changes to the Q-values for all state-action pairs predicted to lead to state s^* , known as predecessor state-action pairs. These predecessor state-action pairs were added to the queue, along with their corresponding priorities.

The simulations with the model-based agent were identical to those with the model-free agent. However, the model-based agent used different parameter values. Its discount rate γ was set to 0.3, its learning rate α was set to 0.05, and N , the number of Q-value updates based on simulated experiences for each update based on a real experience, was set to 5. In preliminary simulations, these values were found to be best in the sense that they led to performances that most closely matched human performances.

The combined results for the experimental conditions using linear causal structures are shown in the right graph of Figure 3 (once again, results for the other experimental conditions were similar). The learning curves of the model-based agent are more similar to those of human subjects than the curves of the model-free agent. Indeed, the curves of the model-based agent and of the human subjects are nearly identical. Our findings suggest (but do not prove) that subjects may have achieved near-optimal performances on the perceptual matching task by building internal models of how their actions influenced the external environment. By using these models to reason about possible action sequences, subjects quickly learned to perform the task.

Conclusions

Sequential decision-making tasks are commonplace in our everyday lives. Here, we studied whether people were successful at learning to perform a perceptual matching task, an instance of a sequential decision-making task. We used two benchmarks to evaluate the quality of subjects' learning. One benchmark was based on optimal performance as defined by a dynamic programming procedure. The other was based on an adaptive computational agent that used Q-learning to learn to perform the task. Overall, our analyses suggest that subjects learned to perform the perceptual matching task in a near-optimal manner. When doing so, subjects learned, at least partially, the causal structure underlying the task. In addition, subjects' learning curves were broadly consistent with those of model-based reinforcement-learning agents that built and used internal models of how their actions influenced the external environment.

The cognitive science literature now contains several studies of human performance on sequential decision-making tasks. Some studies have suggested that human performance is optimal, whereas other studies have suggested the opposite. To date, our field does not have a good understanding of the factors influencing whether people will achieve optimal performance on a task. Future research will need to focus on this critical issue. Previous articles in the literature suggested that perceptual aliasing (Stankiewicz et al., 2006) or the existence of actions leading to large rewards in the short-term but not the long-term (Neth, Sims, & Gray, 2006; Gureckis & Love, 2009) seem to be factors leading to sub-optimal performance. Here, we propose a new understanding of when people will (or will not) achieve optimal performance. We hypothesize that people will achieve near-optimal performance on sequential-decision making tasks when they can detect the effects of their actions on the environment, and when they can represent and reason about these effects using an internal mental model.

Abstract

Perceptual aliasing arises in situations where multiple, distinct states of the world give rise to the same percept. In this study, we examine how the degree of perceptual aliasing in a task impacts the ability of human agents to learn reward-maximizing decision strategies. Previous work has shown that the presence of perceptual cues that help signal distinct states of the environment can improve the ability of learners to adopt an optimal decision strategy in sequential decision making tasks (Gureckis & Love, 2009). In our experiments, we parametrically manipulated the *degree* of perceptual aliasing afforded by certain perceptual cues in a similar task. Our empirical results and simulations show how the ability of the learner improves as relevant states in the world uniquely map to differentiated percepts. The results provide further support for the model of sequential decision making proposed by Gureckis & Love (2009) and highlight the important role that state representations may have on behavior in dynamic decision making and learning tasks. **Keywords:** perceptual aliasing, dynamic decision making, reinforcement learning

Introduction

A crucial problem facing both human and artificial learners is correctly perceiving and interpreting the current state of the environment. For instance, imagine a traveler staying in an unfamiliar hotel, with each floor and exit decorated identically. Based on perceptual cues alone, this guest may experience difficulty navigating towards his room, since each floor is effectively indistinguishable. In order for navigation to be successful, the traveler must overcome the problem of *perceptual aliasing*, in which relevant “states” or situations in the world map to a single percept (Whitehead & Ballard, 1991; McCallum, 1993). In this example, that current state is the location of the traveler in the building, and the percept is the various cues available that might indicate this location. Note that environments may be aliased along a continuum from the perspective of any individual. For example, suppose that only every other floor in the building is decorated identically. In this case, the guest will be able to differentiate at least half the floors, and his ability to navigate might be somewhat improved. This example can be extended to cases where each floor of the hotel is uniquely decorated, such that salient perceptual cues indicate the traveler’s location at

any moment. Across these cases, the decision-making ability of the learner is expected to improve as the potential confusion is reduced, and relevant states in the world become mapped to differentiated percepts.

In this paper, we examine how the degree of perceptual aliasing in a task environment impacts the ability of humans to learn effective decision strategies in a dynamic task environment. A growing body of work suggests that human trial-and-error learning shares a similar computational foundation with algorithms developed in the reinforcement learning (RL) literature (see Dayan & Daw, 2008 for a review). However, less work has examined how the identification and categorization of distinct task states might interact with these learning and decision-making processes to determine human performance.

Previous Work

Our work builds upon previous studies of behavior in the “Farming on Mars” task (Gureckis & Love, 2009b, 2009a; Otto, Gureckis, Love, & Markman, 2009). In this task, participants make repeated selections between two “robots” presented on a computer screen. Selection of each robot results in a certain number of “oxygen” points. Participants’ goal is to maximize the total amount of oxygen generated over the entire experiment. One robot (the “Short-term” option) always returns more points than the other (the “Long-term” option). However, unknown to participants at the start of the task, the experienced reward structure (i.e., payoff for selecting either robot) continually changes in response to the recent choice history of the participant. In particular, a dynamic is set up so that when the immediately attractive alternative is selected (i.e., the Short-term option), the long-term expected value of both robots is generally lowered on the following trial (Figure 1 illustrates the payout function used in previous Farming on Mars task experiments). Conversely, selections of the immediately worse option (the Long-term option) cause the expected value of both options to increase (in particular, the payoff for each option depends on the number of selections of the Long-term option over the last nine trials). As a result, the optimal reward-harvesting strategy is to learn to choose the option that

Figure 1: Illustrative payout function of the Farming on Mars Task. The horizontal axis in the figure represents the number of selections out of the last nine in which the Long-Term robot was chosen. The upper diagonal line measures the reward earned from choosing the Short-Term robot as a function of recent choice history, while the lower line illustrates the reward produced from Long-Term selections.

appears worse on each individual trial, since this strategy leads to the greatest cumulative reward.

Critically, performance in the task requires an appropriate balance of *exploration* (in order to discover the hidden contingencies) as well as *exploitation* of choice options known to be rewarding. In addition, a key observation about this task is that there are multiple distinct “states” of the environment (which correspond to the number of Long-term robot selections over the previous trials). When participants fail to recognize this structure, and the fact that the state of the system is changing as a function of their past response history, it becomes difficult to learn the reward-maximizing strategy. Consistent with this, Gureckis & Love (2009a,b) found that providing participants with simple perceptual cues that readily aligned with the state structure of the task improved their ability to learn the reward maximizing strategy. In their experiment, participants’ display screen was augmented with a horizontal row of ten indicator lights which served as a cue indicative of the current state of the system. Participants who were given cues that correlated with the underlying task state performed better than participants attempting to learn without these cues. Further, results revealed that cues which supported generalization from one situation to the next had a more beneficial effect on performance relative to cues that effectively limited such generalization (see also Otto, et al., 2009). Gureckis & Love suggested that associating separate perceptual cues with each task “state” could reduce perceptual aliasing and facilitate more effective learning in the same way that appropriate state representations help artificial learning agents based on Q-learning (Sutton & Barto, 1998; Watkins, 1989).

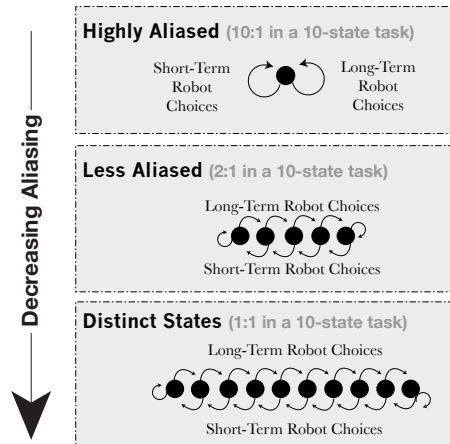

Figure 2: Degrees of perceptual aliasing. At the top is an example of a highly aliased environment where multiple distinct states maps onto a single percept (many-to-one). At the other extreme, distinct perceptual information disambiguates all states (one-to-one). Intermediate levels maps a subset of states to a single percept.

The Present Studies

The present studies were designed to test a key prediction of Gureckis & Love’s RL model. As anticipated by our example of the traveler in an unfamiliar hotel, the perceptual aliasing of states in the environment to distinct percepts can vary along a continuum (see Figure 2). At one extreme, every state in the world could map to the same percept (a many-to-one relationship). At the other extreme, each state in the world could map to a distinct percept (a one-to-one relationship). Intermediate cases exist where only a subset of distinct environmental states are perceptually aliased. One possibility is that any time distinct states are poorly differentiated, performance in situations such as the Farming on Mars task should suffer. Alternatively, it is possible that learners may still be able to acquire effective decision strategies when the representation of the task suggested by perceptual cues and the true structure of the task misalign, given that this misalignment takes a particular form. In other words, learners may not need to have a completely accurate representation of the task environment in order to still acquire a near-optimal reward-maximizing strategy. Indeed, this latter hypothesis is what is predicted by Gureckis & Love’s RL model which can still find optimal policies in some cases given misleading or inaccurate cues about the structure of the task. In the following experiments, we explore how various types of misalignment between perceptual information and task state information influences human learning. In particular, we are interested in how misalignments between perception of the world and the actual structure of contingencies influence learning and exploration behavior. Understanding the nature of this process is important since it is unlikely that human learners have completely accurate informa-

tion about the state structure of the environment at all times.

Experiment 1

In Experiment 1, each subject was randomly assigned to one of four conditions in the Farming on Mars task. Participants in each condition were given different types of perceptual cues which suggested a different interpretation of the nature of the task. Besides the type of cues displayed, each condition was identical with respect to the payoff function and task dynamics. The overall manipulation (providing different types of perceptual cues to learners in the task) parallels the approach in Gureckis & Love (2009).

In one condition (the *no-cue* condition), participants were given no additional cues as part of the display, and thus had to rely on memory and non-perceptual cues in order to uncover the optimal task strategy (c.f., Bogacz, McClure, Li, Cohen, & Montague, 2007). In the second condition (the *two-cue* condition), the interface screen was augmented with a simple cue consisting of two lights. At any point in time, only one of these lights was active, and a shift between the two cues indicated a change in the underlying task system. The position of the activated light was determined by the number of times the Long-term robot was selected over the previous nine trials of the experiment (this condition reflects a many-to-one situation with 5 states mapping to each percept). In the third condition (the *five-cue* condition), a circle of five lights (see Figure 3) was presented on the interface. The indicator lights were organized in a consistent array along the circle, such that the active light moved one position either clockwise or counterclockwise as the task state was updated. The five lights were mapped onto the underlying task system using a “modulus” rule, resulting in two distinct task states mapping to each percept. In the final condition, a display of ten lights was employed, such that each light corresponded exactly to a distinct numerical state in the underlying task system (one-to-one mapping).

Consistent with Gureckis & Love (2009a), we predicted that providing participants with light cue arrays which readily align with the underlying state of the system will limit the aliasing of functionally distinct states, and improve subjects’ ability to learn the reward maximizing strategy. Thus, we predict that conditions where perceptual cues limit this aliasing (i.e., the ten-state condition) will result in better overall performance. In addition, we expect that participants’ induced representation of the task will strongly influence the strategies they use to balance exploration and exploitation in the task.

Methods

Participants One hundred and ninety-two New York University undergraduates participated for course credit and a small cash bonus based on task performance. A

Figure 3: Example of the task interface used in the experiment. The display shows the indicator lights used in the five-cue condition. Additionally, the screen illustrates how rewards were conveyed to participants.

total of 12 participants were dropped from the analysis for responding with the same button on more than 95% of the trials. The remaining participants were randomly assigned to one of four conditions: the *no-cue* condition ($N = 44$), the *two-cue* condition ($N = 45$), the *five-cue* condition ($N = 45$), and the *ten-cue* condition ($N = 46$).

Materials and design The experiment was administered on standard Macintosh computers using an in-house data collection system written in Python¹. Participants were tested individually over a single one-hour session. Extraneous display variables, such as which robot corresponded to the left or right choice option, the position of the lights, and which direction the active light moved (clockwise or counter-clockwise), were counterbalanced across participants. On each trial, the payoff for selecting the Long-term robot was $40 + 70 \cdot h / 9$, where h is the number of times the Long-term robot was selected in the last 9 trials. In contrast, the payoff on each trial for the Short-term robot was $30 + 70 \cdot h / 9$. The final values were scaled by 110 and displayed as a percentage on the sliding oxygen meter.

Procedure Participants were tested in the basic Farming on Mars task as described above. At the beginning of the experiment, subjects were presented instructions on the screen which conveyed the basic cover story for the task. The instructions were identical for all conditions, and there was no explicit reference to the function or purpose of the indicator lights/cues. On each trial, participants were shown a display with two large response buttons. Between these buttons was a video display which presented trial-relevant feedback. After a robot selection was made, the quantity of oxygen produced for that trial was presented on the video display. The amount of oxygen points earned was presented visually with a vertical, sliding bar which filled green to

¹<http://www.pyspyexp.org>

varying levels. The oxygen level display was shown for 800 ms, after which the screen was reset to indicate the start of a new trial. No information regarding cumulative oxygen generation was presented, but instructions did emphasize that participants should try to “maximize the number of oxygen points generated over the entire experiment.” In the two-light, five-light, and ten-light conditions (but not in the no-cue condition), the screen was augmented with an array of indicator lights as described above and shown in Figure 3. The experiment consisted of 500 separate trials divided into five blocks of 100 trials. In order to maintain motivation, participants were informed that they would receive a small cash bonus of \$2-5 dollars based on total oxygen generated by the end of the task.

Results

The primary dependent measure in our experiment was the proportion of Long-term robot selections (i.e., reward-maximizing responses) made by the participant. Total mean proportions by condition are presented in Figure 4. Overall, the proportion of Long-term choices were significantly higher than chance in all conditions, except for the five-cue condition (all $p < .05$). Given the binary outcome choice data, we conducted a series of binomial regressions using the χ^2 distributed deviance-based test as our measure of model selection². There was an overall significant effect of condition $\chi^2(3) = 15.6$, $p = .001$. In addition, the pattern of results across conditions was best predicted as a quadratic function of the number of perceptually distinct task states compared to a linear relationship ($\chi^2(1) = 11.32$, $p < .001$, the quadratic term was reliably above zero, $\beta_{cond^2} = .02$, $p < .001$). Pairwise contrasts (using an Bonferroni-adjusted $\alpha = .05/4 = .0125$) between the individual conditions revealed a significantly higher proportion of maximizing responses in the ten-cue condition compared to both the five-cue condition, $\chi^2(1) = 13.46$, $p < .001$, and the two-cue condition, $\chi^2(1) = 11.62$, $p < .001$. Surprisingly, there was a relatively small difference between the ten-cue and no-cue conditions which did not reach significance, $\chi^2(1) = 3.59$, $p = .06$. Note, however, that in a similar task, Gureckis & Love (2009b) and Otto, et al. (2009) found an advantage for one-to-one percept-state representations. Also, note that when given only two state cues, performance was not significantly better than when participants are given five state cues, $\chi^2(1) = 1.04$, $p = .3$.

In order to better understand the genesis of the aliasing effect, we examined the *dynamics* of exploration in the task. In particular, even if the marginal proportion of maximizing choices is constant, it is possible that the distribution of those choices in time could vary. For

example, participants in the different conditions might adopt alternative strategies for exploring the task. One way to quantify these differences is to plot the percentage of total trials participants spent in each true (latent) state in the task. Remember that “states” in this dynamic task are defined by the percent allocation of choices to the Long-term option over the last nine trials. Figure 1 plots this distribution for each of the four conditions. Interestingly, the structure of the cues in the task has a strong impact on the way participants explored the task dynamic. In particular, participants in the two-cue condition spent a much larger percentage of time in intermediate states (indicated roughly equal allocation to both choices for extended periods of time). For example, a one-way ANOVA on proportion of time spent in states 3-7 revealed an effect of condition, $F(3, 132) = 4.57$, $p < .005$. Specifically, participants in the two-cue condition spent more total time in these intermediate states than in the no-cue, $t(64) = 2.95$, $p < .005$, five-cue, $t(66) = 2.31$, $p < .02$, and ten-cue, $t(66) = 3.43$, $p = .001$, conditions (since these are post-hoc analyses significance should be interpreted using a conservative $\alpha = .05/3 = .016$). On the other hand, there was also a significant effect of condition on how long participants spend in the end point states (i.e., state 1 & 2 and 9 & 10), $F(3, 132) = 3.25$, $p < .025$. Post-hoc test revealed this was driven primarily by the lower percentage of total time spent in these states in the two-cue condition compared to the 10-cue condition, $t(66) = 3.17$, $p < .003$.

Discussion

The results of Experiment 1 show that participant’s conceptualization of the state structure of the task can influence both their exploration strategies as well as their ability to identify a reward maximizing strategy. In particular, when cues about the underlying state of the states were more highly aliased (the two-cue and five-cue conditions) participant’s overall task performance suffered. Closer examination of the way in which participants explored the task revealed that the alignment of the cues in the task had a dramatic effect on behavior, even when overall performance differences appeared smaller. In particular, relative to the other conditions, participants in the two-cue condition spent a considerably longer time in intermediate states, consistent with a choice strategy involving alternations between the short-term and long-term options.

Experiment 2

In Experiment 1 we found that reward-maximizing performance was worst when a circle of five indicator lights was presented on the interface, such that two different task states mapped to the same perceptual display. However, it is as yet unclear if the performance difference for highly aliased environments results from the num-

²We also analyzed these data through a one-way ANOVA and a series of t-tests which revealed an identical pattern of significant results.

Figure 4: *Panel A*: Average proportion of Long-Term (maximizing) responses made throughout the experiment as a function of condition. The horizontal line at 0.5 shows chance performance. Error bars are standard errors of the mean. *Panel B*: Average percentage of total experiment spent in each state. State 1 corresponds to 0 of the last nine choices being to the Long-term option. State 10 corresponds to 9 of the last 9 choices being to the Long-term option.

ber of implied states (5) or how those states “blend together” by the dynamics of the focal cue (i.e., the active light). For example, in the *five-cue* condition of Experiment 1, the active cue moved one position either to the left or right as the state of the underlying system was updated. Thus, a participant who steadily progressed from states 1-10 would experience the active light looping twice around the circle of indicator lights. An alternative display which maintains the same level of perceptual aliasing (two true states for every one distinct percept) would be to have the active light remain in the same position across two consecutive state updates. In this design, a participant who steadily progressed from states 1-10 would observe the active light making a single loop around the five indicator lights, ‘doubling-up’ at each individual light position. In other words, if the letter A-E represent the five locations for the state cue, then the mapping from the 10 latent task states to the display would be 1,2,3,4,5,6,7,8,9,10→A,A,B,B,C,C,D,D,E,E. In Experiment 2, we compare task performance in this *single-looped* condition with performance in the *twice-looped* condition (which is identical to the ‘five-cue’ condition of Experiment 1).

Our prediction was that performance in the twice-looped condition would be lower than in the single-looped condition. The rationale was that participants in the single-looped condition would be better able to recognize that the “gradient” of reward was rising as the light moved in a particular direction. In contrast, the twice-looped condition would be more likely to be confused as a state that they had previously experienced to have low reward (e.g., state cue position A) might later also be associated with high reward. The prediction that

the perception of a correlation between the movement of the light and the magnitude of the reward is supported by previous studies showing that participants use such information even when it is against their best interest in the task (Otto et al., 2009).

Methods

Participants Forty New York University undergraduates participated for course credit and a small cash bonus based on task performance. Participants were randomly assigned to either the *twice-looped* condition ($N=21$) or the *single-looped* condition ($N=19$).

Materials and design All aspect of the materials and design were identical to Experiment 1, except for the changes to the five-cue display described above.

Procedure The general procedure was the same as in Experiment 1.

Results

As before, the primary dependent measure in our experiment was the proportion of Long-term robot selections (i.e., reward-maximizing responses) made by the participant. However, there was no overall effect of condition $\chi^2(1) = 0.26$, $p = .61$, $M=0.52$ in the twice-looped condition and $M=0.54$ in the single-looped condition. Closer examination of the distribution of overall performance scores indicated that the distribution was strongly bimodal in the twice-looped condition, while it was uni-modal in the single-looped condition. As shown in Figure 5, this bi-modality arose from the way that participants explored the latent task states. In particular, a 2-way repeated measures ANOVA on condition

and time spent in each state found a significant effect of state, $F(9, 342) = 4.12$, $p < .001$, and a significant state by condition interaction, $F(9, 342) = 3.17$, $p < .001$. At least a subset of participants in the twice-looped condition appeared to have spent a disproportion amount of time in state 6 which is the point where the display looped back on itself suggesting that they were attempting to keep the state cue from crossing back around to the state associated with the lowest reward. In contrast, participants in the single-looped condition spent more time in the lower states (1-4) indicating that they had an overall bias towards the short-term option that a subset of participants eventually overcame.

General Discussion

Across a set of two experiments we explored how perceptual cues concerning the underlying state structure of a dynamic decision making task influenced learning. Consistent with previous work (Gureckis & Love, 2009b, 2009a), we find that when task states are aliased, participants' ability to identify an optimal task strategy is impaired. It is important to point out that the effects we see here are unlikely to be a simple consequence of participants ignoring the primary task (to earn oxygen points) and instead exploring aspects of the display. First, participants were clearly instructed that the primary goal was to control the system to earn as many points as possible. In addition, participants were paid a small cash bonus tied to their performance in the task which increased the relevance of the primary task. Finally, our analysis of the dynamics of exploration (i.e., the percent of time spent in each state) reveal systematic differences related to the structure of the cues we provided.

One possibility is that the structure of the perceptual cues provide a kind of strategy "affordance" in the task, limiting the space of exploration/response policies that participants considered. Note that in a separate study, we recently found that motivational manipulations can also impact participant's exploration behavior in a similar task (Otto, Markman, Gureckis, & Love, in review). A theoretical analysis of these results and evaluation of their implication for the Gureckis & Love (2009) model are currently underway. However, preliminary simulations show a close correspondence between the results reported here and the behavior of the model. Future work will continue to evaluate how RL models can be used to understand the motivational and cognitive influences underlying dynamic decision-making.

Abstract

The control of attention and the control of movement in space share a similar optimal control structure—mediating the trade-off between exploiting one locale and exploring others. A common spatial foraging strategy observed in many species is area-restricted search, in which animals respond to resources or their absence by moving between local and global search strategies, respectively. When resources are clustered, area-restricted search can represent an optimal foraging strategy. Surprisingly few studies have investigated whether humans display such behavior in the context of spatial navigation. Here we present two experiments in which human participants search for resources distributed over a large virtual environment. By systematically manipulating the specific distribution of the resources the first experiment investigates human's ability to perform area-restricted search. The second experiment probes for the patch-leaving rules humans apply when facing resources distributed in patches that differ in quality. Our results indicate that humans forage in space using an area-restricted search, but do so in a non-optimal way—consistent with other studies showing non-optimal search strategies in memory.

Keywords: Foraging; area-restricted search; navigation.

Introduction

Picking bananas from banana trees, searching for nebulas in the night sky, and hunting for schools of tuna in the open ocean all involve the ability to detect and respond to spatial resource distributions. Since the foundations of animal foraging behavior were laid by MacArthur and Pianka (1966) and Emlen (1966) decades of research have shown that non-human animals respond adaptively to these spatial resource distributions; moreover, their responses are often optimal with respect to long-term rate maximizing models (reviewed in Stephens & Krebs, 1987). For humans, these models have been shown to predict patterns of search in information foraging on the internet (Pirulli & Card, 1999), the foraging strategies of hunter-gatherer societies (e.g., Hawkes, Hill, & O'Connell, 1982), and the search patterns of humans in their own memory (Hills, Todd, & Jones,

2009; Hills, Todd, & Goldstone, 2008). However, surprisingly, almost nothing is known about how humans search in 3-dimensional environments like those described for the bananas, nebulas, and tuna (but cf. Smith, 1983, for an overview of anthropological research).

How *do* humans forage in space? Are they capable of detecting and localizing resources in space, with or without the help of visual cues? Moreover, are their foraging strategies adaptive, or near optimal in terms of rate maximization? In this article, we use 3-dimensional virtual representations of fields and orchards to investigate how people forage in open environments, and in particular, whether or not they show patterns consistent with area-restricted search.

Area-restricted search (ARS) is one of the most well-studied behavioral patterns in animal foraging, and has been observed in a wide variety of animals (e.g., Hills, Brockie, & Maricq, 2004; Krebs, 1973; Smith, 1974). It can also produce patterns of movement that look like Levy walks—another commonly observed foraging pattern (Benhamou, 2007). ARS involves high turning angles following resource encounters but lower turning angles elsewhere. It indicates an adaptive response to spatial distributions in clustered (or patched) environments because in clustered environments - when prior knowledge about resource locations is limited to the time since they were last encountered - ARS is optimal (Walsh, 1996; Grunbaum, 1999). ARS, like an annealing strategy, localizes animals where resources are most dense (Karieva & Odell, 1987). The success of this strategy and its minimal information requirement are consistent with the evidence that ARS had an early evolutionary origin amongst mobile animals. Moreover, the evolution of this strategy may have provided the biological building blocks for the subsequent evolution of human attention (proposed in Hills, 2006).

If humans respond to clustered resources with increased turning, but don't do so when resources are uniformly or dispersedly distributed, they are showing foraging patterns consistent with ARS. However, evidence for ARS in human

spatial foraging requires more than simply noting that humans respond to clustered resources with more turning. A number of potentially viable foraging heuristics are consistent with ARS at a gross level, but fail to meet its more strict definition of *turning mediated by decaying memories of resources*. These alternate hypotheses include the fixed-number rule and the fixed-time rule (see Stephens & Krebs, 1987).

For the *fixed-number rule*, the forager collects roughly the same amount of items in every patch regardless of the time to achieve this goal: $n_1 \approx n_2 \approx n_i$. If participants used a fixed-number-rule, they would yield insignificant differences in gathered items across patches. Additionally, re-visited (and therefore emptier) patches should receive significantly more time than during first encounter.

The *fixed-time rule* states that a foraging organism will devote roughly the same time to all patches it visits: $t_1 \approx t_2 \approx t_i$. If humans used a fixed-time-rule, there should be no significant differences in patch visit times, regardless of patch quality. Additionally, re-visited (and therefore emptier) patches should receive the same attention than during first encounter.

Like the fixed-time rule, ARS uses temporal cues to determine patch departures. However, ARS adds time to the total patch residence time by incrementing the time in the patch (by turning) following each resource encounter. If a certain temporal threshold without resources is exceeded, the patch is abandoned. As Iwasa, Higashi and Yamamura (1981) mention, this heuristic—sometimes called the *incremental rule* or *Green's assessment rule* (Green, 1984)—is highly appropriate among variable patch sizes. Several studies have indicated that humans use this kind of incremental strategy when foraging in a lexical problem space (Payne, Duggan & Neth, 2007; Wilke, Todd, & Hutchinson, 2009).

In the present study we investigate human spatial foraging in a 3-dimensional environment by first asking if participants show behavior consistent with area-restricted search in clustered resource distributions (versus uniform distributions). Second, we ask if humans can detect the difference between high and low quality patches, and if so, do they respond using one of the foraging heuristics described above. That is, are their foraging patterns most consistent with an incremental rule, or are they more likely to be fixed-time or fixed-number rules?

Experiment I

Experiment 1 investigated whether human foragers are sensitive to the distribution of resources in the environment displaying a foraging pattern consistent with area-restricted search (ARS). In the experiment, participants were placed in large virtual environments that contained resource items. These were either uniformly distributed about the entire space or organized in patches. Participants could not see the items prior to encountering them; there were no visual cues to help them harvest resources. Participants had to actively

navigate through the environment, searching for resource items.

Method

Environments A circular virtual environment with a radius of 110m was constructed. The environment consisted of a textured ground plane resembling a large meadow and was surrounded by a fence. Three large landmarks (mountain, city skyline, and skyscraper) surrounded the environment providing global direction cues (see Figure 1).

Fig. 1: Participants' perspective during the task. One of the global landmarks (mountain) is visible in the distance.

1440 individual resource items (mushrooms, modeled as 3d objects) were then either evenly distributed about the environment (*dispersed condition*) or they were arranged in 24 patches that were randomly scattered about the environment (*patched condition*; see Figure 2). Each patch had a radius of 8.65 m and contained 60 resource items. The minimal distance between any two resource items in the patched environments was 1.53m, in the distributed world it was 2.35m. For each type of resource distribution (dispersed or patched) five different environments that differed in the specific arrangement of the resource items were created. The resource items in both conditions were visible only from close proximity – i.e. from a distance smaller than 1.25m – similar to real mushrooms in long grass.

Fig. 2: The two types of resource distributions: left: one of five 'dispersed' environments; right: one out of five 'patched' environments.

Participants navigated through the environments in the first person perspective using the arrow keys of the

keyboard. Translation speed was set to 4m/s and turning velocity was set to 75°/s. The motion model allowed for either forward translations or rotations but did not allow combining translations and rotations. Thus, the resulting trajectories resembled segmented paths (see Figure 4). Participants collected resource items simply by moving closer than .75m to an item. This pick-up distance was just below half of the minimal distance between any two resource items and therefore assured that participants gathered only one item at any time. The collection of a resource item was signaled by an auditory cue. Once an item had been collected it was removed from the environment.

Participants Thirty-two participants (17 women) aged 19 to 28 ($M = 22.28$, $SD = 2.41$) took part in the experiment. They were mainly students from Freiburg University and received course credits or monetary compensation for their participation.

Procedure Participants were randomly assigned to either the dispersed or the patched condition (counterbalanced for gender) and were then briefed about the experiment: Their task was to navigate through the environment and to collect resource items. Each participant was given 5 trials. Each trial was carried out in a different environment with the same type of resource distribution (dispersed or patched). At the beginning of each trial, participants were placed in the center of the environment. A single trial was terminated either after 600 seconds or when participants collected 90 resource items. The experiment ended after participants completed all 5 trials. Participants were offered a fixed compensation, independent of the time required to do the experiment. Thus, they were motivated to finish as quickly as possible and the usual (biological) energy cost variable was transformed into a temporal equivalent.

Results

Search time A two-way mixed ANOVA (factors: trial, condition; sphericity assumed: $\chi^2(9) = 14.015$, $p = .122$) reveals a main effect for trials: $F(4, 120) = 4.703$, $p < .01$, $\text{partial-}\eta^2 = .136$ which is due to significant differences between trials one and three, and one and five (both Sidak-corrected p 's $< .05$). Even though completion time was higher for the patched versions ($M = 442.63$, $SE = 12.94$ vs. dispersed: $M = 422.95$, $SE = 12.94$) there is no main effect of condition ($F(1, 30) = 1.158$, $p = .291$, $\text{partial-}\eta^2 = .037$), as well as no significant interaction between trials and condition: $F(4, 120) < 1$ (see Figure 3).

Search time results did not demonstrate a significant difference between experimental conditions (patched vs. dispersed condition). The reduction in search time over trials, however, indicates an adaptation of search strategy (see Figure 4) leading to a higher rate of item encounter.

An alternative explanation is that participants learned to control their movements more effectively as the experiment progressed.

Fig. 3: Mean search time for each trial in the two conditions. Error bars depict one SE.

Fig. 4: Example trajectories in the dispersed (left) and the patched condition (right).

Turning rate As argued above, an increase in overall turning rate in environments with clustered resources as compared to environments with evenly distributed resources indicates an adaptive response to spatial distributions. This would be perfectly consistent with area-restricted search. Figure 5 shows the average total turning angles per second.

Fig. 5: Average turning angle per second for the two conditions. Error bars depict one SE.

A two-way mixed ANOVA (factors: trial, condition; due to violation of sphericity [$\chi^2(9) = 52.293$, $p < .001$, $\epsilon = .589$] the Huynh-Feldt correction for degrees of freedom was used) demonstrates both, a main effect of trials ($F(2.356, 70.675) = 6.353$, $p < .01$, $\text{partial-}\eta^2 = .175$) as well as a main effect of condition ($F(1, 30) = 5.143$, $p < .05$, $\text{partial-}\eta^2 = .146$). Specifically, total turning angle per second in the

patched condition was higher than in the dispersed condition (patched: $M = 8.59^\circ$, $SE = .91$; dispersed: $M = 5.67^\circ$, $SE = .91$), demonstrating an adaptive response to the specific distribution of resources. The interaction of trial and condition did not yield a significant effect: $F(4, 120) < 1$.

Trajectories and turn rate after item encounter Visual inspection of the trajectories corroborates the latter analysis that demonstrates that participants search behavior differed in the patched and the dispersed condition (cf. Figure 4). These findings, however, do not necessarily demonstrate area restricted search, which specifically involves an increase in turning angle after resource encounter.

Fig. 6: Turning angle as a function of time after item encounter. Error bars represent one SE.

Figure 6 shows the effect on turning immediately after encountering a resource item. Note that in order to capture items, participants must be moving forward in a straight line. Therefore, turning angle at time of capture will always be zero. Participants in the patched condition are clearly turning more sharply following a resource encounter, as demonstrated by a mixed-model ANOVA (within-participant factor: time after item encounter; between-participant factor: condition). Due to violation of the sphericity assumption ($\chi^2(44) = 270.664$, $p < .001$, $\epsilon = .327$) the Huynh-Feldt correction for degrees of freedom was used. The interaction of time and condition is significant ($F(2.943, 88.283) = 3.616$, $p < .05$, $\text{partial-}\eta^2 = .108$), because turning angles at time bins '3', '4', and '5' differed significantly (all Sidak-corrected p 's $< .05$). This also resulted in a main effect of condition: $F(1, 30) = 4.403$, $p < .05$, $\text{partial-}\eta^2 = .128$.

Discussion

How *do* humans forage in space? Do they detect resources in the environment and adapt their search behavior when facing different distributions of resources? Experiment 1 demonstrated that participants increased their turning rate and turned more sharply after resource encounters in environments in which resources were patched. These results are consistent with area-restricted search and suggest that human foragers adapted their search strategy according to the specific distribution of resources in the environment. People do search differently when faced with different

spatial distributions of resources; moreover, they show more evidence of area-restricted search in environments where such a search strategy is optimal.

Experiment II

Results from Experiment 1 suggest that human foragers, when searching for resources in a spatial context, are sensitive to the distribution of the resources. However, in Experiment 1 all resource patches featured the same amount of items, i.e. the quality of all patches was identical. Experiment 2 was designed to investigate how human foragers interact with resource patches that differ in quality, but that are visually identified by the presence of a tree. Can they tell a good from a bad patch? And, given that foragers have a priori knowledge about the distance to the next patch (by the distribution of trees), how do they determine when to leave a patch in order to harvest at another patch? Also, this experiment allowed to more directly test for area-restricted search in comparison with the other patch leaving rules outlined in the introduction.

Method

Environment The same circular virtual environment as in Experiment 1 was used. In addition, 19 trees, arranged on a hexagonal grid (see Figure 7), were planted in the virtual environment. Resource items were distributed under the trees in patches with a radius of 8 meters. The hexagonal arrangement of the trees (patches) ensured that for each patch the distances to all neighboring patches were identical. Each patch featured either 15 (*poor patches*) or 30 (*rich patches*) resource items.

Fig. 7: Left: overview of the environment and the 19 patches (9 poor and 10 rich); right: participants' view while navigating.

As in Experiment 1, participants navigated through the environment (see Figure 7) using the arrow keys of the keyboard. They could not see resource items from the distance, but only in close proximity (viewing distance: 1m). In order to increase the costs associated with moving from one patch to another, translation speed was reduced to 2m/s. Thus, moving from one tree to a neighboring tree took 25 seconds.

Participants Thirty-two participants (16 women) aged 14 to 30 ($M = 23.06$, $SD = 3.37$) took part in the experiment. They were mainly students from Freiburg University and received course credits or monetary compensation for their

participation. None of the participants took part in Experiment 1.

Procedure Participants were first briefed about the experiment: Their task was to navigate through the environment and to collect a total of 125 resource items. Participants were also told that resource items were to be found in the vicinity of the trees: The instruction mentioned a certain type of mushroom that only grows under and in the close vicinity of trees, but never further away. Participants were unaware that the patch quality differed between patches. At the beginning of the experiment, participants were placed in the center of the environment. The experiment was terminated after participants collected the last of the 125 resource items required. As in Experiment 1, participants were motivated by being assured that they would receive a fixed compensation for their participation, independent of the time required to solve the task. For the purposes of patch leaving rule analyses, the first and the last patch participants visited were discarded from the analyses.

Results

Patches visited On average, participants visited 18.84 (SD = 10.02) patches (including re-visits). The minimum number of patches visited was seven the maximum 45 visits (see Figure 8).

Fig. 8: Trajectories in the actual environment for the minimum (left) and maximum (right) amount of visited patches.

Time On average, participants needed 1804.87 (SD = 347.81) seconds to complete the experiment. Participants considerably differed with respect to the time needed to complete the experiment (range = 1161). Given the time required to move between patches (25 seconds), time to complete the experiment strongly correlated with the number of patches visited ($r(32) = .55$, $p < .001$).

Time spent in patches As stated above, the fixed-time rule would result in foragers devoting the same amount of time to every patch regardless of its quality. *Time in patch* is calculated as the time difference between the first and the last item encounter within each patch. In order to control for quality of the patch at time of encounter, only the first visit of each patch entered this analysis; revisits were discarded. Participants spent significantly more time – roughly twice as much – in richer patches ($M = 112.25$ sec, $SE = 3.15$) than in smaller patches ($M = 64.57$ sec, $SE = 3.16$; random-factor

ANOVA: $F(1, 34.319) = 63.663$, $p < .001$, partial- $\eta^2 = .65$). This indicates that participants were not using a fixed-time rule when foraging in this environment.

Amount of collected items The fixed-number rule predicts that foragers collect an equal amount of items in every patch, regardless of the time it would take to succeed. Again, in order to control for the patch quality at the time of encounter, only the first visit of each patch entered this analysis; revisits were discarded. Participants collected more than twice as many items in rich patches ($M = 13.71$, $SE = .27$) as compared to poorer patches ($M = 6.06$, $SE = .27$): random-factor ANOVA: $F(1, 32.405) = 95.685$, $p < .001$, partial- $\eta^2 = .747$. This poses strong evidence that participants were not using a fixed-number rule.

Giving-up-densities Giving up density was lower for rich patches ($M = 54.3\%$, $SE = .012$) than for poor patches ($M = 59.6\%$, $SE = .012$; $F(1, 34.552) = 5.99$, $p < .05$, partial- $\eta^2 = .148$). This may indicate that participants are leaving the different patches at different inter-item retrieval times, i.e. they are more patient in rich than in poor patches.

Fig. 9: Mean inter-item retrieval times for the last four item encounters over patch quality. Error bars represent one SE.

To test this, we subjected the time between encounters for the last three items within a patch to a random-factor ANOVA. Results (see Figure 9) show a significant difference between the two patch qualities¹: $F(1, 34.28) = 6.631$, $p < .05$, partial- $\eta^2 = .162$. This is due to the last three inter-item retrieval times being higher in the poorer ($M = 12.94$ sec, $SE = .45$) than in the richer patches ($M = 11.09$ sec., $SE = .39$).

Discussion

In summary, Experiment 2 demonstrates that participants were not using fixed-time or fixed number rules, but were

¹ There is also a main effect for the development of the last three inter-item-retrieval times ($F(2, 71.085) = 3.277$, $p < .05$, partial- $\eta^2 = .144$) which is due to an increase in time towards the last time difference. There is no interaction of the two measures ($F < 1$).

instead using a strategy similar to area-restricted search (i.e., an incremental rule) - staying longer in richer patches and shorter in poorer ones. Given the nature of the patch types (one rich and one poor), this strategy is optimal. However, unlike the optimal foraging strategy predicted by the marginal value theorem (Charnov, 1976), participants do not appear to be leaving patches at equal rates of resource capture.

General Discussion

Our results provide evidence that people are using an evolutionarily old foraging strategy—area-restricted search—when foraging in patchily distributed spatial environments. The same strategy has been observed in a variety of ‘internal’ foraging tasks (e.g., Payne et al., 2007; Hutchinson et al., 2008). Moreover, the same neuromolecular processes facilitate area-restricted search across species as facilitate the control of human attention, suggesting a possible evolutionary origin for human attention (reviewed in Hills, 2006). This is a fascinating possibility because fluid intelligence, working memory, executive control processes, and spatial foraging may all be largely about appropriately mediating a similar kind of trade-off between exploitation and exploration of goal structures and associative relations (e.g., Kane & Engle, 2002). Optimal control of focus is a problem common to many tasks, both internal and external.

Interestingly, while our participants show evidence of utilizing ARS, they do so non-optimally—using different departure rules for different quality patches. This too has been observed in memory search (Young, 2004), and suggests that foraging tasks may provide an important paradigm for understanding the control of attention and the influence of environmental structure on that control.

Acknowledgments

We thank Gavan Wilhite and Inka Hähnlein for their help building the virtual environment, recruiting participants and collecting the data. This work was partially funded by the Volkswagen-Stiftung, and the SFB/TR8 of the German Research Foundation (DFG).

Abstract

In our daily lives we often make quantitative judgments based on multiple pieces of information such as evaluating a student's paper based on form and content. Psychological research suggests that humans rely on several strategies to make multiple-cue judgments. The strategy that is used depends on the structure of the task. In contrast, recent research on learning in judgment tasks suggests that learning is relatively independent of task structure. In a simulation study we investigated how the performance of several learning models is influenced by the structure of the task and the amount of learning experience. We found that a linear additive neuronal network model performed well regardless of task structure and amount of learning. However, with little learning a heuristic model performed similarly well, and with extensive learning, associative learning models caught up with the linear additive model.

Keywords: Learning; multiple-cue judgments; Computational modeling

Multiple-cue Judgments

When judging objects on a continuous criterion such as the quality of a research paper, people often rely on multiple sources of information. For example, the clarity of the writing, the novelty of the research and the methodological precision may be used as important aspects for evaluating a paper. Several models have been developed to describe how humans solve these judgment problems. Traditionally, linear additive models have been employed to capture how humans weigh and integrate information. Social Judgment Theory (SJT; see Doherty and Kurz, 1996; Cooksey, 1996) relied on multiple-linear regression models to capture decision policies and researchers have used this approach successfully to describe judgments in many areas (see Brehmer, 1988). Similarly, Anderson (1981) suggested that humans combine information in a linear additive fashion. However, recently it has been suggested that humans may have multiple cognitive strategies available to make multiple-cue judgments. Juslin, Karlsson, and Olsson (2008) suggested that depending on the structure of the tasks, humans may switch between a rule-based cue abstraction approach and a similarity-based exemplar approach. Similarly, von Helversen and Rieskamp (2008, 2009) suggested the mapping model, a heuristic model for multiple-cue judgments, and showed that the model that was best in describing participants' behavior depended on the task structure. More specifically, they showed that the

mapping model described participants' responses well in tasks that could not be solved by a linear model and where participants had knowledge about the cues' polarity; that is, the sign of the correlation between a cue and the criterion. The exemplar model performed well, in non-linear environments with no prior knowledge about cue polarity, and a linear additive model performed well if the task structure was linear.

Learning in Multiple-cue Judgment Tasks

Although many studies in multiple-cue judgment research rely on extensive learning phases, there have been relatively few attempts to understand and model the learning process. However, the learning process is crucial to understand how people come to make judgments and which cognitive processes they rely on. Particularly, if — as suggested — people rely in their judgment on multiple cognitive processes, this should also be reflected in the learning phase. Additionally, the learning phase itself could play an important role in determining how later judgments are made. Recently, Kelley and Busemeyer (2008) compared how well several models could describe the learning process in various multiple-cue judgment tasks. They compared a rule-based neuronal network model with a delta-learning rule (e.g. Gluck & Bower, 1988), which can be seen as a learning version of a linear additive model with an associative connectionist network model (ALM, Busemeyer, Byun, DeLosh, & McDaniel, 1997; Busemeyer, Myung, & McDaniel, 1993). They found that the rule-based neuronal network models described the learning process best in the majority of the tasks, suggesting that learning may be relatively independent of task structure.

These results are somewhat contrary to the research by Juslin et al. (2008) and von Helversen and Rieskamp (2009) on multiple-cue judgments, suggesting that humans rely on a variety of strategies, depending on the structure of the task (e.g. Juslin, et al., 2008; Rieskamp & Otto, 2006). This raises the question of whether learning depends on the task structure and what may be the mechanisms that lead to a switch in cognitive processing during learning. In this paper we investigate two reasons that may cause a shift in cognitive processing during learning in a multiple-cue judgment task. One reason to rely on different learning strategies may be that their learning performance differs depending on the structure of the task. Thus, we will

investigate if task structure influences how well various learning procedures perform that are imbedded in different cognitive models of multiple-cue judgments (e.g. Juslin et al., 2008; Kelley & Busemeyer, 2008; von Helversen & Rieskamp, 2008). Second, the reliance on different learning procedures could also be due to differences in how fast the procedures adapt to different judgment structures. Therefore, we additionally examined if the models differ with respect to their learning speed.

Learning Models

We tested learning versions of cognitive models suggested in the literature for multiple-cue judgments. As a learning model for the linear additive model we relied on a rule-based neuronal network model as implemented by Kelley and Busemeyer (2008). As an exemplar model we extended the ALCOVE model (Kruschke, 1992) to continuous judgments. ALCOVE has been successfully used to model exemplar-based learning in categorization. We also tested a version of the mapping model (von Helversen & Rieskamp, 2008) to allow for learning. Additionally, we included the ALM model as implemented by Kelley and Busemeyer (2008).

Linear Additive Model Much research has shown that linear additive models are good at describing human judgments (Brehmer, 1994). The linear additive model assumes that people weigh each piece of information according to its importance and then add the weighed evidence to reach a judgment. Traditionally, a multiple linear regression is used to capture how much weight people put on each piece of information (i.e. cue). Kelley and Busemeyer (2008) used a rule-based neuronal network with a linear additive structure:

$$g_t = a_1 \cdot c_1 + a_2 \cdot c_2 + \dots + a_k \cdot c_k, \quad (1)$$

where the model prediction g at time t is given by the sum of the cue values c for k cues weighted by their importance a at time t . This learning model updates the weight for each cue according to a delta rule (Gluck & Bower, 1988) with a learning parameter δ capturing the learning rate. An additional decay parameter ω controls the impact of new information.

$$a_{k,t} = a_{k,t-1} + (\delta/t^\omega)(Y_{t-1} - g_{t-1})c_{k,t-1}, \quad (2)$$

with Y indicating the feedback (i.e. the criterion value) and g the model prediction at time $t-1$.

Mapping model We extended the mapping model (von Helversen & Rieskamp, 2008) to allow for learning. The mapping model follows a simple cognitive strategy that makes judgments by first categorizing an object and then retrieving a typical estimate for the category it was put in. According to the mapping model, an object is placed into a

category based on the sum of (standardized) cue values, implying that all cues are weighted equally. The judgment is then determined by the median of the criterion values of all objects in the respective cue sum category. The learning procedure we suggest describes how and how many cue sum categories are formed during learning. In the beginning it is assumed that only a single category is used. In each learning trial, the decision is then made as to whether the new object is put into a new category or into an existing category. A new category is formed if the difference between the cue sum of a new object and the cue sum of each existing category is larger than a distance parameter d . The criterion value estimated for each category is the mean of the criterion values of the objects falling into this category and is updated whenever a new object falls within a category.

ALM The ALM model is an associative connectionist network model. It assumes a layer of input nodes representing each combination of cue values ($2^{\text{Number of cues}}$, with binary cue data). The input nodes are connected to a layer of r output nodes reflecting the criterion values via a one-dimensional grid of equally spaced values. Input nodes are activated by a stimulus based on the similarity of the stimulus' cue values C to the input node's cue values I .

$$A_t = \exp(-\gamma(C_t - I_t)^2), \quad (3)$$

with the activation A of the input nodes at time t further depending on a scaling parameter γ that determines the slope of the activation gradient. The activation of the input nodes is spread to the output nodes via connection weights. The activation of an output node O_r is given by the sum of activations of the input nodes weighted by the connection weights between the input nodes and the output node. The probability of choosing an output node is given by the ratio of the activation of the output node to the summed activation of all output nodes. The judgment is a weighted average of the output nodes, where each output node is weighted with the probability with which it is chosen. Connection weights are updated at each trial according to a delta-learning rule. For this it is assumed that the feedback criterion value produces a feedback activation of each output node F_r based on the similarity of the feedback value p_t to the output node p_r :

$$F_r(p_t) = \exp(-\gamma(p_t - p_r)^2). \quad (4)$$

The connection weights α are updated based on the feedback activation F , the predicted activation O and the input activation A , with a learning parameter δ capturing the learning rate:

$$\alpha_t = \alpha_{t-1} + \delta[F_{t-1} - O_{t-1}]A_{t-1}. \quad (5)$$

ALCOVE We extended ALCOVE (Kruschke, 1992) to continuous judgments. ALCOVE has a similar structure as

the ALM model; however, the input nodes of ALCOVE are restricted to the exemplars encountered during learning. As in ALM the activation of an input node is based on the similarity of the stimulus object to the input node. However in ALCOVE, similarity depends also on the attention given to each cue dimension k , which is controlled by a set of attention weights w .

$$A = \exp(-\gamma \sum_k w_k [c_k - i_k]^2) \quad (6)$$

with the activation A of an input node based on the squared distance of the stimulus value c on dimension k to the value of the input node i on cue dimension k , weighted by the attention w given to this cue dimension and a scaling parameter γ determining the slope of the activation gradient. In the original ALCOVE model, one output node is chosen as response. To allow for continuous judgments we extended ALCOVE with the ALM's estimation mechanism described above.

In ALCOVE, the connection weights are updated in the same way as in ALM, with learning parameter δ_l capturing the learning rate (see Equations 4 and 5). Additionally, the attention weights are also updated according to a delta learning rule. The learning rate is captured in an additional free parameter δ_2 . The attention weights w are updated according to the following rule:

$$w_{k,t} = w_{k,t-1} - \delta_2 \gamma \sum_r \left[(F_r - O_r) \sum_n A_n \alpha_{n,r} (c_k - i_k)^2 \right] \quad (7)$$

with r indexing the output nodes, n the input nodes and k the cue dimensions; F gives the respective feedback activation and O the predicted activation of an output node. A indicates the respective activation of an input node, α is the connection weights between the input and output node and c_k and i_k provide the stimulus value and the input node value on cue dimension k .

Method

To test how the performance of the learning models in solving judgment tasks depend on the task structure, we compared the models' performance by computer simulations in two environments: a linear environment and a multiplicative environment. Furthermore, we varied the amount of learning to examine the relationship between the models' performance and the size of the training set.

Simulation Environments We created two different environments: a linear environment and a multiplicative environment similar to the environments used by von Helversen and Rieskamp (2008; Experiment 3), which revealed a strong effect of task structure on people's judgment processes. Each environment consisted of 1000 objects described by 5 binary cues, with randomly drawn

values (0 or 1). The criterion in the linear environment Y_L was generated by a linear additive function:

$$Y_L = 30 + 33c_1 + 22c_2 + 20c_3 + 15c_4 + 5c_5 + \varepsilon. \quad (8)$$

The error term ε was drawn from a normal distribution with a mean of zero and a standard deviation of 10. The multiplicative criterion Y_M was generated by a multiplicative function:

$$Y_M = 1.2 \cdot \exp(Y_L / 30), \quad (9)$$

resulting in criterion values with similar ranges (about 0 to 140) in both environments.

Simulation Procedure For the simulation we drew a random training sample of 250 objects 50 times and a hold-out set of 100 from each of the environments. Then we fitted the free parameters of the four models to the training data minimizing the square deviation between the model prediction and the training data. For the linear additive model we assumed that in the beginning, equal weight would be given to all cues. For the associative models we assumed that the connections weights and attention weights had equal starting values. Based on the estimated parameter values we generated model predictions for the hold-out set after seeing 20, 50, 150 and 250 objects from the training set. As a measure of prediction accuracy we calculated the root mean square deviation (*RMSD*) between the model prediction and the criterion in the hold-out set after the four points of learning and averaged across the trials of the simulation at each point of learning. Since parameters are fit on a separate data set, the performance of the models in the hold-out set can be compared without needing to further adjust for the complexity of the models.

Results

The mean best fitting parameter values for the models are reported in Table 1, indicating similar learning in both environments.

Table 1: Mean parameter values (SD)

Parameters	Environment	
	Linear	Multiplicative
Linear additive: δ	.45 (.30)	.30 (.17)
Linear additive: ω	.45 (.14)	.47 (.13)
Mapping: d	0 (0)	.02 (.14)
ALCOVE: γ	.30 (.36)	.22 (.17)
ALCOVE: δ_1	.42 (.56)	.46 (1.44)
ALCOVE: δ_2	145 (50)	173 (63)
ALM: γ	2.72 (.31)	1.78 (.30)
ALM: δ	.14 (.07)	.22 (.07)

The models differed with regard to how well they learned the criterion values in the training set. In particular, the two

associative models performed less well than the mapping model and the linear additive model (see Table 2).

Table 2: Mean model performance in *RMSD* (SE) in the training set

Models	Environment	
	Linear	Multiplicative
Linear additive	11.09 (.07)	9.78 (.21)
Mapping	14.60 (.08)	9.87 (.16)
ALCOVE	15.18 (.09)	10.32 (.18)
ALM	15.05 (.12)	11.51 (.17)

The results in the hold-out set suggest that the performance differences in the training set are partly due to a slow initial learning process of the associative models. Figures 1 (linear environment) and 2 (multiplicative environment) show that the linear additive model and the mapping model learn rather quickly even with as little as 20 learning trials. However, the two associative models that performed worse with less than 50 learning trials caught up with the other two models after extensive learning of 150 trials or more.

The environment crucially influenced the performance of the models. Unsurprisingly, in the linear environment, the linear additive model performed best regardless of the amount of training. With fewer than 50 learning trials, the mapping model performed somewhat worse than the linear model, but better than the associative models. However, with more than 150 trials of learning the two associative models performed better than the mapping model and almost as good as the linear additive model.

Figure 1: Model performance (*RMSD*) in the hold-out set in the linear environment after 20, 50, 150 and 250 trials of learning. Error bars denote one standard error of the mean.

Figure 2: Model performance (*RMSD*) in the hold-out set in the multiplicative environment after 20, 50, 150 and 250 trials of learning. Error bars denote one standard error of the mean.

In the multiplicative environment, the advantage of the linear additive model was less pronounced. To begin with, it performed equally well as the mapping model, but gained a bit on the mapping model with more than 150 trials of learning. The two associative models again performed worse than the linear and the mapping models with little learning with fewer than 50 learning trials, but caught up after more than 150 trials of learning.

In summary, the linear additive model performed well in both environments and at all stages of learning. Furthermore, we found evidence that the amount of training affected which models are well suited to making accurate judgments. More specifically, the associative models only made accurate judgments after extensive training. In contrast, the mapping model performed reasonably well with little training, but failed to improve to a similar degree as the other models with further training.

Discussion

We investigated how different learning models can solve a multiple-cue judgment task depending on the amount of learning and the structure of the task. We found that a linear additive neural network model performed well in both environments and regardless of the amount of training. However, we also found differences due to task structure. In the multiplicative environment, the mapping model was

equally as good as the linear additive model, in particular with little learning experience. With extensive learning experience the two associative models, ALCOVE and ALM, performed similarly well to the linear additive model and the mapping model. The results are in line with the finding of Kelley and Busemeyer (2008) that a neural network with a linear basis was well suited to describe participants' judgments over a broad range of tasks. Our results also support research illustrating the robust performance of linear models for judgment tasks (Hogarth & Karelaia, 2007).

However, our results seem to contradict results that suggest task-dependent changes in strategy use in multiple-cue judgments (Juslin, et al., 2008; von Helversen & Rieskamp, 2008, 2009). These authors found in a task with a similar structure as in our simulation, that the model that was best in describing participants' judgments changed depending on the task structure. However, the judgment process people rely on might not only depend on the judgment performance of the learning process (e.g. Ashby, Alfonso-Reese, Waldron & Turken, 1998). Instead, the learning speed and also other factors such as the cognitive effort of relying on a specific cognitive process could also influence which judgment and learning process people follow (see also Enkvist, Newell, Juslin, & Olsson, 2006). Particularly, in the multiplicative environment the mapping model may provide an equally good but arguably cognitively simpler alternative, which could explain why a majority of participants were best described by the mapping model in the multiplicative condition of Experiment 3 by von Helversen and Rieskamp (2008). On the other hand, associative processes seem to provide a valid alternative to a linear additive model after extensive training, in particular in a multiplicative environment. If following the assumption that associative similarity-based processes may be executed without conscious awareness and be thus cognitively less demanding (e.g. Ashby & Maddox, 1994), this could still make it attractive for participants to rely on such processes, particularly after extensive training. This could explain the reliance on exemplar-based processes (Juslin, et al., 2008) and also the considerable minority of participants that were best described by the ALM model (see Kelley & Busemeyer, 2008).

Lastly, the available context information may also influence people's strategy choices. Information about cue polarity seems to trigger rule-based processes (Newell, Weston, Tunney, & Shanks, 2009; von Helversen & Rieskamp, 2009). While in the study by Juslin et al., (2008) participants had no information about cue polarity, most studies analyzed by Kelley and Busemeyer (2008) provided context information that allows drawing conclusions about cue polarity and thus could have increased the reliance on rule-based processes.

Conclusion

In sum, our results suggest that linear additive learning models are generally robust. However, the performance advantage depends on the task structure and the amount of

learning opportunity. On the basis of these results future research will test whether people's judgments depend on task characteristics and learning opportunities.

Introduction

Peter wants to get the beer that he left in the refrigerator. Predicting Peter's behaviour correctly is usually an easy matter, but understanding how people correctly predict his behaviour with ease is a much more difficult task. Thirty years of research on theory of mind has focused on the interesting few cases in which people fail to reason about mental states correctly, however it is perhaps more interesting to explore the common, reliable cases of successful theory of mind reasoning. This symposium presents research exploring successful instances of theory of mind reasoning using a variety of experimental approaches, and examines the ability to succeed consistently across the lifespan, with results from toddlers, preschoolers, young children, and adults. Important conclusions are drawn from the presented research, which includes the first evidence that children as young as 2.5 years of age can succeed on explicit false belief tasks (Scott & Baillargeon), the most direct behavioral evidence to date for inhibitory processing in successful behavior prediction based on false belief and avoidance desire in preschoolers and young children (Petrashek & Friedman), and, in adults, evidence from a probabilistic modeling approach to theory of mind and social learning development with extensions to pragmatic language usage and natural pedagogy (Goodman).

Why do infants succeed in false-belief tasks when toddlers fail? Evidence for a response account

Rose M. Scott & Renée Baillargeon

Recent evidence suggests that infants in the second year of life can represent a variety of different false beliefs, as well as reason about false perceptions and deception (e.g., Baillargeon, Scott, & He, in press). If infants can represent false beliefs, then why do children fail standard tasks until age 4? Here we argue that this discrepancy reflects the use of different responses. Traditional tasks require children to answer a direct question about an agent's false belief (elicited-response tasks), whereas recent tasks measure children's spontaneous reactions to a scene (spontaneous-response tasks). Simultaneously representing a false belief and planning a response may be too difficult for young children. Since spontaneous tasks do not require a planned response, children succeed much earlier. To examine this possibility, we tested 2.5-year-olds in a novel false-belief task that closely matched the demands of standard tasks but did not require answering a question. While viewing a picture book, children heard a story about an agent who hid her apple in one of two locations; in her absence, the apple was moved to the other location. In the test trial, one picture showed the agent searching for her apple where she had originally hidden it, and one picture showed the agent searching for her apple in its current location. Children looked reliably longer at the original- than at the current-location picture, suggesting that they successfully represented the agent's false belief.

We next tested whether 2.5-year-olds could succeed in an elicited-response task if the response component were made easier for them. Specifically, we provided children with practice with the required response (pointing to one of two locations). In each trial, an experimenter either recited a line of the story (story trials) or asked a question (question trials). On story trials, one picture was shown; on question trials, two pictures were shown and the question required the children to point to one of them. In the final trial, children were asked to point to where the agent would look for her apple. Most children pointed to the correct location (e.g., where the agent falsely believed her apple was

located), suggesting that even 2.5-year-olds can succeed at an elicited-response false-belief task when the response demands are reduced.

The signature of inhibition in theory of mind

Adam R. Petrashek & Ori Friedman

Three-year-olds typically fail standard false belief tasks, whereas four-year-olds typically pass. Much has been made of this transition from failure to success, and it is now widely believed that improvements in inhibitory processing during the preschool years are at least partly responsible for improvements in theory of mind reasoning during the same period (Carlson & Moses, 2001). However, the role of inhibition remains unclear. One promising possibility is that inhibitory processing is involved in certain types of explicit mental state reasoning, such as predicting behaviour based on false belief, and directly affects *how* children perform on theory of mind tasks (Leslie, Friedman, & German, 2004).

Our research capitalizes on the lingering property of inhibition – once a response is inhibited, this inhibition lingers, making it more difficult to select than uninhibited responses. This signature of inhibition is highlighted in inhibitory accounts of negative priming and inhibition of return, which both occur in children.

In four experiments, we provide decisive evidence for the view that inhibitory processing is necessary to make explicit behavioural predictions based on avoidance desires and false beliefs. Attributing false beliefs may require inhibiting a default tendency to attribute true beliefs and, in Experiments 1 and 2, we show that inhibition lingers after 5- and 6-year olds predict an agent's behaviour based on a false belief. Attributing avoidance desires may require identifying the target to be avoided and then inhibiting it. In Experiments 3 and 4, we show that inhibition also lingers after 3-year-olds predict behaviour based on avoidance desire. In demonstrating a signature of inhibition in children's theory of mind reasoning, these four experiments clearly support the view that inhibitory processing is involved in how children successfully predict behaviour based on avoidance desires and false beliefs.

Learning what others know

Noah D. Goodman

Civilization is possible because no human needs to re-discover every fact and idea from the natural world alone. Instead, we can learn what other humans already know. What computational processes underlie this social learning, particularly early in development, before formal schooling begins? I will describe a probabilistic modeling approach to theory of mind, which addresses this problem. In this approach an understanding of other agents as goal-directed and an assumption that they are knowledgeable about the world supports social learning which is much more rapid than learning from the natural world alone. I will apply this framework to explain several experiments on social learning, and indicate how it extends to aspects of pragmatic usage of language and natural pedagogy.

Discussant

Rebecca Saxe

An Assistant Professor at the Massachusetts Institute of Technology, Dr. Saxe utilizes a multi-method, multi-directional approach to studying the cognitive neuroscience of theory of mind in both typical and atypical populations of infants, children, and adults. Saxe has received several prestigious awards and has been published extensively in top journals, including *Trends in Cognitive Sciences*, *Psychological Science*, and *Cognition*.

Disentangling Representation from Conceptualisation

Nancy Adrienne Salay (salay@queensu.ca)

Queen's University, Department of Philosophy, Watson Hall 309
Kingston, ON K7L 3N6 CANADA

Abstract

Drawing on recent work in the area of episodic memory, I suggest a novel way of dissolving the representation/anti-representation debate; if we treat representation and conceptualisation as two separate capacities, the latter being parasitic on the former, we unify the insights of both camps, but succumb to none of their failings. I provide a sketch of how we might understand de-conceptualised representation and I show that, on this new approach, many of the old problems, e.g. grounding, disappear.

Keywords: representation; anti-representation; intentionality; episodic memory; cognitivism; cognition; dynamic systems

Introduction

One of the central debates in cognitive science is the dispute over the role of representation in cognition: on one view, cognition is taken to be a kind of conceptual process; on the other, it's seen as a particular sort of physical process. But this characterisation of the two perspectives leads to a deeply unsatisfying theoretical divide: either our interactions with our world are mediated by our representations or we do a lot less modelling than we think. Accounts situated in the representational camp are plagued by the problem of intentionality, while those leaning towards the anti-representational side seem incapable of saying anything theoretically interesting about the higher-level conceptual type of cognition that purportedly develops out of the underlying non-representational physical processes. This unhelpful polarisation is due, I think, to a presupposition that drives the debate; the idea that representations are conceptual¹, that is, that they stand in for classes of things, not for particulars. I want to suggest that if we unpack this, and treat representation and conceptualisation as two separate capacities, the latter being parasitic on the former, we get a more nuanced and robust theory of cognition that unifies the insights of both camps.

In what follows, I'll take Hubert Dreyfus' arguments against cognitivism (computational/representational approaches) as paradigmatic of the anti-representational camp, since his are the most explicit and best worked out in the literature. I'll describe the competing views, uncover the underlying intuitions that motivate the respective

positions, and then suggest a new paradigm for understanding mental re-presentations as symbols of particulars.

Why Cognitivism is in Trouble

The central point of contention between Dreyfus and the cognitivist is whether or not cognition is ultimately a matter of *symbol* manipulation. Cognitivism begins with the idea that a cognitive system responds intelligently to its environment *by way of* its internal symbols but it is precisely this commitment, Dreyfus thinks, that constitutes cognitivism's fatal flaw. As soon as one thinks that internal stuff can stand for external stuff, the problem of how the symbols are connected to their objects arises. What makes the symbols *symbols*? How do the inner representations get to be *about* the things they represent? What makes the inner models, *models* of the external world and, further, models of this specific part of the external world? If, as Quine so eloquently argued (1951), concepts are so deeply entangled with one another that having one entails that one must also have a host of others, this web of concepts – even if internally coherent – could never model the stuff out there; such a system could never decide, for example, that a particular real-world situation is a birthday party situation because the rule for recognising a birthday party situation would cite other concepts that would in turn need rules of application and those rules would also cite concepts that would need rules of application and so on *ad infinitum*.

Now of course one way to hold on to the representational story, but avoid the infinite regress, is to reject concept holism and suppose that there is some level of symbols for which the fixing process is not mediated by other symbols, that is direct in some non-representational way. This is the project of giving a naturalistic account of intentionality. If all holistically inter-linked symbols are 'grounded' in a level of symbols that have their contents fixed in some non-intentional way, the idea goes, the regress will end there. Recognition that representational accounts that don't have some grounding layer – we should think of these as disembodied or ungrounded cognitivist approaches – face serious problems of exactly the sort that Dreyfus raises has made the project of "solving the grounding problem" an increasingly topical one.² But, for Dreyfus, grounding cannot be a way out of the vicious circle since grounding requires a commitment to some form of concept atomism – the view that individual symbols can represent

¹ Indeed, Fodor (1990) goes to some length to argue that being a generalisation is a *requirement* for being a representation; symbols that stand in for particulars only are mere "labels" on his view. I think this is deeply mistaken and rests on the confusion that is the focus of this paper.

² See Taddeo & Floridi (2005) for a good review of the current state of work in this area.

independently of all other symbols – and he thinks that there are independent reasons for thinking that concept atomism must be false.

Dreyfus thinks that concept atomism is wrong in two ways. Not only does it not speak to the Quinean intuitions about concept holism – that concepts come in groups, not as individuals – but it assumes that our most basic relation with the world is a conceptual one. Dreyfus thinks that both the atomists and (some) holists are wrong in thinking that, at base, we come to know our world by theorising about it. He follows Heidegger in insisting that fundamentally our relation to the world is not a theoretical one, but a practical one. On this Heideggerian view, the idea that *things in the world* are meaningful in isolation from our *practices* is incoherent. Things are what they are and play the role they play partly because of their natural features – being heavy, being sharp, and so on – and partly because of the background practises of the culture within which those roles develop.

Although practical understanding – everyday coping with things and people – involves explicit beliefs and hypotheses, these can only be meaningful in specific contexts and against a background of shared practices. And just as we can learn to swim without consciously or unconsciously acquiring a theory of swimming, we acquire these social background practices by being brought up in them, not by forming beliefs and learning rules. (Dreyfus, 1980, p.7)

Practical understanding underwrites and makes theoretical understanding possible: meaning is always situated, that is, it arises out of holistic, dynamic, inter-relations between agents and their environment. Meaning *arises*, as a whole, out of activity, and never individually, as a result of assignments:

To say a hammer has the function of being for hammering leaves out the defining relation of hammers to nails and other equipment, to the point of building things, and to our skills – all of which Heidegger called readiness-to-hand – and so attributing functions to brute facts couldn't capture the meaningful organization of the everyday world. (Dreyfus, 2008, p.1138)

Thus, it's the complex nexus of background practices *and* (sometimes) conceptual relations that holds together hammers, nails, wood, etc., that connects *hammer* with hammers. Any view that *requires* a base-level of concept-detectors, as it appears cognitivism does if it is to avoid the regress, has been completely derailed. The fact that it was the initial assumption of representationalism that was responsible for this flight towards conceptual atomism, Dreyfus urges, should be a red flag that something is deeply wrong with that assumption.

Now some might think that Dreyfus is creating much ado about nothing, that if there is any debate here it's merely a terminological one since the internal states, or at least some subset of them, that underlie our practical understanding just

are the low-level representations that ultimately ground a higher-level theoretical conceptual structure. The rising influence of neuroscience in the cognitive sciences coupled with the widespread acceptance of some kind of information theoretic account of representation has made this idea that conceptual cognition might be grounded in a simple capacity for object detection a natural one.

But this is no mere terminological conflict; it is a deep and confounding burden of proof debate: there seems to be no non-question-begging way of specifying what constitutes a representational system. If we are loose with our use of the term “representation” and we suppose that nomic covariance relations are sufficient to establish representation relations, then we are in danger of begging the question in one way, of assuming that *using a representation* and *acting in a way that can be interpreted as using a representation* are two sides of the same coin. This “loose” understanding is mainstream in neuroscience. When a neuron or a cluster of neurons is found to be ‘sensitive’ to a particular class of objects, and the underlying explanation is taken to be that a nomic causal relation between the objects of some class and the activation of a neuron or cluster of neurons has been found, that neuron or cluster is said to represent that class. There is a dispute, to be sure, over whether or not localist, single-cell, representations are possible or whether neural representations are distributed over clusters of neurons; but there is very little discussion (except among the anti-representationalists of course) about whether or not nomic covariance is sufficient to warrant representational attribution³.

But surely, one might think, there is a difference between what I do when I consult a map in order to find the shortest route across the city and what I do when I follow a series of instructions for crossing the city. In the first case I am using the map in virtue of its content, but in the second case, while the entire sequence of steps taken together could be viewed as a model of the shortest distance across the city, I do not follow the instructions in virtue of their semantic content, I follow them in virtue of their syntactic properties – turn left at Bank Street, proceed for two blocks, and so on. If I didn't understand the semantic features of the map, e.g. if I didn't know that the black lines represented streets and the red lines stood for highways, I wouldn't be able to use the map; on the other hand, whether or not I understood that, taken as a whole, the sequence of steps represented the shortest path across the city, I could follow the instructions for taking that path. In the first case I am using the representation, but in the second I am merely acting in a way that could be interpreted as using a representation. Neuronal chain reactions, looked at from an investigator's vantage point, can certainly be interpreted as

³ See, for example, the recent debate – rekindled by Jeffrey Bowers (2009) – concerning localist vs. distributed neural representations. Nowhere in this discussion is the question of whether or not we should be calling these regularities representational at all raised.

representational, in the same way that the sequence of steps can be seen as a model of the shortest route across the city, but unless one has some kind of story to tell about how one part of the system, or perhaps the system taken as a whole, makes use of the content of those neural states, we have no reason to think that these neuronal impulses actually play a representational role. Of course, by stating the distinction in this way, I am also begging the question, in the other way, since to get to my conclusion one has to first assume that *using a representation* and *acting in a way that can be interpreted as using a representation* are different. This is why the debate about representation seems so intractable; the competing intuitions that undergird the various positions are so polarised.

William Ramsey does a good job of making the gap between these alternative perspectives explicit when he argues that any account of representation must meet what he calls the *functional specification challenge*: “a minimal requirement for a successful functional specification of any notion of representation is that the content—or, if you like, the fact that the representation has semantic content—be an explanatorily relevant fact about that state.” (2003, p. 129) In other words, one needn’t go so far as to show that a system is actually using a representation in order to make the case that the system is a representational one (as in my map example) – it’s unclear how one could ever give a naturalistic account of intentionality if this were the requirement – but one does need to provide a justification for treating a system as though it were using a representation; that is, the fact that the internal indicator states have some content must play *some* kind of role in one’s account.

Fred Dretske’s information theoretic account of representation (1988), perhaps the most robust and ambitious indicator theory of representation that has been offered thus far, looks like the best candidate for meeting this challenge. According to that account, what makes one internal state X a representation of some class of things or actions Y is the following:

1. The presence/absence of X covaries with the presence/absence of members of Y;
2. The co-variance is under-written by a nomic causal relation, that is, the presence/absence of members of Y cause or are a necessary part of the cause of the presence/absence of X; and,
3. The functional role of X, within the system within which it arises, is to carry information about the presence/absence of members of Y.

It’s condition three that makes this account a candidate for meeting the functional specification challenge, since it’s this requirement that makes the content of the purportedly representational state relevant to a complete description of its functional role in the system. Or so it seems. Ramsey argues that it doesn’t. To support his contention, Ramsey develops a distinction between *carrying information about* –

“possess[ing] states that could inform about other states of affairs” (2003, p.135) and *being an informer*— “be[ing] plugged into the right sort of system in the right sort of way, such that the relevant entailment relations are put to a very specific sort of use.” (2003, p. 135) It’s the latter that is required to meet the functional specification challenge, since only in such cases is the information actually playing some kind of role in the overall account. But in none of Dretske’s examples, Ramsey argues, is the *informer* condition met.

I won’t rehearse here Ramsey’s support for this claim since ultimately it’s not important that we be convinced of Ramsey’s conclusion; indeed, one of the morals of this paper is that so long as some of our key presuppositions about the nature of representation remain, we will never be able to solve this burden of proof debate. Ramsey’s insights are important, however, because they uncover the fact that information theoretic accounts of representation are convincing only if we assume a particular (impoverished, on one view) understanding of representation; consequently, we shouldn’t be optimistic that an information theoretic grounding account could ever settle the score.

But as I’ve already noted, for anti-representationalists like Dreyfus, the entire grounding agenda, information theoretic or not, is misguided ultimately because it cannot accommodate our dynamic nature as systems who are continually responding to and causing changes in our environment. Any view on which it makes sense to see coping skills as decomposing into finer and finer grained skills at dealing with object types, even those that are “action-oriented” or Gibsonian, is a representational view by Dreyfus’ lights and thus one that he rejects. On the representational view, our interactions with the world are mediated by categories and we see the world *as* divided up into hammers and tables and chairs. In coping, on the other hand, there is no “seeing as” at all. One copes with situation wholes, as unfolding happenings, rather than as composites of objects.

Dreyfus’ anti-representationalism is thus quite radical; he rejects *any and all* representational interpretations of the internal states that underpin our coping skills. There is no mere terminological argument here.

Re-Presentation: A New Model

Dreyfus’ deep and important insight into the way we think has led us to the following impasse: any disembodied or ungrounded AI founded on the principle that cognition is fundamentally a matter of concept manipulation will be caught in an infinite regress of concept consultation and, consequently, its concepts will fail to be about the things they purportedly represent. But the mainstream cognitivist response, to close the concept-world gap by grounding conceptual schemas, requires that we take concept atomism seriously. Dreyfus rejects this route and takes the fact that this looks to be the only way out of the infinite regress as a

clue that the initial representational assumption must be at fault. Others, who are more firmly rooted in the Cartesian tradition, are not as quick to reject the grounding possibility; they think that some kind of information theoretic atomism will eventually provide the answer. But, as Ramsey show us, low-level concept detectors alone can't provide us with a naturalistic account of representation, since they cannot play the required functional role of concepts or even proto-concepts unless they are already part of an intentional system, a system capable of *using* semantic content. Such grounding theories, instead of solving the problem, merely push it back a level. Dreyfus urges us towards an anti-representational AI, but I suspect the radical see-saw between the full-blooded representationalist and the strident anti-representationalist is a tug 'o war that no-one is likely to win, likely because, as Andy Clark and others (1994, 1997, 2002) have been suggesting all along, the truth lies somewhere in the middle. I suggest that we take Dreyfus' charge seriously, but explore other ways out of the impasse. His solution is to reject the foundational commitment to some form of representationalism outright, but I want to argue that even if we accept Dreyfus' arguments that cognition isn't fundamentally a conceptual process, we need not accept his more radical and less helpful conclusion that it is also not a representational process.

As evolved biological agents, there is no doubt that, as Dreyfus emphasises, we first and foremost cope with our environment in an entirely non-representational way – we avoid obstacles, recoil from harmful situations, and are drawn towards safe and pleasant ones in an unmediated way. But we're not *just* biological agents; we're cognitive ones as well. And as such we are able to respond not only to the intricacies of present situations, but to past and future ones as well. I am able to respond to the subtleties of the ebb and flow of traffic, while I'm driving my car, while at the same time, thinking about how my class went yesterday and considering ways in which I will do things differently or the same in next week's class. But while this ability does require that we have some capacity to re-present the past and imagine future situations, it need not require a conceptual ability, an ability to generalise beyond the specific cases to a class. I have in mind here the distinction, first proposed by Endel Tulving, between episodic and semantic memory. Episodic memories are re-presentations of past experiences (and imaginings of future ones), while semantic memories are conceptualisations of past experiences – they consist in the knowledge we distil from our experiences, that is, the generalisations we make on the basis of experience. Proust's *In Search of Lost Time* gives us wonderfully vivid descriptions of both. The narrator has an episodic memory of a particular moment in his childhood, when he'd tasted a bite of his aunt's lime-tea-soaked madeleine, and in this re-experiencing he tells us that "immediately the old grey house upon the street, where her [his aunt's] room was, rose up like a stage set to attach

itself to the little pavilion opening on to the garden which had been built out behind it for my parents (the isolated segment which until that moment had been all that I could see); and with the house the town, from morning to night and in all weathers, the Square where I used to be sent before lunch, the streets along which I used to run errands, the country roads we took when it was fine." (p.50) This memory is portrayed in stark contrast with his more conventional semantic memories of Combray, the village of his childhood summers, where his aunt lived: "Many years had elapsed during which nothing of Combray, save what was comprised in the theatre and the drama of my going to bed there, had any existence for me." (*ibid.*) The ability to have an episodic memory, then, is the ability to re-experience some situation not present, while to have a semantic memory is to have some capacity for generalisation. Tulving, both when he first suggested the distinction and today, sees episodic memory as parasitic on semantic memory:

Episodic memory is a recently evolved, late-developing, and early-deteriorating past-oriented memory system, more vulnerable than other memory systems to neuronal dysfunction, and probably unique to humans. It makes possible mental time travel through subjective time, from the present to the past, thus allowing one to re-experience, through autonoetic awareness, one's own previous experiences. Its operations require, but go beyond, the semantic memory system. (Tulving, p. 6)

Martin Conway, however, has recently suggested an intriguing new way of understanding episodic memories as a tripartite structure only elements of which are entwined with semantic memories. His analysis provides us with a new way of understanding the relationship between mental representations and conceptualisation, one that can serve as the foundation for the theoretical bridge between our coping skills and our conceptual abilities.

On this new picture, episodic memories can be analysed into inter-related parts:

1. Episodic elements (EE's) – these are snippets of experiences, Proustian experience snapshots;
2. Semantic episodic memories (SEM's) – these are small sets of EE's grouped by a contextualising conceptual frame, for example, one's breakfast routine; and,
3. Conceptual episodic memories (CEM's) – these are groupings of SEM's by a higher-order conceptual frame, for example, a day at work.

Of these, the most basic are EE's:

Episodic elements are the most event-specific, most experience-near representations in long-term memory. They are often in the form of visual images (which may be the main representational format of episodic memories) and they represent moments of experience or summaries of moments of experience, particularly

and perhaps exclusively, moments of conscious experience. (Conway, p. 2308)

Importantly, on Conway's view, and contra the received wisdom, EE's are a-conceptual and conceptually *a priori*. This means that the capacity for semantic memory is not a requirement for having episodic elements; indeed, he suggests, the relation goes the other way – episodic elements are required for semantic memory.

An interesting question that then arises is: how can EEs be associated with conceptual frames in an infant's memory? One answer to this is that the ability to form EEs is hard-wired and functioning prior to birth.

Conceptual knowledge is abstracted from EEs. (p. 2312)

Conway here is suggesting that free-floating EE's, what I'm calling re-presentations, that aren't yet grouped and framed, might be the building blocks of our concepts. At some point in a human infant's development, EE's begin to be grouped. These groupings form 'proto-SEM's', the beginnings of conceptual frames. The mechanism for grouping is of course the big ticket question since, on this view, this just is the mechanism for conceptualisation. An initial suggestion is that both the temporal contiguity of EE's and closeness with respect to sensory attributes are likely factors in how EE's are grouped in long-term memory.

Obviously, more work needs to be done in this area before we can claim anything as bold as a theory of concept development, but in speaking to the insights of both the representational and anti-representational camps, EE's as re-presentations play an important role in the cognitive story we have collectively been telling thus far. The anti-representationalist is motivated by the bottom-up observation that cognitive agents such as ourselves are, most fundamentally, dynamical physical systems and, as such, are best described in terms of the low-level mechanisms from which our higher level capacities emerge. That re-presentations are the building blocks out of which our conceptual capacities emerge supports this picture since re-presentations themselves are just responses to past experiences, neurally encoded and re-played and, in that sense, are no different from other coping responses. The representationalist, on the other hand, is motivated by the top-down observation that, unlike most physical systems, cognitive agents are able to respond to past events and possible future ones in addition to present situations. Here again, the insight is captured since a re-presentation is either a response to an experience that has already happened or is a playing out of a possible future one: "The temporal dimension in episodic memory extends then both backward and forward in time and we have recently termed this the *remembering-imaging window*." (p. 2307)

Recall that attempts to ground conceptual schemas directly in some kind of body-world relation (this is what the detector accounts try to do) can never resolve the clash of intuitions. Either the attribution of representation to

internal indicator states will be unwarranted, given a more robust notion of representation, or it will be justified only if we assume that the overall system is already intentional, which is the very thing we are trying to explain. Instead of responding to this observation by embracing the opposing intuition, as Dreyfus does, I'm suggesting a possible theoretical middle ground. We do rely on inner models of our environment in our interactions, but, as part of a low-primitive cognitive capacity, these models are wholly particular, not conceptual. There is no gap between a re-presentation and the world that needs to be bridged (as in the case of conceptual representation); the re-presentation is just another situation to be (re)experienced. Re-presentations do not threaten the underlying anti-Cartesian picture of ourselves as, ultimately, dynamic copers, since re-presentations don't mediate our interactions with the world; although they do make mediation possible, since it is out of these snapshots that concepts develop. Finally, re-presentations meet the functional specification challenge without begging the intentional question. Being a neuronal response and thus embedded within a network of connections, a re-presentation triggers other responses as well. As a first response, of course, not re-experienced, there is nothing representational about the underlying neuronal structure that encodes that response. But once that set of neural encodings is re-activated, it now has the role of carrying information about the original situation for the system to which it is being re-presented. Not just any set of neural encodings can count as representational then, no matter how detector-like they behave; only those in a system that is capable of re-presenting to itself count as representations, since only in such systems is the experience as a whole, that is to say, the content of the experience, playing a role.

Conclusions and Speculations

It sounds like we get to have our cake and eat it too. Is this too good to be true? Perhaps, but it certainly opens up some new avenues of investigation where now we seem to be stalled. The anti-representationalist seems incapable of offering a theory of cognition, distinct from a theory of, say, action, because he ignores our theoretical capacities; the representationalist, on the other hand, seems incapable of offering a theory of embodied cognition because she begins the cognitive account too high up – already at the level of concepts. If we let go of the idea that a representation must relate some particular to a class, we have a way of marrying the insights of either approach and moving forward with a new conception of intentionality: an intentional being is one that has the capacity to respond to its own response to some past experience. Intentionality, on this view, is a *prerequisite* for conceptual cognition; that is, giving an account of intentionality and giving an account of mental concepts are separate endeavours. And this is very happy news because until now we've had the proper order of investigation backwards; the thought was that once we

understood conceptual representation, the right story about intentionality would follow. But no naturalistic account of conceptual cognition is forthcoming, no surprise, since that story is parasitic on, not precedent to, an account of intentionality. This scaled back understanding of intentionality as the capacity for re-presentation, however, looks like a much more promising candidate for naturalisation. If we can manage that, we'll have, at last, a naturalistic grounding for a theory of conceptual representation.

Abstract

We examine the proposal that thinking is a combinatorial operation on mental representations, and argue that it cannot be. If the argument is successful it shows that cognitive science cannot explain intelligent linguistic behavior by explaining what thinking is. We point out that this does not impugn the practice of cognitive scientists interested in human language, which, properly understood, consists in the framing and testing of hypotheses about the causally necessary enabling conditions of intelligent linguistic behavior.

Keywords: Wittgenstein; thought, language, mental representation, language of thought.

Introduction

We regard understanding as the essential thing, and signs as something inessential. (Wittgenstein, 1974)

...the limits of possible thought are the limits of the possible expression of thought.
(Bennett & Hacker, 2003)

If strong Wittgensteinian cross currents still ran into the mainstream of contemporary philosophy of mind and language, these philosophical waters would be much more turbulent than they now are. Indeed it is not even clear that they would be running in roughly their present direction. As things stand the river flows wide and slow, almost undisturbed by substantial impediments to its progress, and serious attempts to change its course are liable to seem naive or over ambitious – uncomprehending of the forces at work.

The argument we present here, which is Wittgensteinian in spirit, is meant to push quite hard against the prevailing drift. It's an argument to the conclusion that thinking is not mental representing and thoughts are not mental representations. We are not, by any means, the first to make this sort of argument. Indeed, on a plausible reading of his two great works, the very theory Wittgenstein (1921/2001) defends in the *Tractatus* is the theory he repudiates in the *Philosophical Investigations* (Wittgenstein, 1958), and at its heart is the thesis that thinking is mental representing. Our aim here is to say precisely what it is about the claim that thoughts are mental representations (and that thinking is mental representing) that runs counter to the direction in which Wittgenstein's later arguments lead. This, we

believe, is not a direction cognitive scientists should be reluctant to travel in; for it takes us further and further away from Cartesian conceptions of mentality that can only hamstring research.

Overview of the argument and some preliminary points.

The argument we present here starts with the premise that to think that something is so is to perform combinatorial operations on representations, and it moves to the negative conclusion that to think that something is so cannot be to perform combinatorial operations on *mental* representations. This should not be taken to imply that thinking is a combinatorial operation on non-mental representations like words and sentences. Certain cases of thinking may be that¹, but there is nothing in the argument which entails the strong view that to think is to speak silently to oneself in a natural language. The aim is only to rule out a widely held view about what thinking is, not to defend a competing one. The view that is ruled out is that for Sam to judge that ducks run is for her to perform an operation on representations of a radically different kind than those on which she would operate were she to make a corresponding assertion. On such a view when she asserts that ducks run, operations are performed on two sorts of representation, one mental one not; and when she judges that ducks run but asserts nothing they are performed only on mental representations. On this sort of view internal mental representing need not be connected to external spoken representing in any way; so what a creature can say sets no limits on what it can think.

If the argument of this paper is successful we will have shown that it can't be because linguistic behaviour is linked with hidden events and processes that it counts as linguistic. This is liable to upset very widely held assumptions both about the nature of thinking and about the shape of cognitive scientific explanations. On these assumptions, what is important about Sam's assertion that ducks run is how it stands to various items or events in, or states of, her brain. Illuminating explanations will consist in claims about this standing. That implies a certain conception of what makes assertions into meaningful speech acts and differentiates them from grunts and squawks. On it, for Sam

¹ Bennett & Hacker (2003) contains an excellent series of reminders of how many different things we ordinarily call thinking.

to assert that ducks run is for her to make known the occurrence of a certain sort of mental act – a judgement, and for her to judge that ducks run is for certain syntactical operations to be performed (by Sam, or perhaps by a mind, a brain, or a brain-part) on certain information bearing states or structures (mental representations), which are themselves states of, or items/structures in, brains (or are realised in such states, items or structures). If that is what assertions are then linguistic behaviour must be an incidental outward accompaniment of mental representation. It is only because linguistic behaviour serves to indicate the occurrence of internal processes that it counts as *linguistic* (the parrot's squawks may sound like bits of linguistic behaviour but they aren't), but mental representations counts as mental representations whether or not they happen to be indicated by observable behaviour. On this view – which is profoundly Cartesian – the link with mental representation is an essential feature of linguistic behaviour, but the link with behaviour is an inessential feature of mental representation.

This conception of the relation between thought and linguistic behaviour could easily seem an essential feature of a cognitivist account of language.² The aim of cognitive science is precisely to explain intelligent behaviour by appeal to internal processes, and the distinction between speaking and thinking looks like a kind of paradigm of the distinction between intelligent behaviour and internal process (or processing). If we accept this appearance at face value, and if we identify mental representation with thinking, it will seem that a theory of mental representation will perfectly conform to the basic aim of cognitive science by providing an explanation of linguistic behaviour by appeal to internal goings on.

These appearances are deceptive. On our view, cognitive science can retain its commitment to explain behaviour by appeal to inner processes, events and states, whilst abandoning the Cartesian project of explaining linguistic behaviour by appeal to thought, and giving up the identification of thinking with mental representation. We take it that a cognitivist account of linguistic behaviour should take the form of an attempt to model and identify the states of and processes in (and around) the brain that are causally necessary conditions of linguistic behaviour. To identify such states and processes would be to provide an explanation of behaviour by appeal to obscure inner states and processes; so it would conform to the cognitivist brief. But to discover the causally necessary enabling conditions of linguistic behaviour is not to discover what thoughts are and what thinking is – for thoughts are expressed in behaviour, but a causal condition is not expressed in what it causally enables (see Trigg & Kalish 2010 (submitted)).

² E.g., Hauser, Chomsky & Fitch (2002) say, “In the varieties of modern linguistics that concern us here, the term “language” is used quite differently to refer to an internal component of the mind/brain (sometimes called “internal language” or “I-language”). We assume that this is the primary object of interest for the study of the evolution and function of the language faculty.” p1569

It is all too easy to confuse thinking, which speaking and writing is often expressive of, with the brain events and processes that are causally necessary conditions for intelligent linguistic behaviour. A Cartesian conception of the relation between thought and its linguistic expression makes such confusion almost inevitable, for in characterising thought as an inner accompaniment to observable linguistic behaviour it lumps it in with the various neural events and processes which are causally necessary for linguistic behaviour. But, Wittgenstein reminds us, intelligent speech does not consist in a series of observable movements of the face and throat on the one hand, and a series of hidden mental events and processes on the other. Rather, thought is *in* intelligent speech in roughly the way that distress is in an anguished cry and amusement is in a spontaneous peel of laughter. So, contrary to the apparently innocent Cartesian intuition, a person's thoughts are typically not hidden behind their words, but precisely revealed by them. If we remember this we will not so easily seek to identify thinking with the neural conditions of speech, for it is obvious that these conditions are not revealed, as a person's thoughts typically are, by the things they say. Of course these neural conditions are not hidden behind the linguistic behaviour they causally enable in the dramatic way Cartesian thoughts are supposed to be hidden behind some of the noises people make, for they count as hidden only because they are in the thinker's skull, not because they are in the thinker's mind.

Cognitive science, on our view, has the job of framing and testing hypotheses about the causally necessary enabling conditions of familiar psychological phenomena like thinking, imagining, remembering and willing. As long as these familiar phenomena are not conceived as private, inner accompaniments to observable behaviour and then *identified* with unfamiliar operations on mental representations, cognitive science can make a substantial contribution to our understanding of them. There is even a sense in which it might be appropriate to characterise neurological states, structures, events and processes which causally enable familiar phenomena like assertoric thinking (judgement) as mental representations, since without them it would be impossible for people to represent the world in the way that they do.

Initial Clarifications – Mental representation and the language of thought

If one holds that cognition is mental representation, and that mental representation consists in combinatorial operations performed on mental representations, then one seems compelled to accept that cognition is a quasi-linguistic operation. The basic idea here is that to combine representations to form complex ones is to perform *syntactic* operations analogous to those involved in combining words and sentences to form more complex sentences. (Fodor, 1975, 2008) In both cases, it may be supposed, the representational properties of complex representations will depend in a systematic way on the representational

properties of the simpler ones. Thus a finite stock of elemental representations together with a finite number of syntactic rules for the combination of these, will yield an unlimited number of possible complex representations. This picture, which is surely very widely accepted (see, e.g., Schneider, 2010), seems to require what Fodor famously called a ‘language of thought’. The thesis that mental representation, like spoken and written representation, is linguistic, still plays an important, though poorly defined role in cognitive science. It is not hard to see why it is so popular. For one thing it seems to provide a way of explaining the unlimited number of different intelligent things intelligent creatures can do in reference to an equally unlimited number of different representational states their minds or brains can be in. For another it seems to support a computational theory of mind or cognition, since the relevant combinatorial or syntactic operations seem well suited to be conceived as computational operations of a kind that might be run by something like an organic equivalent to a computer.

Whilst the hypothesis that there is a language of mental representation consisting, not of words and sentences but of mental representations is a natural way to develop the concept of mental representation, it is no more than that. It could be discarded and the notion of mental representation retained. So it is important to appreciate that the argument we present is directed at the very idea that there are two ways to represent, for example, ducks as running, one mental, the other not. If it tells against this idea it will, as a matter of course, also tell against formulations of it on which to think that ducks run is to make an assertion in the (or a) silent language of thought.

The Mental Representation Argument

On a picture of the relation between thought and language that deserves to be called the classical picture the purpose of speech and writing is to make thought, which is essentially private and psychological, public and perceptible. The basic problem with this picture, however its details are worked out, is this: if, when Paul says ‘Ducks run.’ there are two types of operation he is performing (one mental, inner and private, one physical, outer and public), and two kinds of item he is operating on (one mental, inner and private, one physical, outer and public), we will have to explain what the relation is between these operations and these items. That is, we will have to explain how, on the one hand, the combining of mental representations stands to the combining of words; and on the other, how the combined mental representations stand to the combined words. It should be clear, at least with a little reflection, that the prospects of providing such an explanation look dim. If we conceive mental representations as components of a non-verbal language we will have to explain how non-verbal thoughts are to be translated into verbal utterances; if we conceive mental representations as mental images or pictures we will have to explain what it is to translate images into words. But such explanations are hopeless for at

least three sorts of reason. There is no such thing as translating what is said in a mental language into something said in a public one, so no such thing as doing it correctly or incorrectly (try to compare your translation of a mental representation with the mental representation it is a translation of so as to check if you’ve translated it correctly). Neither is there any such thing as translating – as opposed to describing – an image. Finally, since any image can be described in indefinitely many equally faithful ways, images do not determine what does and doesn’t count as faithfully describing them. So being able to say what one is thinking cannot be a matter of being able to describe a certain mental image correctly; since any description of a particular image could count as a correct description of it, talk of the (or even of a) correct description of an image is empty.³

If these weighty considerations do not convince thus baldly presented, we can turn to Wittgenstein’s celebrated (misunderstood and neglected) private language argument to drive them home. This succeeds in showing, quite categorically, that when, e.g., Paul says ‘Ducks run.’ he does not perform two types of operation, one on mental representations and one on verbal representations, but only one. It shows this by showing that operating on representations must be a normative or rule-governed affair (the type of thing that can be done incorrectly or correctly) and that operations performed on items, events or states available only to the operator could not be a normative or rule-governed affair. According to our argument if one assumes that thinking is a combinatorial operation on representations one has to deny that thinking is mental representing; that is interesting, for it is precisely that assumption that has led so many cognitive scientists to conclude that it must be mental representing. What follows then, is an argument to the conclusion that thinking cannot be an operation on mental representations which exploits Wittgenstein’s argument that language cannot be private:

To think, in the sense under discussion, is to think that something or other is so. To do that is to have a thought or to make a judgement, such that the thought one has or the judgement one makes will be the thought or judgement that things are thus and so. If things are that way the thought one has will be true, if not, then false.

For the purposes of argument let us assume that to think (or to judge, doubt or suppose) that something is so is to perform a certain kind of operation on a certain kind of representation. This operation must be productive of further representations that have the characteristic of being evaluable for truth; so it must be an operation on representations (that may or may not be of a truth-evaluable type) that yields representations (that are of a truth-evaluable type). So, for example, it could be an operation on words or sentences that produces sentences. Such operations must be combinatorial. What other than a combinatorial operation could produce the type of representation that is

³ See e.g. G. McCulloch (1989), pp. 152-163.

evaluable for truth out of representations that are, very often, not evaluable for truth; and what other than a combinatorial operation could generate indefinitely many truth-evaluable representations out of a few non-truth evaluable ones?

Not every possible combination of representations will yield representations capable of truth. For example ‘Green was a depressing silently were or jam’ is a combination of representations, but it is nonsense, so the question of its truth cannot arise. There are many different ways of combining representations in such a way as to produce nonsensical representations not capable of truth. To combine representations in at least some of these ways that produce nonsense is to combine representations incorrectly. What can be done correctly or incorrectly must be a rule-governed activity. That is to say that for representations to be combined in the relevant way is not just for a series of orderly events to occur, but for a rule-governed activity to be engaged in. When a given process does not unfold as it usually does we can say that an irregularity has occurred in it but not that a mistake has been made in carrying it out. But many nonsensical combinations of representations are not just irregular; they are wrong. That entails that they run counter to rules of representation combination that do not merely capture actual regularities exhibited by representation combining activities but prescribe how those activities should be carried out.

Now if a given representation is knowable as the representation it is only by whatever it is that performs combinatorial operations on it, the rules determining how it may be combined with other representations must be private rules. There can’t be public rules that determine how private items, events or states should be manipulated, because it would be impossible to assess putative observations of such rules for correctness. If the rule is, “Perform operation *p* when *y*-type items appear, or *x*-type events occur, or *r*-type states are actualised,” and if *y*-type items, *x*-type events and *r*-type states are knowable only to the performer of *p*, then performances of *p* cannot be publically checked or assessed for correctness.⁴ So they can be checked for correctness only privately.

Now it seems that *mental* representations must precisely be representations knowable as what they are only by whichever thinker or representer is operating on them. To say that a given representation is a *mental* representation is to say that the dealings thinkers have with it are not perceptual. For a mental representation to be available to a thinker need not require that a certain publically available mark be seen or sound heard, but only that thinking be going on. Thinking is conceived here precisely in contrast to observable behaviour, as an inner or psychological operation. Such an operation must be an operation on items, structures or states knowable as the representations they are only to the relevant operator.

If that is right, and if there can’t be public rules for the combination of private representations, then the rules that

determine what it is to combine private mental representations correctly must be private rules.

Having reached this result, it only remains to be established that there can be no private rules for the combination of representations (or anything else), and it will have been shown that thinking cannot be a combinatorial operation on mental representations. Wittgenstein showed how to establish exactly that.

There can be no private rules governing the operations performed on mental representations because there can be no difference between its seeming to a thinker or representer on a given occasion that they are following a private rule and their really following a private rule on that occasion. Say Sam’s putative rule, *p*, is – “Whenever an item relevantly similar to *this* one (pointing inwardly to a relevant sample) comes before my mind, I will perform operation *r* on it (or whenever I am in *this* sort of state – pointing inwardly to an appropriate state – perform operation *r* on it)”. In these sorts of case there could be no difference between its seeming to Sam at *t* that the relevant item was before her mind, or that she was in the relevant state, and that item really being before her mind, or her really being in that state. In that case, Sam cannot have invented a rule *p* governing his performance of operation *r*, because any future performance that seems to Sam to be a performance of *r* in accordance with *p*, will thereby be a performance of *r* in accordance with *p*. In situations that do not allow for a distinction between what seems justified and what is, talk of being justified or unjustified is out of place.

To conclude, if thinking is a combinatorial operation on representations it must be a rule-governed combinatorial operation on representations; but now, since private rules for the combination of representations are impossible, and rules for the combination of *mental* representations would have to be private, thinking cannot be a combinatorial operation on *mental* representations. This argument shows that there is a fundamental conflict between the idea that thinking is an activity subject to normative constraint, and the idea that thinking is a private psychological affair: if thinking can be done incorrectly it cannot consist in manipulations of private mental representations.

Here is a concise formulation of the argument just given.

1. To think – in the relevant sense – is not just to think of something but to think that something is the case.
2. To think that something is the case is to combine representations that may or may not be the sort of representations capable of truth, so as to produce representations that are the sort of representations capable of truth.
3. It is possible to combine representations so as to produce representations that are not capable of truth as well as those that are.
4. To combine representations in such a way as to produce representations not capable of truth is to combine representations incorrectly.

⁴ See Wittgenstein (1958) e.g. section 258.

5. If something, *p*, can be done incorrectly there must be rules that determine what counts as doing *p* correctly; *p* must be a rule-governed activity.
6. By 2, 3, 4 and 5, thinking must be a rule-governed activity. (Not just a process exhibiting regularities).
7. Rules for the combination of representations knowable as what they are by only one representer would have to be private rules.
8. Representations that are *mental* must be knowable as what they are only by one representer.
9. So – by 7 and 8 – rules for the combination of mental representations must be private rules.
10. There can be no private rules.
11. The combination of *mental* representations – by 7, 8, 9 and 10 – cannot be a rule-governed activity.
12. Thinking – by 6 – must be a rule-governed activity.
13. Thinking – by 11 and 12 – cannot be a combinatorial operation on *mental* representations.

An Objection

Without further ado, let us consider an objection to this argument. It concerns premise eight - the claim that mental representations, *qua mental*, must be private, that is, must be knowable as the representations they are only by whatever it is that represents by operating on them. Many cognitive scientists and philosophers of mind might eagerly reject this premise on the ground that it depends upon an unacceptably Cartesian notion of what mental representations are. It will be said that if we reject this out-dated Cartesianism, and think of the mental representations in question as states of, or items in, brains, (or as realised in such items or states), we can deny that they are private, and so allow room for the idea that there could be public rules for their combination.

The problem with this objection is that it is inconsistent with the claim that thinking is *mental* representing, so can't be used to defend it. The claim that thinking is mental representing depends on a certain way of conceiving the distinction between representing done in thought and representing done in (public) language. On this conception representing done in thought (mental representing) is what makes representing done in public language what it is; it is because Sam's assertions do, but his sneezes do not, depend somehow on his thoughts, that his assertions count as meaningful utterances rather than mere noises. It turns out, we will now argue, that this conception allows for the possibility that a representer may be wrong about the *assertion* they are making, but it excludes the possibility that a representer may be wrong about the *judgement* they are making (the thought they are having). We argue that rejection of premise 8 is incompatible with the Cartesian view that a thinker cannot be wrong about which judgement they are making, and that this Cartesian view is an essential feature of the position rejection of this premise is meant to defend. Thus, whilst the anti-Cartesian feel of the objection now under discussion may be congenial in itself, it is quite inconsistent with the conception of the relation between

thought, mental representation and language that it is meant to defend.

Speakers are sometimes wrong about what they are saying. This is not to say that speakers are sometimes insincere; it is to say that speakers can think they are saying one thing when they are really saying another. How shall we explain the possibility of this sort of mistake?

If we hold that to think is mentally to represent, and that thoughts are mental representations we will have to hold that to make a sincere assertion is to translate or otherwise convert a mental representation into a non-mental one. This commits defenders of this conception of thinking to the view that for a speaker to be wrong about what they are saying is for a speaker to be wrong about the relation between what they are saying and what they are thinking. Mistakes of that kind are mistakes made in translating or converting mental into non-mental representations. Now, on this conception of how it is possible for a speaker to be wrong about what they are saying, no conceptual room is left for the possibility that they could be wrong about what they are thinking. This is because, on this view, whilst a speaker has to convert or translate their thoughts into sentences in order to make an assertion, they do not have to translate or convert their thoughts into anything in order to have them. If one can be wrong about what one is saying because one can translate or convert one's thoughts into words incorrectly, and one does not have to translate or convert one's thoughts into anything in order to have them, one cannot be wrong about what thought one is having at a given time.

To see this, consider the following argument. If we explain what it is for someone to make a mistake about what they are saying by appeal to the idea that they can be wrong about the relation between what they are saying and what they are thinking, we will have to deny that they can be wrong about what they are thinking, on pain of generating an infinite regress. For if it were possible for a thinker, Sam, to be wrong at *t* about what she is thinking at *t*, that possibility would require explanation. Any such explanation would have to appeal to a difference between what Sam is thinking at *t* and what she thinks she is thinking at *t* – we will have to say that whilst she thinks she is thinking one thing she is really thinking another. But as soon as we say that, we will also have to allow the possibility that there can be a further difference between what Sam thinks she is thinking at *t* and what she thinks she thinks she is thinking at *t*, and so on. This regress is by no means benign, for it requires a thinker to have an infinite number of appropriate thoughts at *t* if they are to know what they are thinking at *t*. As soon as we open an anti-Cartesian gap between what Sam is thinking at *t* and what she thinks she is thinking at *t*, for her to know what she is thinking at *t* it will not be enough that she thinks it at *t*. Suppose she thinks that ducks run at *t*. If she is to know that she is thinking that ducks run at *t*, she has to think that she is thinking that ducks run at *t*, and if she is to know that, she has to think that she is thinking that she thinks that ducks run at *t*, and so on.

So if we are to avoid this regress we have to embrace Cartesianism; we have to say, that is, that Henry's knowledge of what he is thinking is both incorrigible and evident; incorrigible because if he thinks he is thinking that *p* he is thinking that *p*, and evident because if he thinks that *p* he thinks that he thinks that *p*. If we take thoughts to be mental representations and assertions to be translations of mental representations into perceptible signs, we commit ourselves to an explanation of how a speaker can be wrong about what they are saying which only Cartesianism will save from incoherence.

Now of course the relevant point is that this Cartesian account of the relation between a thinker and the thoughts they have is flatly incompatible with the proposal that mental representations are not private. To see this, it is important to appreciate first that to say that a given mental representation is publically available is not just to say that it is identical with certain brain states that are publically available. It is conceivable that Sam should be acquainted with a certain brain state, *p*, which is in fact identical to a certain mental representation *r*, but know neither that *p* is a mental representation nor that *p* is mental representation *r*. (If I know the butcher, and the butcher is the president, then I know the president, but I may not know that the butcher is the president). So what is required is that George and Harry can come to know that Grace is thinking that *p* by becoming acquainted with a certain state of Grace's brain.

Now that possibility is rather dramatically incompatible with the Cartesian conception of thinking to which we have just shown our opponent to be committed. It makes Grace's way of finding out what thought she is currently having into just one of many ways of finding that out. So a situation will be conceivable in which Grace tries to find out what she is thinking using her introspective method, George and Henry do the same by observing her brain, and Grace fails whilst George and Henry succeed. If that is thinkable, then not only could Grace be wrong, and George right, about what Grace is thinking at any time, but Grace could be wrong and George right about what she is thinking at all times!

The problem remember is not just that these possibilities are absurd in themselves – although the idea that something could count as a thinker whilst *always* being wrong about what it thought is pretty unsatisfying all on its own – but that they are incompatible with the Cartesian conception of the relation between thought and language to which our opponent is committed.

So the thesis that to think is to operate on mental representations cannot be defended by rejection of premise 8. If mental representations are constitutive of thoughts they must be private, and if mental representations are private combining them cannot be a rule-governed operation.

Conclusion

We take it that the mental representation argument shows that thinking cannot be mental representation, that is, that it cannot be a combinatorial operation on mental representations. While there are objections to this argument

that we have not explicitly considered here, they will have to turn either on the denial that thinking can be done incorrectly or on the claim that there can be private rules, and these responses seem to head off in unpromising directions. The only plausible option open to the representationalist is to conceive thinking as a combinatorial operation on the representations constitutive of a natural language like English (Malcolm, 1973). We have said nothing either for or against that position here – though it is perhaps worth noting that anyone attracted to it will have to hold that it is persons as we ordinarily conceive them and not minds or brains that think (since it is indubitably human beings and not minds or brains that know how to use the words of a natural language).

So thinking is not mental representing, and, for example, asserting is not converting or translating mental into non-mental representations. Does this result show that a cognitive scientific account of linguistic behaviour is impossible? Not at all. It shows that if we identify mental representing with thinking we cannot explain intelligent linguistic behaviour by appeal to mental representing. But if we think of mental representing not as identical to thinking but as a causally necessary condition on it (Trigg & Kalish, 2010), then the idea that mental representation underlies intelligent linguistic behaviour is in good shape. It is, of course, profoundly plausible that if certain very complex events did not take place in a person's brain at *t* they would not be able to think or speak at *t*. Nothing in the argument just presented is incompatible with this idea, and nothing suggests that the difficult business of finding out about these events is not a scientific undertaking of the greatest interest.

What Is Domain Specificity (and Why Does It Matter)?

Muhammad Ali Khalidi (khalidi@yorku.ca)

Department of Philosophy and Cognitive Science Program,
York University, 4700 Keele Street
Toronto, ON M3J 1P3 Canada

Abstract

The distinction between domain specificity and domain generality is widespread in cognitive science. Yet, the difference between the two types of cognitive capacities has rarely been made in a principled manner. Moreover, some of the examples that are put forward to illustrate it in the literature are either spurious or misleading. In this paper, I use a number of examples to determine what domain specificity is, and just as importantly, what it is not. A domain-specific cognitive system is one that is in principle generalizable, but which the cognizer does not extend to cases that the system did not originally evolve to deal with.

Keywords: domain specificity; modularity; innateness; animal cognition.

Introduction

There are many contexts in cognitive science in which it is useful to distinguish domain-specific cognitive capacities from domain-general ones. For instance, according to many evolutionary psychologists, human cognition consists largely of domain-specific cognitive capacities, and this feature of our cognitive makeup provides evidentiary support for the pervasive influence of evolutionary processes on the formation of the human mind (Carey & Spelke 1994, Cosmides & Tooby 1994). By contrast, according to other researchers, domain-general cognitive abilities are the norm in the human mind and are what distinguish human cognition from that of most other animals (Samuels 1998, Fodor 2000). Yet, the distinction between the two kinds of capacities is not easily drawn and it is often drawn erroneously by the researchers who aim to make it. After identifying some misleading examples of domain specificity, I will put forward some better examples of the phenomenon drawn from the literature. Then, I will use these examples to try and spell out a more satisfactory account of the phenomenon of domain specificity. Finally, I will draw on this new understanding to try to shed light on the significance of this concept and its importance for cognitive science.

Domain Specificity and Its Confounds

Domain specificity is a feature of cognitive capacities that is often associated with several other such features, notably: modularity, innateness, and brain localization. In this section, I will examine the connections that may or may not exist between domain specificity and these other features, in order to gain a preliminary understanding of the concept of domain specificity.

By virtue of the way in which modularity was initially defined by Fodor (1983), there is a strong link between modularity and domain specificity. Indeed, it follows from Fodor's account that domain specificity is one of the defining features of modularity, and therefore that all modular cognitive capacities are domain-specific.¹ Of course, a case might be made for rejecting this definition on the grounds that it is unwarranted by the empirical facts or otherwise detrimental to cognitivist research, but I will not try to make the case, nor do I think that the case ought to be made. I will simply follow Fodor and much subsequent theorizing in accepting it. Hence, I take it as uncontroversial that domain specificity is a necessary feature of modularity, though the two features ought not to be conflated, since the former is subsumed by the latter.

The case is more complicated when it comes to innateness. Although there is also a widespread assumption that there is a link between innateness and domain-specificity, there is no convincing reason for inferring such a link. It is neither the case that all innate cognitive capacities are domain-specific, nor that all domain-specific cognitive capacities are innate. To illustrate, human beings may have an innate cognitive capacity for associative learning that may be entirely domain-general. Conversely, there may be certain domain-specific cognitive abilities that are not innate but mainly learned, such as chess-playing ability. However, despite the lack of a direct link between the two features of cognition (innateness and domain specificity), a case could be made for an indirect link between them. It has been argued that when it comes to domain-specific abilities, it is easier to tell whether and to what extent they are innate or not (Khalidi 2001). In other words, the link between the two features is epistemic or evidential rather than intrinsic, since we can more easily gauge the amount of explicit learning or relevant experience in the case of domain-specific cognitive capacities than in the case of domain-general ones. This is so because it is easier to rule out relevant sources of information in the former case than in the latter.

As for the link between domain specificity and brain localization, this is also widely made, as is the link between

¹ In addition to being domain-specific, according to Fodor (1983) modular cognitive capacities are supposed to: 2) process items automatically and in a mandatory manner, 3) be inaccessible to consciousness, 4) be fast, 5) be cognitively impenetrable (e.g. resistant to being unlearned), 6) process "shallow" or highly salient features, 7) have fixed neural architecture, 8) have specific breakdown patterns (as in aphasia, agnosia), and 9) have fixed ontogeny (standard pace and sequence of development).

brain localization and modularity (which, as seen above, subsumes domain specificity). However, there does not seem to be a cogent reason for making either link. For instance, there are good grounds for thinking that various cognitive capacities are modular (and hence domain-specific) even though they are not localized in one region of the brain, indeed even though they are scattered across a range of brain regions. Modularity and domain-specificity pertain largely to the functioning of a cognitive capacity rather than its neural manifestation, so there is limited scope for inferring brain localization from either of these phenomena.

In distinguishing domain specificity from other features of human cognition, I have relied on an implicit preliminary understanding of the phenomenon. As the term implies, what it is for a cognitive capacity to be domain-specific is for it to pertain to a single domain or to a restricted range of domains, and more importantly, for it not to be generalizable to other domains. Moreover, this last proviso highlights the importance of restricting domain specificity to aspects of cognition that are in principle *generalizable* across domains, although they are not in fact *generalized*. In other words, it would be vacuous to describe as domain-specific some cognitive system that is not even in principle generalizable. For example, a body of information pertaining to some domain or another is not generalizable, since its subject matter is in principle restricted to a certain domain. By contrast, a rule that is deployed by a cognizer in one domain but that *could* be deployed in another domain is in principle generalizable. Hence, rather than domain-specific capacities it may be more fruitful to talk about domain-specific *rules* or *principles*. These are the kinds of cognitive structures that can be generalized across domains and that are therefore candidates for being domain specific, though they may not be the only cognitive structures that can be so generalized. This point will be developed further in subsequent sections.

One issue that might be raised here concerns the nature and scope of a domain. If we do not explicitly specify what a domain consists in, we may open ourselves to the following objection. Suppose it is claimed that some linguistic rule *R*, which is part of a subject's cognitive repertoire, is domain-specific since it only pertains to the domain of language. Now suppose someone objects to this on the grounds that language itself is not a single domain but rather that it comprises various domains, say syntax, semantics, pragmatics, and so on. Hence, this objector might contend that the rule is in fact a domain-general one since it ranges over several domains. This example suggests that it may always be open for someone to claim that a putative domain-specific rule is in fact domain-general unless we have some principled way of delimiting the scope of a domain. How could we define domain specificity without specifying the scope of a domain? In response, I would argue that it is not enough to show that a rule does in fact apply to what are supposed to be different domains. Rather, to demonstrate true domain generality with respect to some

rule *R* used by some cognizer *C*, it should be shown that *C* has the ability to deploy *R* in some previously unencountered situation or to apply it to some new cases. In practice, it does not seem to pose much of a threat to our account of domain specificity if we do not have a principled way of distinguishing domains. Typically, it will suffice to show that a cognitive mechanism is truly domain-general if we can show that it can be deployed in unfamiliar contexts that are new to the cognizer. Conversely, it suffices to show that a cognitive mechanism is domain-specific if we can demonstrate that when one attempts to apply it to new cases, the mechanism either does not function or gives systematically erroneous answers. This point will be justified further in due course in discussing what constitutes a new case or a new domain.

Preliminary Examples

Spurious examples of domain specificity, or genuine examples of domain specificity that are misleadingly described, are not difficult to find in cognitive science. Two such instances stand out in Cosmides and Tooby (1994), in the context of an argument that domain-specific cognitive mechanisms are more efficient and adaptive than domain-general ones. Cosmides and Tooby (1994, 90) state: "A woman who used the same taste preference mechanisms in choosing a mate that she used to choose nutritious foods would choose a very strange mate indeed, and such a design would rapidly select itself out." Clearly, something has gone wrong here: a rule that chooses mates on the same basis as foods is not a domain-general rule but one that is based on an error. If we have a cognitive mechanism that enables us to recognize edible foods, it should only be sensitive to perceptual stimuli that are plausible candidates for food. Otherwise, it is not a genuine food-preference cognitive mechanism. Hence, this is not a plausible example of a domain-general mechanism being inferior to a domain-specific one. In describing the example, Cosmides and Tooby seem to be trading on the ambiguity of the term "taste", which can either refer to gustatory discrimination or a broader notion of discrimination, which could comprise mate selection.

A case of domain specificity that is misleadingly described can be found in another example given by Cosmides and Tooby (1994). Although the following example is a genuine case of domain specificity, it is improperly contrasted with a putative case of domain generality. By examining it, we can get a better handle on the phenomenon of domain specificity. Cosmides and Tooby explicate the well-known example of the alarm calls of vervet monkeys, who give three different calls in response to three different kinds of predators (leopard, eagle, and snake), leading conspecifics to take three different types of evasive action (respectively, climbing a tree, looking up or diving into bushes, and standing on hind legs and looking into the grass). In this case, they state: "A single, general-purpose alarm call (and response system) would be less effective because the recipients of the call

would not know which of the three different and incompatible evasive actions to take” (Cosmides & Tooby 1994, 89-90). The problem here is not there could not be a general-purpose alarm system; there clearly could. But a general-purpose alarm system is not one that would issue the same call for every predator. That would be a system that fails to discriminate among different stimuli. Rather, an all-purpose alarm system would be one akin to the human linguistic alarm system, which issues a different linguistic warning in the case of different predators. There are clearly certain advantages to such a system, since it is capable of handling a much wider range of predators (“Lion!”, “Hawk!”, “Stampede of buffalo!”) and of being made more precise in various ways (“Tiger to the right”, “Hyena to the northwest”, “Human with weapon right behind you”, etc.). However, it may also involve certain disadvantages, since given the diversity of inputs and outputs, it may take more processing time to issue the correct alarm, there may be more opportunity for error in both transmission and reception, and the evasive action involved may have to be figured out from scratch by the respondent once the alarm is sounded. Determining which of these two alarm systems, the domain-specific vervet system or the domain-general human system, is more efficient and adaptive is not an easy matter. It will clearly depend on various contingencies such as the nature of the environment, and Cosmides and Tooby may ultimately be right that in certain circumstances a domain-specific system may be superior to a domain-general one. But they have not made the appropriate contrast between domain specificity and domain generality.

This example is instructive since, once modified in the way that I have just done, it provides a fairly clear contrast between a domain-specific and a domain-general cognitive mechanism. In the following section I will attempt to give a more satisfactory formulation of domain specificity and illustrate it with better examples drawn from the literature.

Domain Specificity Revised

To refine our understanding of domain specificity, it is useful to build on the example mentioned in the previous section and attend to its instructive features. The first feature that can be gleaned from the vervet monkey alarm call system is that a cognitive mechanism for alarm calls is at least in principle generalizable. That is to say, even though the vervet alarms are only issued for a small set of specific predators, it is easy to conceive of an alarm system that would extend to other predators. Hence, it seems safe to conclude that for one to speak meaningfully of a domain-specific cognitive system, that system must have the following feature:

- 1) A *domain-specific* cognitive system is one that is in principle generalizable to new domains.

This condition may appear vacuous, but it is designed to rule out cognitive systems that consist of a “database” rather than rules or principles, as mentioned above. Domain

specificity, to be meaningful, must be a feature of the cognitive capacity rather than a feature of the subject matter. Though this point may seem obvious, the attribute of domain specificity is often conferred on bodies of knowledge possessed by subjects that are not obviously generalizable, such as knowledge of animate as opposed to inanimate domains (e.g. Caramazza & Shelton 1998).

The first proposed feature of domain specificity makes reference to “new domains,” which is a notion that needs further explication and justification. The new domain involved need not be what we might regard as an entirely disparate area of inquiry. In the case of the vervets, the original domain is something like: predators commonly encountered by vervets in the wild. It is *in principle* generalizable to include the new domain: all predators, or even, all threats. The vervet alarm system is domain-specific because it fails to generalize to these new stimuli. But these new stimuli do not, strictly speaking, have to be drawn from what we would normally consider to be another domain, such as a new sensory modality or a new area of inquiry. At this point, it might be asked, by virtue of what are they to be considered genuinely new stimuli? They must at least be stimuli that the cognizer has not encountered before. But that condition is surely too weak, since the domain-specific vervet alarm system clearly generalizes to new exemplars of leopards, eagles, and snakes, which the individual has not encountered before, indeed ones which perhaps no vervet monkey has encountered before. Rather, in this context, new stimuli are ones that the system was not originally designed to cope with. This is admittedly a vague formulation and brings in thorny evolutionary considerations concerning the *proper function* of an evolved trait (Millikan 1989, Neander 1991). Though it is not always easy to determine what the proper function of a cognitive system is, some reference to it seems inevitable, since cognitive systems have evolved to fulfill a certain purpose and their generalizability consists in part in being able to extend beyond that purpose to cases that they were not designed to cope with, or ones that are not normally encountered in the environment in which the system evolved.² Hence, I propose that the second crucial feature of a domain-specific cognitive system is as follows:

- 2) A *domain-specific* cognitive system is one that systematically fails to yield a correct result in the case of stimuli that the system did not evolve to deal with.

The aptness of this second feature can be further justified by reflecting on appropriate examples from the literature. One such case is provided by Cheney and Seyfarth (1985, 197), who describe the domain-specificity of certain cognitive capacities in vervet monkeys, as follows: “Within the social group, the behavior of monkeys suggests an understanding of causality, transitive inference, and the notion of reciprocity. Despite frequent opportunity and often

² A similar conclusion has been reached by Boyer and Barrett (2005, 98), who write: “The domain of operation of the system is best circumscribed by evolutionary considerations.”

strong selective pressure, however, comparable behavior does not readily emerge in dealings with other animal species or with inanimate objects.” In this example, both features outlined above are clearly in evidence. First, the principle of causality and the rule of transitivity clearly have application outside the realm of social interaction with conspecifics. The transitivity rule can be used to infer hierarchy relations among monkeys (if *A* ranks higher than *B* and *B* ranks higher than *C*, then *A* ranks higher than *C*) but it can also be used to infer information about size, quantity, and other matters (if object *A* is larger than object *B* and *B* is larger than *C*, then *A* is larger than *C*). However, despite the clear applicability of this rule to domains that go beyond social interactions with conspecifics, Cheney and Seyfarth claim that vervets do not so apply the rule. Second, it is clear that vervets do not use the rule of transitivity on other species or inanimate objects simply because they evolved the rule to deal with the restricted domain of social interaction with conspecifics, which may have been a more pressing adaptive problem. In this case, it may seem obvious that interactions with other animal species and with inanimate objects constitute genuinely new domains. There may not appear to be a need to use the second feature of domain specificity to justify the judgment that it does not generalize to genuinely new domains. But even though it may not play this role in this case, there are other cases in which the second condition is necessary to enable us to make a judgment concerning domain specificity.

Some recent studies of cognition in non-human animals have debated whether animals have the cognitive capacity to teach others. Thornton and McAuliffe (2006) demonstrate that mature meerkats provide young conspecifics with specimens of their usual prey, scorpions, that are either dead, disabled (stings removed), or intact. Which of these three types of scorpion is provided depends on the perceived age of the young meerkat. Younger pups are provided with disabled but alive scorpions and this provides them with the opportunity to learn how to kill the scorpion without being exposed to the possibility of a sting. Thornton and MacAuliffe (2006, 228) conclude that “the provisioning behavior of meerkat helpers constitutes a form of ‘opportunity teaching’ in which teachers provide pupils with opportunities to practice skills, thus facilitating learning.” Moreover, they support their findings by relying on a definition of teaching derived from Caro and Hauser (1992), according to which an individual is a teacher if it modifies its behavior in the presence of a naïve observer, at some cost to itself, and as a result allows the observer to acquire knowledge or skills. In this case, it appears more difficult to rule decisively that the teaching is domain-specific rather than domain-general, since as Csibra (2007, 96) argues: “the opportunity teaching that has been demonstrated in meerkats does result in the acquisition of a generalizable skill: it not only provides youngsters with food but also ‘teaches’ them how to kill scorpions.” However, despite the apparent (limited) generalizability of this skill, what rules it out as a genuinely domain-general skill is that it appears to be

restricted to behaviors designed to facilitate preying on scorpions. Moreover, this is likely to be the function for which this behavior was evolved. Unless one can demonstrate otherwise, it is safe to conclude that this is a domain-specific capacity. (Whether that rules it out as a genuine case of teaching is another matter.) Hence, the second condition on domain specificity enables us provisionally to decide that this is indeed a domain-specific cognitive capacity.

Further Evidence

So far, the examples I have considered derive primarily from studies in evolutionary psychology and comparative cognition. But the concept of domain specificity has also had considerable influence in cognitive neuroscience and developmental psychology. I will now consider whether the notion as I have characterized it can be pressed into service in other areas of cognitive science.

There is a well-established body of evidence indicating the existence of category-specific semantic deficits in a range of patients with brain lesions and other neural abnormalities. However, the correct interpretation of this evidence remains a source of contention. Caramazza and colleagues have interpreted this evidence as indicating that semantic information is “domain-specific” (Caramazza & Shelton 1998; Caramazza & Mahon 2003). Other researchers have adopted different models to explain some of the same findings. Tyler and Moss hold that the selective deficits are an emergent phenomenon. Even though concepts are represented in a unitary distributed system, different types of concepts are structured differently. Since concepts in different domains have different internal structures, impairment of brain function leads to their being differentially affected (Tyler & Moss 2001).

On the face of it, much of this evidence, and the surrounding debate, seems to pertain not to the question of domain specificity but rather to that of brain localization. When damage to a certain part of the brain results in selective impairment in naming animals but not plants or body parts, the question is whether this is evidence that representations underlying our semantic information concerning animals is localized in a particular area of the brain, or whether they are not localized but that some of them are more impaired than others by such damage. Although this is an important question in its own right, it does not bear on domain specificity as such.

Similarly, neuroimaging data that has been brought to bear on this controversy is largely pertinent to the question of localization rather than domain specificity. On the one hand, Caramazza and Mahon (2003, 358) think that “there clearly does seem to be neural differentiation by semantic category” based on neuroimaging data. But Tyler and Moss (2001, 246) find that: “The most striking aspect of the neuroimaging data is the extent to which living and non-living concepts activate common regions with only small and inconsistent differences between domains.” The neuroimaging data is obtained mainly by testing healthy

subjects on a variety of tasks (e.g. silent naming, word-picture matching) and then using various techniques (fMRI, PET scans) to determine whether different areas of the brain are differentially involved when processing content derived from different domains (e.g. animals, tools, food items, etc.). But this does not seem to enable us to draw conclusions regarding whether our capacity to think about such domains involves abilities that are generalizable or not. If our knowledge of animals activates different brain areas than our knowledge of tools, that does not mean that any cognitive abilities that range over such domains are restricted to these domains and cannot be applied to others.

Among developmental psychologists, a debate has also raged concerning the domain specificity of our cognitive capacities. For instance, Carey and Spelke have argued that children have innate systems of knowledge that apply to distinct sets of entities and phenomena. Moreover, the domains of human knowledge, such as knowledge of language, physical objects, and number, center on distinct principles. These “core principles” serve to distinguish one domain from another. But despite the fact that Carey and Spelke hold that our cognitive makeup consists of distinct domains, they also claim that conceptual change in these domains occurs in part by constructing mappings between these domains. For instance, mappings between the domains of physics and number play a role in children’s reconceptualization of matter and material objects. Though the mapping is slow and difficult, children eventually succeed in using this mapping from one domain to another to differentiate the concept of weight from the concept of density (Carey & Spelke 1994, 191-192). But if one can transplant certain principles of reasoning from one domain to another, then those principles are surely not domain-specific. As I have already argued, it is wrong to argue that a cognitive capacity is domain-specific merely on the grounds that it pertains to a distinct body of knowledge. Rather, generalizability of rules or principles is key, and in this instance that condition would seem to be satisfied, thus casting doubt on whether the capacities in question are truly domain specific (as opposed to innate).

Opponents of the claim of domain specificity also sometimes seem to aim their criticism at a different target. Bates (1994/2001) is at pains to distinguish the claim of domain specificity from claims of innateness and (brain) localization. She rightly stresses that a cognitive capacity can have any two of these features without the third. However, her characterization of domain specificity is vague; with respect to language, Bates (1994/2001, 134) says that the claim of domain specificity is that “localized language abilities are discontinuous from the rest of mind, separate and ‘special’...” Moreover, despite her explicit cautionary notes, in presenting the arguments for and against domain specificity, she sometimes argues against innateness or brain localization instead. For instance, she argues against the domain specificity of language on the grounds that the brain systems that support language show an extraordinary degree of neural plasticity (Bates

1994/2001, 139). But that does not have a direct bearing on the issue of whether knowledge of language or the capacity to learn language can be generalized to other domains. She also characterizes the controversy over the domain specificity of language as follows: “Have we evolved new neural tissue, a new region or a special form of computation that deals with language, and language alone?” (Bates 1994, 138) Whether or not there is a brain region that has evolved to deal with language alone concerns innateness and brain localization rather than domain specificity.

A more promising case for testing this account of domain specificity can be drawn from the research on face recognition. Researchers tend to be divided as to whether the human capacity to recognize the faces of conspecifics is a domain-specific capacity, or whether it is a capacity that is acquired as a result of more general cognitive processes, of the type used to acquire expertise in other areas of human cognition. Without trying to rehearse the voluminous evidence involved, I will mention just two findings that are pertinent to the issue of domain specificity. Humans do not develop expertise for recognizing the hands or bodies of conspecifics that is at all comparable to their expertise for recognizing their faces, as measured by accuracy and reaction time (McKone, Kanwisher & Duchaine 2007, 12). Similarly, humans show decrease in accuracy in identifying faces when those faces are inverted but do not show such a decrease in identifying houses in the inversion condition (Yovel & Kanwisher 2004). The capacity to recognize upright faces rapidly and accurately does not seem to generalize to other visual stimuli. Object recognition is a skill that is in principle generalizable to domains beyond faces (e.g. hands, bodies, houses), but it fails to be so generalizable in humans. This is clearly in keeping with the first and second conditions outlined above.

What of the evolutionary clause in the second condition? Though it is not always explicitly mentioned by the researchers who work in this area, I venture that it is at least implicitly assumed. Consider the following scenario. Suppose it were found that humans can indeed generalize their face recognition capacities to encompass the faces of dogs. Proponents of domain specificity might not give up on their claim that this capacity is domain-specific, but rather insist that it is a domain-specific capacity that is specific to the domain of faces in general, or perhaps mammalian faces. Indeed, even if further evidence came to light suggesting that this extends to other objects like the facades of houses, they might continue to posit that it is a domain-specific capacity dedicated to the detection of objects with certain parts in particular configurations. What would rule out such a challenge? As I argued earlier, there are no ready-made domains that would enable us to dismiss it in principle. Rather, it seems natural to say that such hypothetical data would not be evidence of domain specificity (albeit across a broader domain) because of evolutionary considerations. Since it is likely that such a cognitive ability would have arisen to detect faces rather than, say, faces of humans and dogs (given the relative recency of the domestication of

dogs), any extension beyond the domain of human faces is indeed a generalization of this ability, and an indication that it is not truly domain-specific. In fact, this is explicitly acknowledged by proponents of domain specificity in this area of research. McKone, Kanwisher and Duchaine (2007, 12) hold that the domain-specific theory “proposes that a face template has developed through evolutionary processes, reflecting the extreme social importance of faces.”

Conclusion

In this article, I have tried to provide an analysis of domain specificity in cognition that enables us to make a theoretically useful distinction between domain-specific and domain-general cognitive systems. Drawing on examples from the literature, both genuine and spurious, I have tried to show that there are two features that make a cognitive system domain-specific. First, the cognitive system must be one that is in principle generalizable. Hence, it cannot be something like a body of information concerning a particular area, but something more like a rule or principle that has wider applicability. Second, it must be a system that the subject cannot apply to genuinely novel cases, where novel cases are ones of a type which this system was not originally evolved to deal with, or that are not within what has been termed the *proper function* of this cognitive system. This second condition is important in that it provides us with a principled way of delimiting domains, since these are not antecedently given. This condition is meant to help to address the question of whether or not a creature can go beyond the cases for which its cognitive capacities were evolved. The distinction between domain specificity and domain generality matters because a central debate in contemporary cognitive science concerns the extent to which our cognitive capacities are domain-specific tools evolved to solve certain problems in the evolutionary environment, or whether they are domain-general problem-solving capacities. A resolution of this disagreement depends on a clear means of demarcating domain-specific from domain-general system. In addition, it has often been claimed that one of the main points of difference between human cognition and that of other animals is its domain-general nature. Again, this debate cannot be properly adjudicated unless we have a principled way of making the distinction.

Cognition for action: an architectural account for “grounded interaction”

Anthony M. Harrison (anthony.harrison@nrl.navy.mil)

J. Gregory Trafton (greg.trafton@nrl.navy.mil)

Naval Research Laboratory
Washington, DC 20375 USA

Abstract

The effects of priming are not limited to semantics but have also been witnessed in visual-motor tasks (Tucker & Ellis, 2001). By generalizing ACT-R's (Anderson, 2007) existing spreading activation account to include visual representations and broadening the context within which associations are established, we have been able to replicate this small but reliable phenomenon both in simulation and embodied on a humanoid robotic platform. This model illustrates that the effect doesn't require strict embodiment (e.g., Barsalou, 1999) but can instead be accounted for with abstract representations that are “grounded by interaction” (Mahon & Caramazza, 2008).

Introduction

One of the current drumbeats in cognitive science is that cognition is for action. The strongest evidence for cognition for action comes from experiments that show that there is a much tighter coupling of perception and action than previously thought. For example, Glenberg and Kaschak (2002) found that when a sentence implied action in one direction (e.g., “Close the drawer”), participants had difficulty making a sensibility judgment that required a response in the opposite direction. Similarly, when participants indicated whether an object like a teapot was upright or upside down, reaction times were fastest when the response hand was the same as the hand that would be used to grasp the object (e.g., the right hand response was fastest if the teapot's handle was on the right) (Tucker & Ellis, 1998). Many of these researchers argue that this data shows that our thinking is fundamentally embodied, not abstract.

The main idea behind the embodied cognition movement is that cognitive representations and operations are firmly grounded in their physical context and that cognition relies heavily on modality-specific systems and actual bodily states (Tucker & Ellis, 1998; Barsalou, 1999; Wilson, 2002; Niedenthal, Barsalou, Winkielman, Krauth-Gruber, & Ric, 2005). The typical counter to embodied cognition theories are old-style abstract/symbolic theories (Newell & Simon, 1972; Pylyshyn, 1984), which argue that actual experience occurs in modality-specific representations, but those modality-specific states are abstracted and preserved as abstract, amodal symbols. Given the strength of abstract/symbolic theories, some have suggested that the only way that these theories can explain embodied effects is by adding increasingly complex post hoc assumptions about representations and processing (Barsalou, 1999; Niedenthal et al., 2005).

Mahon & Caramazza (2008) argue that the strict embodiment argument against abstract/symbolic theories neglects to consider the possibility that activation, spread through abstract symbols to modal representations, can account for these very same phenomena. While recognizing that abstract/symbolic theories could accommodate such tight perceptual/action coupling, they acknowledge that most theories do not adequately specify the computations and representational content that would permit such coupling through the spreading of activation. Such an abstract/symbolic system would be “grounded by interaction” (Mahon & Caramazza, 2008), if the abstract symbols come to be tightly coupled with their related percepts and required actions through experience acting in the environment. In this manner, the system would be able to exploit both the flexibility of the abstract representations and the richer context afforded by grounded representations.

We present an ACT-R (Anderson, 2007) model that fits within Mahon & Caramazza's “grounded interaction” framework (2008) that provides a process explanation of a classic embodied phenomenon – the visual-motor compatibility effect observed by Tucker & Ellis (2001).

Tucker & Ellis (2001)

Tucker & Ellis (2001) report a series of experiments that show a small but significant effect of visual presentation on grasp responses. In experiment 1, participants viewed a series of objects of different categories (e.g., natural or man-made) that were either large or small. The object size maps directly to the normal grasp used to manipulate the object: a power-grip (i.e., full hand) for large objects and a precision-grip (i.e., thumb and forefinger) for small ones. Objects were placed either near the response hand (15cm) or far away (2000cm). Subjects responded with either a power- or precision-grip response based on the category (i.e., natural/man-made) of the object seen. The task response-mapping (e.g., natural/precision) was varied between subjects.

While there were some simple main effects, the critical result from the first experiment was the interaction between the size of the object and response-mapping. Despite the fact that the size of the object was irrelevant to the task, its compatibility with the response-mapping resulted in reduced reaction times and error rates (figures 1 & 2). Specifically, when viewing large objects, power responses were faster and more accurate than precision responses. Similarly, viewing small objects resulted in faster and more accurate precision responses than power responses.

In experiments 2-4b, Tucker & Ellis used a go/no-go paradigm, with the response-mapping cued by a tone and go/no-go cued by the object category. Experiment 2 presented the response-mapping cue tone 500ms *before* object presentation. The lack of a compatibility effect in the results showed that prior knowledge of the required response was sufficient to override the phenomenon.

Figure 1. Visual-motor compatibility effect for latency (Tucker & Ellis, 2001, experiment 1). Dotted lines are model fit ($R^2=0.99$, RMSE=2.95ms).

Figure 2. Visual-motor compatibility effect for accuracy (Tucker & Ellis, 2001, experiment 1). Dotted lines are model fit ($R^2=0.88$, RMSE=2.48%).

Experiment 3 reversed the time delay of the prior experiment and presented the response-mapping cue tone 300ms *after* object presentation. In this circumstance the compatibility effect was present. These results and those from experiment 2 show that the effect is dependent upon the motor system not already being prepared for a particular response.

In experiments 4a and 4b, the visibility of the object was manipulated. In 4a the object disappeared at the same time as the response-mapping cue tone was presented. In 4b the object disappeared 300ms *before* the response-mapping cue tone. The compatibility effect was present in 4a and not 4b, showing that the object's visibility at response selection is critical.

To summarize, Tucker & Ellis have shown that when the object's normal grasp response is compatible with the experiment's response-mapping, there is a small but significant benefit (experiment 1). However, this is conditional on the motor system not already being prepared for a particular response (experiments 2 & 3) and that the object is visible at response selection (experiments 4a & 4b). They discount the theory that this is an example of the percept *directly* priming a particular motor response, arguing that the object would have to be within reach and that such a mechanism would not work for images of objects as well (Tucker & Ellis, 1998). Instead they propose that this is evidence of "a more general representational mechanism that describe object properties in motor terms" (Tucker & Ellis, 2001).

Architectural Account

Within the ACT-R cognitive architecture (Anderson, 2007), the time it takes to retrieve a specific memory (i.e., chunk) is inversely related to that chunk's activation. The chunk's activation is composed of three primary components: base-level activation, spreading activation, and some stochastic noise. Base-level activation is a learned quantity subject to decay that incorporates the effects of frequency and recency of the memory's use. Spreading activation is context dependent, allowing chunks that are the focus of attention to activate related memories. In this way, the chunks within a given buffer (i.e., the focus of attention for a given module in ACT-R) can make related concepts more readily retrievable. Spreading activation is the mechanism used to account for semantic priming effects (Anderson & Reder, 1999). This same mechanism is used here to model the visual-motor priming reported by Tucker & Ellis (2001).

ACT-R defines the current context as the contents of the chunks currently in the model's buffers. If chunk i is in a buffer k , then all of the chunks that i references are in the context. The source activation of buffer k is shared equally among those context chunks, and they in turn spread that activation to all the chunks that contain references to them. ACT-R only establishes associative links from the referenced chunk to the referring chunk. The more chunks that reference a specific chunk j , the weaker its associative strengths are to the referring chunks. Chunk j becomes a less effective retrieval cue because the weaker associative links spread less of the source activation.

This mechanism of spreading activation through associative links from the currently defined context allows ACT-R to model semantic priming (Anderson & Reder, 1999). However, in order to address the visual-motor priming shown in Tucker & Ellis (2001), ACT-R's existing mechanisms must to be modified slightly. These modifications are not complex post-hoc assumptions, rather they are consistent with the existing framework.

Visual Representation and Activation Normally, ACT-R models use only the intentionality system (i.e., goal buffer) as a source of activation, even though all buffers have the capability. Obviously, in order to support visual priming,

the visual buffer must also be used as a source of activation. However, the utility of visual activation is limited due to the traditional structure of the visual representations. The visual representation does not represent a semantic concept; rather, it is a raw percept made up predominantly of non-chunk, primitive features (e.g., numbers, strings). They are therefore highly insular, having little connection to other chunks, which dramatically limits the spread of activation. Typically the visual object's *value* slot (usually a string literal) is used to uniquely associate it with the semantic representation of that percept (i.e., its symbol). To allow a visual percept to activate a semantic symbol, as well as other chunks related to that concept, the *value* slot was modified to reference the semantic symbol chunk directly. To access the semantics, a retrieval must still be made, but now the percept itself can prime that retrieval.

Co-occurring Contextualization Canonical ACT-R only establishes associative links between chunks through symbolic references (i.e., chunk *j* can activate chunk *i* since *i* directly references *j* as a slot value). We propose that symbolic links can also occur through co-occurrence. The context within which processing occurs is not limited to the symbolic structure of the chunks currently in buffer, but actually includes the patterns within the processing units (i.e., productions) that execute cognition. If a production matches against both contents of the goal and visual buffers in order to fire, then the contents of those buffers do not define the context independently, but jointly, and should be linked associatively. Because productions can contain perceptual and motor patterns, perception and action can become linked through co-occurrence.

The application of this mechanism is relatively straightforward. Specifically, the semantic symbol of a percept and the motor command used to grasp the object are associated with each other even though neither has a direct symbolic relationship to the other. These associations are learned from the environment as a consequence of attending to an object, considering its meaning, and manipulating it.

In the language of Mahon & Carmazza (2008), the semantic symbol that is linked to a percept provides the abstract representation that mediates perceptual processing and motor activation. The motor and visual representations are grounded to this abstraction through a history of interaction, allowing the establishment and strengthening of associative links through co-occurrence. Activating the abstract symbol propagates activation both to experienced percepts and motor commands.

Model Details & Fit

The model presented here focuses on a simplification of Tucker and Ellis' (2001) first experiment; how it accounts for the subsequent experiments will be saved for the discussion. Because their presentation distance manipulation had no influence on the visual-motor compatibility effect, it was eliminated from the simulation. Otherwise the simulation is identical to the actual experiment including the timing of object presentations.

Execution The model completed 160 trials (as did participants) where it was presented small and large objects that were either natural or man-made (e.g., strawberry, key, potato, frying pan). Retrieving the visual-symbol associated with the percept, the model was able to classify the object. With this information the model retrieved the appropriate response-mapping for the classification (e.g., natural/precision or man-made/precision). The final retrieval was of the appropriate grip command itself. Once the motor command was retrieved it was passed to the motor system to be executed as the trial response.

Assumptions This model relies upon three key assumptions. First, that activation is spread through not only the goal buffer but also the visual buffer. Second, that the process of encoding a visual percept includes linking that percept to its semantic representation (i.e., its visual-symbol). Finally, associative links are not limited to containment relationships. Over the history of interacting with the environment, both the visual-symbol for a percept and the motor command used to manipulate the object come to be associated with each other via co-occurrence.

Since priming within ACT-R is function of spreading-activation, base-level activations are not of theoretical interest. However, these values do come into play with respect to the rapid retrieval times in the data (figure 1) and are discussed in detail later.

Spreading Activation The model proposes that the visual-motor compatibility effect reported in Tucker & Ellis (2001) is due to activation spreading both from the intentionality (i.e., goal) and visual systems. Once the object is visually encoded, activation is spread to the learned motor response through the co-occurrence associative link between it and the visual-symbol. When the model has retrieved the appropriate response-mapping for the object's category, activation is spread to the task appropriate response. For incompatible responses, activation is spread to two different motor commands. However, when the responses are compatible, both activation sources converge on a single motor command (figure 3). Because of the higher total activation of the compatible motor response, it can be retrieved faster. The lower activation of the incompatible response also makes misretrieval more likely since noise might exceed the differences due to spreading activation.

Figure 3. Total activation of incompatible and compatible response motor commands (with noise).

Results and Fits 1000 iterations of the model were run on the simulated version of the experiment. Reaction time fits were quantitatively very strong ($R^2=0.99$, $RMSE=2.95ms$, figure 1). Accuracy fits were less strong, but captured the qualitative effect ($R^2=0.88$, $RMSE=2.48\%$, figure 2). The weaker accuracy fit was due largely to the exclusion of base-level learning from the model. With only spreading-activation, compatible response trials are effectively immune to noise making false retrievals impossible (figure 2 & 3).

Parameters The fits reported above required the manipulation of a few parameters, some of which were dictated by the architecture and the structure of the model.

The maximum associative strength was set to 3.1 (default of 1). This parameter is completely constrained by the structure and connectivity of the model. Conceptually, any chunk that has many references should be a weak retrieval cue; that is its associative strength should be near zero. A maximum associative strength of less than 3.1 would result in negative (i.e., inhibitory) associative strengths for the most heavily referenced chunks. If one of these chunks were to be used as a retrieval cue, it would actually become harder to retrieve its related concept.

The source activation from the goal buffer was kept at the default value of 1. The activation from the visual buffer was set to 0.3, instead of the default of 0. This allows the contents of the visual buffer (namely the semantic symbol) to weakly prime the normal motor response for the object.

While base-level learning was not used in this model, base-level activations were still critical to achieve the rapid retrieval times implied by the average response time of 490ms. Three separate factors influenced the selection of the base-level activations for the visual-symbol, grasp-command, and response-mapping chunks. First, the model, as implemented, requires five productions with three retrievals before a response can be started. At 50ms per production, an additional 85ms for the visual object encoding, and a minimum motor execution time of 50ms,

there is only 105ms left for the three retrievals. Second, we assume that over a lifetime of observing and interacting with these objects, the base-level activations for the visual-symbols and grasp-commands are both stable (i.e. relatively immune to decay) and strong. Since we generally see objects more often than we grasp them, visual-symbol activations were set greater than the grasp-commands. Finally, while the response-mapping chunks would benefit from recency, their frequency of use would still be small, so base-level activations were set lower than those of the grasp-command chunks. Base-level activations of 5, 3, and 2.25 were used for the visual-symbol, grasp-command, and response-mapping chunks respectively. While these values are necessary for the low RMSE latency fit, the qualitative (R^2) fit is less sensitive to the base-level values.

To account for the errors in performance, the model relied upon misretrievals. This was accomplished by setting the activation noise parameter to 0.06. The qualitative error results are largely unchanged for most published noise values since the noise only affects the incompatible responses (unless noise exceeds the activation spread to the chunks by the visual buffer). The model's fit of the accuracy data is weaker due largely to the simplification of removing base-level learning. Since compatible responses receive all of the spreading-activation, they are effectively immune to noise (figure 3), which results in 100% accuracy for those trials. To achieve the average 3.5% error rate for compatible trials seen in the data, base-level learning would have to be enabled. This could produce situations where successive retrievals of one particular response might boost its base-level activation such that it could falsely intrude on a subsequent trial. Attempting to fit the error data in this manner would have required seven additional parameters (base-level learning rate, and average age and access counts for the visual-symbol, grasp-command, and response-mapping chunks) instead of the three fixed base-levels used.

Robotic Embodiment

One of the challenges in modeling embodied cognition is the lack of a physical body. This lack is especially relevant because one of the embodied cognition claims is that the body is central to both perception and action; it is disingenuous to claim that we can account for embodied cognition phenomena without a body.

One aspect of running cognitive models on embodied platforms is that actual perception and action must occur. Critically, both perception and action must use cognitively plausible representations and cause the physical body to move.

We have modified ACT-R by allowing it to perceive and act on the physical world by attaching robotic sensors and effectors to it; we call our system ACT-R/E (*Embodied*) (Trafton, Harrison, Fransen, & Bugaska, 2009). Changes to the visual and motor modules are described below.

The Visual Module is used to provide a model with information about what can be seen in the current environment. ACT-R normally sees information presented

on a computer monitor. We modified the original visual module to accept input from a video camera. The visual module allows access to object identification through fiducial (Kato, Billingham, Poupyrev, Imamoto, & Tachibana, 2000) and face (Fransen, Hebst, Harrison, & Trafton, 2009) trackers.

Traditional ACT-R has a virtual motor system that allows virtual hand movements (e.g., typing, mouse movements). ACT-R/E's motor module allows control over all of the robot's effectors. When a motor chunk enters into the motor module, a specified motor controller executes the actual physical response.

Our current robot platform is the Mobile-Dexterous-Social (MDS) Robot (Breazeal, 2009). The MDS robot neck has 18 degrees-of-freedom (DoF) for the head, neck and eyes allowing the robot to look at various locations in 3D space and 11 DoF on its four-fingered hand, allowing it to make various gestures and grips. Perceptual inputs include two color video cameras and a SR3000 camera to provide depth information. For the current project, the MDS head can identify various objects through the fiducial tracker and can move its hands in a power or precision grasp.

The 10ms visual-motor compatibility effect is completely obscured by the robot's motor system's slower execution times. In order to illustrate the effect, we dramatically increased the retrieval time scalar. In the video (see acknowledgments for the URL) the visual-motor priming accounts for around a 500 ms performance improvement.

Discussion

ACT-R has a long history of accounting for semantic priming effects (Anderson, 1974), but its perceptual/motor integration has been less explored. To address this theoretical gap, we have modified the visual representation linking the percept to its derived abstract symbol. This allows source activation to usefully spread from the visual system, instead of just from the intentionality system (i.e., goal buffer). We also present a broadened definition of predictive context for the establishment of associative links. Traditional ACT-R only establishes associative links from the contained chunk to the container. In this way, when another chunk has a reference to the contained chunk, it is potentially predictive of the need for the containing chunk. We augment spreading activation to deal with co-occurrence so that we can establish a richer context. In this manner, the visual-symbols and motor commands come to be associated as productions fire that simultaneously match both of the representations in their respective buffers. While only the consequences of this mechanism are exploited in the model presented, the actual process is under active investigation.

A particular limitation of this account is that it does depend upon both visual and motor experience with a given object. Lacking such experience, the modal representations will not be associatively linked to the abstract symbolic representation. As such this model cannot account for

related effects when novel objects are used; such as those seen when subjects concurrently perform a compatible manual rotation during the classic Shepard & Metzler (1971) mental rotation task (Wexler, Kosslyn, & Berthoz, 1998).

Experiments 2-4 While the model presented only addresses Tucker & Ellis's (2001) first experiment, its extension to the other experiments is fairly straightforward. All of the subsequent experiments used a go/no-go paradigm where the response to be given was cued by a tone and the go/no-go was determined by the object's category. Recall that in experiment 2, subjects heard the response cue 500ms before the object was presented. This 500ms window of time would allow the model to retrieve the appropriate motor response before it had to determine whether or not to execute it. The lack of a visual-motor compatibility effect observed would be due to the fact that the response had already been selected, leaving visual priming no opportunity to influence performance.

In contrast, in experiment 3 the response cue tone was presented 300ms *after* object presentation. As in experiment 1, the visual presence of the object would allow activation to spread to the learned motor response, facilitating retrieval when it was compatible with the response cued by the tone.

Experiment 4a removed the object at the same time as the cue tone was presented. If the model were able to retrieve the motor command at the moment of the cue-onset and visual-offset, the compatibility effect would be observed. However, ACT-R's encoding time for auditory information would actually result in the retrieval starting at least 50ms after presentation. Since ACT-R's spreading activation mechanism is instantaneous, that activation would drop to 0 immediately after the percept disappeared, eliminating visual priming entirely. The results from experiment 4b are more easily accounted for. Since the object was removed 300ms before the cue tone, the activation of the learned motor response would have been eliminated before the retrieval of the task response. However, theoretical proposals that would allow spreading-activation to decay gradually (e.g., van Maanen & van Rijn, 2007) would not only support the compatibility effect in experiment 4a but also make predictions regarding how long the delay in 4b would have to be before the effect disappeared.

Conclusions

Tucker & Ellis interpret their results through a lens of strict embodiment (e.g., Barsalou, 1999). They argue that the phenomenon could not be due to the perceptual priming of the motor response, rather posit that the evidence supports activation of a more general representation that incorporates both visual and motor properties (Tucker & Ellis, 2001).

Mahon & Caramazza (2008) counter that this line of reasoning unjustifiably discounts the possibility that abstract/symbolic systems could account for visual-motor priming by the spreading activation through abstract

symbols. They propose that the challenge for abstract/symbolic systems is to “1) develop a model of the computations and representations that mediate between perceptual processing and motor activation, and 2) specify the conditions under which those computations are deployed” (Mahon & Carmazza, 2008). In this paper, we present a cognitive model that addresses both of those challenges while remaining within ACT-R’s existing architectural constraints. While ACT-R is a traditional abstract/symbolic system, this work moves the architecture towards one that is “grounded by interaction”, allowing it to not only exploit the flexibility of disembodied abstractions but also the richly contextualized representations inherent in more strictly embodied accounts (Mahon & Carmazza, 2008).

Combining the generalization of activation spread and co-occurrence associations allows ACT-R to account for semantic (Anderson & Reder, 1999), visual-motor (Tucker & Ellis, 2001), and potentially even motor-visual (Craighero, Fadiga, Umiltà, & Rizzolatti, 1999) priming. This richer account may also be a fundamental component in enabling symbol acquisition/grounding within ACT-R (Barsalou, 2003; Mahon & Carmazza, 2008).

The resolution of ambiguity during conversation: More than mere mimicry?

Abstract

Interlocutors often omit important words during conversation, which can lead to miscommunication during ambiguous scenarios (Rayner, Carlson, & Frasier, 1983). Haywood, Pickering and Branigan (2004) show that under ambiguous situations, listeners are highly sensitive to syntactic primes. The studies reported here evaluated the effects of linguistic and nonlinguistic cues to ambiguity. Experiment 1 implemented a syntactic prime and a visual mistake from a pseudo-confederate to promote disambiguation. Participants were successfully primed to disambiguate their statements during the pseudo-conversation but the visual mistake had no effect. Experiment 2 evaluated the effect of the visual mistake in the absence of a prime during an ambiguous pseudo-conversation. There was a significant effect of visual mistake for participants who believed they were speaking with a real person. Overall, participants did not merely mimic their pseudo-conversation partner's syntactic prime, but perceived other cues to the breakdown in communication to better clarify their own statements.

Keywords: Priming; conversation; language; linguistics; nonverbal communication

Introduction

Verbal and nonverbal communication requires individuals to correctly decode meaning behind an intended message. However, there is a great deal of ambiguity that naturally occurs during conversation. This may occur because individuals are presented with a multitude of information during communication scenarios (i.e., foreground and background information, with an influence from visual, auditory, and motor events). Yet interlocutors have the ability to interpret the intended message with relatively little difficulty (Garrod & Pickering, 2004; Pickering & Garrod, 2004). In fact, miscommunication often occurs (e.g., leaving out a seemingly useless bit of information because its utility is not recognized; Guhe & Bard, 2008). Individuals often leave out a single word that could help clarify the intended meaning behind a statement (e.g., "that" to group two objects as one, Haywood, Pickering, & Branigan, 2004). Some researchers have suggested that choices in the use of syntax are influenced by ease of production (Bock, 1986; Branigan, Pickering & Cleland, 2000).

This ease in production may help explain why interlocutors often omit information during conversations. Individuals may leave out words because it is initially easier to exclude information when s/he is unsure of what his/her communicative partner already knows (Lee, 2001; Levelt, 1989; Horton & Keysar, 1996). This strategy may save the speaker time in the beginning, but it will be costly in the

end. Recent research suggests that this strategy of responding is relatively egocentric. This often occurs because cognitive load is initially reduced at the onset of the conversation, especially when common knowledge has not been fully established (Bard, Anderson, Chen, Nicholson, Harvard, & Dazel-Job, 2007; Rayner, Carlson, & Frasier, 1983; Schober, 1993). Taking an egocentric perspective may eventually become quite cumbersome if the speaker must continually adjust his/her own previous statements when the message is unclear (Levelt, 1989; Miller & Johnson-Laird, 1976). In order to resolve the confusion, interlocutors must perceive the existing ambiguity early on in the conversation. If the existing ambiguity is realized, then there will be no need to restate the message because it will not be misunderstood. Therefore, it is important to investigate how individuals recover during these instances of miscommunication.

Haywood, Pickering and Branigan (2004) have demonstrated an effective method in which conversation partners may resolve instances of ambiguity. These authors suggest that syntactic priming is an effective and automatic strategy interlocutors use to communicate effectively with each other (Garrod & Pickering, 2004). They maintain that under certain situations (e.g., giving instructions) conversation partners will initially respond ambiguously unless they are primed to disambiguate. This type of syntactic strategy shows the listener how to correctly clarify his/her statements. Haywood, Pickering, and Branigan have also shown that syntactic priming has a quite substantial effect on future utterances. This is beneficial to the speakers, because s/he realizes how to disambiguate his/her own statements without explicitly being instructed to do so.

Priming clearly has a dominant influence in dialogue, but interlocutors rarely implement this strategy on their own (Haywood, Pickering, & Branigan, 2004). It should be considered that the effect of the prime might merely represent the automaticity of aligning at the syntactic level (Garrod & Pickering, 2004; Pickering & Garrod, 2004). This level of alignment could represent conversational mimicry, rather than the understanding of why the speaker is required to disambiguate. Other strategies are possible and it is imperative to evaluate other cues speakers may retroactively use to elucidate confusing situations (Horton & Keysar, 1996). The studies reported here will evaluate the contribution of linguistic and/or non-linguistic behavioral cues to the breakdown in communication. If priming truly represents the mechanism behind disambiguation, then there

should be no differences between the use of a prime and the inclusion of a non-linguistic cue.

Experiment 1

The original Haywood, Branigan and Pickering (2004) study used a live confederate to prime participants to disambiguate during a two-referent instructional task. They found that participants were more likely to disambiguate on future trials if they were exposed to a syntactic prime (e.g., the complementizer “that”) that resolved existing ambiguity. This study was successfully replicated using a pseudo-confederate (pre-recorded confederate statements; Roche, Caucci, Dale, & Kreuz, 2009; Roche, Dale, & Caucci, 2009). The next logical step to understanding how interlocutors resolve ambiguity during conversation was to evaluate other possible strategies they might use to disambiguate. The current study evaluated the contribution of a prime (“that”) and a non-linguistic behavior cue (a visual mistake) to disambiguating ambiguous scenarios. If participants recognize the non-linguistic cue as a salient indication of their own ambiguity, they should then increase the number of times they disambiguate during the entirety of the conversation.

Method

Participants. Participants included 23 University of Memphis undergraduate students (mean age = 19.84 years years; 13 females). All participants were native speakers of American English with normal to corrected vision and no reports of hearing/speech impairments.

Materials. The experiment took place in a private laboratory room. Participants were seated at a comfortable distance from a 20-inch iMac computer screen. A headset with microphone was used to present and record acoustic data. MATLAB PsychToolbox-3 programs (Brainard, 1997) controlled stimulus presentation and recorded participant responses for the conversation.

Stimuli. There were 3 conditions (ambiguous, unambiguous, and incorrect), 12 rounds and 8 instructions per round (4 participant and 4 pseudo-confederate instructions per round). Experimental object stimuli included twenty-five images placed in a 5x5 grid. These grids contained four types of images (13 containers and/or objects, 4 containers + objects and 8 geometric shapes; see Figure 1a for an example of object placement; with 8 empty cells by the end of the round). Auditory stimuli included 48 pre-recorded pseudo-confederate statements (44.1kHz, 16 bit sampling rate, with equated RMS amplitude to adjust for comfortable listening level and to prevent unwanted acoustic cuing) that described 4 types of instruction statements about the object to be moved [e.g., container, object, “that” prime (container + object), no prime (container + object), see Table 1 for example statements]. It should be noted that there was only one prime from the pseudo-confederate per round (12 primes total). However,

there were two instances in which the participant could disambiguate his/her instructions. Finally, visual stimuli included 48 pre-recorded pseudo-confederate video responses to the participant statements. Each condition contained a total of 48 videos, which differed by the type of pseudo-confederate video response the participant received (mistake or correct).

The *unambiguous* condition included 7 videos that contained a mistake in which the pseudo-confederate moved the wrong container or object. The *ambiguous* condition included 7 pseudo-confederate videos comprised of a container and object that was initially moved, but then the correct container + object was moved. Finally, the *incorrect* conditions included 7 pseudo-confederate videos comprised of cases in which the corresponding separate container and object were moved, but the correct grouped (C+O) object was never moved (see Figure 1b, for an example of video presentation). It should be noted that the video files that contained mistakes all occurred in the beginning (first 24 trials) of the experiment and were pseudo-randomly assigned to each condition.

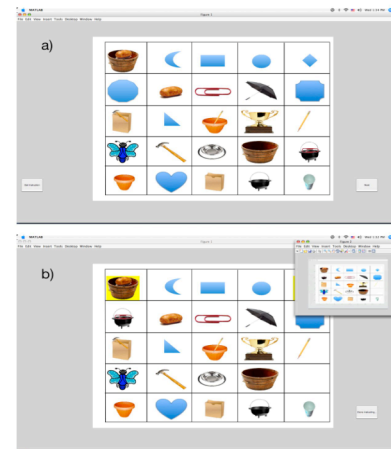

Figure 1. a) The 5x5 grid of objects to be moved by the participant; b) Represents the screen participants see after they have finished giving their instruction to the pseudo-confederate (the small box in the right corner was the video presented to the participant).

Table 1. Examples of pseudo-confederate instructions (C: Container, O: Object, C+O: Container + Object).

Object	Prime	Statement
C	No	“Put the bucket on the circle.”
O	No	“Put the paperclip on the stop sign.”
C + O	No	“Put the pencil in the flowerpot on the rectangle.”
	Yes	“Put the potato <i>that’s</i> in the bucket on the diamond.”

Procedure. To begin, the participant was seated next to a Caucasian female confederate while completing the informed consent, but separated during the experimental sessions. This is an important to control, because much of

perceived talker variability is related to race and gender (Ryalls, Zippner, & Bauldauff, 1997; Walton & Orlikoff, 1994). Therefore, it was important to match the confederate to the pseudo-confederate's race and gender, to conceal the deception of the task. Participants were then told that their conversation partner (the confederate) would receive instructions first, in a separate room. Once the participant and confederate were separated, the participant was told that they were separated from his/her conversation partner in order to obtain uncontaminated auditory recordings, because individuals often speak over each other during conversations.

Participants were assigned to 1 of 3 conditions that differed based on the pseudo-confederate's video responses (*i.e.*, ambiguous, unambiguous or incorrect). The participant and pseudo-confederate took turns giving instructions about moving objects around the screen (8 instructions per round: 4 participant and 4 pseudo-confederate). It should be noted that each pseudo-confederate statement and video file had a 2s delay before its presentation to imply she was thinking about giving and receiving the instruction.

Participants were informed that the pseudo-confederate would initiate the conversation because she had been viewing the first screen longer. After each pseudo-confederate response, the participant was asked to follow the instructions provided by his/her conversation partner. Once the participant finished moving his/her object, s/he would click a button to transition to another screen to provide instruction to his/her partner (e.g., the object to be moved had a yellow background, and its location had a yellow highlight around it). Once the participant finished giving his/her partner instructions, a smaller window would pop-up on the screen showing the participant if his/her partner made a correct or an incorrect response.

To ensure participants understood the task, they were presented with a brief video prior to the experimental session. This video included 3 mock trials, with 2 male talkers providing each other with instructions and moving the objects around the screen. Once the video was finished, the researcher then asked the participants to rephrase the instructions for the task in their own words. When the researcher felt the participant understood the task, the participant was then asked to make a mental note of how many mistakes were made by his/her conversation partner during the experiment (this helped the researchers determine if they were paying attention to the mistakes). All participants recognized the existence of the mistakes, but on average reported viewing 3-5 out of 12 mistakes (this was not surprising, since the experiment lasted about an hour). Upon completion of the experimental session, the confederate returned and participants were asked, "Would you be surprised if I told you that you were not actually speaking with the person sitting next to you?" The resulting percentage of deceived participants was 92.3%.

Results

A 3 (Condition: ambiguous, unambiguous, & incorrect) x 3 (Block: rounds 1-4, 5-8, & 9-12) mixed fixed effects, repeated measures model with a compound symmetry variance-covariance structure was used to assess the proportion of disambiguated responses from participants during the pseudo-conversation. This model provided non-significant results between the three conditions (see Table 2 for means and standard errors). However, it should be noted that the results from the current experiment did in fact replicate Haywood, Pickering and Branigan's (2004) study, suggesting that participants were significantly affected by the prime (no prime: 25% said "that", 15% disambiguated; prime: 53% said "that", 60% disambiguated).

Table 2. Means and standard errors for the proportion of disambiguation for each condition.

Condition	Mean	SE
ambiguous	0.55	0.15
unambiguous	0.63	0.09
incorrect	0.49	0.14

Discussion. The results from Experiment 1 replicated Haywood, Pickering and Branigan's (2004) study suggesting that participants used the syntactic prime "that" reliably to disambiguate their statements. This suggests that the use of a syntactic prime is effective for disambiguation. Unfortunately, including a visual mistake with a syntactic prime did not seem to significantly influence interlocutors. The interpretation of this non-significant effect may be that the results are an indication of the strength of the prime "that". The prime may have been a highly effective cue participants used to disambiguate. However, the prime alone may have created a ceiling effect in which participants were unable to find a more creative strategy of responding, thus leaving the effect of the behavioral cue hidden. An egocentric perspective may prevent participants from using a syntactic prime, such as "that". Under more natural situations, interlocutors must find other methods to help them disambiguate confusing scenarios.

Experiment 2

Experiment 1 replicated Haywood, Pickering, and Branigan's (2004) study, but failed to show an effect of the visual mistake. Regardless of the null effect, it is still important to evaluate the influence of non-linguistic behavioral cues to communication breakdown. Haywood, Pickering and Branigan suggest that interlocutors often do not automatically use complementizers on their own to disambiguate. They suggest that a listener should be primed to do so, but this is not to say syntactic priming of this nature never occurs naturally. Interlocutors must find other methods to demonstrate the ambiguity perceived, if the syntactic strategy is not naturally elicited. This is especially

important when it is too costly to explicitly describe the ambiguity (e.g., under time constraint).

Therefore, evaluating the use of other strategies interlocutors may enlist during perceived ambiguity is crucial. Again, a syntactic prime is an extremely effective and powerful strategy interlocutors may use to disambiguate ambiguous scenarios. The prevailing nature of the syntactic priming effect might have dampened the effects of the non-linguistic behavioral cue to communication breakdown in Experiment 1. The purpose of Experiment 2 was to evaluate the effects of non-linguistic behavioral cues to miscommunication in the absence of a syntactic prime. If this is an effective cue to disambiguation, then priming that may never occur naturally may be unnecessary under certain communicative scenarios.

Method

Participants. Participants included 16 University of Memphis undergraduate students (mean age = 19.64 years; 12 females). All participants were native speakers of American English with normal to corrected vision and no reports of hearing/speech impairments.

Materials. All the materials were identical to those in Experiment 1.

Stimuli. There were 2 conditions (correct or mistake), 12 rounds with 8 instructions per round (4 participant and 4 pseudo-confederate instructions per round). The object stimuli for this experiment were identical to Experiment 1. The auditory stimuli were identical to Experiment 1, except the prime “that” was removed. The vocally produced word “that” was clipped at the zero crossing at the onset and offset of the production from the original sound files using Audacity. The video stimuli consisted of either a correct response or a mistake provided by the pseudo-confederate. There were a total of 12 mistakes pseudo-randomly assigned throughout the mistake condition. The construction of the mistake was identical to the mistakes created for the “incorrect” condition in Experiment 1 (the incorrect objects were moved).

Procedure. The setup and instructions to the participants were identical to Experiment 1. It should be noted that the pseudo-confederate video presented to participants was moved to the middle of the computer screen to increase the likelihood that the participants would see the mistake. All participants noticed the mistakes and were able to reliably describe the mistakes when asked, but reported seeing on average 2-3 mistakes out of 12. This is not surprising since the experiment lasted about an hour.

Results

Upon the completion of the experimental session, participants were asked, “Would you be surprised if I told you that you were not actually speaking with the person sitting next to you?” The resulting percentage of deceived

participants was 67%. Since some participants were not deceived by the experimental design, the statistical analysis for this experiment will include Deception as a factor.

A 2 (Condition: correct & mistakes) x 2 (Deception: deceived & not deceived) x 3 (Block: rounds 1-4, 5-8, & 9-12) mixed repeated fixed effects model with a first-order auto-regressive (AR1) variance-covariance structure, was used to evaluate the probability that individuals disambiguate their statements during an ambiguous instruction task. Upon initial analysis of the variance-covariance structure, the AR1 variance-covariance structure was used because it seemed to have the best fit for the data. The results from this model suggests there was a significant main effect of deception [$F(1, 14.139) = 10.593, p < .01$]; see Figure 2] and block [$F(2, 24.933) = 5.087, p < .05$]; see Figure 3]. The model also revealed a significant Condition x Deception interaction [$F(1, 14.139) = 12.682, p < .005$]; see Figure 4].

The main effect of deception revealed that deceived individuals disambiguated their statements 36.9% more than participants who were not deceived (see Figure 2).

Figure 2. Means and standard errors for the proportion of disambiguated statements for deceived and not deceived participants.

Post-hoc adjusted Bonferroni pair-wise comparisons for the main effect of block revealed that there were significantly fewer instances of disambiguation in block 1, relative to block 2 (19.7%, $p < .05$) and marginally different than block 3 (18.5%, $p = .08$; see Figure 3 for means and standard errors).

Figure 3. Means and standard errors for the probability of disambiguating during the 1st four rounds, 2nd four rounds and last four rounds.

Post-hoc adjusted Bonferroni pair-wise comparisons for the Condition x Deception interaction revealed that deceived participants who viewed the pseudo-confederate mistakes

disambiguated 52.2% more than participants who did not view mistakes ($p < .001$). However, there were no significant differences between the participants who were not deceived and the condition they were in ($p = .206$).

Figure 4. Means and standard errors for the probability of disambiguating when a behavioral cue was provided (a mistake) or not provided (correct).

Discussion

Upon initial evaluation, only 67% of the participants were deceived. However, when participants were asked why they felt the deception failed, many of the participants said that they were aware of the deception that usually occurs during psychological experiments. Many of these participants who were not deceived reported being upper division psychology students or had experience participating in other psychology experiments. This resulted in differential responding between deceived and not deceived participants in Experiment 2. This may have been due to the fact that some participants were more invested (deceived participants) in helping their conversation partner because they may have felt they were truly influencing another person's behavior. The individuals who were not deceived may have felt it was unnecessary to disambiguate, because there was nothing to lose or gain by instructing ambiguously.

Overall, all of the participants disambiguated their statements more as their interaction progressed. This suggests that participants may begin instructing their partners in an egocentric manner because they are initially unsure about the task at hand, but as time progressed they were able to take the other person's perspective into account. Also, the Deception x Condition interaction suggests that when the conversation scenario seemed relatively natural, providing a nonverbal behavioral cue to miscommunication was highly effective. The non-linguistic behavioral cue may have been successful above and beyond the use of a prime to communicate during ambiguous situations [Experiment 1 incorrect condition = 49% disambiguation; Experiment 2 mistake condition = 80% disambiguation; $F(2,18.386) = 50.928, p < .001$].

This suggests that a nonverbal cue to miscommunication may be a more effective cue to use during conversations that are ambiguous. Therefore, addressing such a concern will allow for the evaluation of a non-linguistic behavioral cue such as this under conditions that require interlocutors to quickly and accurately provide information to their conversation partner.

General Discussion

Under conditions in which an interlocutor aligns with a pseudo-conversation partner, priming has been shown to be highly effective (Haywood, Pickering & Branigan, 2004). When ambiguity exists and no prime is naturally produced, participants must find another method to help them disambiguate. The results from these studies do in fact support the notion that priming interlocutors is highly effective under ambiguous scenarios. This finding is supported by Garrod and Pickering's (2004) theory of interactive alignment, which suggests interlocutors automatically align at many levels (syntactic being one of them; Pickering & Garrod, 2004). The use of a syntactic prime may be a successful conversation strategy if at least one of the interlocutors is aware of the ambiguity in the beginning of the conversation. However, if neither participant realizes the magnitude of the ambiguity that exists, both partners might be less likely to adopt a syntactic strategy.

The efficiency of a syntactic prime is apparent, but the nature of participant responses may represent mere mimicry. The possibility that participants are mimicking the syntactic prime may lead to disambiguation. Within this artificial, confederate/pseudo-confederate design, it is quite possible that participants may never become aware of the ambiguity. This disregard of ambiguity may create a situation in which s/he may never realize why s/he needed to disambiguate his/her own statements. This strategy may never be elicited, if conversation partners do not naturally prime each other syntactically, because the ambiguity of the situation is not apparent. This seems to be evident in Experiment 2, when deceived participants in the correct condition disambiguate significantly less than participants who received the non-linguistic behavioral cue. The problem of ambiguity still exists, in which interlocutors never use disambiguating strategies if they do not realize there was a failure in comprehension.

Thus, providing a visual mistake or some other type of behavioral cue should be an alternative and effective strategy interlocutors have available for use during natural conversation scenarios. This notion was supported by Experiment 2, in which the non-linguistic disambiguating cue did in fact help the participants recognize the ambiguity. Recognizing the vagueness in their productions was retroactively beneficial, which allowed them revise their statements to accommodate their listener (Horton & Keysar, 1996). This type of cue to communication breakdown allowed participants to respond effectively and creatively when resolving the confusion.

Unfortunately, the pseudo-confederate paradigm was less effective because some of the participants recognized the artificial nature of the conversation in Experiment 2. This created a situation in which participants may have felt that it was unnecessary to disambiguate their own statements because there was no cost/benefit in doing so. This supports the concept that there may have been a perceived social exchange or *reciprocal altruism* necessary for the

conversation to work properly (Cosmides & Tooby, 1992). When the participants perceived no benefit in disambiguating, they expended less effort and disregarded the constraints of the conversation.

Another assumption in previous literatures has suggested that humans are generally egocentric in regards to their conversation strategies. This suggests that interlocutors rarely take the other person's perspective into account. However, when participants were deceived by the paradigm, they were highly affected by the mistake. This suggests that when interlocutors interact with each other, if there is something to gain or lose during a conversational situation, they are more likely to take the other person's perspective into account. Therefore, the presentation of a behavioral cue may help interlocutors assess the degree to which they invest their energies into the conversation.

It should also be noted, that upon evaluation of the types of syntactic structures the deceived participants chose, they not only used the word "that", when not primed to do so; they also used other syntactic strategies to group the "container+object" images. This supports the view that once speakers become aware of the ambiguity, they are better able to implement a syntactic strategy in the future and a prime may be unnecessary. A non-linguistic mistake has a dominant influence on the strategies interlocutors use to disambiguate scenarios. Therefore, if participants understand that they are communicating ambiguously and there are direct perceived consequences, then they will more quickly try to recover from their mistakes by any means available to them.

Though the pseudo-confederate paradigm was not as effective during the implementation of the nonverbal cue, it was still relatively successful. Future studies should evaluate other scenarios in which the use of a nonverbal behavioral cue to the breakdown of communication might be useful. For example, future studies should evaluate nonverbal behavioral cues under time-constrained tasks. These non-linguistic behavioral cues should also be assessed in more natural conversation scenarios. Future evaluation of such issues will help clarify whether or not a non-linguistic behavioral cue to miscommunication helps interlocutors resolve ambiguity within their own statements quickly and naturally. Understanding the role of such behavioral cues should provide valuable insight into how individuals are able to communicate within their own environment.

Abstract

We report the results of three experiments designed to test priming percolation ('alignment boost effects') from one grammatical level to another. In the first two experiments, we set off to replicate in Dutch the results of Branigan, Pickering & Cleland (2000) for lexical boosts of syntactic alignment, adding a baseline control condition without priming. In the third experiment, we tested direct syntactic boosts of phonological alignment, using invented verbs. The direct link between syntax and phonology (without any interference from the lexicon) has been postulated in the past, but so far no empirical evidence has been offered in its favor. Our experimental results so far largely confirm the predictions of the Alignment Model (Pickering & Garrod, 2004), including the relation between syntax and phonology. Speakers, who were instructed to use the same syntactic structure as their dialogue partner did, also invented a verb that resembled more their partner's invented verb.

Keywords: Priming; alignment; phonology; syntax; boost effect.

Introduction

Speakers in all age categories adapt their speech to their linguistic environment. They order coffee with milk as 'caffè latte', 'cappuccino' or 'café au lait', depending on what they perceive to be the addressee's choice and they do so even if their personal preference would be to use a different expression (Garrod & Anderson, 1987; Metzing & Brennan, 2003; Branigan et al., in press). Speakers are also likely to copy the syntactic structure previously used by their interlocutor (Levelt & Kelter, 1982; Bock, 1986; Pickering & Branigan, 1999). Even babies only a few months old have been observed to use a higher pitch when interacting with their mother and lower pitch when interacting with their father (Liberman, 1967) and also older children appear to adopt the intonation patterns (low/high boundary tone) when naming pictures, depending on the tone they previously heard from their dialogue partner (Nilsenová, Swerts, Houtepen & Dittrich, 2008). Other documented cases of phonetic/phonological alignment include pronunciation of vowels and consonants, pitch, accent and speech rate (Natale, 1975; Gregory & Hoyt, 1982; Giles, Coupland & Coupland, 1992; Gregory & Gallagher, 2002; Pardo, 2006; Delvaux & Soquet, 2007).

Interestingly, it appears that if the experimental task forces participants to use the same form or structure as their dialogue partner, it increases the likelihood that they

will also align on other forms/structures. In other words, alignment on one level of representation "boosts" alignment on other levels. For example, Branigan, Pickering and Cleland (2000; see also Branigan, Pickering, McLean & Cleland, 2007) found that in English, adaptation on lexical level significantly increases the frequency of aligned syntactic structures. In particular, if the subject is instructed to use the same verb as the confederate in the sentence she produced to describe a picture, the subject will be more likely to also use the syntactic structure the confederate did rather than an alternative one. In another series of experiments, Hartsuiker et al. (2008) illustrated the existence of boosts effects in written and spoken computer-mediated communication (see also Raffray, Pickering & Branigan, 2008).

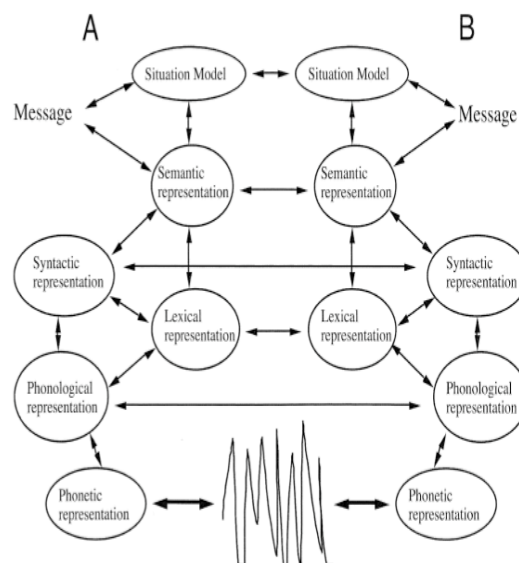

Figure 1: The Interactive Alignment Model (Pickering and Garrod, 2004:177).

Pickering and Garrod (2004) used the phenomenon of alignment boosts to support their (Interactive) Alignment Model. Although the model has been subjected to a number of critical remarks (e.g., Krauss & Pardo, 2004; Schiller & de Ruiter, 2004, and others in the volume), it offers a useful theoretical background for the testing of relations among

various levels of representations. In particular, the vertical lines that stand for possible percolation effects between linguistic representations have for the most part not been tested on empirical data.

Current project

What is of particular interest to us in our current study is the postulated direct link between the syntactic representation and the phonological representation, which in the model appears to be possible even without the intervention of the lexicon (see figure 2). To our knowledge, empirical evidence supporting this relationship is lacking. This is, perhaps, not surprising, since even the expectation of a phonological alignment appears to be rather far-fetched. At least on the level of phonemes, it is unlikely that speakers should be producing strings with identical phonemes (or even strings with comparable phonemic properties, e.g., with respect to the place or manner of articulation). If we exclude the lexical representation, we should be able to observe speakers producing utterances with identical syntactic structures and phonemic properties, turning a conversation into a game of anagrams. In our project, we thus set off to test what appeared to be the ‘weakest link’ of the Alignment Model, starting with a reproduction of the already established lexical boosts on syntactic alignment.

Figure 2: The part of Pickering & Garrod’s Alignment Model predicting a direct boost effect of syntactic alignment on the phonological representation (and *vice versa*).

Experiment I.

In the first experimental study, we sought to extend the results of Branigan, Pickering & Cleland (2000) for English by adapting their experimental design for Dutch (for another contribution, see Hartsuiker et al., 2008). Contrary to previous studies, apart from two experimental conditions with a confederate, we also measured the preferred syntactic choices of Dutch speakers in a baseline condition without priming.

Methodology Thirty-nine Dutch speakers were randomly divided into three experimental conditions (A, B, C).

In condition A, the **‘base’ condition**, the participants were describing drawings depicting either

monotransitive events (one agent only, e.g., a woman drawing a picture; 16 drawings in total), or ditransitive events (including an agent and a recipient, e.g., a woman handing an apple to a boy; 12 drawings in total), viz. figure 3. All the drawings included either a monotransitive (for pictures with an agent only) or a ditransitive verb and the participants were instructed to use the verb in a simple sentence when describing the event.

In condition B, **without lexical alignment**, the participants took part in a confederate-governed task of describing 28 drawings (12 ditransitive stimuli + 16 monotransitive fillers, same as in the baseline study), while being primed alternatively with a syntactic structure of the form ‘ditransitive verb + direct object + prepositional indirect object’ and a structure of the form ‘ditransitive verb + (nonprepositional) indirect object + direct object’. For their description, they were asked to use the verb given under the drawing. Each time, the verb differed from the verb used in the confederate’s prime.

In condition C, **with lexical alignment**, participants performed the same task but they were asked to use the verb indicated to them underneath each drawing, identical to the immediately preceding confederate prime. To balance for order effects and verb effects, in both conditions, there were 4 confederate variants with structures alternating per verb.

During the experimental session in conditions B and C, the participant was seated opposite to the confederate who pretended to be ignorant as to the purpose of the experiment. The experimental leader was present in the same room to answer questions and make sure that the participant followed the experimental instructions. The experiment was presented as a game of describing and finding pictures, where both the correctness of the response (picture found) and the time needed to do so would be compared across conditions. The participants were explicitly told that rather than performing the task quickly, they should attempt to be as precise as possible. The output for all the three conditions was recorded on paper (by the participant in condition A and by the confederate in condition B and C), as well as digitally for the spoken dialogue. After each experimental session, the transcripts were compared to the audio recording and corrected if necessary.

The confederate and the participant were taking turns in describing the pictures (see figure 3), with the confederate always initiating the turn (in other words, priming the participant). The confederate picture set included full sentence descriptions of the pictures but in order to maintain the appearance of being a participant as well, the confederate pretended to be making up the descriptions on the spot. The participant was not aware of what was in the confederate set but assumed that it resembled his/her own.

After the experimental session, the experimental leader asked both the confederate and the participant if they noticed anything unusual. Only after that did she disclose

the real purpose of the experiment and the role of the confederate.

Figure 3: The drawings which the participants were describing depicted either monotransitive (a) or ditransitive events (b). The monotransitive items were used as fillers.

Results In the experimental conditions (B and C), there was a significant effect of lexical alignment on alignment in syntactic structure ($t(21)=3.344$, $p<.005$, $\eta^2 = .035$). The participants in the condition C (with lexical alignment) aligned their verbal syntax more frequently ($M=9$, $SD=1.9$) than the participants in the condition B (without lexical alignment; $M=6.7$, $SD=1.4$). When compared to the condition A (baseline without priming), it turned out that the participants in the condition B and C used the primed constructions significantly less frequently ($F(1.9, 49.403)=5.146$ (sphericity not assumed), $p<.05$, partial $\eta^2 = .165$), see figure 4.

Figure 4: In the experimental conditions with syntactic priming (B and C), participants chose the primed structures less frequently than in the baseline condition without priming (A).

Discussion The comparison of the experimental conditions extends the results of Branigan, Pickering & Cleland (2000) for English to Dutch. We observed that syntactic priming received a lexical boost in the condition in which participants were using the same verb as the confederate in his/her prime. However, the puzzling outcome of the

comparison of the experimental conditions with the baseline seems to suggest that syntactic alignment as such does not occur: speakers were more likely to use the prepositional and dative ditransitive constructions spontaneously than when actually primed with them. One possible explanation for the result could be the fact that the ditransitive verbs used in the experiment, such as ‘give’ (*geven*), ‘hand’ (*overhandigen*) or ‘send’ (*sturen*), can be used in monotransitive constructions in Dutch. Unlike in the English version of the task, our Dutch participants in the condition B and C could thus have been influenced by the monotransitive fillers. In fact, they were interpreting them as primes, albeit not in the immediately following turn. To test this hypothesis, we adapted the stimuli from experiment I. in a second experiment.

Experiment II.

In the second experiment, we attempted to account for the outcome of experiment I. (syntactic priming in conditions B and C resulted in less of the primed constructions being used than in condition A with no priming) by changing the structure of the fillers from simple monotransitive clauses of the form ‘agent – finite verb – direct object’ to clauses containing an adverbial phrase with a preposition, i.e., of the form ‘agent – finite verb – direct object – adverbial phrase’ (e.g., “The man is painting a picture on the wall” instead of “The man is painting a picture”).

Methodology The procedure was the same as in experiment I., only with a different set of fillers as described above. Twenty-two Dutch speakers were randomly divided into one of the two experimental conditions either without or with lexical boost (B and C, respectively).

Results As in experiment I, participants in the condition without lexical boost (B) aligned less frequently ($M=6.6$, $SD=.84$) with the syntactic prime than participants in the condition with lexical boost (C; $M=9.1$, $SD=1.38$), $t(20)=4.963$, $p<.001$, $\eta^2 = .55$. Contrary to experiment I, this time we observed no uses of monotransitive constructions in descriptions that involved ditransitive events. In other words, once we replaced the monotransitive fillers with fillers involving a prepositional phrase (e.g., a locative), the participants used no alternative constructions on the experimental trials to describe the ditransitive events; they always chose either the prepositional dative construction or the non-prepositional dative.

Discussion On the basis of the results obtained in the second experiment, we concluded that participants in experiment I were, in fact, adapting to the monotransitive fillers used by the confederate in the turn preceding the ditransitive prime. When the monotransitive fillers were adapted to longer sentences resembling the experimental primes, their effect disappeared.

Experiment III.

In the third experiment, we explored the effect of a syntactic boost on phonological alignment. In order to test for the relationship directly, it was necessary to exclude the effects of the lexicon that is likely to facilitate phonological alignment in spontaneous data.

Methodology In the baseline condition, twelve drawings depicting a ditransitive event were presented to 17 Dutch speakers who were asked to describe the picture using a monoclausal sentence and a verb they would invent on the spot. In the experimental conditions, the participants again engaged in a confederate-steered task during which they were describing 24 drawings (same as in experiment I and II) with an invented verb, following a syntactic prime by the confederate which also involved an invented but Dutch-sounding verb (with correct morphology). The participants were being primed alternatively by a monotransitive construction or a structure with a direct object followed by a prepositional indirect object, or a structure with a non-prepositional indirect object followed by a direct object. The phonological primes (i.e., the invented verbs) were alternatively monosyllabic and disyllabic words with a systematically varied phonological structure.

In the pilot version of the experiment, twenty-two participants received no instructions regarding the syntactic structure they were expected to use to describe the pictures. One third of the invented verbal primes contained two plosives (in the onset and the coda for the monosyllabic primes, or in the onsets of the two syllables of the disyllabic primes), another third contained two nasals, and yet another third contained two fricatives. There was no systematic variation of vowels and liquids which were inserted freely to make the verb appear Dutch-like.

When we compared the syntactic output of the participants to the baseline condition, however, we observed that there was no significant difference in the use of the three alternative structures to describe the depicted events (viz. figure 5). In other words, the participants in the experimental conditions were not aligning syntactically and hence it was not possible to measure the effect of a syntactic boost on phonology. Moreover, while the participants appeared to be taking over some phonological features of the verbal prime, the manner of articulation of the consonants did not appear to be a perceptually prominent feature.

Twenty-three speakers of Dutch took part in the third experiment. On the basis of the outcome of the pilot experiment, with respect to syntactic alignment, we adapted the task in such a way as to force the speakers to use the same structure as the confederate. In particular, we instructed them to start describing the picture by a clue that was given to them as an NP + relative clause underneath the drawing. In practice, the speakers were filling in an invented verb into a blank of the form NP – who – IO – DO (e.g., *De man die de non een appel...* – “The man who ... the nun an apple.”) or NP – who – DO – PO (e.g., *De man die een*

appel aan de non... – “The man who ... an apple to the nun”). Furthermore, we changed the phonological primes so that the systematic variation in the confederate’s verbs consisted (1) in the number of syllables (one or two) and the initial phoneme (a vowel or a consonant), see table 1.

Figure 5: In the pilot version of the experiment, participants in the condition with phonological priming did not differ from the participants in the baseline condition (without priming) in their choice of syntactic structures, $F(2,74)=.825$, $p=.442$.

Table 1: Nonsense verbs used as primes in experiment III.

Initial phoneme	Monosyllabic	Bisyllabic
Vowel	<i>oeft</i>	<i>oegert</i>
	<i>aapt</i>	<i>eivelt</i>
	<i>oot</i>	<i>affelt</i>
	<i>iert</i>	<i>uitert</i>
	<i>eift</i>	<i>iemelt</i>
	<i>eemt</i>	<i>okkelt</i>
Consonant	<i>proest</i>	<i>manilt</i>
	<i>kniert</i>	<i>pippelt</i>
	<i>bort</i>	<i>lippert</i>
	<i>vlaapt</i>	<i>zachelt</i>
	<i>slinkt</i>	<i>poenkert</i>
	<i>loept</i>	<i>niesert</i>

Results The nonsense verbs created by the participants were transcribed by the experimental leader during the experimental session, as well as recorded digitally. The transcriptions were made in such a way as to reflect the rules of the Dutch spelling system and checked against the audio recordings first by the experimental leader and

subsequently by another linguist. We calculated the proportion of phonological alignment by (i) comparing the number of syllables in the prime and the verb created by the participant, (ii) comparing the initial phoneme of the verb (vowel or consonant), and (iii) comparing the Levenshtein distance between the prime and the participant's verb. The Levenshtein distance between two strings A and B is the (uniform) cost for insertion, deletion and substitution of characters in string B needed to make it identical to string B. The comparison was used to account for cases where the participant did not align phonologically on the systematically manipulated features (number of syllables and initial phoneme) but still appeared to create a new verb strongly influenced by the prime (consider, for instance, the invented verb 'choeft', which was independently created by three experimental participants as a response to the prime 'achelt').

When we compared the two experimental conditions, there was no significant difference between the group that aligned syntactically and the group that did not with respect to the initial phoneme of the invented verbs they created. Regarding the number of syllables, we observed a trend in the data suggesting some effect of the syntactic boost ($t(21)=1.855$, $p=.095$, $\eta^2=.14$). The boost effect, however, was clearly present when we measured the Levenshtein distance between the prime and the participants' responses, with verbs created in the syntactic boost condition resembling the primes more ($M=108.42$, $SD=12.42$) than the verbs created in the condition without boost ($M=126.882$, $SD=24.31$; a lower mean stands for less operations needed to make the strings identical), $t(14.597)=-2.255$, $p<.05$, equal variances not assumed, $\eta^2=.26$.

Discussion The results of the third experiment indicate that there is a link between the syntactic and the phonological component that does not have to be mediated by the lexicon. In particular, when speakers align on the syntactic level with their dialogue partner, they are also more likely to align phonologically. The phonological adaptation, however, is rather subtle and, at least in this experiment, was not obvious when we looked at traditional phonological features like the number of syllables or the word-initial phoneme. However, the resemblance between the prime and the response could be detected by calculating the Levenshtein distance between the two strings.

Conclusion

There is evidence that conversational participants adapt to each other's language use at various grammatical levels. This phenomenon has been well documented in a number of experiments, as well as studies of corpus data (Gries, 2005). The focus of our current study was the nature of percolation effects, which have been documented in priming experiments with lexical boost where participants who were forced to use the same verb as the confederate turned out to

be more likely to use the same syntactic construction as well, compared to participants who could use a different verb. The evidence for other kinds of boosts has so far been lacking, despite the fact that these effects are interesting in that they offer insights into the architecture of the language model.

In the current study, we examined the link between the syntactic and the phonological component, which at first blush appeared to be rather arbitrarily postulated in the Alignment Model of Pickering and Garrod (2004). In order to approach the topic of alignment boosts in Dutch in a systematic manner, we started with a replication of Branigan, Pickering and Cleland's (2000) study concerning the effect of lexical alignment on syntax, enriched with a baseline study involving no primes. The results of the first experiment were more complex than the English findings due to the difference in selection properties of the Dutch ditransitive verbs, but both the first and the second experiment confirmed that alignment on the lexical level increases the frequency of aligned syntactic structures.

Finally, our data confirmed the prediction of the Alignment Model regarding a direct boost effect of syntax on phonological alignment. The role of the lexicon was excluded in the setup by making use of invented verbs that the participants had to come up with on the spot.

One open question that needs to be answered in follow-up studies concerns the relation between the spoken and the written form of the invented verbs (for example, the combination of graphemes 'oe' is pronounced as /u/ in Dutch but when calculating the Levenshtein distances, we based ourselves on the graphic representation rather than the pronunciation). In general, experimental evidence is needed for other types of boosts apart from the lexical and the syntactic one explored in the current study.

Acknowledgments

The authors would like to thank Annabelle Adams for her help with collecting the experimental data, to Holy Branigan for her suggestions regarding the design of the third experiment, to Erwin Marsi for his permission to use his script to calculate the Levenshtein distances, to Jan Peter de Ruiter for a helpful discussion in the initial stages of the project and to the CogSci 2010 reviewers for their helpful comments. The results of experiment I and of the pilot version of experiment III were reported as a poster at the Architectures and Mechanisms of Language Processing Conference in Cambridge, UK, 2008.

Abstract

Structural priming, the tendency to repeat previously uttered syntactic structures, can give insight into human language processing and acquisition. We report two corpus-based studies of children's structural priming that test the following claim of the item-based account of language acquisition: as older children generalize over structures, priming increases with age. A hypothesis derived from this claim, viz., that the lexical boost effect decreases with age, is also tested. We fit mixed-effects logistic regression models on data from children aged 2 to 7.5 years from the CHILDES corpus. We demonstrate structural priming of arbitrary syntactic structures for the first time in child language data. We also find evidence that priming increases with age, but fail to confirm the hypothesis that the lexical boost effect decreases with age.

Keywords: Syntactic priming; Child language; Corpus studies; Mixed models; Age effects in language acquisition.

Introduction

Priming occurs when an initial stimulus, called the *prime*, causes a bias towards a related stimulus later on. Adaptation to the prime manifests itself in the latter stimulus, the *target*, which is comprehended faster or more accurately, or produced more frequently. A wide range of priming effects has been documented, including the priming of words, syntactic structures, and discourse patterns. The phenomenon is neither intentional nor conscious (Bock & Loebell, 1990). Establishing which aspects of a linguistic stimulus adapt to priming—and which ones do not—gives insight into the mental representation of language and the process by which speakers comprehend and produce sentences.

The vast majority of priming research has been carried out with adults, but there are some recent studies that investigate priming in children (e.g., Savage, Lieven, Theakston, & Tomasello, 2003; Huttenlocher, Vasilyeva, & Shimpi, 2004; Kemp, Lieven, & Tomasello, 2005). Such studies make it possible to examine the development of linguistic representations, based on how priming effects change over the time course of language acquisition, i.e., with the age of the child. Priming can therefore be used as a tool to test specific questions about human language acquisition.

One of the key questions in language acquisition is whether grammatical rules are acquired conjointly with individual words or, alternatively, syntactic knowledge is abstract from lexical knowledge. In the latter case, the question arises of the source of knowledge of the abstract structure of a language,

since children's only input to language acquisition is the lexical expressions that they hear. Tomasello's (2000) *item-based hypothesis* proposes that children's early language consists of word-for-word chunks copied from adults' phrases, from which they only gradually abstract patterns and therefore grammar rules. An alternative view is that all children are born with a *universal grammar* (Chomsky, 1980); this theory suggests that abstract grammatical knowledge is innate in the human brain, and merely needs to be parametrized during the course of language acquisition.

This paper explores the item-based hypothesis by studying structural priming in corpora of child language. If a child adapts to structural priming—that is, the child shows a tendency to reuse syntactic constructions heard or produced recently—then this indicates that the child is using old syntactic representations to express new ideas with different words. The item-based hypothesis predicts that this behavior should increase with the age of the child: if syntactic development is a gradual shift from lexically dominant phrase repetition towards generalized grammatical rules, then structural priming should be more frequent in older children, who have more abstract syntactic representations available.

In a well-studied phenomenon called *lexical boost*, structural repetition rises when the target and the prime share a content word, i.e., lexical adaptation boosts structural adaptation (Pickering & Ferreira, 2008). We hypothesize that if grammatical abstraction is thought of as curtailing reliance on words, then priming may show decreased effects of lexical boost as children age.

In this paper, we test both hypotheses: that overall priming increases with age, and that the lexical boost effect decreases with age.

Background

Many experimental studies create an atypical context of language use, requiring the participant to respond to a number of similar trials, where the high repetition of trials may condition participants to become more practiced in their responses, or alternatively, participants may show fatigue. Priming studies, in particular, often present made-up nonce words and observe participants' comprehension or use of them (e.g., Brooks & Tomasello, 1999; Kemp et al., 2005). Teaching a participant a novel word requires multiple exposures which means multiple primes, and it is not clear what effect additive priming

might have. Likewise, several priming experiments, especially with children (e.g., Savage et al., 2003; Kemp et al., 2005; Huttenlocher et al., 2004), entail both hearing and then repeating every prime, again double-priming all targets. Corpus studies are not subject to these confounds, and they can help verify that a phenomenon observed in a few children in a few contexts can be generalized to child language as a whole.

With few exceptions, experimental and corpus studies alike have looked for priming of a small set of specific syntactic alternations—different syntactic forms that express the same semantics—providing very limited coverage of grammar. Recent corpus studies have overcome this limitation, and have found that priming is a more general phenomenon (Reitter, Moore, & Keller, 2006; Reitter, 2008), and that less frequent structures show more priming than more frequent ones (the inverse frequency effect).

In the current paper, we present the first corpus-based investigation of priming in children. In the first of two studies, we replicate an experimental study of the priming of passive and active constructions in children (Savage et al., 2003). Our second study generalizes these results by modeling adaptation to the priming of arbitrary structures. The studies bear on the item-based hypothesis of language acquisition. In particular, we investigate the role of a child’s age as a predictor of priming, and consider the influence of lexical similarity.

Modeling Methodology

We used mixed-effects logistic regression to model how various explanatory variables affect structural repetition between pairs of sentences from the CHILDES corpus.

Data

The CHILDES corpus (MacWhinney, 2000) contains over 100 databases of transcriptions of face-to-face interactions between young children and their caretakers. The corpus studies described in this paper used a subset of these databases that contain multiple interviews with a child over different dates, so that priming could be compared at different ages of the same child.¹ For naturalness, the phrase “the corpus” will refer to this subset of CHILDES. The corpus comprises utterances from 84 child speakers, as well as speech from their adult interlocutors.

The most current collection of CHILDES transcripts as of April 17, 2009 was processed to remove structures containing unrecognized words, babble, test words, and fillers (onomatopoeia and child-invented word forms that could be recognized were kept). Certain types of clitics were separated to correspond with morphosyntactic annotations (e.g., *they’ll* \Rightarrow *they will*), as were assimilations (e.g., *wanta* \Rightarrow *want to*). Disfluencies, retracings, and repetitions were kept.

CHILDES includes annotations of morphemes and syntactic categories, which are automatically generated by super-

vised taggers (MacWhinney, 2000). This is in turn used to generate labeled dependency structures based on grammatical relations between words (Sagae, Lavie, & MacWhinney, 2005). Sagae et al. evaluate the dependency hierarchy accuracy to be 90.1% on child language transcripts.

Mixed-Effects Logistic Regression

We used mixed-effects logistic regression to identify which variables influence priming in our corpus. Our dependent variable Y is a binary variable that indicates whether there is structural repetition between two sentences ($Y = \text{TRUE}$) or not ($Y = \text{FALSE}$). Logistic regression is a generalization of linear regression that predicts the logit of the probability p that Y is TRUE , as a function of explanatory variables $X_1 \dots X_N$:

$$\text{logit}(p) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_N X_N.$$

The logit link function is $\text{logit}(p) = \ln\left(\frac{p}{1-p}\right)$. Its inverse is the logistic function, ensuring that as a probability $0 \leq p \leq 1$:

$$p = \text{logit}^{-1}(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_N X_N) \\ = \frac{1}{1 + e^{-(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_N X_N)}}$$

Mixed-effects regression allows the optional inclusion of *random effects* in order to generalize beyond the groups represented in a limited statistical sample. Modeling random effects allows for the possibility that, say, different children have different repetition behaviors, or that each child’s repetition behavior changes in different ways as he or she gets older. In the first example, a random effect variable CHILD would be defined to model trends that are specific to each one of its grouping factors: Abe, Abigail, Adam, Allison, etc.

For each possible value g of the random-effects grouping variable, let α_g be the deviation of the dependent variable’s mean for group g from the entire dataset’s mean; α_g is a random variable from a normal distribution with a mean of zero and unknown variance. α_g is added to each datum taken from group g , effectively adjusting the intercept of regression independently for each group so that uncontrolled effects specific to each group do not unfairly distort the overall model.

Model Specification and Fitting

In the corpus studies reported here, we fitted mixed models with random intercepts grouped by the child speaker of target utterances, which were further nested by database to account for random effects of different annotators, interview strategies, etc. In Study 2, random intercepts were also defined for the syntactic structure being investigated in each datum, which is particularly important because the frequencies of the structures vary greatly, approximating a Zipf distribution.

The corpus data is strongly biased towards younger children, with relatively few utterances from children above five years old. Unlike natural cases of sparsity (e.g., spoken language uses far fewer passive sentences than active ones) the sparsity of data for older children is an artifact of CHILDES. Still, it presents a potential problem, as the model-fitting algorithms had to deal with higher variance for older children.

¹The subset comprised the following databases: Bloom73, Brown, Demetras1, Demetras2, Feldman, Gathercole Gleason, Kuczaj, MacWhinney, Sachs, Suppes, Wells. The Wells database contains British English; all the others contain American English.

Models were fit using Laplace’s method by the `lme4` software package for the R programming environment. All explanatory variables were centered around the mean to reduce multicollinearity between higher-order interactions and their constituent main effects. We built minimal models by dropping non-significant explanatory variables (unless explicitly relevant to the experiment, or necessary as the component of a significant higher-order interaction).

Study 1: Priming of Active and Passive Voice

To confirm that mixed-model regression analysis of corpus data can provide an insight into structural priming similar to what can be accomplished in experiments, we replicated an experimental design utilized by Savage et al. (2003) and compared the qualitative results of the two methods.

The experiment of Savage et al. (2003, experiment 1) proceeded as follows: In interviews with 84 children from age 2;11 to 7;1 (*years; months*), children heard and repeated a prime sentence—either active or passive—describing some transitive action depicted in a cartoon. Then they were shown another cartoon of a different action with different participants and asked “What’s happening?”. The target sentences the children produced in response were classified as *PASSIVE* or *ACTIVE*. Experimenters also varied the amount of lexical overlap that the child could potentially find between the given prime sentence and the child-produced target.

Method

All sentences in the specified subset of the CHILDES corpus (see Modeling Methodology above) were automatically identified as active, passive, or other, guided by heuristics. Whereas all passives primed in Savage et al.’s (2003) experiment included an agentive *by*-clause (e.g., *The ball got caught by the net*), the corpus contains only four examples of children using a passive form with expressed agent, one of which is recitation from a storybook. Agentive *by*-clauses are optional in English, and their sparsity appears to be representative of natural language production (Huttenlocher et al., 2004). Accordingly, the present study considered agentless passives (e.g., *I got caught*) along with agentive passives.

The Savage et al. experiment considered “only the first sentence-like utterance ... produced after exposure to each prime sentence,” so we also compared only adjacent utterances from the corpus. Only pairs where the target was spoken by a child from age 2;0 to 7;6 were included; the potential primes were spoken by adults and children of all ages, but were always spoken in the presence of the target child. Furthermore, pairs were omitted from the analysis if either of the two sentences contained a negation or was a *wh*-question, which were not used by Savage et al., or if a sentence was not identified as obviously passive or active. A contingency table of the remaining pairings already makes clear that an active prime is much more likely than a passive one to precede an active target; see Table 1.

To answer the main questions of whether children’s priming is dependent on their age and on lexical overlap, we fit

Table 1: Frequencies of adjacent prime-target pairings in Study 1, where the target was spoken by a child.

		Target	
		Active	Passive
Prime	Active	359	13
	Passive	14	13

Table 2: Study 1 parameter estimates. Explanatory variables estimate the logit of the probability that TARGET (the utterance immediately following PRIME) is passive.

	β	$p(> z)$
(Intercept)	-4.447	$\ll 0.001$ ***
PRIME[PASSIVE]	1.597	0.082 ·
AGE	0.351	0.179
LEXBOOST	-1.373	0.274
PRIME[PASSIVE]:LEXBOOST	16.285	< 0.002 **

*** $p < 0.001$, ** $p < 0.01$, * $p < 0.05$, · $p < 0.1$

a mixed-effects logistic regression model where the voice of the target sentence was predicted by the following main effects and their interactions:

- PRIME: the voice of the prime utterance (*ACTIVE* or *PASSIVE*);
- AGE: the child’s age represented as decimal years with precision to the day;²
- LEXBOOST: the ratio of the number of words in common between both utterances to the total number of words in the target utterance;
- PRIMETYPE: *CP* for comprehension-production priming (another speaker produces the prime and the child comprehends it and produces the target) or *PP* for production-production priming (the child produces both the prime and the target).

Results

Table 2 above gives the coefficients of the mixed model together with significance values. We find a significant interaction of PRIME and LEXBOOST. All other interactions and the main effect of PRIMETYPE were evaluated and found to be non-significant regressors, so the model was refit without them. In particular, the model shows no influence of a child’s age on his production of active or passive sentences, with or without active or passive primes (no main effect of AGE, no interaction PRIME:AGE).

The dependent variable TARGET was mapped such that passive targets yield *TRUE* and active targets yield *FALSE*. The positive coefficient for the PRIME[PASSIVE]:LEXBOOST interaction therefore means that together, a passive prime and lex-

²Where a child’s age was specified to only monthly precision, the median value of 15 days after the start of that month was assumed.

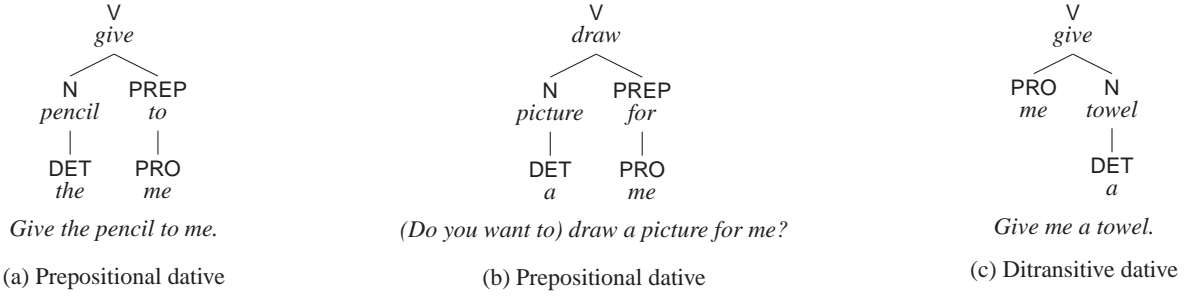

Figure 1: Two prepositional datives share the same structural analysis, which differs from a ditransitive dative

ical boost *increase* the probability that the target will be realized as a passive (as opposed to an active). The marginally significant main effect of PRIME_[PASSIVE] lends weak evidence for priming of passives also in the absence of lexical overlap.

Discussion

Our method of modeling the corpus is not identical to the analyses Savage et al. (2003) performed on their experimental data, but the results are comparable in qualitative terms. Savage et al. performed separate analyses of variance (ANOVA, an instance of linear regression), one for each target voice. For both voices, Savage et al. found reliable main effects of PRIME. The reliable interaction between PRIME and LEXBOOST we found in the corpus data was also present in Savage et al.’s ANOVA for passive targets. Meanwhile, PRIME and LEXBOOST formed part of a significant three-way interaction with AGE only in their ANOVA of active targets; they further broke down the active targets to find the PRIME:LEXBOOST interaction in their three- and four-year-old participants but not in six-year-olds. As mentioned above the CHILDES corpus is sparse in data over age five, which likely explains why we did not find any interaction with age.

That the effect of age was only found in active targets suggests that the sparsity of passive targets in both datasets is also important. This weakness cannot be overcome with the studies structured as they are—neither in experimental data nor in corpus data—simply because of the natural sparsity of passives in children’s spoken language. Therefore, instead of relying on only a single alternation for insight into children’s language, in the next study we investigated children’s to priming of arbitrary syntactic structures.

Study 2: Priming of Arbitrary Structures with Decay

Most priming studies to date have only considered structures for which a semantically equivalent alternation exists. This limits the generality of conclusions that can be drawn, and data sparseness is a potential problem, as illustrated above. In the present study, we therefore use an approach that does not require the existence of an alternation, asking instead whether the appearance of a prime structure increases the probability that the *same structure* will appear again.

We define priming in probabilistic terms: the appearance of a prime structure increases the conditional probability that

the same structure will appear again:

$$p(S_{\text{prime}} | S_{\text{target}}) > p(S_{\text{prime}})$$

where $p(S_u)$ is the prior probability that an arbitrary structure S will appear in any utterance u . Using this approach, general structural priming—not only for specific structures—can be quantified in a single model.

Besides the sparsity of passives, both Study 1 and the experiment on which it was based had another limitation. By considering only adjacent utterances, they treated priming as an immediate phenomenon and ignored its well-documented temporal decay (Branigan, Pickering, & Cleland, 1999; Pickering & Ferreira, 2008). The formalism just presented is easily extended to estimate $p(S_{\text{prime}} | S_{\text{target}}, d)$, that is, the probability that structure S appeared in the d -th utterance before TARGET was spoken (Reitter et al., 2006; Reitter, 2008).

Structural Overlap

To measure repetition of arbitrary syntactic structures, we need a way to identify whether two constructions share the same structure or are syntactically distinct. We used the hierarchical structure supplied in the form of CHILDES’s dependency annotation for this purpose, based on evidence that priming relies on shared hierarchical syntactic rules (Bock & Loebell, 1990; Reitter, 2008). However, priming is not sensitive to thematic roles (Bock & Loebell, 1990), so the relation labels in the annotation are not useful. We therefore used the part-of-speech tags from the CHILDES morphological annotation instead, imposed upon the dependency hierarchy. This combination gives the same analysis to those structures typically considered correspondent in priming studies (Figures 1a and 1b) while producing different analyses for their characteristic alternations (Figure 1c vs. 1a and 1b).

For this study, we used the subset of such structures that have exactly three levels. Of this subset, those with very low frequency—fewer than about twenty occurrences over the entire corpus, according to a manual evaluation—were usually incorrect analyses derived from inaccurate annotations in CHILDES (either in the morphosyntactic or the dependency structure). Thus data points corresponding to structures with frequency less than twenty were discarded. This leaves 4,279 unique structures for consideration, representing 81.3% of the original data. No outliers on the high end of the frequency spectrum were discarded, as they were correct analyses.

Method

Each structure S in some child’s (age 2;0 to 7;6) utterance t was considered a potential target of adaptation, primed by the structures in all utterances p within the window of the fifteen utterances preceding t . For each combination of t , $S \in t$, and d ($1 \leq d \leq 15$), a record was created of whether S was in $p = t - d$. That is, the model’s binary dependent variable represents *repetition* of a certain structure across a certain distance. Consequently, the parameters estimated by the regression model are effects on mere structural repetition. Priming is identified in this formulation by its decay, so only interactions with the variable DIST (which represents d) can be interpreted in terms of priming; specifically, negative coefficients of DIST indicate priming.

Because measuring grammatical abstraction requires differentiating between lexical and structural repetition, data points showing structural repetition resulting from complete lexical repetition (i.e., not differing by at least one word)—one-half a percent of the dataset—were dropped for this study. Structures in the first fifteen utterances of any interview session also were not considered as targets because they may have been influenced by primes not captured in the corpus. The remaining data points were segregated into strata, one stratum for each three-month period of each child. Two-thousand five-hundred data points were randomly sampled from each stratum, unless the stratum contained fewer than 2,500 points, in which case the entire stratum was used.

A mixed-effects logistic regression model was built to correlate structural repetition across distance (DIST) with explanatory variables AGE and PRIMETYPE as described in Study 1 and with the following variables:

- LEXBOOST: a binary variable that is TRUE if the heads of both hierarchical structures use the same *root morpheme* (lemma);
- ln(FREQ): the logarithmically transformed frequency of the structure in the entire corpus.

This experimental setup crucially relies on the assumption that priming decays. Figure 2 plots the sampled probability that an arbitrary structure is repeated between two utterances separated by a variable distance. It clearly shows the probability of repetition diminishes as a function of distance, with higher repetition across shorter distances—in short, structural priming decays.

There is evidence that both human attention and priming decay logarithmically (McKone, 1995). This is supported by Figure 2, and indeed the mixed-effects model yields a better fit when variable DIST is transformed logarithmically than when it is linear.

Results

Table 3 shows parameter estimates of the full model specification. We find a significant, negative coefficient for ln(DIST), showing the decay of priming of arbitrary structures in children’s speech. In line with previous research (Reitter, 2008), the significant interaction ln(DIST):ln(FREQ) demonstrates

Figure 2: Decay of priming in children. The dashed line is the mean squared prior probability of structures, estimated over comparisons of up to fifteen utterances; since priming raises the probability of a structure above its prior, the true mean will be closer to the repetition probability at DIST = 15.

that less frequent structures show stronger adaptation. Note that the interaction’s positive coefficient needs to be interpreted in the context of the negative slope of ln(DIST) (repetition decreases with increasing distance) and the positive slope of ln(FREQ) (less repetition for more frequent structures).

We also observe a significant positive coefficient of ln(DIST):LEXBOOST, suggesting that priming (that is, the decay of DIST) may weaken under lexical boost, all other factors held fixed. Meanwhile, ln(DIST):ln(FREQ):LEXBOOST has a negative coefficient: the decay effect increases with lexical boost and increasing frequency. This means we find the lexical boost effect to be stronger for high-frequency items.

The ln(DIST):AGE interaction is marginally significant ($p = 0.075$), providing only weak evidence for the claim that structural priming increases with age. More convincing support of this prediction is offered by the significant ln(DIST):ln(FREQ):AGE interaction. Its positive coefficient means that priming (the decay of DIST) becomes stronger if age increases while frequency decreases, or weaker as age and frequency increase. In other words, the inverse-frequency effect is stronger for older children than for younger children.

ln(DIST):AGE:LEXBOOST is not significant. We therefore find no evidence for our suggestion that lexical boost may influence structural priming differently as children gradually abstract grammar from phrasal repetition.

The marginally significant ln(DIST):PRIMETYPE interaction hints that children may be more inclined to repeat their own previous constructions (PRIMETYPE = PP) than primes by another speaker.

Discussion

This model shows that priming of arbitrary structures is evident in children, a population in which priming of only a few syntactic alternations had been studied previously. This study also provides an estimate that priming’s main efficacy lasts

Table 3: Study 2 parameter estimates. Explanatory variables estimate the logit of the probability of structural repetition. **ln(DIST)** terms are emphasized to remind that this model provides insight to priming only through the DIST variable.

around six utterances, during which it shows strong decay and after which its decay is negligible (see Figure 2). Most importantly, this study enables us to quantify priming effects according to age during first language acquisition.

Crucially, the results do not support the conjecture offered in the Introduction that structural priming's reliance on lexical boost decreases as children age. It is important to bear in mind that this conjecture is not strictly predicted by the item-based hypothesis, which does not specify precisely what types of analogies children must make to abstract a grammar from word patterns. Kemp et al. (2005) provide evidence similar to our results, observing in one experiment that two-year-olds adapted to structural priming without regard to lexical influence.

On the other hand, we did find evidence that overall structural priming increases with age. If this is true, it supports the item-based hypothesis of language acquisition which holds that over time children gradually abstract grammatical rules from the sentences they hear.

Conclusion

This paper reported two corpus-based studies of structural priming during first language acquisition. Study 1 replicated an experiment on passive/active priming in children,

and found similar effects in corpus data to those reported experimentally (Savage et al., 2003). Both studies tested the hypothesis that structural adaptation increases with age. Study 2 found evidence for this claim, though the change is not as large as might be expected by an item-based account of language acquisition. Neither study supports our conjecture, influenced by the item-based hypothesis, that the lexical boost effect should decrease with age, as children move from lexicalized to abstract syntactic knowledge.

Abstract

Linguists build theories of grammar based largely on acceptability contrasts. But these contrasts can reflect grammatical constraints and/or constraints on language processing. How can theorists determine the extent to which the acceptability of an utterance depends on functional constraints? In a series of acceptability experiments, we consider two factors that might indicate processing contributions to acceptability contrasts: (1) the way constraints combine (i.e., additively or super-additively), and (2) the way a comprehender's working memory resources influence acceptability judgments. Results suggest that multiple sources of processing difficulty combine to produce super-additive effects, but multiple grammatical violations do not. Furthermore, when acceptability judgments improve with higher working memory scores, this appears to be due to functional constraints. We conclude that tests of (super)-additivity and of differences in working memory can help to identify the effects of processing difficulty (due to functional constraints).

Introduction

Grammatical theories are designed to reflect, explain, and predict what is and is not possible to say in a language. Potential utterances are usually classified as “possible” or “impossible” on the basis of native speaker judgments of their acceptability. Whether they are the judgments of theorists themselves or of a sample of naive speakers, these judgments are not a perfect window into the speaker's grammatical competence: the judgments themselves are colored by performance factors. This problem has been discussed since Miller and Chomsky (1963) pointed out that some sentences that native speakers judge to be unacceptable, such as triple center embeddings (1), are better ruled out by their extreme difficulty than by grammatical constraints.

- (1) The salmon that the man that the dog chased smoked fell.

Miller and Chomsky's assessment that functional constraints on the language processing system underlie the unacceptability of these examples is fairly uncontroversial. However, it is often difficult to determine what

role functional constraints might play in other acceptability contrasts. In the domain of island violations, for example, both processing and grammatical constraints have been proposed to account for the unacceptability of island-violating sentences (Ross, 1967; Chomsky, 1973, 1986; Kluender, 1998, *inter alia*).

Assessing whether functional constraints underlie acceptability contrasts may be difficult, but it is critical in determining which acceptability contrasts should be taken as evidence for the existence of grammatical constraints. But what tools do we have for recognizing when acceptability contrasts are a consequence of functional constraints? This paper will explore two properties of processing constraints that could help theorists to recognize their effects on acceptability. First, individuals have a limited set of cognitive resources that they can use to understand language (Just & Carpenter, 1992; Kluender, 1998; Cowan, 2001). Extreme sentence processing difficulty can exhaust these resources, resulting in a strong perception of unacceptability, as in (1). Second, the extent of this limited pool of resources arguably varies from one individual to another, as suggested by Just and Carpenter (1992).

To explore the first property, we will consider what happens when multiple possible sources of unacceptability are combined. There are three logically possible outcomes of combining two manipulations that each individually cause acceptability decrements: a significantly smaller penalty than the sum of the two individual penalties (a result which we will refer to as *sub-additive*), a penalty that is statistically indistinguishable from the sum of the two individual penalties (which we will refer to as *additive*), or a penalty that is significantly larger than the sum of the two individual penalties (which we will call *super-additive*).

Super-additive effects may result from combining two manipulations that tax the same set of limited resources, if the manipulations are sufficiently strong to deplete the available resources. Thus, super-additivity could result when multiple sources of processing difficulty co-occur, depending on the degree of difficulty. On the other

hand, formal (grammatical) violations are not expected to combine super-additively. At least for theories that distinguish between formal and functional constraints, grammaticality violations do not cause decrements due to the taxing of a limited set of resources but to the violation of grammatical rules. They could combine additively – if each violation influences judgments independent of the other – or sub-additively, if one violation overwhelms the other or the overall acceptability of the sentence depends simply on the most egregious violation. When formal and functional sources of unacceptability appear in the same sentence, either additive or sub-additive decrements could be the result, for the same reasons, but again, this combination should not produce a super-additive decrement.

To explore the second property, we will compare the performance of people with different processing resources on acceptability judgment tasks. If an acceptability contrast reflects overtaxing the resources of comprehenders, then comprehenders with greater processing resources should experience less difficulty and the contrast should be reduced. However, when acceptability contrasts are due to grammaticality violations, comprehenders with greater processing resources should, if anything, show enhanced contrasts, because they are better able to parse the sentences and notice the rule violations.

In order to evaluate these predictions, we conducted three acceptability judgment studies, combining two processing manipulations (Experiment I), two grammaticality violations (Experiment II), and a processing manipulation with a grammaticality violation (Experiment III).

Experiment I: Processing Difficulty

To investigate the role of processing complexity in acceptability judgments, we manipulated the distance between two dependent arguments and their syntactic head.

Participants Stanford University students ($n=32$) participated in exchange for payment. All self-identified as native speakers of English.

Materials Twenty-four items were selected from Grodner and Gibson (2005). In these items, the hierarchical distance between a subject and object noun phrase and their subcategorizing verb was varied. This was achieved by varying (1) the presence/absence of a relative clause between the subject and verb [2a,2c vs. 2b,2d] and (2) positioning the object NP immediately after the verb or before the subject NP by relativizing it:

- (2) a. The nurse from the clinic supervised the administrator who scolded the medic while a patient was brought into the emergency room. [**short-short**]
- b. The nurse who was from the clinic supervised the administrator who scolded the medic while a patient was brought into the emergency room. [**long-short**]
- c. The administrator who the nurse from the clinic supervised scolded the medic while

a patient was brought into the emergency room. [**short-long**]

- d. The administrator who the nurse who was from the clinic supervised scolded the medic while a patient was brought into the emergency room. [**long-long**]

These items were selected because reading time evidence from Grodner & Gibson (2005) show that increasing the hierarchical distance in examples like these leads to slower processing at the critical integration sites. The 24 experimental items appeared with 72 fillers (24 of which were the items from Experiment III).

Procedure To acquire acceptability ratings from participants, we used the thermometer judgment methodology described in (Featherston, 2008). This paradigm resembles the Magnitude Estimation (ME) technique of gathering judgments (Bard, Robertson, & Sorace, 1996; Sorace & Keller, 2005), where participants are asked to rate the magnitude of acceptability difference between test items and a reference sentence (e.g. twice as good, three times as good, half as good, etc.). In both ME and thermometer judgment experiments, participants are not limited to a particular set of values that they can assign to sentences - in principle, every sentence could receive a different judgment.

There are, however, several key differences between the ME and thermometer methods of judgment collection. In the latter paradigm, participants are not instructed to evaluate test items in terms of the magnitude of acceptability compared to the reference item, as evidence shows that participants ignore these instructions and rate sentences in terms of their linear distance from the reference. In addition, in thermometer judgment studies, participants judge items relative to two reference sentences. One of these references is quite good and the other quite bad, and we follow Featherston (2008) in assigning these sentences the arbitrary values 20 and 30. For all of our experiments, we used the same reference sentences.

- (3) a. The way that the project was approaching to the deadline everyone wondered. = 20
- b. The architect told his assistant to bring the new plans to the foreman's office. = 30

While participants could theoretically assign any real number value to the test items, including negative or decimal values, participants almost always assign positive integer values, typically between 10 and 40.

Sentences were presented to participants on a computer screen one word at a time for a fixed duration, via the DMDX software package (Forster & Forster, 2003). The duration that each word stayed on the screen varied with the number of characters in the word ($250 \text{ ms} + 33.34 * \text{number of characters}$), so that longer words remained visible for longer periods. We chose word-by-word presentation over full sentence presentation to prevent participants from excessive introspection about the test sentences, and we used auto-paced presentation

Figure 1: Acceptability z-scores for experiment I. Error bars show (+/−) one standard error.

rather than self-paced presentation to prevent differences in how long each participant studied a given stimulus.

Each participant also completed a reading span task during the same session, used to assess their working memory capacity (Daneman & Carpenter, 1980). For the analysis of reading span scores, we scored each test using the partial credit method outlined in Conway et al. (2005): successful recall of a word in a study list counts toward the final reading span score, even if the entire item set was not recalled correctly.

Results

Prior to statistical analysis, we log-transformed judgment ratings to normalize the data and to reduce the effect of extreme data points. Subsequently, we computed z-scores for each subject on the basis of all data in the experimental data set (except practice items), including fillers. This reduces the impact of varying uses of the interval scale by subjects. Finally, we excluded data points with z-scores more than 2.5 standard deviations from the mean for each participant. For Experiment I, this outlier removal process affected 2.0% of the data. The resulting z-scores constitute the data on which we conducted statistical analyses.

For all experiments, we used linear mixed effects models to estimate the effects of the experimental manipulations. Such statistical analyses remove the need for prior averaging over subjects and items, are more robust in the presence of missing data, and do not require the assumptions of sphericity that are inherent to analyses such as repeated measures ANOVAs (Baayen, 2004, 2007). This method of statistical analysis also allows for the evaluation of additional factors such as list position alongside effects due to experimental manipulation.

Prior to analysis, all predictors were centered—higher order variables (interactions) were also based on these centered predictors. Linear mixed effects models do not directly yield p-values (due to complications in estimating the degrees of freedom), but Monte Carlo Markov Chain (MCMC) sampling can be used to conservatively estimate p-values. For all p-values reported here, we utilized 25,000 MCMC samples to estimate the values.

The acceptability judgment results demonstrate main effects of both manipulations—subject distance ($\beta = -.242$, $t = -6.412$, $p < .0001$) and object distance ($\beta = -.211$, $t = -5.584$, $p < .0001$). In addition, there was a highly significant interaction between these factors ($\beta = -.328$, $t = -4.343$, $p < .001$). This interaction reflects the result of combining multiple processing difficulties: the acceptability decrement produced by two processing manipulations was more than expected on the basis of the decrements produced by each manipulation in isolation.

Reading span score was also a highly significant predictor of acceptability scores ($\beta = .050$, $t = 3.685$, $p < .001$). In particular, higher reading span scores predicted higher judgments of acceptability. This effect appears to be largely driven by the conditions with multiple processing manipulations and a dislocated object phrase (the most difficult conditions according to Grodner and Gibson (2005)), which is reflected by the significant interaction of reading span score and the object distance manipulation ($\beta = .068$, $t = 3.858$, $p < .01$).

Discussion

According to the results, while these kinds of processing manipulations may have only minor effects on acceptability in isolation, they can have highly significant effects on judgments when combined. In this study, increasing the distance between a single dependent argument and its head only slightly lowered judgments. But when we increased the hierarchical distance of both dependents to their syntactic head, a sharp drop in acceptability judgments occurred. Consequently, these results indicate a super-additive effect on judgments resulting from the co-occurrence of multiple sources of difficulty in sentence processing.

In addition, estimates of working memory (operationalized as performance on the reading span test) indicate that better working memory predicts higher judgments of acceptability for items with processing challenges. This suggests that a positive linear relationship between reading span scores and acceptability scores indicates significant processing difficulty in the test items. The strength of these conclusions, however, depends on whether a similar relationship appears in sentences with grammatical violations.

Experiment II: Grammatical Violations

Experiment II evaluates how multiple grammatical violations affect judgments when they co-occur in the same sentence. Since grammatical violations do not affect acceptability via overtaxing processing resources, combining them should not result in super-additive decre-

ments (unlike the processing manipulations in Experiment I). In addition, for the same reason, comprehenders with greater working memory capacities should if anything show a greater decrement for grammatical violations than low-capacity comprehenders (also unlike the results of Experiment I).

Participants Stanford University students ($n = 28$) who had not participated in Experiment I completed this experiment in exchange for payment.

Materials The 24 experimental items in Experiment II contained either 0, 1, or 2 grammaticality violations. We manipulated the grammaticality of two separate but nearby constituents to yield a 2×2 design. The first manipulation targeted the morphological form of a verb in a subject relative clause. Subjects either saw the correct form (4a,4b) or they saw a form that was missing the appropriate inflectional morphology (4c, 4d). Additionally, participants either read an object pronoun with the proper case-marking (4b,4d) or they read a pronoun with unlicensed nominative case-marking (4a,4c):

- (4) a. The friend who **visited** Sue asked **she** whether the value of the house had dropped since the recession began. [good-bad]
- b. The friend who **visited** Sue asked **her** whether the value of the house had dropped since the recession began. [good-good]
- c. The friend who **visit** Sue asked **she** whether the value of the house had dropped since the recession began. [bad-bad]
- d. The friend who **visit** Sue asked **her** whether the value of the house had dropped since the recession began. [bad-good]

72 filler items appeared along with the critical items.

Procedure Procedure was identical to Experiment I.

Results

Data were analyzed using the same methods as in Experiment 1. Outlier removal affected 1.2% of the data. The acceptability results indicate that the manipulations of both inflectional morphology ($\beta = -.415$, $t = -8.525$, $p < .0001$) and case ($\beta = -.624$, $t = -12.817$, $p < .0001$) had significant effects on acceptability judgments. There was also a statistically significant interaction ($\beta = .234$, $t = 2.402$, $p < .05$); however, the interaction differs from the interaction found in Experiment I. Here, it emerges because the case error produces lower judgments than the verbal inflection error. This interaction is *not* due to super-additivity, as it was in Experiment I; two errors yield acceptability decrements that are approximately the sum of decrements caused by sentences with each error in isolation.

In further contrast with the results from Experiment I, reading span scores do not show an overall significant linear relationship with acceptability z-scores. For the conditions judged the worst by participants, memory estimates actually exhibit a negative linear relationship with z-scores, i.e. individuals with higher reading span

Figure 2: Acceptability z-scores for Experiment II. Error bars show (+/-) one standard error.

scores judged these conditions worse, compared to individuals with lower reading span scores. The difference between the conditions leads to a statistically reliable interaction of reading span score and the effect of the case manipulation ($\beta = -.098$, $t = -3.028$, $p < .01$).

Discussion

Grammaticality violations appear to affect acceptability judgments in a qualitatively different way than processing manipulations. Most notably, grammaticality violations in this experiment combine additively—the effect of two co-occurring, proximal violations does not reduce judgments further than expected on the basis of each violation in isolation. These results align with independent evidence from Sorace and Keller (2005) that grammaticality violations combine additively.

The other important contrast between the first two experiments involves the relationship between reading span scores and acceptability scores. While we found a positive linear relationship between the two in Experiment I, in this experiment, reading span predicted *lower* judgments for the conditions judged worse (those with a case error). However, because the two types of manipulations were investigated in separate experiments, these high- and low-reading span participants were different individuals across experiments. In Experiment III, we directly compared the effects of grammaticality manipulations and processing manipulations in the same experiment and the same individuals.

Experiment III: Grammar and Processing

Participants This experiment was conducted in the same session as Experiment I, and involved the same 32

Stanford University students.

Materials Experiment III investigated how grammaticality violations and processing manipulations interact with one another. Experimental items appeared with either a correctly inflected verb (5a,5b) or incorrectly inflected verb (5c,5d). Dependency locality was utilized again to vary processing difficulty; the *wh*-dependencies in (5b) & (5d) are shorter than those in (5a) & (5c).

- (5) a. They couldn't remember which lawyer that the reporter interviewed had defended the elderly man at the courthouse. [**hard-good**]
- b. They couldn't remember which lawyer had defended the elderly man that the reporter interviewed at the courthouse. [**easy-good**]
- c. They couldn't remember which lawyer that the reporter interviewed had defending the elderly man at the courthouse. [**hard-bad**]
- d. They couldn't remember which lawyer had defending the elderly man that the reporter interviewed at the courthouse. [**easy-bad**]

The 24 experimental items were included alongside the materials from Experiment I and 48 additional fillers.

Procedure Procedure was identical to Experiments I and II.

Results

Data were analyzed using the same methods used in Experiments I and II. Removal of outliers affect 1.2% of the dataset. Results show that grammaticality significantly influences acceptability judgments ($\beta = .626$, $t = 15.583$, $p < .0001$). In contrast, the effect of processing difficulty on judgments is not statistically significant ($\beta = -.065$, $t = -1.628$, $p > .1$); however, there is a significant interaction between processing difficulty and grammaticality ($\beta = -.215$, $t = -2.680$, $p < .05$). As Figure 3 illustrates, this interaction arises because processing difficulty lowers judgments in sentences without grammatical violations, but it does not do so in sentences with grammatical violations.

While reading span does not emerge as a significant predictor for judgments across all condition types ($\beta = -.014$, $t = -.868$, $p > .1$), this seems to be because the grammatical and ungrammatical conditions pattern in different ways. The data reveal that individuals with higher reading span scores judge ungrammatical items worse, but in the grammatical conditions, better reading span performance predicts higher judgments of acceptability, leading to a significant interaction of reading span score and grammaticality ($\beta = .093$, $t = 4.986$, $p < .001$). In other words, estimates of memory capacity only show a positive linear relationship with judgments in the absence of grammar-based constraint violations.

Discussion

The results of Experiment III are consistent with our predictions and with the results of the first two experiments. Processing constraints and grammatical con-

Figure 3: Acceptability z-scores for Experiment III. Error bars show (+/-) one standard error.

straints combine sub-additively. Presumably, the grammaticality violations were so extreme as to “drown out” the effects of the processing manipulations in the ungrammatical conditions, i.e. a floor effect occurred. In general, if processing constraints and grammatical constraints reflect distinct and largely independent cognitive resources, super-additive combinations are unexpected. The present results support this hypothesis.

In addition, the relationships between reading span scores and judgments are as expected based on Experiments I and II: comprehenders with higher working memory scores find ungrammatical sentences worse, but difficult sentences better, compared to their low working memory counterparts. Experiment III shows that these contrasts can be observed even with the same set of subjects and minimally different items.

General Discussion and Conclusions

Three word-by-word acceptability judgment studies showed that (1) grammaticality violations combine additively, (2) differences that stem from functional constraints can combine super-additively with one another, and (3) grammaticality violations and processing manipulations can combine sub-additively with one another. These patterns suggest that when two constraints combine super-additively in acceptability decrements, it is likely that they are both functional constraints. Furthermore, participants' reading span scores predict sentence judgments differently for different types of manipulations. Participants with higher reading spans tend to judge ungrammatical sentences as being worse than their low-span counterparts do, yet they tend to judge difficult sentences as being better than participants with lower reading spans. These effects are not due to differ-

ences in comprehension accuracy, as this did not differ between conditions in any of the experiments.

It might be tempting to extend the findings of these experiments to the inverses of the relationships we have reported here; that is, if super-additivity indicates a processing contribution to an acceptability decrement, then does the absence of super-additivity rule out processing contributions? While it would be helpful for interpreting acceptability judgments if this were true, neither the present results nor general principles of language processing license this inference. If two sources of processing difficulty are sufficiently weak, they will not overtax the available resources, and should combine additively. Likewise, if two sources of processing difficulty were sufficiently extreme, the presence of just one might so overwhelm processing resources that the presence of the other was undetectable, resulting in a sub-additive combination.

It is also not possible to infer the inverse of the relationship we reported between reading span scores and processing difficulty. The lack of a positive linear relationship between reading span scores and acceptability judgments does not entail that the sentences do not cause processing difficulty. Further experiments not reported here involving center-embeddings show that reading span scores do not exhibit a positive linear relationship with acceptability judgments in the presence of massive processing difficulty. This could occur if language comprehension is not likely at a certain level of difficulty, and thus having greater language comprehension abilities might not produce better judgments. In other words, some stimuli may be so hard to process that virtually no one will have sufficient cognitive resources to understand the stimuli.

Given that these inverse inferences are not supported, tests of the functional origins of acceptability contrasts that seek to take advantage of the relationships of super-additivity and working memory capacity we demonstrate here must be designed accordingly. When super-additivity and/or positive linear relationships between acceptability and working memory measures are observed, however, these relationships will support conclusions that grammatical constraints are not necessary to account for the observed acceptability contrasts. This paper is a first step in what we hope will be a continuing process of developing criteria for establishing the role of functional constraints in acceptability contrasts – a necessary part of collecting and assessing evidence for grammatical theory-building.

Acknowledgments We gratefully acknowledge discussions and input from Daniel Casasanto and the assistance of David Kettler in conducting the experiments.

Abstract

Do young children treat labels as features or as category markers? The current study addressed this question by examining the effect of labels on young children's classification and induction. The first experiment replicated previous study on adults demonstrating that adults treat labels as category markers. The other two experiments applied the same paradigm to young children. Children were trained by classification in Experiment 2A and by induction in Experiment 2B, whereas both experiments used the classification and induction tasks that were identical to those in Experiment 1. The results from the three experiments indicated that adults treated labels as category markers, whereas no such evidence was found for young children.

Keywords: Cognitive Development, Classification, Induction, Label, Psychology, Human Experimentation.

Introduction

The ability to use linguistic labels to generalize from the known to the unknown is crucial for learning new information. Although a substantial body of experimental evidence has demonstrated that label has an impact on categorization and induction processes (Gelman & E. Markman, 1986; Sloutsky, Lo, & Fisher, 2001; Welder & Graham, 2001; Yamauchi and A. Markman, 1998, 2000), the mechanism underlying the role of labels is hotly debated. Are labels used as features (similar to other objects' properties) or as category markers representing category membership? This issue is particularly contentious with respect to the role of labels in early development and developmental changes in this role.

Some researchers have argued that labels are more than features. According to this view, labels are category markers used for representing a category. For example, E. Markman and Hutchinson (1984) found that children regarded words presented as count nouns changed the way young children grouped objects. Without labels children grouped objects thematically (e.g., a police car was grouped with a policeman), whereas when the same police car was referred to by a count noun, children

grouped objects taxonomically (e.g., the police car with a passenger car). Gelman and Heyman (1999) demonstrated that young children were more willing to generalize properties from one person to another when both persons were referred to by a noun (i.e., "carrot-eaters") than when both were referred to by a descriptive sentence (e.g., "both like to eat carrots").

This evidence, however, does not lend unequivocal support to the idea that labels have to be category markers to make inductive inferences. For example, some researchers suggested that contribution of labels is driven by attentional rather than conceptual factors (Napolitano & Sloutsky, 2004; Sloutsky & Napolitano 2003). There is also evidence that labels contribute to the overall similarity of compared entities and thus to both categorization and induction (Sloutsky & Fisher, 2004). Sloutsky and Fisher (2004) also demonstrated that similarity computed over labels and appearances can accurately predict young children's responses with the Gelman and E. Markman (1986) task. These findings suggest that reliance on labels does not necessarily indicate that labels are more than features.

In a series of studies, Yamauchi and A. Markman (1998, 2000) designed a paradigm that could address this issue directly. Specifically, they compared participants' performance on classification tasks (e.g., is X a dax?) with that on induction tasks (e.g., given that X is a dax, does it have Y?). The tasks are structurally identical, except a critical difference. In the classification task participants predicted the category label of an item given all of its feature values. In contrast, in the induction task, participants predicted the value of a missing feature of an item given its category label and other feature values. These researchers argued that if the label is a feature then performance on classification and induction task should be symmetrical. However, if labels are more than features, then performance on induction tasks should be better than performance on classification

tasks. Upon finding predicted asymmetries between the two conditions (i.e., participants were better at using the label to predict other features than at using other features to predict the label), these researchers concluded that participants are more likely to regard labels as category markers instead of object features.

However, this paradigm has not been applied to children. Does the asymmetry found in adults exist in children? Finding such an asymmetry would support the idea that labels are more than category features, whereas a symmetric performance in the classification and induction conditions would support the idea that labels are features. The primary goal of this study is to address these questions.

The current study consists of three experiments. Experiment 1 replicated Yamauchi and A. Markman's paradigm (2000) with adults. Based on their findings, it was hypothesized that adults would regard labels as category markers. Experiments 2A and 2B, using comparable learning and testing conditions, examined how labels would affect young children's performance.

Experiment 1

Method

Participants Sixteen adults participated in this experiment. Participants were undergraduate student from the Ohio State University participating for course credit. Three of them gave one type of response to over 95% of all trials. Their data were excluded from the analysis due to the response bias.

Figure 1. The prototypes of stimuli used in this study.

Stimuli The stimuli were artificial creatures accompanied by a category label ("Flurp" or "Jalet") and two categories of objects that were created using five features varying in color and shape (see Figure 1). As shown in Table 1 and 2, the two categories have a family-resemblance structure, which is derived from two prototypes (F0 and J0) by modifying the values of one of five features. For example, to produce the stimulus F1, the value of the antenna is changed from 1 to 0 so that it has four features consistent with the prototype F0 and one feature consistent with the prototype J0. The degree of similarity between test stimulus and the prototype is defined by the number of matching features of the test stimulus to the prototype of the corresponding category (Table 1 and 2).

Table 1. Category structure used in learning.

Flurp							Jalet						
Stimuli	Head	Body	Hands	Feet	Antenna	Label	Stimuli	Head	Body	Hands	Feet	Antenna	Label
F1	1	1	1	1	0	1	J1	0	0	0	0	1	0
F2	1	1	1	0	1	1	J2	0	0	0	1	0	0
F3	1	1	0	1	1	1	J3	0	0	1	0	0	0
F4	1	0	1	1	1	1	J4	0	1	0	0	0	0
F5	0	1	1	1	1	1	J5	1	0	0	0	0	0
F0	1	1	1	1	1	1	J0	0	0	0	0	0	0

Note. The value 1 = any of five dimensions identical to "Flurp" (see Figure 1). The value 0 = any of five dimensions identical to "Jalet" (see Figure 1). F = Flurp; J = Jalet. F0 and J0 are prototypes of each category.

Table 2. Stimulus structure used in testing.

Flurp								Jalet							
Stimuli	Head	Body	Hand	Feet	Antenna	Target Label	Match	Stimuli	Head	Body	Hand	Feet	Antenna	Target Label	Match
F11	1	1	1	1	0	1	High	J11	0	0	0	0	1	0	Low
F12	1	1	1	0	1	1		J12	0	0	0	1	0	0	
F13	1	1	0	1	1	1		J13	0	0	1	0	0	0	
F14	1	0	1	1	1	1		J14	0	1	0	0	0	0	
F15	0	1	1	1	1	1		J15	1	0	0	0	0	0	
F21	1	0	1	0	0	1	Low	J21	0	1	0	1	1	0	High
F22	0	1	0	1	0	1		J22	1	0	1	0	1	0	
F23	0	0	1	0	1	1		J23	1	1	0	1	0	0	
F24	1	0	0	1	0	1		J24	0	1	1	0	1	0	
F25	0	1	0	0	1	1		J25	1	0	1	1	0	0	

Note. High and low are two levels of feature match. F = Flurp; J = Jalet. Category-accordance responses were the ones consistent with the values indicated in the target features and target labels.

Similar to Yamauchi and A. Markman, there are two levels of similarity (or feature match) in current research: high and low. At the high level of feature match, each test stimulus has four features in common with the prototype of the corresponding category and one feature in common with the prototype of the contrasting category. Similarly, each test stimulus at the low level of feature match has two features in common with the prototype of the corresponding category and three features in common with the prototype of the other category.

Procedure The entire experiment consisted of two phases, learning and testing. During the learning phase, participants were instructed that they should try to remember and distinguish two groups of artificial creatures represented by the labels "Flurp" and "Jalet". And then participants were presented with 36 trials of creatures produced from stimulus structure shown in Table 1 and each stimulus had a correspondent label above it.

The testing phase was administered immediately after the learning phase. The Classification and Induction conditions differed in the type of features being predicted. In the Classification condition, participants predicted the category label of a stimulus given information about all five features with the label covered. In the Induction condition, participants predicted the value of one of five features given the other four features with the label uncovered. The classification question was phrased as "Which group do you think this creature is more likely to belong to, Flurp or Jalet?" The induction question was phrased as "Which antenna do you think this creature is more likely to have?" The order of the testing trials was randomized for each subject. Feedback was given in first 6 trials of each condition. No feedback in other 40 trials in both conditions. The proportion of responses in accordance with the category from which the exemplar was derived (called "category-accordance responses" by Yamauchi & A. Markman, 2000, see Table 2) was the dependent variable.

Results and Discussion

The main results of Experiment 1 are shown in Figure 2. The data were analyzed with 2 (testing type: Classification and Induction) \times 2 (feature match: high and low) analysis of variance (ANOVA). There was a main effect of feature match, $F(1,12) = 165.39$, $MSE = 0.89$, $p < 0.01$, as well as an interaction between testing type and feature match, $F(1,12) = 38.61$, $MSE = 0.32$, $p < 0.01$. At the low level of feature match, category-accordance responses made in the Induction condition were more than in the Classification condition, $t(12) = 4.88$, $p < 0.01$. However, there was no significant difference in these two testing types at the high level of feature match, $t(12) = 2.12$, $p > 0.05$.

Figure 2. Performance for classification and induction tasks in Experiment 1.

The results replicate Yamauchi and A. Markman (2000) pointing to the predicted asymmetry and suggesting that for adults labels are more than objects features. In Experiment 2, we expand this paradigm to young children.

Experiment 2A

Method

Participants There were thirteen preschool children (6 boys and 7 girls) with an average age of 55.8 months participating in this experiment. They were given Classification learning. In Classification learning, children were presented with all five features of a creature and told that it was a Flurp (or Jalet). A memory check was administered after main experiment to examine whether participants could remember the stimuli and correspondent labels. Children were given 5 trials in memory check by presenting a creature and asking them which group this creature came from. One of them answered less than 3 out of 5 memory check questions correctly and these data were excluded from the analysis.

Stimuli and procedure The visual stimuli were identical to Experiment 1 (see Figure 1). The entire experiment consisted of two phases, classification learning phase and testing phase. During classification learning, in contrast to Experiment 1 with adults, children were instructed that there were two groups of creatures, Flurp and Jalet. And then they were trained by presenting creatures with category labels and told: "This is a Flurp (or Jalet)."

Figure 3. Performance for classification and induction tasks in Experiment 2A.

The testing phase was identical to Experiment 1 except how the questions were asked. Unlike the adults participants in Experiment 1 who read the questions presented on screen, children were asked both classification and induction questions by a female experimenter.

Results and Discussion

The main results of Experiment 2A are shown in Figure 3. The data were analyzed with 2 (testing type: Classification and Induction) \times 2 (feature match: high and low) analysis of variance (ANOVA), with testing type and feature match as within-subjects factors. There was a main effect of feature match, $F(1,11) = 43.56$, $MSE = 1.33$, $p < 0.01$, as well as a main effect of testing type, $F(1,11) = 14.77$, $MSE = 0.16$, $p < 0.01$. However, unlike adults in Experiment 1, there was no significant interaction between testing type and feature match, $F(1,11) = 0.02$, $MSE = 0.00$, $p > 0.10$.

Children in Experiment 2A, unlike adults in Experiment 1, made more category-accordance responses on classification questions than on induction questions at both high and low level of feature match. These results indicate that, if anything, the Classification condition elicited better performance than the Induction condition. These results present little evidence that young children treated labels as category markers.

However, the learning type, in this experiment using classification learning, might have a facilitative effect on children's classification. In Experiment 2B, we explored the impact of learning type on children's performance in

the classification and induction tasks by training them with induction instead of classification task.

Experiment 2B

Method

Participants There were fourteen preschool children (8 boys and 6 girls) with an average age of 54.00 months in this experiment. They were given Induction learning. In contrast to the children trained by classification in Experiment 2A, children in this experiment were trained by induction in which they were presented all five features of a creature and told that the creature had a Flurp (or Jalet) inside its body. A memory check, identical to Experiment 2B, was administered after main experiment to examine whether participants could remember the stimuli and correspondent labels. Two of them answered less than 3 out of 5 memory check questions correctly and these data were excluded from the analysis.

Stimuli and procedure The visual stimuli were identical to previous experiments. The entire experiment consisted of two phases, induction learning phase and testing phase. During induction learning, in contrast to Experiment 2A, children were instructed that there were two groups of creatures and something special was inside each group of creatures. One group of creatures had Flurp while another group had Jalet. And then they were trained by presenting creatures and told: "This one has a Flurp (or Jalet)." The testing phase was identical to Experiment 2B.

Results and Discussion

The main results of Experiment 2B are shown in Figure 4. The data were analyzed with 2 (testing type: Classification and Induction) \times 2 (feature match: high and low) ANOVA, with testing type and feature match as within-subjects factors. There was a main effect of feature match, $F(1,16) = 86.84$, $MSE = 2.50$, $p < 0.01$. In contrast to Experiment 2A, children in this experiment did not differ in the two testing types, $F(1,11) = 3.90$, $MSE = 0.03$, $p > 0.05$.

These results, compared to Experiment 2A, suggest that there was an effect of learning type and the induction learning facilitated children's performance on the induction questions. However, children's performance, similar to Experiment 2A, was symmetric in both testing conditions and there was no evidence that children treated differently induction and classification questions.

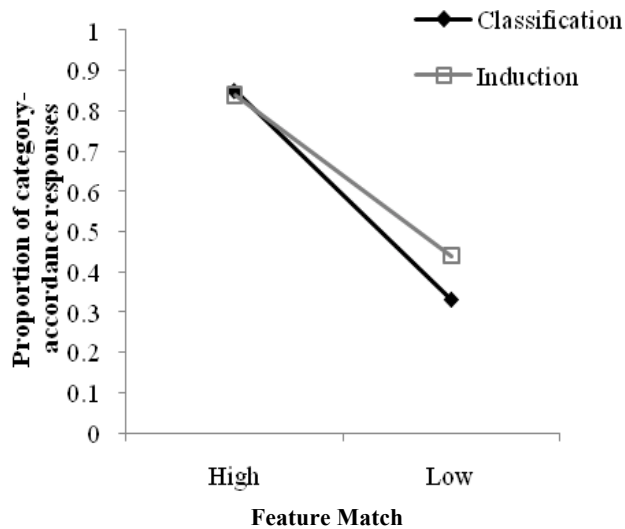

Figure 4. Performance for classification and induction tasks in Experiment 2B.

General Discussion

The results point to two main findings. First, there was an effect of learning. Children had better performance on classification questions when they were trained by classification (Experiment 2A). At the same time, when they were trained by induction (Experiment 2B), their performance on induction questions became equivalent to that on classification questions and there was no significant difference between these two testing types.

And more importantly, there were marked developmental differences in the role of linguistic labels. Adults exhibited better performance in inferring a feature by using a label than inferring a label by using features. These findings are consistent with previous research (Yamauchi & A. Markman, 2000) and suggest that adult may have used labels as category markers. However, labels had little facilitative effect on children's performance – their performance was equivalent whether they were asked to predict labels on the basis of other features (i.e., the classification condition) or to predict a feature on the basis of the label (i.e., the induction condition). Furthermore, regardless of the type of learning (i.e., Classification or Induction), children, in contrast to adults' asymmetry, consistently exhibited a symmetric pattern on classification and induction questions (see Figure 3 and 4). These results suggest that while labels may be different from category features for adults, this is not the case for young children.

These results have important implications for understanding of inter-relationships between language and cognition, and specifically the role of linguistic labels in categorization and category learning. Recall that

according to some accounts, even early in development linguistic labels words affect categorization and inductive inference by marking the underlying category (e.g., Gelman & Heyman, 1999; Gelman & Markman, 1986). According to other accounts, early in development linguistic labels are features of entities. As a result, when two entities share a label, young children may perceive these entities as being more similar than when no labels are introduced (Sloutsky, et al, 2001; Sloutsky & Fisher, 2004). Yamauchi and A. Markman (1998, 2000) developed a procedure enabling the distinction between these accounts. This procedure, however, was never used with young children.

Our results with young children support the latter account, while generating little evidence that young children treat labels as category markers. In addition, although current research does not conclusively eliminate the possibility that for young children linguistic labels are category markers, it demonstrates that the role of linguistic labels changes in the course of development.

Abstract

Previous work in object categorization has shown that people tend to optimize their allocation of attention to object features, and suggests that attentional optimization may best be explained in terms of cost-benefit tradeoffs. In support of this idea, we found that implementing a cost for accessing information about object features in a category learning task facilitates both attentional optimization and category acquisition, contrary to the predictions of existing models.

Keywords: category learning; categorization; access cost; attentional learning; optimization.

An important component of proper psychological functioning is the adaptive usage of limited resources. In many situations, careful conservation of money, food, water, memory capacity, and time can be vital to survival. The choice of strategy for dealing with a particular issue depends largely on the relative availability of the various resources required – for instance, installing hardwood floors might be best accomplished by doing it oneself if money is tight and time is plentiful, while hiring a contractor might be a better idea if money is no object but the job must be done quickly. An optimal strategy for a given problem, then, balances situational priorities (urgency, desire for quality) with available resources (time, money).

This characterization of optimal strategy applies equally to psychological domains such as categorization. Fiske and Taylor (1984) characterized humans as cognitive misers, meaning we will attempt to solve problems using the smallest amount of mental resources possible. Indeed, a good deal of evidence suggests that in category learning, people learn to ignore irrelevant information, thereby optimizing their allocation of attention for the task at hand (Rehder & Hoffman, 2005; Blair, Watson, & Meier, 2009; Blair, Watson, Walshe, & Maj, 2009; Blair, Chen, et al., 2009). The process of selectively allocating attentional resources to task-relevant information is labeled *attentional optimization*.

One approach to characterizing the optimal usage of attentional resources takes the view that the benefits of attending to a piece of information must outweigh the costs. This view of attentional optimization as a process of cost-benefit tradeoffs parallels some of the decisions made in the domain of medical diagnosis. A doctor attempting to diagnose a patient will order only tests which are necessary, and even then will strike a balance between efficacy, cost, and safety. A doctor who suspects a particular condition may be more likely to order a cheap, safe blood test than expensive, dangerous exploratory surgery.

It is not yet clear which resources are conserved as a result of attentional optimization. One candidate is working memory capacity: unattended object features are unlikely to be stored in memory. There is, in fact, evidence that working memory shares a close relationship with category learning: those with low working memory spans are less able to suppress task-irrelevant information, creating a need for selective attention to fill the gap (Conway, Kane, & Engle, 2003). Another resource that may be conserved is time – attending only to what is necessary is likely to result in a reduction in the amount of time required to categorize something. In either view, attending to a particular feature of an object incurs a cost – whether temporal or mnemonic – and attentional optimization minimizes the cost incurred for a successful categorization.

Hayhoe and colleagues (Ballard, Hayhoe, & Pelz, 1995; Ballard, Hayhoe, Pook, & Rao, 1997; Droll & Hayhoe, 2007) provided empirical evidence of cost-benefit tradeoffs in visual perception. When performing a task along the lines of the Blocks World game (an interactive paradigm in which subjects must duplicate a target image by positioning a group of coloured boxes from a resource pool), participants generally gather information from the environment as they need it, minimizing the usage of short-term memory. However, increasing the predictability of the task encourages participants to save time by storing information in memory: time, rather than memory capacity, becomes the focus of their conservation efforts. Similar results were found in a series of studies by Gray and colleagues, many of which also employed the Blocks World paradigm (Gray & Fu, 2004; Gray, Sims, Fu, & Scholles, 2006; Fu & Gray, 2006). When the target window was occluded by a removable square, or participants were forced to make head movements in addition to eye movements in order to direct their gaze about the work area, there tended to be a switch to a memory-intensive strategy in order to save time and energy.

It appears that saving time is not the only advantage of adopting a memory-based strategy in tasks along the lines of Blocks World, although the evidence is not unequivocal. Gray et al. (2006) found that participants in a memory-intensive variation of the Blocks World task made fewer errors and mastered the task sooner than others performing a standard task. While this contradicted earlier results by Gray and Fu (2004), the results of Gray et al. (2006) are supported by the research of Waldron and colleagues on interface design (Waldron, Patrick, Howes, & Duggan, 2006; Waldron, Patrick, Morgan, & King, 2007; Morgan, Patrick, Waldron, King, & Patrick, 2009). As in the Blocks

World literature, Waldron and colleagues found that an increased information access cost leads to a change in information-gathering strategy in a variety of different paradigms. Implementing a time delay for accessing information on the target encourages the usage of memorization, in contrast to the default strategy of scanning back and forth (Waldron et al., 2006). This strategic shift was found to be beneficial to memory for particular system states, general understanding of the system, competence in the absence of available information (Waldron et al., 2007), and the ability to fluently resume a task after interruption (Patrick et al., 2009), though it has its costs in the form of increased response time (Waldron et al., 2006).

While the above research suggests that there are some benefits (and some penalties) resulting from a shift toward memory-based strategies in response to increased information access costs, it is not yet clear whether increased attentional optimization is one of them. None of the studies by Waldron and colleagues involved the presence of irrelevant information. This is not surprising, as interface design tends to avoid including irrelevant data in a display; however, in object categorization it is often vitally important to be able to divert one's attention away from unimportant information (e.g. Rehder & Hoffman, 2005).

In spite of the evidence regarding the importance of cost-benefit considerations in the allocation of attention, it is possible (and, until recently, routine) to develop a coherent model of attentional optimization without making any mention of costs. Computational models of category learning, such as ALCOVE (Kruschke, 1992), simply shift attention away from irrelevant information and towards relevant information. However, in a disease diagnosis paradigm, Matsuka and Corter (2008) found that participants appeared to optimize attention in a way consistent with a sensitivity to cost-benefit considerations. When presented with stimuli with two different features which perfectly and redundantly predicted category membership, people attended to only one of them. The idea of attentional optimization as a cost-benefit tradeoff explains this result quite well: the benefit of viewing one feature far outweighs the cost of accessing it, while the second feature provides no additional information to offset its access cost and is thus ignored.

If attentional optimization is indeed based partially on cost-benefit considerations, then the degree to which people optimize their attention should depend on the additional cost incurred in attending to irrelevant features. A high information access cost should provide more motivation to avoid the waste of time or resources associated with attending to irrelevant information, increasing the rate of attentional optimization. In contrast, optimizing one's attention would provide only a minimal benefit in a situation in which accessing information is nearly or entirely free, and as such may be less of a priority for those who are able to master the task.

All other things being equal, then, a category learning task with a high information access cost should result in

more attentional optimization than a task with a low or nonexistent access cost. In addition, implementing a high access cost should encourage the use of a memory-based strategy, resulting in improved learning. The present experiment sought to test these hypotheses using the stimuli and category structure from Experiment 2 of Blair, Watson, Walshe, and Maj (2009). Since the stimuli involved three spatially separate features, we were able to manipulate access cost by obscuring the features with overlays and implementing a variable time cost to remove them.

Method

Participants

149 undergraduate students from Simon Fraser University students participated in exchange for course credit in introductory Psychology classes.

Apparatus

The computer program used in the present experiment was developed using E-Prime 1.1 (Psychology Software Tools), and was run on four Apple iMac computers running Windows XP. Responses were made using the computer mouse.

Design

The present experiment consisted of a supervised category learning task. Participants were shown computer-generated pictures of fictitious microorganisms (see Figure 1) and asked to categorize them as members of one of four different species. The microorganisms (following Blair, Watson, Walshe, and Maj, 2009), varied on three binary organelle-like features, each located in a distinct area of the cell. One organelle looked like either a muscle or a thin tube, another was a mitochondrion-like structure with either

Figure 1: A sample microorganism stimulus with response buttons in the corners of the screen. The subject has revealed the top right feature by moving the mouse over it, while the other two are still occluded by overlays.

Table 1: Sample category structure.

Feature 1	Feature 2	Feature 3	Category
1	0	Irrelevant	A1
1	1	Irrelevant	A2
0	Irrelevant	0	B1
0	Irrelevant	1	B2

two or four internal compartments, and the third resembled an iris and pupil with either a green or a brownish coloration. Each feature occupied its own lobule of the cell, evenly distributed around the screen and counterbalanced across subjects.

There were four possible category labels for each stimulus: A1, A2, B1, and B2. One feature was always relevant, and determined whether the stimulus was a member of an A category or a B category. Of the two remaining features, one determined whether an A stimulus was A1 or A2, and the other determined whether a B stimulus was B1 or B2. Thus, only one of the two was relevant on any given trial, and the identity of the first feature informed the participant of which of the other features would be relevant (see Table 1). Feature relevance was counterbalanced across subjects, and category labels were assigned randomly according to the structure described above.

Procedure

Following a brief introduction to the experimental task, participants began a series of supervised categorization trials. A stimulus was presented, with its three variable features covered up by noisy square-like overlays. In order to remove an overlay and see the feature underneath, participants were required to hold the mouse on top of it for a predetermined period of time.

Participants were randomly assigned to a high-cost or low-cost condition. In the no-delay (low-cost) condition, the overlays disappeared instantly; in contrast, participants in the delay (high-cost) condition had to hold the mouse on top of an overlay for a full 3000ms before the feature was revealed. During this interval, the overlay was replaced by a black box marked “SCANNING...” In either condition, upon moving the mouse away from the revealed feature, the overlay would instantly reappear. The position of the mouse was tracked and recorded over the course of the experiment. Thus, at most one feature was available for viewing at one time. This allowed for a sensitive and dynamic measure of attentional allocation, similar to that of eye-tracking, and prevented participants in the delay condition from using the additional wait time to inspect other features.

Immediately after participants responded, they were presented with corrective feedback and were able to re-inspect stimulus features, with the same overlay restrictions as before, if they so desired.

By default the experiment lasted for 200 such categorization trials. An early learning criterion was implemented such that participants who learned the category

Figure 2: Mean number of trials taken to reach the learning criterion by condition. Error bars represent SEM.

structure well enough to provide 25 consecutive correct answers immediately proceeded to a 72-trial transfer phase where corrective feedback was not provided. Those who were unable to reach this criterion point by the 200th trial did not proceed to transfer. There was no time restriction on the experiment; participants were free to spend as long as desired on each trial. While there was some individual variation in completion times, the entire experiment took approximately 45 minutes to complete.

Results

20 participants were excluded due to computer errors or random responding, leaving 65 participants in the no-delay condition and 64 in the delay condition. The no-delay condition produced 45 learners and 20 non-learners, compared to 49 learners and 15 non-learners in the delay condition. This did not constitute a statistically significant difference, $\chi^2(1) = .877, p > .30$. Among those who were able to learn the category structure, however, participants in the delay condition reached criterion accuracy significantly earlier ($M = 57.5$ trials) than those in the no-delay condition ($M = 76.2$), $t(92) = 2.37, p < .05$ (see Figure 2).

We calculated attentional optimization scores for each trial following the formula used in the eye-tracking experiments of Blair, Watson, Walshe, and Maj (2009):

$$\frac{\bar{X}_{relevant} - \bar{X}_{irrelevant}}{\bar{X}_{relevant} + \bar{X}_{irrelevant}}$$

This amounts to a comparison of the average length of time spent attending to relevant versus irrelevant features, where $\bar{X}_{relevant}$ is the total time during which relevant features were visible divided by the number of relevant features and $\bar{X}_{irrelevant}$ is the total time during which irrelevant features were visible divided by the number of irrelevant features. Our measure of attentional optimization thus ranged from -1 (fixating only irrelevant features) to 0

Figure 3: Mean optimization in the first 110 trials by condition. Error bars represent SEM.

(equal time spent fixating all features) to 1 (fixating only relevant features). Over the course of the experiment, subjects in the delay condition displayed significantly greater optimization ($M = 0.623$) than those in the no-delay condition ($M = 0.520$), $t(92) = 2.193$, $p < .05$.

Since the delay condition resulted in faster learning and thus an earlier end to the experiment, we elected to examine optimization between conditions over a set number of trials as an alternative comparison between conditions. We calculated the mean optimization over the first 110 trials (the approximate length of the shortest experimental run) for each successful learner. In this trial range, participants in the delay condition displayed a mean optimization score of .531 (SD .281), compared to .355 (SD .245) for the no-delay condition. This was a significant difference, $t(92) = 3.34$, $p < .01$ (see Figure 3).

As attentional optimization has been known to occur after categorization errors cease (Blair, Watson, & Meier, 2009), it is possible that the contribution of access cost to optimization in the first 110 trials was purely a product of the earlier learning criterion in the delay condition. With more error-free time to optimize, a greater degree of optimization would not be surprising. To examine whether access cost had an effect on optimization independent of its contribution to early accuracy, we performed a mediation analysis using the hierarchical multiple-regression techniques described by Baron and Kenny (1986). Having already demonstrated an association between access cost and criterion point (see Figure 2) and a connection between access cost and optimization in the first 110 trials (see Figure 3), we performed a hierarchical multiple regression analysis predicting early optimization from criterion point in the first step, and adding delay condition as a new predictor in the second. Criterion point proved to be a significant negative predictor of optimization, $\beta = -.777$, $t(92) = -11.85$, $p < .001$, as expected. Condition, when added to the model, contributed to optimization even after controlling for criterion point, $\beta = .140$, $t(91) = 2.11$, $p < .05$, indicating a

partial-mediation relationship. Access cost contributed to optimization both indirectly (via earlier learning) and directly.

Finally, we suspected that the time course of optimization may have differed between conditions – it is possible that a long delay encouraged earlier optimization, but participants in the no-delay condition may have caught up later on in the experiment. To investigate this possibility, we calculated each learner's mean optimization scores before and after their criterion point. A 2 (pre-criterion/post-criterion) \times 2 (delay/no-delay) mixed ANOVA revealed no interactive effect of stage and delay on optimization, $F(1,92) = .106$, $p > .70$, suggesting that attentional learning was uniform over the course of the experiment in both conditions.

Discussion

The results of the present work indicate that increasing the temporal cost of accessing information contributes not only to improved category learning, but also to more optimal allocation of attention. Learners in the high-cost delay condition reached the learning criterion earlier than those in the no-delay condition, and displayed greater attentional optimization over the course of the experiment. These findings support the counterintuitive idea that making information access more difficult improves multiple aspects of performance, extending earlier findings in disease-diagnosis (Matsuka & Corter, 2008) and interface design (Waldron et al., 2007). Taken together, this body of research provides compelling evidence for the validity of the conception of attentional optimization as a balancing act between costs and benefits.

In addition to cost-benefit considerations, one potential contributor to the improved learning in the presence of a high temporal access cost is the fact that such a cost encourages a strict sequential progression of attention. In recalling the positions of objects in space (Yamamoto & Shelton, 2009), as well as in recalling lists of words or letters (Frick, 1985; Goolkasian, Foos, & Krusemark, 2008), performance is significantly improved when information is presented sequentially rather than simultaneously. When access cost is low, participants are able to switch their attention back and forth as they please; in contrast, a high access cost discourages jumping back and forth between costly pieces of information and promotes a strategy of sequential attention.

Somewhat unexpectedly, in spite of the earlier criterion point among learners in the high-cost condition, there was not a concomitant difference in the number of learners. This may be an issue of motivation: while the increased access cost appears to facilitate learning by encouraging the use of memory-based strategies, participants in the delay condition may have become frustrated with the inconvenience of having to wait for features to become visible and applied less effort as a result. This possibility may be a fruitful topic for future research. Further investigation in this area may also benefit from some variance in the number of trials given to reach criterion; in the present study, participants in

both conditions were given 200, a number far in excess of the mean number of trials to criterion (58 for delay, 76 for no-delay).

The practical implications of the present research for training in interface design and related fields are obvious: implementing an access cost can in certain circumstances facilitate learning. However, caution should be taken, as a high temporal access cost can greatly reduce the temporal efficiency of a training period. While a subject might learn a particular system in fewer trials with a high access cost, the cost may make each trial so long that the net effect is ultimately more time spent on training. If it holds true that the learning advantage that comes with an increased access cost is largely the product of a shift toward memory-based strategies, there is probably a point beyond which increasing access cost confers no additional benefit. In addition, there may be more practical ways of encouraging the adoption of memorization strategies, such as only presenting information for a short period of time (Waldron et al., 2006) or implementing a non-temporal cost, such as money, tokens, or effort.

Within the field of category learning, researchers have long focused on tasks where all of the relevant information is immediately and simultaneously available to categorizers. Learning, according to the major models, is in most cases exclusively based on the accuracy of the response (e.g. ALCOVE; Kruschke, 1992). This is because they were designed around a specific event – the categorization trial – rather than around the dynamic unfolding of the task through time (though see Lamberts, 2002). While this has been a helpful simplification, it is becoming increasingly untenable in the face of dynamic measures of attention such as eye- and mouse-tracking (Rehder & Hoffman, 2005; Blair, Watson, Walshe, & Maj, 2009), as well as a number of results indicating a level of complexity untouched by the current generation of computational models. The time spent waiting for stimuli to appear can have implications for strategy selection and memory performance (Morgan et al., 2009), the information participants choose to access depends on which information was previously accessed during the trials (Blair, Watson, Walshe, & Maj, 2009), and the length of time spent viewing feedback impacts learning speed (Watson & Blair, 2008). Investigations of missing data (White & Koehler, 2004; Wood & Blair, 2010), tasks which present new sources of information (Blair & Homa, 2005), and studies of the speed of perceptual processing of features (Lamberts, 2003) are further evidence that the amount and order of known information exerts a considerable influence on the course of category learning.

These and other temporal effects on learning and performance are accumulating and will eventually force researchers to embed extant theoretical work in a dynamic, temporal framework in order to account for them.

Abstract

Models of category learning can take two different approaches to representing the relationship between objects and categories. The generative approach solves the categorization problem by building a probabilistic model of each category and using Bayes' rule to infer category labels. In contrast, the discriminative approach directly learns a mapping between inputs and category labels. With this distinction in mind, we revisit a previously studied categorization experiment that showed people are biased towards categorizing objects into a category with higher variability. Modelling results predict that generative learners should be more greatly affected by category variability than discriminative learners. We show that humans can be prompted to adopt either a generative or discriminative approach to learning the same input, resulting in the predicted effect on use of category variability.

Keywords: human category learning; generative models; discriminative models; rational models; Bayesian models

Introduction

Categories can be learned using a variety of approaches. Here we examine two distinct approaches that humans can use to learn categories: *generative* and *discriminative* learning. While relatively unexplored in human categorization, this distinction has been widely studied in machine learning (e.g., Ng & Jordan, 2001). The distinction comes down to whether the ability to categorize objects is the result of estimating a distribution for each category, or learning a mapping from objects to categories. Both of these strategies can be used in learning real life categories. For example, you could learn the food preferences of a friend by observing the foods he eats and trying to infer a probability distribution, or by recording his affective responses to different kinds of foods and trying to identify which factors lead to positive or negative reactions.

More formally, generative and discriminative models represent two distinct strategies for estimating the probability that a particular object belongs to a category. Generative learners solve this problem by building a probabilistic model of each category, and then using Bayes' rule to identify which category was most likely to have generated the object. Discriminative learners estimate the probability distribution over category labels given objects directly. These different strategies have implications for the performance of these models. Theoretical and empirical analyses have shown that generative and discriminative models differ in their generalization behavior, as well as the speed and accuracy of learning (Efron, 1975; Ng & Jordan, 2001; Xue & Titterton, 2008).

While the generative/discriminative distinction has been studied extensively in machine learning and statistics, it has been little examined in human behavior. A recent study has

shown humans can adopt these two different strategies while learning an artificial language (Hsu & Griffiths, 2009). In this paper, we explore whether people can adopt these two strategies in category learning.

The paper will be presented as follows. First we will provide an overview of generative and discriminative categorization models. Second, we will review related work from the existing human categorization literature. Third, we will revisit a previously studied paradigm that showed people are sensitive to category variability, being more likely to assign an object equidistant from the mean of two categories to the category with higher variance (Stewart & Chater, 2002; Cohen, Nosofsky, & Zaki, 2001; Rips, 1989; Smith & Sloman, 1994). Modelling results show that a generative model exhibits greater sensitivity to category variability than a discriminative model. We use this analysis as the basis for an empirical investigation of whether human learners can be prompted to take these two distinct learning approaches. Our results support the idea that humans adopt generative and discriminative approaches when appropriate. This provides new insight into the factors affecting human category learning.

Generative and discriminative models

Rational models of categorization identify the underlying problem as one of estimating the probability of a given object x belonging to a category c , as expressed by the distribution $p(c|x)$. The difference between generative and discriminative approaches to categorization comes down to how this probability distribution is estimated. Generative models build a probabilistic model of the input by learning the probability that an object x is generated given that the category is c , $p(x|c)$, and then solving the categorization problem by applying Bayes' rule. Discriminative models estimate $p(c|x)$ directly. Generative models thus assume that observed objects are sampled in a way that reflects $p(x|c)$, while discriminative models do not make any assumptions about the distribution from which the input is sampled. These two approaches to categorization are illustrated schematically in Figure 1.

Comparison of generative and discriminative approaches to category learning has been done in the machine learning and statistics literature, where the classic *generative-discriminative pair* being compared is usually (generative) naïve Bayes vs. (discriminative) logistic regression (Efron, 1975; Ng & Jordan, 2001; Xue & Titterton, 2008). Under certain conditions, these two models are identical in the asymptotic form of the function $p(c|x)$ that they produce, differing only in how that function is estimated.

Figure 1: Generative and discriminative models. Generative models aim to estimate the probability distribution over the input given the category label. Discriminative models find a direct mapping between inputs and category labels.

Such generative-discriminative pairs can thus be used to explore the consequences of adopting these different strategies through mathematical analysis and simulations. For example, if the training data consist of two normally distributed samples, generative models learn categories more quickly (Efron, 1975; Ng & Jordan, 2001). However, when the training data come from other distributions, discriminative models are asymptotically more accurate (Xue & Titterton, 2008), though in some cases generative models may perform better initially and arrive at their (higher) asymptotic error more quickly (Ng & Jordan, 2001).

Summary of related work

Previous models of categorization have used both generative and discriminative strategies, without necessarily recognizing that the significance of the distinction. The commonly cited prototype and exemplar models can be applied both generatively and discriminatively. Prototypes and exemplars are psychological models of category representation whereas discriminative and generative are statistical models of learning. Thus, prototype and exemplar models can be used under either approach, depending on how learning takes place. For instance, ALCOVE (Kruschke, 1992) is an exemplar model akin to discriminative kernel methods. SUS-TAIN (Love, Medin, & Gureckis, 2004) is a discriminative model that chooses between exemplar and prototype representations. Decision bounds (Maddox & Ashby, 1993) can be either discriminative or generative depending on how model parameters are estimated. While rational models of categorization can adopt either approach, the ones proposed so far have taken a generative approach (e.g., J. R. Anderson, 1990; Griffiths, Canini, Sanborn, & Navarro, 2007). These generative categorization models span the range between exemplar and prototype representations. At the extremes, generative prototype models estimate parameters of category distributions (usually a Gaussian with a mean and variance) and gen-

erative exemplar models estimate category distributions using kernel density estimation (Ashby & Alfonso-Reese, 1995).

Despite the prevalence of human categorization models with both discriminative and generative approaches, most experimental paradigms seem more consistent with discriminative learning: stimuli are presented, participants guess the category and feedback is given. However, a few exceptions this can be seen in previous work on classification vs. inference learning, and observational vs. feedback learning. While not explicitly mentioned in previous work, both of these paradigms are potentially related to our discriminative vs. generative distinction.

Classification vs. inference learning

Another line of experiments has shown that human category learning can also be influenced by using different tasks to teach people about the relationship between categories and features. The effect of using these two different tasks is similar to that of changing the direction of a learned causal relationship. (A. L. Anderson, Ross, & Chin-Parker, 2002; Markman & Ross, 2003; Ross & Murphy, 1996). In these experiments, all participants were presented with exactly the same training stimuli, consisting of the features and category membership of a set of objects. In one condition, learning took place via through *classification*: Participants were provided with the values for (some of) the features of an object asked to predict category membership. In the other condition, learning was based on making a predictive *inference*: The category membership and/or values of some of the features were provided and participants were asked to predict the value of another feature. Because participants in both conditions were given feedback, they were both ultimately provided with exactly the same information about categories and features. However, learning results differed in terms of performance accuracy and generalizations made. For example, inference learners performed better than classification learners on single-feature classification tasks but more poorly when all of the features were provided (A. L. Anderson et al., 2002). While this study was not motivated by generative and discriminative learning, people may have adopted these different strategies in the different conditions: Classification learning can be done using a discriminative model, while inference learning requires a generative model.

Observation vs. feedback training

Another study, by Ashby, Maddox, and Bohill (2002), has also examined how learning of the exact same input was affected by presentation style. Here they compared what they called *feedback* training (where the category label appears after the object) with *observation* training (where the category label appears before the object). Their results showed that participants in the feedback condition performed significantly better than those in the observation condition for information-integration categories, where category membership could not be expressed in terms of a rule using a single feature. These two forms of training might encourage learners to adopt gen-

erative and discriminative strategies. Feedback training gives an error signal that can be used to adapt a discriminative model. Observation training is more relevant for learning object features based on the category label, which is the generative approach.

Summary

Generative and discriminative models use different approaches to solve the problem of categorizing objects. Existing models of human category learning differ in which of these approaches they use. Previous work has not explored whether people are able to switch the approach they take in learning categories, although the effects of different training regimes that might encourage one approach over the other have been investigated. In the remainder of the paper, we explicitly test whether people can adopt these two approaches to learning categories, using a phenomenon that is diagnostic for one generative-discriminative pair of models.

Differential use of category variability

Several experiments have shown an effect of category variability on human categorization judgments. In these experiments, the stimuli belong to one of two categories with different means and variances. The key question is how stimuli with features lying (perceptually) in between the two categories are categorized. The results of these experiments all showed that there was a bias towards categorizing stimuli into the high-variance category (Stewart & Chater, 2002; Cohen et al., 2001; Rips, 1989; Smith & Sloman, 1994). Here we propose that the degree of preference for the high variance category may be affected by whether the learner is adopting a generative or discriminative approach.

Intuitively, we expect category variability to have a greater effect on generative learners because estimating $p(x|c)$ for each category requires being sensitive to the variance of that category. In contrast, one need not consider the variance of the stimuli in simply learning a function from x to c , $p(c|x)$. Indeed many discriminative models used in machine learning, such as support vector machines (Schölkopf & Smola, 2002), focus just on the location of the most extreme members of each category. We are not claiming that all generative models are sensitive to category variance, or that all discriminative models are insensitive, but that these approaches differ in the extent to which they are sensitive to this property of the stimuli. To illustrate this, we will explore the predictions of one generative-discriminative pair of models.

We follow previous work exploring the difference between generative and discriminative models (e.g., Ng & Jordan, 2001) and focus on the generative-discriminative pair of naïve Bayes and logistic regression. Since we will focus on continuous stimuli, we assume a Gaussian generative model, with

$$p(x|c = i) = N(\mu_i, \sigma_i) \quad (1)$$

where μ_i and σ_i are the mean and variance of the i th category with $i \in \{1, 2\}$. The parameters μ_i and σ_i can be estimated

by maximizing the likelihood $\sum_{j=1}^n \log p(x_j|c_j, \mu, \sigma)$, where c_j and x_j are the category membership and features of the j th stimulus respectively. The probability a novel stimulus belongs to a category, $p(c|x)$, is then computed by applying Bayes' rule, with the prior probability of each category being proportional to the number of observed stimuli from that category. The naïve Bayes model is similar to the Gaussian decision bound model used in Normal general recognition theory (Stewart & Chater, 2002; Maddox & Ashby, 1993).

The discriminative model uses logistic regression to estimate $p(c|x)$ directly, with

$$p(c = 1|x, w, b) = 1/(1 + \exp\{-w^T x - b\}) \quad (2)$$

where w and b are the parameters of the model and x is a vector of feature values. The parameters w and b are estimated by maximizing the log likelihood $\sum_{j=1}^n \log p(c_j|x_j, w, b)$. In general, w and b are vectors of length equal to the number of stimulus features. However, we will be using one-dimensional stimuli (x_j is scalar), so w and b will be scalars in our case.

Figure 2: Stimuli used in the experiment. Category A and B were the low and high variance categories respectively

To examine the predictions of these models, we used stimuli based largely on those of Cohen et al. (2001). Stimuli consisted of vertical lines of varying lengths. Training stimuli belonged to one of two categories, A and B. Category A is the low variance category. Category A contained lines of length 110, 120, 130, 140 and 150 pixels. Category B was the high variance category. Category B contained lines of length 300, 375, 450, 525 and 600 pixels. All stimuli were equally likely within each category (categories had a flat distribution of stimuli). We also included novel transfer stimuli in the test

stimuli. There were eight transfer stimuli, equally spaced between the highest value of A and the lowest value of B (see Figure 2). A range of intermediate transfer stimuli were used in case the middle stimulus in psychological space differed from the numerical middle stimulus. The precise location of the middle stimulus is not important for our purposes, as the difference in results between generative and discriminative models is the question of interest.

Figure 3: Generative and discriminative model predictions for the probability of categorization stimuli into the high variance category. The model predictions are that a generative learner is more likely to categorize in between stimuli in the high variance category

We trained a generative naïve Bayes model and discriminative logistic regression model on all labeled examples from category A and B. Our naïve Bayes model had uniform category priors, i.e. both categories were assumed to be equally likely. Parameters for both models were fit using maximum likelihood estimation. To compare the outcomes of the two models, we analysed categorization predictions for our transfer stimuli using these generative and discriminative models. The generative model predicts intermediate transfer stimuli will be classified to the high-variance category more often than the discriminative model (see Figure 3). This is because it is more likely that intermediate stimuli are extreme values from the high-variance category than the low-variance category. These results illustrate that sensitivity to category variability may be a diagnostic indicator of whether learners are using a generative or a discriminative strategy. In the next section we present an experiment that uses this indicator to determine whether human learners switch between these strategies depending on the way in which a categorization task is presented.

Human generative and discriminative learning

Method

Participants We collected data from 24 participants (12 in each condition). Participants were undergraduates at the University of California, Berkeley and received course credit.

Stimuli Stimuli was the same training and transfer stimuli used in the model simulations described in the previous section. In the experiment, these stimuli were presented as white vertical lines in a black circle.

Procedure While previous related work had paradigms that may have encouraged discriminative or generative learning (Ashby et al., 2002; A. L. Anderson et al., 2002), the connection between these paradigms and the distinction was tentative. Thus, we will use our own experimental manipulation in order to encourage participants to adopt the distinct approaches as strongly as possible. Participants in both learning conditions were trained under the same randomized sequence of trials. In order to prompt generative or discriminative learning, the two conditions differed in the instructions, category-stimulus presentation order and question presented during testing blocks. Participants in both conditions were told they will see “signs” from an alien tribe. Participants in the *generative* condition were told that two aliens, one from each tribe (A and B) will appear and produce signs from their respective tribes. A picture of two aliens, who were identical except for the letter on their chest, was shown alongside the instructions. These instructions were intended to make it clear that the observed stimuli were generated from a probability distribution associated with the target category, consistent with the assumptions of a generative model. Participants in the *discriminative* condition were told that there are signs from two alien tribes and they would be shown a single alien translator who can report which tribe a sign was from. A single alien was shown alongside these instructions with a question mark on its chest. These instructions were intended to establish a situation in which participants learned a function from stimuli to category membership, consistent with a discriminative model.

For all participants, the experiment contained 10 blocks of 20 trials (each of 10 training stimuli were shown twice). Training blocks (odd blocks) were interleaved with testing blocks (even blocks). During training trials, participants were shown a black circular background on which the “sign” appears as a white vertical line, next to an alien with either A or B written on its chest. In the *generative* condition, the alien appeared 500 ms before the sign during training and the alien disappeared between trials to simulate different aliens appearing. In the *discriminative* condition, the sign appeared 500 ms before the alien and the alien did not disappear between trials to simulate one constant alien interpreter. In both conditions, once both stimulus and letter had appeared, both remained simultaneously on the screen for 1.5 s (see Figure 4). The total length of each training trial was 2 s and there were 700 ms between each trial.

During test trials, participants were shown a sign (white vertical line) on the black circular background. Participants in the *generative* condition were asked “Which alien was more likely to have produced this sign?”. Participants in the *discriminative* condition were asked “Which alien tribe does this sign belong to?”. Stimuli during each test block consisted of

every example stimulus in categories A and B, along with the eight transfer stimuli that were equally spaced between and highest value of category A and the lowest value of category B. (The highest value of category A and lowest value of category B were seen twice during each test block to make up the 20 trials.) No feedback was given during testing in either condition.

Sign 3/200

Figure 4: Screen shot of the experiment

Results

The human learning results correspond to the predictions of the models: Generative learners are more likely to categorize transfer stimuli that lie in between the two categories in the high-variance category relative to discriminative learners (see Figure 5). A two-way within-between ANOVA revealed statistically significant effects of test stimulus ($F(9, 198) = 76.88$, $MSE = 0.036$, $p < .001$) and condition ($F(1, 22) = 5.43$, $MSE = 0.216$, $p < .05$) and a marginally significant interaction ($F(9, 198) = 1.90$, $MSE = 0.036$, $p = .054$). Planned comparisons using two-sample t-tests showed statistically significant effects of condition for stimuli 216 ($t(22) = 2.57$, $p < .05$) and 233 ($t(22) = 2.46$, $p < .05$). These statistics are calculated under the most conservative assumption, under which the responses from each participant for each stimulus are averaged together and treated as a single response.

The “middle stimulus” that lies midway between the two categories in human perceptual space (i.e. equally likely to be categorized in both categories in the discriminative condition) is of length around 200 pixels. This is smaller than the numerical middle (225 pixels). This is approximately the same value as the perceptual “middle stimulus” that was found in previous work (Cohen et al., 2001). Accounting for this shift, the discriminative model predictions match fairly well with the discriminative human results. The generative model predictions are significantly shifted to the left compared with our generative human results, meaning the generative model predicted an even stronger tendency to categorize the in-between stimuli in the high variance category. This difference in degree between model predictions and human judgments could be explained in many possible ways. One possibility is that perceptual stimuli might follow Weberian compression for

the larger stimuli (Stewart & Chater, 2002). As a result of this compression, the perceptual variability of the longer length lines (which made up the high variability category) may have been significantly smaller than the absolute numerical variability values that were used in our models. If this were the case, a suitable transformation, such as to log space, would leave our qualitative results the same, while resulting in an appropriately less strong variability preference for the generative model. Another possibility is that people are not making the Gaussian assumption that was made by our model. This is plausible as our stimuli were very non-Gaussian. In this case, it is possible that the probability of belonging in the high variance category under a Gaussian assumption is greater than the probability estimates that generative participants might have made for our actual stimuli. Finally, participants may not be behaving fully generatively, or that the instructions resulted in a mixed population of generative and discriminative learners in this condition.

Figure 5: Probability of categorizing transfer stimuli in high variance category for participants in the generative and discriminative learning conditions. Total values are the average of all probabilities for individual stimulus lengths.

Discussion

The distinction between generative and discriminative approaches to categorization has played an important role in machine learning research, but has not previously been explored in cognitive psychology. Our results show that people can be cued to take these two different approaches to category learning through the way in which a categorization task is presented. These results have implications for understanding human category learning, and for establishing links between the communities studying human and machine learning.

The finding that people behave differently when encouraged to adopt these two different approaches to category learning may shed light on previous empirical results in cognitive psychology. For example, some previous experiments have shown effects that may be partly due to learning paradigms that encouraged participants to adopt generative or discriminative learning approaches (e.g., Ashby et al.,

2002). The generative/discriminative distinction also has potential implications for previously proposed models of categorization. For example, it seems appropriate that connectionist models (Kruschke, 1992; Love et al., 2004) will best characterize behavior when humans adopt a discriminative learning approach whereas rational models (J. R. Anderson, 1990; Griffiths et al., 2007) will best describe behavior when humans adopt a generative learning approach. Developing a deeper understanding of how this distinction plays out in human learning may provide additional insights into long-standing debates on category learning.

Showing that people can adopt both generative and discriminative learning strategies establishes a new connection between human and machine learning. While many of the goals of machine learning are inspired by human capabilities (e.g., the ability to recognize and categorize complex structures quickly and efficiently), the principal issues that are topical in machine and human learning seldom coincide. By showing that a key distinction long studied in machine learning research is also significant to human learning, this work begins to build an important bridge between machine learning and human learning communities. This will encourage collaboration between the two research communities where computational models of learning provide insight into human learning and human learning, in turn, inspires computational modelling. It also establishes a way to know how advances in specific aspects of machine learning, such as improved discriminative models, might be relevant to predicting aspects of human learning.

Identifying the relevance of the generative/discriminative distinction in human categorization also opens up many new avenues of research questions. For the neuroscience community, one can ask: What neural mechanisms are implementing these two very different learning strategies? Are the neural circuits involved similar or different? This research also provokes many questions about learning more generally: When does human learning tend to be generative or discriminative? How flexible are learners in alternating between generative and discriminative learning approaches? Can learning approaches be retrospectively altered? (i.e. if input is learned with a discriminative perspective and learners were later made to understand that the data was generated from a probability distribution, would they switch their categorization judgments?) Since much of human learning in everyday life consists of a mix of scenarios in which one or the other of these strategies is more appropriate, clarifying when people use generative and discriminative approaches will help us understand differences in learning among individuals and across situations. We anticipate that exploring these questions will result in improved models of human category learning, and a tighter coupling between research on human and machine learning.

Category Learning Through Active Sampling

Abstract

Laboratory studies of human category learning tend to emphasize passive learning by limiting participants' control over the information they experience on every trial. In contrast, we explore the impact that *active* data selection has on category learning. In our experiment, participants attempted to learn categories under either entirely passive conditions, or by actively selecting and querying the labels associated with particular stimuli. We found that participants generally acquired categories faster in the active learning condition. Furthermore, this advantage depended on learners actually making decisions about which stimuli to query themselves. However, the effectiveness of active sampling was modulated by the particular structure of the target category. A probabilistic rule-learning model is proposed that explains the results in terms of a strong prior bias towards uni-dimensional rules which impairs learning of alternative category boundaries. Active learners appear to be able to bootstrap their own learning, but this ability may be strongly constrained by the space of hypotheses that are under consideration. **Keywords:** categorization, active learning, information sampling, rule learning, decision-bound models

Despite the widely held view that people learn better by *doing* than simply *observing*, there have been surprisingly few detailed accounts of the impact that “active” information acquisition has on the learning process. In particular, theoretical models which explain how people learn new concepts from examples usually treat learners as passive accumulators of evidence about the structure of categories. For example, the standard procedure in most category learning experiments is to exhaustively and randomly sample the set of training stimuli. However, in everyday life, human learners can often control their own learning by selectively “sampling” particular observations they estimate to be useful or informative. The goal of the present paper is to understand the cognitive consequences of this type of learning.

There are at least two explanations for why active sampling might result in better learning than passive observation. First, rather than being limited by the flow of information from passive experience, active learners are free to select which information they want to learn about. For example, by making directed queries that take into account their current uncertainty, the learner may be able to optimize their experience (e.g., avoiding redundant data). Research in machine learning has shown that the principle of uncertainty sampling (selectively querying data that is expected to be informative) can have a dramatic impact on the amount of training needed to reach a performance criterion (Settles, 2009).

Independent of the advantage of better data, active learners may also benefit from greater engagement in the learning task. For example, the very act of planning interventions or deciding which samples to take may necessitate deeper evaluation of the problem structure and of how observed experi-

ence relates to different hypotheses (c.f., Bruner, 1961). In a study of active intervention during a causal learning task, Sobel and Kushnir (2006) showed that active learners were more likely to learn a hidden causal structure than participants that were “yoked” to their interventions (i.e., a group with the same data but who did not independently make sampling decisions). Similar concerns are often used to support educational practices that emphasize “inquiry” or “discovery”-based instruction (Kuhn et al., 2000).

The aims of the present study were two-fold. First, we were interested if participants could adaptively structure their own learning experiences when acquiring new concepts. Second, we were interested in how the effectiveness of active sampling might interact with the specific structure of categories. While a number of recent studies have explored how learners make information sampling decisions to support their own learning (Castro et al., 2008; Kruschke, 2008; Gureckis & Markant, 2009; Steyvers et al., 2003), there has not yet been a systematic evaluation of how this ability might vary across different category structures.

Overview of the present experiment

Our experiment adapts a well-studied paradigm for perceptual category learning using multidimensional, continuous-valued stimuli. In the task, participants learned to classify perceptual stimuli into different abstract groups. Two types of category structures were used: *rule-based* (RB), in which the decision rule is defined as a criterion along a single dimension, and (2) *information-integration* (II), in which the decision rule is a function of at least two dimensions (see Figure 1). Participants in the experiment were further divided into three training conditions. In the *passive-normal* condition, participants observed training stimuli that were generated from two bivariate normal distributions (i.e., a standard training procedure). In the *active* condition, participants were able to “design” stimuli for which they received feedback about the category label. In the *passive-yoked* condition, each participant was linked to an active learner, passively observing the samples they made and receiving the same feedback.

There are three key aspects of the design worth highlighting. First, in binary classification tasks, the optimal sampling strategy is simply to make queries close to the current estimate of the category boundary (or margin) — the region of greatest uncertainty. However, we anticipated that participants' ability to do so might vary between the RB and II learning tasks. Previous research has suggested that these two types of category structures may be learned in fundamentally different ways (Ashby, Alfonso-Reese, Turken, & Waldron,

Figure 1: **Top:** Category distributions used in the experiment. 'X's indicate training stimuli shown to participants in the passive-normal condition with color indicating the generating distribution (actual feedback received by participants was probabilistic). The uniform grid of points over the stimulus space indicate the set of unlabeled test stimuli. **Bottom:** An example stimulus (left) and the interface used in the active learning condition.

1998). In particular, RB categories are thought to be learned by reasoning about verbal or explicit hypotheses (which is the default learning mode), while the structure of II categories precludes a simple verbal description and are instead thought to be learned via implicit or procedural learning. To the degree that effective sampling relies on explicit reasoning about uncertainty, people may perform better in the RB condition where this uncertainty may be better articulated. Similarly, active learning may be more effective in the RB case because the category aligns with default biases people bring to the task (Ashby et al., 1999; Kruschke, 1993).

Second, the comparison of active learners with the passive-normal group allowed us to test if active learning could lead to a performance advantage above and beyond the typical training procedure in such tasks. We expected that if active learners were able to make useful queries, they would be faster at learning the correct category distinction than the passive-normal participants. Again, if active learners are less successful at making useful queries in the II task, any learning advantage may be attenuated. Moreover, since successful learning in the II task may be contingent on abandoning rule-based strategies in favor of a more procedural type of learning, active learning might even lead to a learning *impairment* by encouraging perseveration in the search for a sub-optimal rule.

Finally, the inclusion of the passive-yoked training group allowed us to separately evaluate the impact of selecting samples from the statistical information contained in those samples (since the distribution of training data is identical for both groups). While previous research (in causal learning settings)

suggests that active or intervention-driven learning may lead to advantages over comparable yoked conditions (Lagnado & Sloman, 2004; Sobel & Kushnir, 2006; Steyvers et al., 2003), it is unknown how these results generalize to other tasks.

An Experiment

Participants One hundred eighty undergraduates at New York University participated in the study. The experiment was run on standard Macintosh computers in a single 40 min session. Each participant was assigned to either the rule-based (RB) or information-integration (II) task condition, and to one of three training conditions: active (A), passive-normal (P), or passive-yoked (PY).

Stimuli Stimuli were defined by a two-dimensional continuous-valued feature space, where one dimension corresponded to the size (radius) of a circle and the second dimension corresponded to the angle of a central diameter (see example in Figure 1, bottom). One-hundred and twenty-eight training stimuli were created for the passive-normal training condition using bivariate normal distributions (see Figure 1, top) with mean and covariance parameters slightly modified from Ashby et al. (2002). Test stimuli were drawn from a uniform grid of samples over the feature space (depicted by the gray dots in Figure 1). Thirty-two stimuli were presented in each test block, amounting to a total of 256 test trials.

Procedure Participants were told that the stimuli in the experiment were "loop antennae" for old televisions, and that each antennae received one of two channels (CH1 or CH2). The channel received by any antennae depended in some way on the two dimensions described above, and participant's goal was to learn the difference between the two types of items. The feedback associated with each item during training was probabilistic and was proportional to the relative likelihood of either category for the ideal observer who knew the true category distributions. Participants were given instruction that the antennae were sometimes "noisy" and would pick up the wrong channel and that it would be beneficial to integrate over a number of trials when learning. The experiment consisted of 8 blocks, with each block divided into a set of 16 training trials followed by 32 (no feedback) test trials.

Training – Active Condition. On each training trial the participant "designed" a TV antenna and learned about its category membership. Each trial began with the presentation of a randomly generated stimulus in the center of the screen. The participant could then alter its size and orientation by moving the mouse from left to right while holding down either the 'Z' or 'X' key, respectively (see Figure 1, bottom). Only one dimension could be changed at a time, but participants could make any number of changes and use as much time as needed. When the stimulus was the desired size and orientation, participants pressed the mouse button to reveal the category label, which appeared above the stimulus and was visible for 1500ms. Querying the category label was not permitted until the participant had made a change to the initial stimulus.

Training Trials – Passive-Normal Condition. In the passive-normal condition, participants were unable to interact with the stimuli in any manner¹. Instead, in each trial they were presented with a stimulus generated from the category distributions described above. On each trial, a fixation cross was presented, followed by the stimulus (for 250ms), followed by the category label (above the stimulus for 1500ms). When the category label was displayed, the participant was required to press a key corresponding to that category in order to end the trial. This procedure is equivalent to the observational learning condition used in Ashby et al. (2002).

Training – Passive-Yoked Condition. The purpose of the yoked

¹In this design passive participants are not matched to active participants in terms of perceptual-motor task demands (e.g., precisely adjusting the stimulus). However, pilot data suggested that equating this made learning much more difficult for the passive group, potentially playing into any hypothesized active learning advantage.

Figure 2: Accuracy in RB (left) and II (right) tasks for the three training conditions. Error bars show the standard error of the mean.

condition was to mimic the passive training experience, but to use a sequence of observations that were selected by a participant in the active condition. Each yoked participant was assigned to a matching participant in the active learning condition that had already completed the study. Training samples from the active participant were used as the set of training items for the yoked participant, and were presented in the identical order as they had been generated by the active participant. All other aspects of the yoked condition were identical to the passive-normal condition.

Test – All Conditions. On each test trial, a single item was presented in the center of the display and participants were asked to classify the item according to the channel the item was most likely to receive. A response was required to complete the trial, and participants responded at their own pace. No feedback was provided on individual test trials. At the end of each block participants were told their cumulative accuracy during the block they just completed, as well as their accuracy during the preceding test block.

Results

Responses during test blocks were scored according to whether the participant identified the correct category of each test item (with respect to the true discriminant function). Overall accuracy across tasks and conditions is shown in Figure 2. A 2-way ANOVA with task type (RB/II) and training condition (A/P/PY) as between subjects factors found significant main effects of both task ($F(1, 174) = 155.97, p < 0.001$) and training condition ($F(2, 174) = 15.34, p < 0.001$), but no interaction ($F(2, 174) = 0.27$). In the RB task, overall accuracy was significantly higher in the active condition than in both the passive-normal ($t(58) = 2.69, p < 0.01$) and passive-yoked ($t(58) = 3.96, p < 0.001$) conditions, while there was no difference between the two passive conditions. Similarly, in the II condition, the active group was more accurate than both passive groups (P: $t(58) = 2.58, p < 0.05$; PY: $t(58) = 4.27, p < 0.001$), while there was no difference between passive-normal and passive-yoked ($t(58) = 1.57, p = 0.12$). Note that while active learners generally outperformed their passive counter-parts, active samplers in the II task only achieved 75% correct on average which may reflect a variety of sub-optimal rule-based strategies.

For participants in the II task, a 2-way ANOVA on average accuracy revealed a main effect of condition ($F(2, 609) = 8.74, p < 0.001$), a main effect of block ($F(7, 609) = 3.92, p < 0.001$), and a significant condition-by-block interaction ($F(14, 609) = 1.74, p < 0.05$). Examination of this

interaction suggested that it was driven by an early learning advantage for the active learners which was reduced later in the task. A similar analysis in the RB condition found only a main effect of training condition ($F(2, 87) = 6.65, p < 0.005$) and block ($F(7, 609) = 17.31, p < 0.001$).

Sampling behavior. Figure 3A shows the distribution of queries for active participants in the RB and II tasks for the final training block. In both tasks, participants begin by widely distributing their samples over the stimulus space, but over time make samples that are closer to the true category boundary. We measured the orthogonal distance of each sample to the true category boundary and computed the average distance within each block. Figure 3B shows that in the RB task average distance was significantly smaller than the null hypothesis of a random sampling strategy by the second training block (one-sample t-test, $t(29) = 4.33, p < 0.001$). This shift toward margin sampling was slower and less extreme in the II task, with average distance reliably smaller than expected from a random strategy starting around the sixth training block ($t(29) = 4.53, p < 0.001$).

Relating sampling behavior and learning. We found that overall sample distance from the boundary (averaged across blocks) was significantly correlated with active learners' overall test performance in both the RB ($r = -0.42, p < 0.05$) and II ($r = -0.8, p < 0.001$) tasks (see Figure 3D, blue line). One question is if being yoked to a high-performing active participant leads to a similar learning advantage for the passive-yoked participants. In contrast to active learners, average sample distance was not strongly correlated with performance in either task condition (RB: $r = 0.36, p = 0.051$, II: $r = -0.05, p = 0.4$, see Figure 3D, orange line). In fact, there was even a trend toward the reverse relationship in the RB task; that is, passive-yoked learners who received the most objectively useful training data were among the worst performers in the group for that task.

One objection to measuring sample “quality” by its distance from the true category boundary is that people may instead evaluate samples relative to their subjective belief about the boundary at any point in time. Using logistic regression we found the best-fit linear decision boundary for subjects' response data on each test block. We then computed the average “subjective” sample distance from that boundary in the following training block, and computed the average over blocks for all active and passive-yoked participants. We found that this distance was smaller in the active group than passive-yoked group in both tasks highlighting the divergence in inference between the two groups (RB: $t(29) = -4.07, p < 0.001$, II: $t(28) = -4.94, p < 0.001$). In addition, subjective distance measure was negatively correlated with overall accuracy in all conditions (RB(A): $r = -0.54, p < 0.005$, RB(PY): $r = -0.47, p < 0.05$, II(A): $r = -0.79, p < 0.001$, II(PY): $r = -0.41, p < 0.05$, see Figure 3E).

Discussion

There are three key behavioral findings from the experiment. First, active learners were more accurate than passive ob-

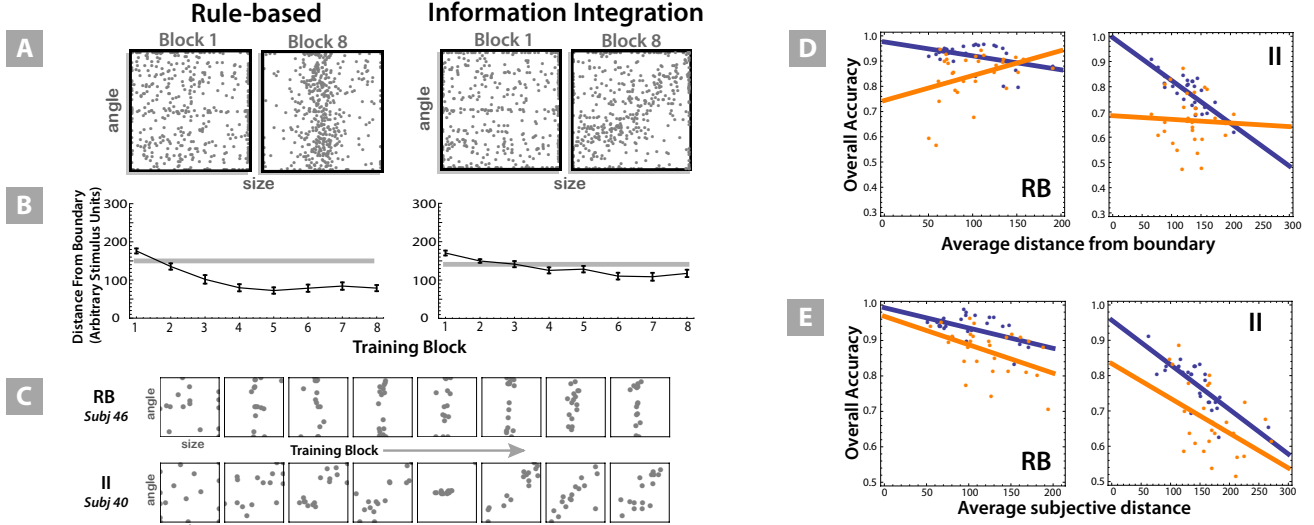

Figure 3: **A:** Composite of samples chosen by active participants in the first (left) and last (right) training block. **B:** Average distance of participants' samples from the true category boundary (black) as compared to average distance expected from random sampling (gray line). **C:** Examples of active participants in both tasks that successfully sample close to the true category boundary. **D:** Samples closer to the true boundary are associated with higher accuracy in active but not passive-yoked learners, while low "subjective" distance from a best-fit response boundary is predictive of higher accuracy in both groups (**E**).

servers in both tasks. One explanation is that active learners are able to query regions in the stimulus space where they are most likely to commit classification errors (i.e., the margin of the category boundary). Since participants in the passive-normal condition received samples from a "true" category distribution, they may be at a disadvantage because they were less likely to observe test items close to the boundary. Nevertheless, it is extremely interesting that naïve participants could intuitively identify what information would most useful to support their own learning in an abstract problem space.

However, the advantage for active learners cannot be explained by a difference in training data alone. Most striking is the finding that yoked participants showed no improvement over the passive-normal group despite learning from the exact same observations as the active group. Indeed, the passive-yoked participants that observed the most objectively useful training data were among the worst performers, particularly in the RB task. If active and passive-yoked learners are assumed to update their beliefs through a common process (as would be predicted by all existing models of human categorization) then this strong pattern of divergence is unexpected.

Finally, we found a main effect of category structure. Overall, participants in the II task performed more poorly at the task. Also, even though active learners in the II condition out-performed their passive counterparts, they were unable to boost performance near to RB levels. In addition, their sampling behavior suggests that (outside of a few surprising exceptions, see Figure 3C) most participants were unable to sample near the diagonal category margin, as would be predicted by an optimal information selection strategy (Oaksford & Chater, 1994). In the following section, we present a simple model-based analysis of each of these effects.

A Probabilistic Model of Decision-Bound Learning

While there have been a number of models proposed for how people classify items using rules in continuous dimension spaces, there have been fewer attempts to articulate an inference procedure for such models (c.f., Nosofsky & Palmeri, 1998). As a result, there were two key properties that guided the development of our modeling framework. First, we wanted a way to specify a strong inductive bias towards uni-dimensional rules along either stimulus dimension (similar to the default verbal system in Ashby et al., 1998). Most existing models can specify a prior bias towards a particular dimension (e.g., based on salience), but not a more general preference for arbitrary uni-dimensional rules (Heller et al., 2009). Second, analysis of the decision rules that participants use from one block to the next suggested that these were updated in a rather rapid fashion characteristic of serial hypothesis testing.

These concerns led us to a probabilistic model of classification which assumes that the goal of learning is to discover the latent parameters of a simple linear decision boundary. In our model, the probability that an observation, o^t , on trial t falls in category A is assumed to depend on a set of latent model parameters $\{\mathbf{w}, b, \sigma\}$:

$$P(o^t = A | \mathbf{w}, b, \sigma) = (1 + \exp(-\sigma(\sum_i w_i o_i^t) - b))^{-1} \quad (1)$$

where o_i^t is the stimulus value of dimension i . Since the classification is binary, $P(o^t = B | \mathbf{w}, b, \sigma) = 1 - P(o^t = A | \mathbf{w}, b, \sigma)$. The weight vector, \mathbf{w} , contains the decision weight assigned to each dimension. The bias term, b , allows fine adjustments to the position of the decision rule in the stimulus space. Finally, the slope of the sigmoid function is controlled by σ

Figure 4: **A:** Expected accuracy of models trained on subject data. Active models which consider multiple hypotheses show an improvement in accuracy. **B:** Samples generated by the models during learning reflect the distribution of hypothesized rules; RB models are initially random but converge on the correct rule by the final block, while II models remain widely dispersed at both points in training.

which reflects how deterministic the decision rule is. Thus, each parameter combination $\{\mathbf{w}, b, \sigma\}$ reflects a unique decision rule or hypothesis about the category. The likelihood of a particular set of labeled observations $\mathcal{D} = \{o^1, \dots, o^t\}$ is given by $P(\mathcal{D}|\mathbf{w}, b, \sigma) = \prod_t P(o^t|\mathbf{w}, b, \sigma)$ (see Courville et al., 2003 for a similar approach). This basic model is equivalent to an equal variance Gaussian mixture model with two components.

We assume that learners are strongly biased toward uni-dimensional rules along either dimension. Accordingly, we defined a prior over the decision weights $\mathbf{w} = \{w_1 = \cos(\theta), w_2 = \sin(\theta)\}$, where θ is the angle of the vector corresponding to the decision boundary. We created a piece-wise scheme for translating θ into relative distances (bound between 0 and 1) from the horizontal axis:

$$r = \begin{cases} (2\theta)/\pi & : 0 < \theta \leq \frac{\pi}{2} \\ (2(\pi - \theta))/\pi & : \frac{\pi}{2} < \theta \leq \pi \\ (2(\theta - \pi))/\pi & : \pi < \theta \leq \frac{3\pi}{2} \\ (2(2\pi - \theta))/\pi & : \frac{3\pi}{2} < \theta \leq 2\pi \end{cases} \quad (2)$$

with $r \sim \text{Beta}(\alpha, \beta)$. Using this form, α and β act as a type of abstract attention weight (i.e., $\alpha = \beta < 1$ result in a general preference for rules along a single dimension. $\alpha, \beta < 1$ but $|\alpha - \beta| > 0$ results in a slight preference for one stimulus dimension over the other. $\alpha = \beta = 1$ implies no preference for rules of a particular orientation). The prior over the bias term was a Gaussian centered in the middle of the stimulus space, $b \sim N(0, 75)$, and the prior on the noise parameter was $\sigma \sim \text{Beta}(2, 1)$ (implying a mild preference for deterministic rules). Given these priors and the likelihood given in Equation 1, it is possible to infer the posterior distribution over the model parameters using Bayes rule. However, since full Bayesian updating in such a model is intractable, we assume that participants maintain an impoverished representation of the posterior distribution using a small set of point estimates from the posterior (similar to Sanborn et al., 2006).

At a given point in time we assume the learner has in mind a decision rule which can be characterized by param-

eter set $p^t = \{\mathbf{w}^t, b^t, \sigma^t\}$. On each trial, a new set of parameters p^{t+1} is proposed (or generated) which represents a change to the current rule. The learner is assumed to compare this new hypothesis to the old one and “accept” it as the new hypothesis if it provides a better account of the data (weighted by the prior belief in that parameter combination). If the new hypothesis results in a worse account of past data, it is accepted in proportion to the relative posterior likelihood of the new hypothesis compared to the old, otherwise the current parameter estimate remains unchanged. This procedure is similar to the Metropolis-Hastings algorithm (a form of Markov-Chain Monte Carlo) with an additional parameter k dictating the likelihood of accepting a proposal with a lower posterior estimate, giving the acceptance function $P(\mathcal{D}|p^{t+1})/(P(\mathcal{D}|p^t) + k)$. Proposals were generated from independent Normal distributions centered on the current parameter estimates: $\mathbf{w}^{t+1} \sim N(\mathbf{w}^t, \pi/2)$; $b^{t+1} \sim N(b^t, 20)$; $\sigma^{t+1} \sim N(\sigma^t, .05)$. The computational demands of this procedure are low: the learner is assumed to maintain a single hypothesis at any point in time. On each trial they must simply generate a new hypothesis and judge its relative quality. While we began with the simplification of assuming that the learner considers a single hypothesis on every trial, it is also possible that participants consider multiple hypotheses which are simultaneously updated in the same way.

Finally, we assume that the learner only stores n recent observations in memory, and evaluates the likelihood of a hypothesis over this limited set. This limitation results in ongoing shifts in the estimated decision rule, consistent with the variability in participants’ response behavior throughout the task. Given the strong prior favoring rules along a single dimension, the estimate of the decision weights \mathbf{w} will tend to bounce between these different modes of the hypothesis space, and convergence on the correct mode will be sensitive to the usefulness of recent training samples. This incremental, top-down hypothesis search may explain divergences between training conditions seen in our empirical results.

Evaluation of the Model The first goal of the simulation was to reproduce the difference in performance between the RB and II tasks. Individual models were trained with the data from passive-normal and passive-yoked participants in our experiment (the active group is addressed below). For this initial simulation the following parameter settings were used: $\alpha = \beta = 0.001, k = 1, n = 4$. Expected accuracy on each test item was calculated using the predicted likelihood that the item belonged to the correct category. Expected accuracy was averaged over test blocks and across 100 runs. The comparison of passive models (Figure 4A) shows a strong difference in accuracy between RB and II tasks as seen in our behavioral results. Due to the strong prior bias toward single-dimensional rules, in the RB task the model quickly converges on a rule similar to the true boundary, despite only retaining a small number of recent observations. In the II task, however, the model alternates between single-dimensional rules on different dimensions.

One way that the model can account for differences between active and passive-yoked groups is by assuming that active participants represent more than one hypothesis at any given time (consistent with the generalized “engagement” hypothesis described in the Introduction). In the model, this might correspond to an increase in the number of point estimates of the posterior maintained in working memory. To evaluate this idea, active participants were modeled using a set of 5 posterior samples per run (in contrast to one sample used for the passive groups), with the additional assumption that learners classify items according to the most likely hypothesis from the set they are considering. As seen in Figure 4A, the greater number of samples leads to higher accuracy over the passive groups in the RB task, but not in the II task. While a change in the number of particles maintained is consistent with the idea that active learners are more cognitively engaged in the task (and thus search the hypothesis space more effectively), further work is needed to directly test this representational hypothesis. At the very least, the potential divergence between the sequence of data observed in the task and the sequence of hypotheses considered by the learner provide a potential mechanism for explaining the active/passive-yoked distinction.

Finally, we were interested if samples generated by the active models show the same pattern as produced by our participants. Simulated samples were generated using *margin sampling*, in which an observation is most likely to occur when its predicted likelihood of belonging to category A and B are equal (i.e., the likelihood of making an observation o' was proportional to $1 - |P(o' = A|\mathbf{w}, b, \sigma) - P(o' = B|\mathbf{w}, b, \sigma)|$). As seen in Figure 4B, the predicted sampling distribution qualitatively matches the behavioral results. In the first block of both tasks, the model produces samples that are widely dispersed throughout the feature space. By the final block, RB models have converged on the true boundary, querying the margin of the boundary where uncertainty is greatest. In the II task, the diffuse distribution of samples reflects the variability in the hypotheses under consideration.

Conclusions

In our experiment, active learners were able to make informative queries to support their own learning, but this ability was more successful for RB categories than for II categories. Our simulation results explain this difference in terms of a bias toward considering rules along a single dimension. In addition, we evaluated one explanation for the divergence between active and passive-yoked participants, namely that active participants consider a greater number of hypotheses about the latent category structure. Our general finding that the effectiveness of active sampling may depend on the structure of the category adds to recent work examining active learning in binary classification tasks (Castro et al., 2008). While a number of theorists have attempted to explain active data selection in terms of optimal information gain (Oaksford & Chater, 1994; Nelson, 2005), our results suggest that the ability to design

useful queries is strongly limited by the hypothesis search process that guides learning. To the degree that participants prefer particular types of rules, their sampling behavior will tend to be sub-optimal when the target rule mismatches these expectations, a similar point made in analyses of active machine learning (Mackay, 1992; Settles, 2009). In summary, active learning may promote learning, but it works best when you have a strong and correct idea of what you are trying to learn.

Abstract

We present an overview of a model for the co-evolution of knowledge and event memory. The model, termed SARKAE (Storing and Retrieving Knowledge and Events), describes the development of knowledge and event memories as an interactive process: knowledge is formed through the accrual of individual events, and the storage of an individual episode is dependent on prior knowledge. We reference two experiments which provide data to inform our theory: these studies involve the development of new knowledge, and then testing in transfer tasks involving episodic memory, retrieval from knowledge, and perception. The results of the transfer tasks indicate a substantial role of pure frequency or raw exposure, in opposition to the contextual diversity accounts of frequency suggested by Adelman et al (2006). An overview of the SARKAE model is presented. The model is able to account for the effects of frequency in the absence of contextual diversity.

Keywords: episodic memory; semantic memory; learning; perception; Bayesian models.

Introduction

The processes involved in the accumulation of knowledge and the formation of event memories are interdependent. Almost every study since the 1890s has shown that the way episodic (or event) memories are encoded depends on the knowledge (or semantic memory) of the individual who is encoding them. Conversely, an individual's knowledge must be formed through the episodes they encounter; this idea was the basis of the REM model's account of priming (Shiffrin & Steyvers, 1997). These interdependent processes create a feedback loop in which knowledge and episodic memory formation develop together over lifelong learning.

Studies of memory and perception in the recent past have provided strong support for the idea that memory processes are robustly influenced by prior experience with the to-be-remembered content. Priming studies, for example, have shown that prior study of a word affects how well that word is identified in a forced choice perceptual identification task (Ratcliff & McKoon, 1997). The REMI model of Schooler, Shiffrin, and Raaijmakers (2001) accounts for these effects through a process in which the lexical representation (or knowledge) of the word is changed through prior study (the "prime"); when a word is studied an event memory is formed, but in addition, novel features of the event, such as

the context of the experimental setting, are added to the lexical representation of the word. When the studied word is then presented for perceptual identification, the context tends to be similar to that at study, increasing the match of the probe cues to the lexical trace, predicting a variety of measurable effects that match those observed. In other words, the knowledge that a subject has about a stimulus, and the inclusion in that knowledge of factors like the experimental context, affect the way that a stimulus is perceived.

There are many models of the storage and retrieval of event memories, and sometimes the addition to existing knowledge of information from recent events (e.g. - Raaijmakers & Shiffrin, 1981, Shiffrin & Steyvers, 1997, Howard & Kahana, 2002, Anderson, 1983). The temporal context model of Howard & Kahana for example provides an explanation for recency and contiguity effects through the storage of both item information and recent contextual information. Other models, such as the ACT-R model of Anderson (1983) also provide eloquent representations of memory storage and retrieval. A few models attempt to explain aspects of the way events produce knowledge, especially for aspects of the role played by words in language (e.g. McClelland & Rumelhart, 1981). However, most of the prior research has been aimed to explain memory and learning when knowledge has already formed (to various degrees). Previous work by Reder et al. has examined the development of knowledge on a set of pseudowords, and used the dual-process SAC model to explain their findings. Although highly relevant and useful in the development of our research, the training study and modeling by Reder et al. did not explicitly model the growth of new knowledge.

Our aim is the development of a model that begins to explain the interacting growth of event memory and knowledge, as they influence both memory storage and retrieval. This co-evolution of the two systems was the focus of the REM-II model, created by Mueller and Shiffrin (2006). In this model, knowledge (or semantic memory) is represented as an accumulation of the co-occurrence of features: Features that are present in an episodic event are coded as occurring together in a matrix representation of semantic memory. REM-II is a quite powerful model, but a simplified version is sufficient to explain the basic concepts

by which event memory and knowledge co-develop, and is sufficient to model the empirical results presented in this paper. However, even a simplified model when applied to five different tasks spanning the range of learning, memory, and perception can grow to appear quite complex. The simplified model uses a representation in which each (separate) trace, whether an event trace or a knowledge trace, is a vector of feature values. Rather than term the model some other variant of REM, we use the terminology “Storing and Retrieving Knowledge and Events”, abbreviated SARKAE.

Role of Experience and Frequency in Cognition

If one hopes to develop a theory in which events accumulate to form knowledge, then it is critical to understand the role of event frequency. Such effects are omnipresent in memory and perception tasks, but the processes responsible for such effects remain in debate.

Researchers have explored the effects of experience in various ways, typically by analyzing existing knowledge, identifying stimuli with different histories of experience, and using the stimuli with different frequencies in memory and perception tasks. The great majority of such investigations use words as stimuli: Words are categorized based on their frequency. Frequency is defined as normative occurrence in the environment, and these frequencies are estimated from various databases of typically textual materials. Words differing in frequency are then tested and exhibit a variety of consistent differences. These are termed the ‘Word Frequency Effect’, especially when found in recognition memory (Glanzer & Adams, 1985). In episodic recognition memory tasks, words that occur rarely in the environment are recognized *better* than words that occur frequently in the environment. Word frequency has also been shown to have effects on recall performance (high frequency words are recalled better), and perceptual tasks such as lexical decision and perceptual identification (forced choice, etc.).

However, given that word frequency is correlated with so many other variables (e.g. meaning, regularity of spelling, length of the word, and virtually every other characteristic one can measure for words), it is hard to know whether experience per se is responsible for the observed effects. In fact, a current debate concerns whether frequency per se or context effects are the primary cause of the observed findings. Adelman, Brown, and Quesada (2006) for example suggest that the diversity of contexts in which a word has been seen is a more accurate predictor of word frequency effects than the actual frequency of the word. By analyzing a large corpora of texts separated both by word frequency and contextual diversity (the number of documents in which a word was present), they concluded that it was the contextual diversity of an item, not the word frequency, that affected response times in word naming and lexical decision for three separate data sets. The difficulty of assessing the cause of frequency effects for words is one

reason we chose to vary frequency of training of novel characters in the present studies. By training novel stimuli we can control with far greater precision the factors correlated with frequency and thereby properly constrain the theory. The studies referenced in this article create experience differences over a fairly lengthy period of training in two quite different tasks, one based on visual search, and the other based on perceptual matching.

In order to control for the confounds produced by word stimuli, our studies use stimuli that are far less related to existing language and numeric knowledge, and far less likely to bring with them existing frequency correlations: Chinese characters. (We select participants for whom such stimuli are unfamiliar). The first study used a visual search task in training. This task was based loosely on that of Shiffrin and Lightfoot (1997). Different Chinese characters appeared with widely differing frequencies during training. Following training, the subjects completed various recognition memory and perception tasks different from the training task, using both the trained characters and new characters as stimuli.

In the interest of space, this first experiment using the visual search training will not be discussed in detail. It is sufficient to mention that the crucial finding of this study was that substantial frequency effects occurred for all transfer tasks. What is more relevant to the discussion of the no-context experiment described below (as well as the SARKAE model) is that the visual search task used for training varied character frequency, but the randomization of trials and foils ensured that higher frequency characters most often occurred in the spatial and temporal vicinity of other higher frequency characters. Thus frequency per se was correlated with what could be termed character context, temporal context, or character diversity. As mentioned previously, Adelman et al. (2006) proposed that only the diversity of contexts in which an item occurs is responsible for most frequency effects. The confounding of frequency and character context made inference about causal mechanisms uncertain, and hence led to the design of the No-Context Experiment described below.

No-Context Experiment

The no-context experiment used a training paradigm not involving visual search. Participants were trained using a same vs. different judgment task: A character was presented briefly twice in succession, and half the time the two presentations varied slightly in size, rotation, or contrast. The participant judged whether the two presentations were exactly the same or varied slightly in one of these three dimensions. Thus a character was its ‘own’ context. Further, to remove the possibility that the test character on the previous trial might provide context for the present trial, one fixed ‘control’ character, different from any of the experimental characters, was tested using the same judgment task between every two experimental character judgments. This extremely high frequency character was not subsequently used in the post-training transfer tasks. If

context is carried forward from the previous trial during training, the context that is carried forward for the experimental characters of different frequency will be equated, because the previous character is always the same one. The no-context experiment used the same frequency distribution (given below) as the visual search training experiment. By removing characters that provide context on any given trial, and by holding constant the character context on the preceding trial, it is plausible to assume that the confound between context and frequency is mostly if not totally eliminated.

Training Methods

Participants. Seven participants, recruited with an email advertisement, participated in the experiment for monetary compensation. All participants reported no prior experience with Chinese characters.

Design and Stimuli. The occurrence of the characters in the same/different task was manipulated to produce four frequency conditions which varied in a ratio of 1::3::9::27. For each subject, a set of 32 characters was selected randomly from a pool of approximately 200 characters. From these 32 characters, 8 were assigned to each frequency condition. In order to keep the complexity of the characters reasonable, all the characters in the pool were composed of 7 strokes or less. In order to fully eliminate context from the training, one “super-high frequency” item was also randomly chosen, making the entire training set 33 characters. This character appeared as a “buffer” item every other trial, and was not used as a stimulus in the post-training tasks.

Procedure. Each trial consisted of two brief (500 ms) presentations of a single Chinese character, which subtended a visual angle of approximately 4.3×4.3 degrees. The two presentations of the character were either identical or varied slightly in size, rotation, or contrast of the character. Only one of these three dimensions varied at a time. There were three levels of each variable (size: small, medium, large; rotation: left, straight, right; contrast: dark, normal, light), and the change between each of these levels varied based on a staircase algorithm. The staircase rules were as follows: when the subject answered two rotation-difference trials correctly, the rotation factor (i.e. – the difference in angle between the three levels) decreased by a given amount. If they got a rotation-different trial wrong, the rotation factor increased by a given amount. This staircase was done separately for each of the three variables. In this way, subjects were kept at approximately 75% accuracy. Subjects completed 12 training sessions, approximately 3 per week. There were a total of 1060 trials for sessions 1-11, and 1140 trials for session 12.

Training Results

Since the training paradigm used a staircase algorithm to keep subjects at approximately 75% accuracy, the results of

training were analyzed by examining the change factors for size, rotation, and contrast. If the subjects are showing improvement at the same/different discrimination, then the change in variable (size, rotation, or contrast) needed to keep them at 75% should decrease over session. Figure 1 shows the mean rotation, contrast, and size changes required (averaged over all subjects) as a function of training session. The results indicate that subjects were becoming more efficient at the task as training progressed, as indicated by the decrease in variable change over session.

Figure 1: Mean change in rotation (panel A) size (panel B) and contrast (panel C) needed to obtain 75% accuracy as a function of training session. Rotation factor is measured in degrees, size factor in percentage size difference, and contrast factor in percentage contrast difference.

Post-training Tasks

Following the training, the subjects completed three post-training tasks: pseudo-lexical decision, episodic recognition, and forced-choice perceptual identification. Testing was carried out again six weeks after training. A programming error, discovered after the immediate transfer tasks, caused the forced choice data to be very noisy and essentially uninformative. These results are therefore neither reported nor analyzed. Also, because forced choice results were not available for immediate test, forced choice testing was omitted for the delayed testing at six weeks.

Pseudo-lexical Decision

Design and Procedure. Subjects viewed one list, which contained all 32 trained characters (excluding the buffer item), as well as 32 new characters. Each of these characters occurred 3 times throughout the list, making the total length of the list 192 characters. Subjects were presented with a single character on the screen, and were asked to decide (by keypress) as quickly as possible whether they had ever seen that character during any of the previous training sessions.

Results. Response time and accuracy were measured for each frequency condition, as well as new items. The results for the trained items when tested shortly after training was completed (2-3 days) are shown in Figure 2. A contrast analysis showed that there was a significant negative relationship between frequency and response time ($t(6)=-2.97, p=.03$), and a significant positive relationship between frequency and accuracy ($t(6)=2.90, p=.03$).

Response time and accuracy were measured again (for 6 of the 7 subjects) approximately 6 weeks after the previous test session. The results followed the same qualitative pattern as they did 6 weeks prior: there was a significant negative relationship between response time and frequency ($t(5)=-2.45$, $p=.058$), and a significant positive relationship between accuracy and frequency ($t(5)=2.44$, $p=.059$, see Figure 2). A contrast analysis showed that there was no significant difference in the magnitude of the effects that occurred in the shortly after training and those that occurred after the 6 week delay for either accuracy ($t(5)=1.14$, $p=.31$) or response time ($t(5)=.51$, $p=.63$).

Figure 2: Mean response time (panel A) and accuracy (panel B) for all subjects in the lexical decision task as a function of frequency. The solid line shows the results when the test was administered after a very short delay (2-3 days), the dashed line corresponds to the data following a 6 week delay.

Discussion. The results of the lexical decision task showed that the absence of character-context during training did not eliminate the effects of frequency on speed and accuracy of decision. Therefore, it follows that there must be some mechanism other than the context present during training that is causing improved recognition that high frequency characters are present in knowledge. In addition, this frequency effect showed little signs of reduction over six weeks.

Episodic Recognition

Design and Procedure. The task consisted of eight pairs of study and test lists. Each study list contained eight trained characters (two from each frequency category) and eight untrained characters. Each test list contained all the items from the study list as well as 16 unstudied items, which included eight trained characters (two from each frequency category) and eight untrained characters. The first four items on the test list were always untrained characters, providing a buffer for the items of interest (trained characters). Subjects viewed each item on the study list for 1000 milliseconds, presented one at a time on the screen. Following the study list, the subjects were presented with the items on the test list one by one, and for each item had to

respond whether the character had been present on the list they had just studied. Subjects were instructed to 'reset' their memory in between each list, and answer 'old' to an item on the test list only if it had been present on the most recent study list.

Results. The data from the episodic recognition task were analyzed by examining the hit rates (correctly identifying a studied item as old) and false alarm rates (incorrectly identifying an unstudied item as old). The hit and false alarm rates (averaged over all subjects) are plotted as a function of frequency in figure 3. When tested shortly after the completion of training, false alarms significantly increased as frequency increased (panel A, $t(6)=3.19$, $p=.02$). There was also a marginally significant decrease in d' due to frequency ($t(6)=-1.86$, $p=.11$). The hit rate analysis however showed no significant effect of frequency.

Six of the seven subjects were tested again following a six-week delay. The results of the delayed test are shown in panel B of figure 3. Statistical analyses showed no significant effect of frequency on hit rates, false alarm rates, or d' . Furthermore, a contrast analysis showed that there was a significant difference in the magnitude of the false alarm rate effect found immediately after training compared to the effect found after a 6 week delay: the increase in false alarms due to increased frequency was (marginally) significantly larger immediately after training ($t(5)=2.11$, $p=.09$).

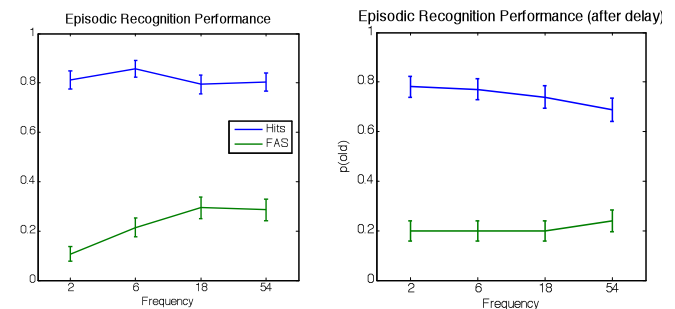

Figure 3: Episodic Recognition Results soon after training (Panel A) and after a 6-week delay (Panel B). Hit rates are shown in blue, false alarm rates in green.

Discussion. When tested shortly after the completion of training, the results in the episodic recognition task are similar to results found in our previous visual search training experiment and in normative word frequency studies: as frequency increases, d' decreases. In the current study, this is due more to an increase in false alarm rates than a decrease in hit rates with higher frequency items. Unlike some previous studies, the no-context training experiment did not show a significant effect of frequency on hit rates.

Unlike the lexical decision task which showed a large persistence of frequency effects after a six week delay, the d' effect and false alarm rate effect found in episodic recognition were largely reduced and possibly absent when

subjects were re-tested after delay. Both the existence of frequency effects in recognition, and the reduction with delay call into serious question the modeling processes used to account for recognition in the one factor model applied to our visual search training experiment. That model assumed poorer performance for high frequency test items was due to increased confusions with traces of list items, because those traces were more similar to the high frequency test probes. The present design should have eliminated such similarity differences. In addition, within list confusions should not have decreased if a recognition task was carried out at a six week remove from training, because the relevant episodic traces should have been those stored in the just seen study list. Thus the elaborated SARKAE model provides an explicit role for frequency per se (especially to explain pseudo-lexical decision findings) and an elaborated model for recognition. Due to spatial limitations, in this paper we present only an overview of the theory that is the foundation of the SARKAE model, with examples of how the theory is implemented to explain our experimental results.

SARKAE – Theoretical Overview

A fundamental storage assumption in SARKAE allows both event memories and knowledge to develop in concert: Each storage episode produces both: 1) an event trace; 2) additional information added to traces in memory that are brought to mind due to similarity to the present event. Such a prior trace can include a previous event trace (the basis for the start of knowledge accumulation), or a developing or mature knowledge trace. There is no fundamental distinction between event traces and knowledge traces in this view. Instead there is a continuum: traces are stored initially for each single event; some of these are retrieved (when a similar new event occurs), gain additional information, and are re-stored. As this process continues over successive occurrences of similar events, a rich knowledge trace results.

In SARKAE, accumulation of knowledge about an item or concept (e.g. for words, its lexical entry) includes features of the surrounding context that is present at the time of learning. Specifically, knowledge traces develop during learning by storing features that come both from the physical properties of the item or concept being learned, and also from the context surrounding the item during learning, both types of storage being modified and governed by attentional focus. These context features arise from other (attended) events nearby in time and the environment, and from the various components of internal and external context that numerous investigators have discussed for many years. For example, during training, when a character is presented, physical features of that item as well as surrounding context features (taken from other characters presented in close temporal proximity) are stored into the knowledge representation. In a more general sense, the knowledge trace that represents the concept of “table” will include information about the physical properties of various types of tables, information about the contents of events that

involved tables (e.g. forks, dinners, conversations, replacing light bulbs), information about thoughts and feelings experienced at tables, and information about other events that occurred in the nearby temporal surround of table events (e.g. dropping of a milk bottle when removing it from the refrigerator). These features include context specific events themselves, such as the breakfast event in a given morning. Knowledge development is therefore built upon the events that accumulate to form the knowledge. Of course a mature knowledge trace includes features of numerous events, so a specific episode tends to be swamped in the accumulation of many episodes and tends not to be retrieved (from the knowledge trace—it can be retrieved as an episodic trace). Thus a knowledge trace in most instances seems to be context free. What do come to be retrievable from a mature knowledge trace are features that are consistent across many episodes, such as the spelling, pronunciation and meaning of a word.

Conversely, the formation of episodic memory traces is determined by prior knowledge and experience. Although certain very primitive features of experience might not depend upon learning and experience (e.g. a loud sound), most features of events are encodings based on prior learning (e.g. encoding and storing a table feature as ‘dinner’). The model therefore creates episodic traces by choosing features of events from knowledge. Such features come from several sources: some are directly related to the central defining elements of the event such as the physical features of which it is composed (e.g. table physical features) and the central organizing concept (e.g. dinner); some come from other knowledge traces that are brought to mind during encoding of the event (e.g. the illness one encountered when eating breakfast last Sunday, or one’s commitment to a new diet); some come from features of other nearby events still in short-term memory at the time of the present event. To some degree, the features chosen are modified by attentional focus. In terms of the experiment discussed in this paper, an episodic memory consists of a combination of physical features of the studied item, features drawn from the knowledge trace of that item, and features drawn from other items in close temporal proximity. One key concept is the perhaps non-controversial idea that the features comprising an event representation in short-term memory, and thereafter the stored event trace, are recruited from knowledge (e.g. one’s prior experience and knowledge regarding tables will influence the formation of an event trace concerning a physically present table).

We have been highlighting mechanisms that produce storage of event memory and knowledge. Very similar mechanisms also occur in retrieval. We adopt the generally accepted view that retrieval is cue dependent, and based on similarity of the retrieval probe to the traces in memory. The generation of such a probe cue can be clearly defined, as when one is asked: “What is the capital of South Dakota”? In other cases retrieval seems more continuous and automatic, as when information moving through short-term

memory acts as retrieval cues to bring other associations to mind. However, because modeling continuous retrieval is quite complex, we will treat all retrieval in terms of discrete retrieval operations occurring one at a time, each based on some defined set of retrieval cues. The features that comprise such a retrieval cue are generated with the same processes that generate features for storage: They come from the query (if there is one), or from feature sets presently in short-term memory and attentional focus, and include features from the contextual surround at the time (internal and external context, and nearby events). More specifically, in the modeling of our experimental results, the retrieval cue consists of a combination of physical features of the test item, features drawn from the knowledge trace of the test item, and features taken from other items in close temporal proximity to the test item.

An absolutely essential component of storage and retrieval is noise in the processes. Following the approach in the REM model, we assume that both storage and retrieval are probabilistic, incomplete and error prone. When errors are made, it is natural to assume they are based on information in the knowledge base, and not completely random. Thus errors in retrieving and storing features are assumed to be relevant and consistent, in the sense that they are feature values for the feature in question (a 'blue' color feature might be retrieved or stored as 'red', but not as 'wet') and occur in proportion to the base rates of such values in knowledge.

When a cue is used to probe memory, it is compared in parallel to the event traces (and/or knowledge traces) in parallel. It would be unworkable and likely unreasonable to explicitly consider the match to each of the essentially uncountable traces in memory. Thus we assume that there is a probabilistic cutoff, only traces sufficiently similar to the probe becoming activated and participating in subsequent retrieval operations.

Similarity plays a role in both storage and retrieval, but we define similarity operations in such a way that similarity is measured as a relative construct: For both storage and retrieval a process based on similarity is defined as similarity of a given match compared to the similarity of matches that could have but did not occur. Thus in recent years we have characterized the match of a probe to an activated trace as a likelihood ratio: The numerator expresses the probability that the probe and cue were generated from the same event, and the denominator the probability that the two were generated by different events. These likelihood ratios occupy the theoretical niche played by 'strengths of activation' in various other theories (such as SAM; Raaijmakers and Shiffrin, 1981).

This brief summary of some of the central tenets of SARKAE provides hints concerning the theory, but is only the barest scaffolding upon which the model is constructed. When the full detailed processes are implemented, the model produces predictions that fit the results of the various post-training tasks from both the initial visual search training experiment as well as the no-context experiment

described in this paper. We cannot fully describe the modeling processes and results here due to space; however the aim of this discussion is not to focus on quantifiable model fits, but instead to convey the basics of the theory that inspired both the experiments described in this paper and the subsequent model development. The SARKAE model provides plausible mechanisms by which knowledge grows from events, and knowledge informs the coding and retrieval of both events and knowledge itself. Based on this theory, or others of a similar character, we hope that future research developments will not focus so strongly on differences among systems as upon the ways they grow together, in highly dependent fashion.

Looking at Nothing Indicates Memory Search in Multiattribute Decision Making

Abstract

The common methods for studying heuristics in memory-based multiattribute decisions provide outcome and response time data but leave the foregoing cognitive processes in the dark. We demonstrate a novel process-tracing method that uses the looking-at-nothing phenomenon to study memory search and cue processing via eye tracking. Participants learned cue information of decision alternatives in spatial frames and later were presented with emptied displays of two alternatives in binary choice trials. With freely chosen and with instructed decision strategies, fixation patterns on former cue locations were in line with memory search and cue processing as postulated for lexicographic and compensatory strategies.

Keywords: Multiattribute decision making, Probabilistic inference, Eye tracking, Take-the-best heuristic, Spatial index

Introduction

Integrating multiple cues in decision making in a completely rational manner that factors in all available information is widely assumed to be cognitively too demanding. Therefore, simple but efficient heuristics are suggested that are applicable in specific task domains (e.g., Gigerenzer & Todd, 1999). The domain we will deal with here consists of simple probabilistic inference tasks with two alternatives and binary cues (e.g. “Which of the cities A and B has more inhabitants?”). Perhaps the best known heuristic for this kind of tasks is Take-the-Best (Gigerenzer & Goldstein, 1996), which belongs to the class of lexicographic strategies (LEX). In a first step, a person using this strategy selects the (subjectively) most valid cue and looks up the cue values of both alternatives. If one alternative has a positive cue value (indicating a higher value on the target dimension) and the other has not, information search is stopped, and the alternative with the positive value is chosen. If the first cue does not discriminate between the alternatives, the second most valid cue is accessed, and so forth.

LEX is a non-compensatory strategy, because cues lower in validity are disregarded. Thus, cues with a low validity cannot compensate for a difference on a more valid cue dimension. An example of a simple but compensatory heuristic is the equal weight strategy (EQW), which ignores cue validities. With this strategy, the positive cue values are counted for each alternative and the alternative with the higher number of positive cue values is chosen.

The third strategy we will consider here - the weighted additive rule (WADD) - is also compensatory but uses information about cue values and validities fully. Cue values are weighed by cue validities and summed up. It has often been claimed that this strategy is computationally too demanding to be performed in a sequence of serial and deliberate cognitive processes. However, WADD can be conceived as a paramorphic model because the choices expected from WADD could be brought about by intuitive-automatic processes as well. Automatic processes that approximate WADD predictions have been simulated as parallel constraint satisfaction (see Glöckner & Betsch, 2008).

Methodologically, it poses a challenge to infer which strategy an individual used in a probabilistic inference task. One reason is that in tasks with a small number of alternatives, several strategies predict the same choices. More importantly, simple strategies are complete sub-models of more complex ones. With appropriately chosen weights, WADD could produce decisions that are indistinguishable of the predictions of LEX or EQW (Martignon & Hoffrage, 2002). Hence, an individual's choices may appear to be generated by LEX even if she is using cognitive processes that are not assumed in this heuristic.

Therefore, process-tracing methods are often used in addition to outcome-based measures. The most prominent process-tracing method is the computer-based information board called Mouselab (Payne, Bettman, & Johnson, 1993). Mouselab records which pieces of information a participant seeks, in which sequence the information is accessed, and how much information is gathered. A central idea is that different decision strategies should be accompanied by different information search patterns. For non-compensatory strategies like LEX a cue-wise information search is expected. A LEX-user that has looked up a cue value of one alternative should subsequently check the value of the other alternative on the same cue dimension and then either decide or, if the values do not differ, switch to the next cue dimension. In contrast, compensatory strategies should be associated with an alternative-wise information search. Users of these strategies should search for all cue values of one alternative before they turn to the other alternative.

Process-tracing methods like Mouselab necessitate that all relevant information is provided by the experimenter and accessible for the participant on the computer screen (or on

written information cards). However, in many real-life situations decisions have to be made from information that is stored in long-term memory. Additionally, proponents of simple heuristics argue that particularly memory-based decisions induce selective and heuristic processing to limit the costs of memory retrieval (Gigerenzer & Todd, 1999). Hence, “inferences from memory” and not “inferences from givens” should be studied to test these postulates. Thus, there is a need for process-tracing methods that can be applied in studies investigating memory-based decisions.

We propose a method that sticks closely to the basic idea of Mouselab. It draws on results by Richardson and Spivey (2000) demonstrating a close link between eye movements and memory retrieval. In a series of experiments, these authors found that participants recalling visually presented information saccade more often to the (empty) region of space where the information was originally presented than to any other region (for an overview of studies on this “looking at nothing” phenomenon, see Ferreira, Apel, & Henderson, 2008). Thus, if specific cue dimensions are associated with specific locations it might be possible to reveal which cue information a person searches in memory by tracking her eye movements.

In the experiment reported below, our participants worked through a learning phase, in which each cue dimension was presented in a different fixed location of a spatial frame. In the decision phase, we presented two empty spatial frames next to each other and recorded participants’ eye movements on these empty frames while they recalled cue information to decide between the two alternatives. Our objective was to test whether participants who were classified as LEX-users based on their decision outcomes showed different gaze patterns than participants classified as using compensatory strategies. More specifically, we report tests of the following three hypotheses:

1. As soon as a cue value on one alternative is found, LEX-users should look for the respective cue value of the other alternative. In contrast, users of compensatory strategies should search for complete cue information on one alternative first. Hence, LEX-users should switch their gaze more often between alternatives than users of compensatory strategies, that is, there should be more transitions between alternatives per second of a trial for LEX-users than for users of compensatory strategies.

2. Because memory-retrieval of LEX-users is more extensive when differentiating cues have lower relative validity, the absolute frequency of transitions between alternatives should increase linearly with the validity rank of the first differentiating cue. In contrast, for users of compensatory strategies the validity rank of the first discriminating cue should not affect the frequency of transitions.

3. LEX-users should disregard cues lower in validity as soon as a higher cue differentiates between alternatives. Hence, fixation durations on former locations of cue values lower in validity should be shorter in trials, in which a cue higher in validity differentiates. Again, users of

compensatory strategies should not be affected by the validity rank of the first discriminating cue and the former locations of all cue values should be fixated for about the same amount of time.

Experiment

The experiment consisted of a learning phase, in which the participants acquired cue knowledge about six objects, followed by two decision phases. In the first decision phase, pairs of objects were presented to the participants for binary choice. In this phase, participants were not instructed with regard to the strategy they should use. Thus, the first decision phase followed a quasi-experimental logic. Here, the aim was to identify groups of participants who spontaneously employed different strategies and to test whether these groups show different patterns of gaze behavior as predicted in our hypotheses. We added a second decision phase to gain better control over the strategies participants used. In this phase, we presented the same binary choice items as in the first phase, but we directly instructed the participants to employ a certain strategy. Thus, with the second phase we realized a simple one-factorial design with two experimental groups (LEX-, EQW-instructions).

Method

Participants. Fifty-three students at the University of Greifswald participated in the experiment (43 women, 10 men; mean age 21.9 years). They received partial course credit for their participation. They were assigned randomly to the different strategy conditions in the second decision phase.

Materials. The participants learned cue descriptions of six alternatives. These alternatives were mushrooms characterized by the four cue dimensions consistency, cell wall material, mineral, and spread. Each of the cue dimensions could have three different values (consistency: soft, elastic or firm; cell wall material: protein, cellulose or lipid; mineral: magnesium, zinc or potassium; spread: frequent, medium or rare). The critical cue values (elastic, protein, magnesium and rare), which indicated a higher value on the target dimension (toxicity of the mushrooms), were not revealed to the participants until the learning phase was completed. In the decision phase, we presented pairs of the mushrooms for binary choice.

A complete paired comparison of the six cue patterns yields 15 choice tasks. The six cue patterns were constructed in a way that allowed for an individual strategy classification of the participants based on the vector of their choices in these 15 tasks (see Bröder & Schiffer, 2003a). Among the 15 binary choice tasks was a sufficient number of items for which each of the decision strategies considered here yields a distinct prediction. (A more detailed description of the cue patterns is given in Renkewitz & Jahn (2010), where we report an earlier experiment in which we used the same patterns.) To attain a more reliable strategy

classification, all 15 items were presented twice in both decision phases. For the second presentation of each item, the order of the alternatives was reversed. Thus, each decision phase consisted of 30 binary choice items after two practice trials.

Figure 1 exemplarily shows two alternatives and their cue descriptions as they were presented in the learning phase. Each mushroom was symbolized by a different geometrical figure. Written descriptions of the cue values appeared in four rectangular frames that were arranged along the borders of the geometrical figures. The position of the frames was constant across all alternatives. For a given participant, values on the same cue dimension were always shown in the same frame (e.g., the respective value of the cue “consistency” was presented in the lower left frame for all mushrooms learned by this participant). Thus, each cue dimension was tied to specific spatial coordinates. We counterbalanced the position of the cues across different validity ranks. For half of the participants, the cues were arranged clockwise in descending order of validity starting from the upper left frame. Hence the two most valid cues appeared in the two upper positions. For the remaining half of participants, the cues were arranged counter-clockwise starting from the lower left frame. Here, the two most valid cues appeared in the two lower positions. Additionally, the labels of the cues were counterbalanced across validity ranks. We used the two validity orders “consistency, cell wall material, mineral, spread” and “spread, mineral, cell wall material, consistency”.

Figure 1: Two of the six alternatives as they were presented in the learning phase. In the decision phases, the rectangular frames containing the four cue values were empty.

In each trial of the decision phases, two of the geometrical figures were presented side by side. The size of the figures was the same as in the learning phase. The rectangular frames that contained the cue values in the learning phase were now empty. So, participants had to actively search their memory for cue information to be able to decide which of the two mushrooms was likely to be the more toxic one.

Procedure. At the beginning of the learning phase, the six alternatives and their cue values were presented one by one. Afterwards, the participants had to reproduce the cue values repeatedly in several testing cycles. The learning phase continued until the participants correctly reproduced at least 22 of the 24 cue values in a final memory test (see

Renkewitz & Jahn, 2010, for more details on the learning phase).

Before the decision phases, the participants were informed about the validity ranks of the cues and the critical cue values. For instance, when the corresponding order of cue validities was used, participants were told that spread gave the most important hint to toxicity and that only rare mushrooms were likely to be toxic. The second most important hint was the mineral and only mushrooms predominantly containing the mineral magnesium were likely to be toxic, and so on. Additionally, a list showing the attributes of the ‘typical toxic mushroom’ was shown.

The 30 test trials of a decision phase were organized in two blocks. Each block consisted of the 15 binary choice items resulting from a complete paired comparison of the six mushrooms. Within each block, choice items were presented in random order. Participants responded with two keys on a standard keyboard.

After the first decision phase was finished, participants were given the strategy instructions for the second decision phase. In the LEX-condition, participants were told to consider attributes in descending order of importance and to decide according to the first attribute indicating that one of the two mushrooms was more toxic. All attributes of lower importance should be ignored. In the EQW-condition, participants were instructed to decide on the basis of the number of attributes indicating that a mushroom was toxic. If both mushrooms had the same number of ‘toxicity attributes’ they should guess. Subsequent to these explanations, an example of the application of the respective decision rule was given. In this example two cue patterns were used that were not part of the test set.

During both decision phases, eye movements were recorded with a desk-mounted SMI RED eye tracker sampling pupil position at 60 Hz.

Results

Behavioral data. We classified the decision patterns of the participants as most probably generated by LEX, EQW, WADD or a guessing strategy with the maximum-likelihood strategy classification method (Bröder & Schiffer, 2003a, 2003b). The strategy percentages in both decision phases are shown in Table 1. In the first phase, when there were no strategy instructions, 49% of the participants were classified as using the LEX-heuristic. This frequency of LEX-users corresponds closely to the findings of similar studies on memory based decision making using verbal stimulus material (Bröder & Schiffer, 2003b; Bröder & Schiffer, 2006; Bröder & Gaissmeier, 2007; Jahn, Renkewitz & Kunze, 2007). The classification results in the second decision phase suggest that the strategy instructions were largely successful. Thus, 80% of the participants instructed to employ the LEX-heuristic appeared to use this strategy and 89% of the participants instructed to use EQW were classified as using one of the compensatory strategies (EQW or WADD).

Table 1: Frequencies (and percentages) of strategy classifications in decision phase 1 (free strategy selection) and decision phase 2 (with LEX or EQW instructions)

Condition	Strategy classification					N
	LEX	EQW	WADD	Guessing	unclassified	
<i>Decision phase 1</i>						
Free	26 (49.1)	14 (26.4)	9 (17.0)	1 (1.9)	3 (5.7)	53
<i>Decision phase 2</i>						
LEX	20 (80.0)	1 (4.0)	1 (4.0)	2 (8.0)	1 (4.0)	25
EQW	2 (7.1)	18 (64.3)	7 (25.0)	1 (3.6)	0 (0.0)	28

Table 2: Mean absolute number of transitions between alternatives depending on the position of the first differentiating cue for groups of participants with different strategy classifications in both decision phases

Strategy	Validity rank of first discriminating cue							
	1		2		3		4	
	M	95% CI	M	95% CI	M	95% CI	M	95% CI
<i>Decision Phase 1 (free)</i>								
LEX	4.64	3.57-5.71	7.00	5.72-8.28	10.45	7.07-12.93	8.07	6.52-9.61
COMP	6.11	4.93-7.29	6.58	5.17-7.99	5.79	3.05-8.52	5.70	4.01-7.40
<i>Decision Phase 2 (instructed)</i>

COMP	5.62	4.58-6.65	5.30	3.99-6.60	4.67	3.38-5.85	5.10	3.41-6.79

Analyses of eye gaze data. In the analyses of gaze behavior we did not consider participants who remained unclassified or were classified as using a guessing strategy because we held no hypotheses concerning these participants. In the first decision phase, we excluded one additional participant (classified as EQW-user) from further analyses because of her unusually long decision times. In the second decision phase, we restricted the analyses to those participants that appeared to follow the instruction to employ the LEX-heuristic and those participants who were classified as using one of the compensatory strategies under EQW-instructions. Finally, we discarded all trials (3.0% in the first phase and 4.4% in the second phase) from the analyses of gaze behavior, in which the tracking data for more than 40% of the trial duration were missing (due to blinks, looking off the screen, or lost pupil or corneal reflectance).

In all of the following analyses, we merged the eye tracking data of EQW- and WADD-users as the result pattern for both compensatory strategies was generally the same and no statistically significant differences occurred between these two groups.

Transitions between alternatives per second. To determine the number of transitions between alternatives, we defined two areas of interest (AOIs), each of which covered one alternative and, thus, almost one half of the screen. A transition was defined as two successive fixations in different AOIs. We counted the number of transitions per trial and divided this number by the trial duration (in seconds) to obtain an index of gaze transitions. The means of this index corroborate our first hypothesis: With instructed decision strategies, LEX-users ($M = 0.68$) switched their gaze faster between alternatives than users of a compensatory strategy ($M = 0.46$), 95% CIs [0.58, 0.78],

and [0.41, 0.51], respectively, $t(43) = 3.52$, $p = .001$, $d = 1.08$. In the first decision phase, when participants spontaneously adopted a decision strategy, the same difference between the LEX-heuristic ($M = 0.60$) and compensatory strategies ($M = 0.39$) was found, 95% CIs [0.54, 0.66], and [0.34, 0.44], respectively, $t(46) = 4.90$, $p < .001$, $d = 1.45$.

Transitions between alternatives depending on the validity rank of the first discriminating cue. According to our second hypothesis, for LEX-users the absolute number of transitions between alternatives should depend on the validity rank of the first discriminating cue in a decision item. The lower the validity of the first discriminating cue the more transitions should occur. In contrast, the gaze behavior of users of a compensatory strategy should be unaffected by the validity rank of the first discriminating cue.

To test this hypothesis, we split the 30 decision items into four sets, according to the rank of the best discriminating cue. Table 2 depicts the mean number of transitions in each of the four sets for LEX-users and for users of a compensatory strategy in both decision phases. Under instructed strategy conditions, for LEX-users the mean number of transitions increased monotonically with the validity rank of the first discriminating cue, as expected. For users of compensatory strategies no systematic effect was associated with the validity of the best differentiating cue. This interaction effect of strategy classification and validity rank of the first discriminating cue was confirmed in a two-way mixed ANOVA, Greenhouse-Geisser corrected $F(2.28, 98.13) = 22.71$, $p < .001$, $\eta_p^2 = .35$. When participants chose freely between decision strategies, we found a similar result pattern. For LEX users the number of transitions again

increased markedly (but not monotonically) with the validity rank of the first discriminating cue. For users of a compensatory strategy this factor had no impact. The cor-

responding interaction effect was again statistically significant, Greenhouse-Geisser corrected $F(1.79, 82.25) = 8.42, p = .001, \eta_p^2 = .16$.

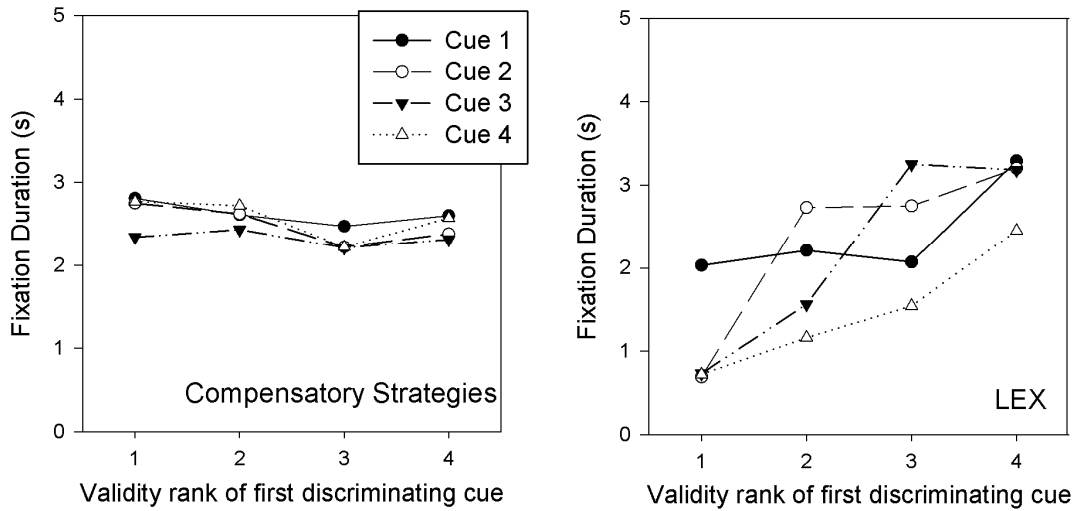

Figure 2: Mean fixation durations at cues with different validities depending on the validity rank of the first discriminating cue in decision phase 2 (instructed strategies). Data are presented separately by strategy classification.

Fixation durations at former locations of cue values. To assess fixation durations at former locations of cue values, we defined AOIs around the empty rectangular frames that had contained the cue values in the learning phase. These AOIs exceeded the original frames by 30 pixels in each direction.

For each trial and each cue, we determined the summed duration of all fixations in the two AOIs pertaining to the respective cue (one AOI for each alternative). These summed durations were averaged per participant across all trials, in which the first discriminating cue had the same validity rank. For participants of all strategy classifications, fixation durations exhibited a gaze bias towards the cue locations in the upper half of the stimuli. This bias was independent of both the specific cues presented at these locations and the validity rank of these cues. Hence, as we were interested in the average fixation durations at locations of cues with different validity ranks, we calculated weighted means across the groups of participants for which the two most valid cues appeared in the upper part of the stimuli and the groups for which these cues appeared in the lower part.

In Figure 2, the weighted mean fixation durations at cues with different validities are plotted against the validity rank of the first discriminating cue for the second decision phase with instructed strategies. As can be easily seen, we found clearly different result patterns for LEX-users and users of compensatory strategies.

Under instructed strategy conditions, users of compensatory strategies looked approximately equally long at all four cues and their fixation durations were unaffected by the validity rank of the first discriminating cue in a decision item. Consequently, in a three-way mixed ANOVA the effects of Cue, Greenhouse-Geisser corrected $F(2.21, 50.88) = 0.22, p = .83, \eta_p^2 = .01$, First Discriminating Cue, $F(2.33, 53.67) = 2.06, p = .13, \eta_p^2 = .08$, and their

interaction, $F(5.00, 114.96) = 0.45, p = .81, \eta_p^2 = .02$, were all not significant (the third factor Position of the Two Most Valid Cues with the levels Upper Half or Lower Half was introduced to control for the gaze bias towards the upper half of the stimuli).

In contrast, in items in which the most valid cue discriminated, instructed LEX-users fixated this cue considerably longer than all other cues. When the second most valid cue was the first to discriminate, the largest increase in fixation durations occurred for this cue. However, also the third cue and the fourth cue were fixated longer than in items in which the first cue discriminated. Similar changes in fixation durations emerged when cues with a lower validity were the first discriminating ones. Thus, the data reveal two trends: First, as expected, cues with a low validity are fixated longer, when no cue higher in validity discriminates. Second, there is a tendency towards all cues being fixated longer when the validity rank of the first discriminating cue is low. Correspondingly, the interaction effect of Cue x First Discriminating Cue, $F(4.18, 75.31) = 5.75, p < .001, \eta_p^2 = .24$, and the main effect of First Discriminating Cue, $F(1.77, 31.83) = 16.94, p < .001, \eta_p^2 = .49$ were significant. The main effect of Cue was not statistically reliable, $F(1.55, 27.94) = 2.57, p = .11, \eta_p^2 = .13$.

When the participants spontaneously adopted a decision strategy in the first decision phase, the pattern of results was similar but somewhat noisier. For users of compensatory strategies, there were again no statistically significant effects. For LEX-users, the effect of First Discriminating Cue was confirmed, $F(2.08, 49.85) = 6.51, p = .003, \eta_p^2 = .21$, whereas the interaction effect of Cue x First Discriminating Cue was no longer statistically significant, $F(4.83, 115.96) = 1.94, p = .09, \eta_p^2 = .08$.

Discussion

The observed fixation patterns on emptied displays of decision alternatives differed markedly and in line with predictions depending on the decision strategies employed. If according to a lexicographic strategy more comparisons between single cue values of alternatives were necessary, more transitions between alternatives were recorded. Furthermore, even the fixation durations on the former locations of specific cues reflected the cues' relative importance according to a lexicographic or a compensatory strategy.

Thus, tracking fixations on emptied information displays provided indicators of information search in memory-based multiattribute decisions similar to those provided by Mouselab methods for "inferences from givens" (Payne, Bettman, & Johnson, 1993). This proves a novel process-tracing method applicable to memory-based decisions. The present results corroborate the outcome-based strategy classification method (Bröder & Schiffer, 2003a) and add to previous response time data on strategies in memory-based multiattribute decisions (Bröder & Gaissmaier, 2007). Now, there is a way to analyze overt behavior that seems to indicate which cognitive processes determine response times and decision outcomes.

The looking-at-nothing phenomenon has been interpreted as an attempt at memory retrieval that triggers an involuntary gaze shift to the former location of the sought information (Richardson & Spivey, 2000). The former location is specified by a spatial index in an integrated representation encompassing conceptual, linguistic, visual and spatial information (Ferreira, Apel, & Henderson, 2008). In the present experiment, several instances of memory retrieval were required in a single binary choice trial. The more information had to be retrieved according to a strategy, the more fixations occurred, however, locations were frequently refixated. Based on the current data we cannot decide whether these refixations are due to repeated retrieval attempts or further processing of the already retrieved information in working memory. We presume that they indicate processing of retrieved information similar to eye movements that occur while visuo-spatial imagery is experienced during discourse processing (Johansson, Holsanova, & Holmqvist, 2006). If this proves correct, the exposition of the LEX strategy has to be modified. The prolonged response times predicted and observed for LEX-users if cues lower in validity have to be processed seem to be due not only to additional memory retrieval, but to extended pondering that includes cue information that does not affect the final decision.

In our attempt to exploit the looking-at-nothing phenomenon for process tracing, we have shown that it manifests itself rather robustly. Here, encoding and retrieval were separated by multiple encoding and retrieval instances with respect to overlapping physical locations. Furthermore, spatial indexing operated relative to visual context that varied in its physical location. Hence, we think that looking-at-nothing has wide applicability. Observing information

search on emptied displays opens up a window on the cognitive processing of memorized information.

Acknowledgments

We would like to thank Sebastian Burchert for his help in conducting the experiment.

Abstract

This study concerns the role of motor simulations in a memory task performed by expert and novice climbers. In a behavioural task, expert and novice rock climbers were shown three novel climbing routes: an easy route, a route impossible to climb but perceptually salient, and a difficult route. After a distraction task, they were given a recall test in which they had to write down the sequence of holds composing each route. No difference emerged between experts and novices on the easy and impossible routes. Differently, the performance of expert climbers was better than that of novices on the difficult route. Results suggest that seeing a climbing wall activates a motor, embodied simulation, which relies not on perceptual salience, but on motor competence. Crucially, it is shown that the ability to form this simulation is modulated by individuals' motor repertoire and expertise, and that this strongly impacts recall.

Keywords: simulation, affordance, embodied cognition, grounded cognition, canonical neurons, mirror neurons, motor memory, memory for actions, motor chunks.

Introduction

A number of studies have shown that seeing an object, such as a cup, affords simple actions, such as reaching and grasping. According to the original definition by Gibson (1979) *affordances* are possibilities for action offered by the environment and perceived directly by an observer. A recent view of affordances, which we endorse here, is that they are potential action patterns activated in the observer's brain while observing objects. In other words, they are the product of the conjoining, in the brain, of visual stimuli and action responses (e.g., Ellis & Tucker, 2000), whose neural bases can be found in the discovery, in the F5 area of the ventral premotor cortex of the monkey, of visuomotor canonical neurons which discharge in the presence of graspable objects when no overt response is required (Murata et al., 1997). Evidence in humans confirms the existence of a parietopremotor circuit active during the observation of manipulable objects (Grèzes et al., 2003). Overall, both behavioural and brain imaging studies have shown that

perceiving affordances activates in observers specific motor programs (Borghi, 2004; Borghi and Riggio, 2009; Martin, 2007). This phenomenon can be interpreted as activation of a *motor simulation*, where 'simulating' means that the same sensorimotor systems that are activated during interaction with objects are activated during object perception (e.g. when observing objects or when listening their characteristic sound), but without the execution of overt movements (Gallese, 2009; Jeannerod, 2006).

A computational framework proposed by Wolpert and Kawato (1998) and elaborated in Frith et al. (2000); Jeannerod (2006); Wolpert et al. (2003) explains motor simulations as the re-enactment of internal models that allow motor control. Internal models come in two varieties, inverse and forward. During motor control, the former compute the necessary motor commands to achieve a certain goal given a starting position, and the latter predict the sensory consequences of those motor commands. In addition, it is possible to re-enact internal models to form a simulation of possible actions by feeding the inverse model with predicted sensory inputs rather than 'true' sensory inputs, and successively feeding the new motor command to the forward models, and so on. This process permits the linking of multiple predictions in order to obtain simulations of possible actions for an arbitrary long number of steps. Note that for this process to work it is also necessary to inhibit 'true' sensory inputs and motor outputs. Indeed, simulating is not the same as performing an overt action, for a variety of reasons: simulation implies a weaker activation of the interested neural areas. In addition, during simulation some kind of blocking mechanisms might intervene that prevents the action to be executed overtly. Finally, during overt action a sensorial feedback is received, while no such feedback is given while simulating (Jeannerod, 2006).

Even if the activation of motor information elicited by object presentation has been extensively studied in the last years, the majority of studies have focused on how single objects or object pairs (e.g., Riddoch et al., 2003) activate an

internal simulation or even overt simple movements, such as reaching or grasping. The role played by multiple affordances for complex actions implying a sequence of movements has not been widely investigated. Imagine observing a mountain path before performing a complex action composed by a sequence of movements, such as hiking. One might observe whether the path is steep or not, how the different stones are displayed, whether tree branches represent obstacles for walking and how to avoid them. In other words, both the characteristics of single objects (e.g., the stones, their orientation and shape) and their placement along the path might afford or impede actions. The same is true for climbing.

Indoor rock climbing consists in reaching the top of a specially-designed wall (i.e., a climbing wall), by grasping climbing holds with the hands and the feet. Climbing routes, which consist in carefully arranged sequences of climbing holds, may have different difficulties depending on the slope of the wall, the length of the route, as well as on the number, kind, and arrangement of the climbing holds. Usually climbers, both during their training and during competitions, spend some time in “studying” climbing routes before climbing them, especially when they have to climb a route for the first time. Then, they can mentally simulate which holds to take, which movements to do, which rest positions they can find, etc. In some cases, they also overtly mimic the hand (and foot) movements that they expect to perform while climbing (see fig. 1).

Figure 1. Athletes studying a climbing route before climbing it. Note the overt hand movements.

The simulation they build might include both information on specific affordances, i.e. the characteristics of the holds (shape, orientation, etc.), and information on their displacement, i.e. the way they are arranged on the wall. Given that routes involve multiple climbing holds, clearly any simulation of a part of the route changes the way the rest of the route is perceived. For example, simulating grasping a certain hold with the right hand makes some other holds affordable to be grasped with the left hand, and some other holds out of reach; see fig. 2. At the same time, the need of reaching a certain ‘goal’ hold determine which holds are affordances retrospectively, and disrupts the affordances of some holds (e.g., far holds) in the climbing wall. For all these reasons, motor simulation in rock climbing should be considered an *affordance calculus* rather than a response to a sequence of individual affordances.

Crucially, the motor competence of climbers also determines what constitutes an affordance. Experienced climbers can hold small holds that are difficult for weak climbers to grasp, and can simulate sequences of actions that are too complex to be picked up by novice climbers, much like how expert chess players ‘see’ complex strategies. We hypothesize that the proficiency of expert climbers allow them to climb better the routes also by understand them better, where understanding should be intended as proficiency in the affordance calculus and in the associated building of appropriate mental simulations before climbing.

Figure 2. A sample sequence of movements in rock climbing. Notice that (i) climbing holds afford different grips, and (ii) the way holds can be grasped depend on which holds were grasped before (and how) as well as which holds the climber intends to reach.

Aims and objectives of the study

Our study addresses the role multiple affordances play in the recall of routes by rock climbers with different level of expertise. An open issue in this field pertains to the extent to which affordances are elicited automatically, upon seeing objects, or are activated when a specific action goal is pursued. In addition, studying recall in expert and novice climbers can contribute by showing to what extent the activation of affordances is modulated by observers’ experience and competence. Finally, we still know very little on how affordances improve recall. Acquired motor skills offer a unique way to test this question.

Here, novice and expert climbers were asked to observe and recall the position of holds of 3 routes that they never climbed: an easy route (ER), a difficult route (DR), and a (motorically) impossible but perceptually salient route (IPSR). Predictions were that their performances would not differ for the ER, because both groups would be able to perform a motor simulation, and for the IPSR route, when for both it was impossible to form a motor simulation of climbing. If this were true, this would demonstrate that the simulation formed is a motor one, and would be activated only when participants have the motor competence necessary to perform the sequence of actions. Accordingly, the performance of experts should overcome that of nonexperts in the DR, when the actions required climbing the route they are shown are part of their motor repertoire.

Method and Materials

Participants

Eighteen climbers who attended to the “Lanciani Climb” arena in Rome volunteered to study. Experts had between 5 and 10 years climbing experience, whereas novices had less than six months climbing experience. Groups were balanced for gender (6 men and 3 women each group) and age. To balance the order in which the different routes were presented, as well as to avoid assigning the task to large groups, we divided the participants in 6 groups of 3 randomly selected participants: 3 groups composed by experts, and 3 by novices.

Materials

Two climbing trainers set up three novel routes from a climbing wall containing 110 holds. Each route was composed of 10 holds (the typical average length for most training routes). Route difficulty depends on the configuration of the holds (their graspability) and the configuration of the limbs in transition between the holds (Smyth and Waller, 1999). Both experts and novices, because of the orientation and arrangement of the holds, could climb the Easy Route (ER) without difficulty. In order to control for perceptual factors that might facilitate memorization, the two other routes differed in perceptual salience. The Difficult Route (DR) was difficult to climb because the holds were not easily graspable due to their shape and orientation, and only expert climbers could benefit from their affordances. All holds in the ER and DR were grey- or dark-coloured and did not differ in size or other perceptual characteristics. The third route, (motorically) Impossible but Perceptually Salient Route (IPSR), was impossible to climb as a whole (but parts of it could be climbed). The difficulty of such route was not due to the fact that participants had to simulate biologically impossible movements (Costantini et al., 2005) but rather on the arrangement of the holds. Specifically, it was impossible to benefit from the affordances offered by the holds and to configure the limbs for a transition from one hold to the other. To facilitate memorization, however, we rendered the holds perceptually salient: they were vividly coloured, compared to the standard grey- or dark-coloured holds.

Procedure

Two experimenters and the trainer were present in the Lanciani Climb arena to administer the task. Before entering the arena, participants were instructed that they have to memorize a route made up of 10 holds, and that later they had to perform an additional task. Groups (of 3 participants) were then invited to enter and to sit in front of the climbing wall. The wall includes 110 holds with different size and orientation, placed uniformly to cover its entire surface. The trainer indicated twice the holds of each route with a stick. After this demonstration, participants had to turn their backs to the wall and perform a distracting task (i.e. to pronounce the letters from A to L). The procedure was repeated for each route. The presentation order of the routes (ER, DR and IPSR) was balanced across participants. Participants

were given a folder containing three A3 sheets, each displaying a picture of the climbing wall (which included all the holds). After the first of the three routes had been shown, they were asked to extract the first sheet and to mark down as quickly as possible (with a time limit of 2 minutes) the sequence of holds composing the first route. The same procedure was repeated for the two remaining routes. Participants were then required to fill in a post-experiment questionnaire in which they were asked to report (by responding yes or no) whether they mentally imaged climbing the wall while being shown the route and while recalling them, whether they believed that imagining the route might be helpful for them, and which route appeared to them the easiest to climb.

Results

All participants performed the task without difficulties. The number of holds reported in a correct sequence for each route was computed for each participant, and submitted to a 3x2 mixed ANOVA with Route (ER, DR and IPSR) as within factor, Expertise (Expert vs. Novice) as between factor and participants as the random factor. Data are plotted in fig. 3. All analyses were conducted using a Type I error rate of .05.

Figure 3. Results of the task. Legend. ER - Easy Route; DR - Difficult Route; IPSR – (Motorically) Impossible but Perceptually Salient Route

Expertise factor was not significant ($F(1, 16) = 1.35$; $MSe = 20.92$; $p = .26$), whereas Route factor was highly significant ($F(1, 32) = 15.45$; $MSe = 3.35$; $p < .0001$). Post-hoc Newman-Keuls showed this was due to the difference between the ER ($M = 6.44$) and the two other routes, DR and IPSR ($M = 3.72$; $M = 3.33$, respectively). As predicted, the ER led to a better performance compared to the two other routes, independently from the degree of expertise of participants. It is worth noting that the average number of remembered sequences was exactly the same for experts and novices ($M = 6.44$).

Crucially to our hypotheses, the interaction between Expertise and Route was significant ($F(1, 32) = 3.60$; $MSe = 3.35$; $p < .04$). Post-hoc test confirmed that there was no difference between Novices and Experts on the Easy Route ($p = 1$). More importantly, the difference between Novices and Experts was not significant with the IPSR (Newman-Keuls, $p = .21$, respectively $M = 2.78$, $M = 3.89$), whereas the performance of Novices was significantly worse than

that of Experts with the DR (Newman-Keuls, $p < .004$, respectively $M = 2.11$, $M = 5.33$). This suggests that the two groups did not differ in memory capabilities when for both of them it was impossible to mentally simulate the motor task, i.e. in the IPSR. This indicates that the impossibility to form a motor simulation clearly affects recall. The impact of motor simulation on recall is confirmed by results with the DR, where the difference between the two groups clearly emerged. Namely, in the DR, the capability to climb the wall was part of the experts' motor repertoire, thus they were able to build a motor simulation. In the post-experimental questionnaire, Experts and Novices did not differ in responding to whether they mentally imagined climbing the route while being shown it (55% of both groups responded using imagination) and while recalling it (44% for both groups responded positively). However, compared to novices, experts seem more aware of the effects of the simulation (22% of novices and 44% of experts reported that imagination helped), even though neither group seemed to believe that imaging was strategically important, as participants did not believe it helped them during recall (only 33% of athletes responded positively for both groups). Experts and Novices differed also in that Novices were less aware of the differences between the routes (55% of novices did not distinguish between them).

Discussion

Our results support the hypothesis that visually perceiving multiple affordances (here, climbing holds disposed in a climbing wall) leads to the activation of a motor simulation, which improved recall. The activation of the simulation is specific, and depends on whether or not the holds are disposed so to afford climbing, and on climbers' motor competence.

We found that both experts and non-experts performed equally well with the Easy Route. This suggests that, when participants have the motor competence allowing them to climb a given route, they simulate doing it, and this very fact improves their recall of the route. In addition, our results allow us to understand what happens with difficult routes, that is, when, for some of the participants, it is difficult or impossible to construe a simulation. Specifically, the design we used allow us to distinguish situations in which participants could rely on perceptual salience for memorization and situations in which only a subset of participants might build a motor simulation grounded on previous climbing experience. We found that the expert participants, who were able to rely on a mental simulation strategy, had better performance than novice ones, who were only able to rely on visual strategies. The advantages of motoric vs. visual strategies were also highlighted by the poor performance of both groups in the (motorically) impossible but perceptually salient route, despite the high salience of the holds that composed the route. Our results indicate that a simulation is evoked only when the holds have perceptual characteristics and also afford actions.

Namely, no simulation is activated when climbers observe holds that are perceptually salient (i.e. having vivid colors) but not useful for climbing the route, that is, when the holds do not represent good affordances. This result helps to qualify the kind of simulation evoked: holds (affordances) elicit an embodied, motor simulation, not a purely visual simulation.

Notice that in this study we do not consider the specificity of the climbing method experts and non-experts adopt; we simply focus on different climbing competence. A few studies have addressed and demonstrated that experts and novices might use different patterns of action. Boschker et al. (2002) found that, differently from inexperienced climbers, experts focused on the functional aspects of a climbing wall, whereas they did not consider its structural features. In Boschker and Bakker (2002) inexperienced climbers who were shown a video of expert climbers learned to use experts modes of climbing (e.g., arm crossing) and climbed faster and with more fluent movements than those who were shown videos of novice climbers or a control video. Overall, our results fit well in the embodied cognition (Glenberg, 1997) literature and have implications, concerning the role of affordances for both simulation and recall, as well as the relationship between motor competence and the capability to form and use motor simulations.

In addition, this finding helps us comprehend the mechanisms on which memory of action relies (see for example Daprati et al., 2005). Overall, our study suggests that the ability to benefit from objects' (holds') characteristics and from their arrangement can help a climber form *motor chunks*, i.e. chunks based on sequences of real action possibilities, which, in turn, leads to better recall of a given route. The idea of "chunks" derives from the study of Chase and Simon (1973) on how competence influences recall of chess positions in novice and expert chess players. The main finding of such study is that expert chess players outperformed novices in the recall of meaningful chess positions, but not in non-meaningful positions. The authors proposed that this is due to the experts' larger set of 'chunks' of chess positions, which permits them to recognize complex patterns of chess positions as individual units and therefore to recall them better. Our study shares resemblances with the study of Chase and Simon (1973), the two main differences being that: (i) we focus on motor competence rather than abstract problems like chess, and (ii) unlike chess players, climbers see the climbing routes for the first time, and there is an immense variety of combinations of holds, orientations, inclinations of the climbing walls, etc. Although the climbers could still pick up abstract similarities between old and new patterns of holds, these similarities are meaningless if untied to body possibilities and more in general (competence-specific) motoric information. For this reason, we could hypothesize that a chunking mechanism could be in play that is similar to the one described in (Chase and Simon, 1973); it can be called motor chunking due to the

importance of motoric information. However, if this is the case, motor chunks cannot be simply retrieved from memory, but should be built anew (or at least reassembled) as part of the planning (and simulation) process, which is of course highly competence-specific, and involves the (partial) re-enactment of motor processes. Note that this view of motor chunking is compatible with the idea of Glenberg (1997) that simulations can be *meshed* with (episodic) memories. Overall, this view could explain why memory performance is better when climbers are allowed to form motor chunks, not when they use memory strategies relying on the visual saliency of some holds. This finding is also compatible with the idea that motor simulations elicit procedural memories (see Pezzulo, 2008; in press; Pezzulo and Castelfranchi, 2009, for a discussion).

Our results suggest also that the activation of a motor simulation is possible only when performing a given sequence of actions is part of participants' motor competence. The better recall of Experts compared to Novices is totally due to the fact that, given that they were able to climb the difficult route, they could mentally simulate climbing (do the 'affordances calculus') and, with the help of the affordances, they were able to recall the sequence of required movements. Novices were impeded from simulating because they did not possess the motor capability to climb the Difficult Route. This suggests that the ability to simulate is modulated by previous motor experiences, in keeping with ideomotor theories of perception and action (Hommel et al., 2001).

Differently from other sports, like dance, in rock climbing both the simulation elicited by action observation (of another rock climber) and the simulation elicited by affordances (simply observing a rock or climbing wall) can be studied. Therefore, our research extends also the results showing that a motor resonance phenomenon occurs when we observe others performing complex movements, such as dancing and playing basketball (e.g., Cross et al., 2006). This phenomenon has its neural basis in the mirror neuron system, which, differently from canonical neurons, are activated both during performance of an action (say, grasping, manipulating and holding objects), and during observation of others performing the same action (Gallese et al., 1996). In line with our results, this motor resonance is stronger when participants observe actors sharing their motor repertoire. Aglioti et al. (2008) demonstrated with a psychophysical study that elite basketball players predicted the success of free shots at a basket earlier and better than expert observers and novice players. The experts' advantage was due mainly to their higher capability to predict by reading body kinematics in the early movement phases. A transcranial magnetic stimulation (TMS) study showed a time-specific motor activation while observing videos of errors. The results of the combined physiological and TMS studies reveal that fine-grained motor resonance occurs after motor practice and that motor expertise specifically contributes to anticipating the actions of others.

Studying a special case, that of rock climbers, our behavioural study showed for the first time that multiple affordances activate a motor simulation, and that this strongly impacts recall, which is then modulated by participants' motor expertise and motor repertoire. Further studies are needed to better understand the neural underpinnings of the complex mechanisms of recall based on affordances and embodied simulation.

One alternative explanation for our results is that experts might be better in fitting visual images of climbers' postures, and thus they could use visual imagery rather than motor simulations. Although our study cannot rule out this possibility, there are reasons to believe that this is not the case. First, while this hypothesis explains the advantage of experts in the DR, it does not explain the good performance of novices in the ER. To explain why novices are better in recalling the ER than the DR, one should say that visual imagery is specifically modulated by one's own (motoric) climbing competence. Second, the exclusive use of visual imagery could hardly help solving our task. Namely, climbers experience the routes for the first time, and cannot see other climbers, so any visual simulation they build has to be done anew. However, spatial and configurational information (position of limbs in space) is not enough to determine which are the climbing positions one should remember, since valid climbing positions also depend on which affordances are offered by the holds, and which are the past and future movements. In other terms, although climbers could use visual imagery as part of their strategies, at least some of the processing required to recall climbing positions is better understood in motoric than purely visual terms. Another possibility is that experts are more experienced with some patterns of holds, much like chess players are supposed to be. As already discussed, however, climbers see the routes for the first time, and there are countless dispositions of holds. More importantly, the visual appearance and the spatial configuration of the holds is not sufficient to understand the best path in a route, or its difficulty. To do so, climbers have to take into account at the same time the individual affordances offered by the holds, the previous movements, etc. Overall, then, due to the highly specific and situated nature of climbing, it is unlikely that a memory retrieval strategy could be sufficient (although it might help), and how memory retrieval could be done in purely abstract terms, without accessing one's own motoric information. (This is why we suggested that motor chunks should be built anew as part of the motor planning.) Before concluding, it is worth mentioning that several studies distinguish between two kinds of motor simulations: conscious and unconscious (see Jeannerod, 2006 for a discussion). Most of the afore-mentioned studies address unconscious motor simulations; in this context, the idea is that seeing a climbing wall automatically activates specific motor processes in climbers. There is, however, another kind of motor simulation, a conscious one, which can be performed by climbers, and is indeed routinely done as part of the athletes' training, and before the start of competitions.

Jeannerod (2006) suggests that the representational content of conscious and unconscious simulations are the same, with different time constraints determining their level of access (e.g., most unconscious motor images arise for the demands of immediate action and simply do not have the time to become conscious). In this study, the climbers were not explicitly instructed to mentally simulate. However, the procedure adopted in this study, and in the afore-mentioned ones, does not permit us to discriminate whether or not participants used a conscious strategy. Further studies are necessary to shed light on the differences between conscious and unconscious mental simulations, and their respective roles in motor planning.

Enactive Social Cognition

72076 Tübingen, Germany

Abstract

In this talk, I extend the enactive approach to cognition to the social domain within a larger framework of varieties of intentionality and argue for a second-person approach to understanding others, emphasizing a difference in our understanding of others depending on whether we are directly engaged with them in interaction or merely observing them. The enactive account is especially persuasive in developmental respects, suggesting that sophisticated forms of cognitive intentionality (e.g. believing) are grounded in motor intentionality (e.g. perception and action): Our own sensorimotor skills are partly constitutive of cognition, and other people's expressions of their sensorimotor skills in turn modulate our cognition of objects and our social understanding. The enactive account explains how young infants acquire the capacities that allow them to move from dyadic to triadic intentional relations at around their first birthday, and it claims that our basic form of social understanding is neither based on theoretical inference nor a kind of simulation, but constituted by an embodied implicit know-how displayed in online interaction.

Keywords: social cognition; embodied cognitive science; enactive approach; intentionality; social neuroscience.

1. Varieties of Intentionality

Intentionality is a technical term referring to the capacity to be directed towards an object, where 'object' is broadly construed: artefacts, events, people, states of affairs in the world, abstract or fictitious entities and mental states of others and of oneself can be the goal of an intentional activity (Brentano 1874). Moreover, there are a multitude of intentional attitudes via which one may be so directed: sensorimotor, affective and cognitive ways of dealing with the world (Barresi & Moore 1996, Crane 2001). One can think about, hope or doubt that it might rain tomorrow and one can perceive or desire a glass of wine or just intentionally grasp it with their hands. At the same time, one can be intentionally directed at something without having a sophisticated *understanding* of such intentional directedness in oneself and in others.

Searle (1983) and Crane (2001) have provided thorough analyses of intentionality, but it is odd that (1) they largely ignore what we may call motor intentionality—a directedness towards an object manifested in grasping and manipulating it, and that (2) they do not even attempt to characterize the subject being intentionally directed at objects, although this is an essential element in the structure of intentionality. My first claim is that a proper integration of these two aspects motivates a thoroughly embodied and enactive account to cognition and intentionality:

The *subject* of intentional relations is best characterized as an embodied agent, possessing a number of skills and capacities, ranging from performing bodily actions, perceiving and grasping objects, to thinking and imagining complex and even counterfactual states of affairs. Conceptualizing the cognizing subject in this way provides a first motivation for understanding intentionality in a broader sense by integrating sensorimotor forms of directedness. *Motor intentionality* has received much attention in recent investigations of perception and social interaction and plays an important foundational role in the enactive approach, as will be elaborated below. This constitutes a radical shift of emphasis: Whereas analytic philosophers of mind have been concerned primarily with intentionality as a feature of mental states, it is better construed as a feature of whole organisms (Thompson 2007, Hutto 2008). A second motivation for considering sensorimotor forms of intentionality is based on recent developments in the cognitive neurosciences and a more general transformation of paradigmatic cognitive science. Regarding the latter, the traditional computational paradigm is currently being replaced by an embodied-embedded cognitive science that does not consider the computational brain in isolation but investigates mental phenomena in the broader context of an embodied agent being situated in her environment, which itself constraints the agent's cognitive projects. Regarding the former, data from animal studies suggest that perceptual capacities are grounded in motor capacities quite generally. More specifically, the discovery of mirror neurons has fostered an ongoing debate about the role of motor intentionality in the overall cognitive architecture of human agents (Sinigaglia 2008). Consequently, this leads to the following general structure of intentionality:

An embodied agent (or organism) is directed towards an object or content by way of one among several sensorimotor, affective, or cognitive attitudes.

Since this structure can be realized in various ways, the task of a comprehensive theory of intentionality is to provide an adequate account for the different varieties of intentionality, differing in complexity and sophistication (Barresi & Moore 1996, Schlicht 2008). In broad strokes, such a framework may look something like this:

1. The most basic and biologically primary forms of intentionality are *perception and action* (Searle 1983). They are essentially dyadic relations to single *existing* objects or agents and depend on being situated and embedded in an environmental context. We share these forms of intentionality with many animals. Ontogenetically, human infants first make use of sensorimotor skills in order to perceive,

grasp and manipulate objects in their vicinity. Only later are they capable of more sophisticated and detached forms like beliefs.

2. On a second level, in scenes of *joint attention*, intentional relations become triadic: either an additional subject enters the subject-object-relation or an object enters the relation between two subjects (mother and child, say). True *joint attention* is not coincidental, i.e. both agents have to be mutually aware of their coordination of different perspectives on the world and actively track and manipulate the attention of each other. Merely looking at the same object coincidentally does not suffice. Joint attention involves a *cognitive* aspect—being directed on the world—and a *social* aspect (being engaged in social interaction with another subject). Numerous studies show that infants are capable of such "triangulation" (Davidson 2001) only from around nine to twelve months of age (Carpenter et al. 1998). Even these complex intentional relations strongly depend on the existence and presence of the object and person one is directed at. All relating agents constitutes a special case of triadic relations, e.g. two adults attending to the infants' actions. This not only seems to occur a few months earlier but also does not involve a proper external *object*.

3. A third level is marked by the partial use of the imagination in the second year of life, for example in pretend play, where functional properties are detached from one object, a telephone say, and assigned to another, a banana say (Leslie 1987). It has also been shown that pretend play mark the onset of truly *collective intentionality*, where two agents pursue a common goal and coordinate their actions accordingly. This also involves an understanding of norms (e.g. rules of a game), and two-year olds have been shown to reinforce these norms (Rakoczy 2006). But even then infants still partly depend on the existence and presence of objects in their immediate environment, although they are already capable of representing an object in its absence.

4. Finally, a fourth level is characterized by an explicit directedness towards mental states like beliefs, desires and intentions of others. At around 4 years, infants display an understanding of other people and have acquired the concept of belief, which is reflected in their passing false-belief-tasks (Wimmer & Perner 1983). That is, they can now explain other people's actions on the basis of what the other believes to be the case rather than in terms of what really is the case.

It may be necessary to modify this model by adding further levels or more fine-grained distinctions, so this first sketch of a theory of intentionality needs to be worked out in much greater detail (see Schlicht 2008). But the approach to intentionality recommended here can be contrasted on the one hand to traditional approaches pursued by many analytic philosophers of mind, who try to explain it from the top down by focusing on propositional attitudes presupposing language and concept possession (Dennett 1971, Fodor 1987, also Brandom 1994), and to reductionist approaches on the other hand, which attempt to reduce everything mental to a different level, e.g. neural processing. The present approach treats intentionality as a "moving target", taking on different

forms and recommends to explain it neither from the top down nor from the bottom up, but following Gallagher (2005), developmentally from the beginning onward. By integrating insights from the neurosciences as well as adequate phenomenological descriptions and distinctions, this strategy promises to account for the 'developments' of the intentional attitude towards cognitive sophistication and of the target object from existing to fictitious and purely mental objects.

Because of its complexity, joint attention may be seen as a "primitive state of consciousness" (Campbell 2005, Eilan et al. 2005): One is at the same time directed at an object of interest and at another subject, with a cognitive and a social dimension. Thus, it is not only interesting with respect to our cognition of worldly objects but also with respect to our understanding of others. It has to be emphasized that joint attention as a complex form of intentionality does not come out of nowhere but has important precursors from the point of view of cognitive development, namely dyadic intentional relations. In the context of investigating the neural correlates of engaging in joint attention, Schilbach et al. (in press) developed an interactive paradigm in which participants' gaze behavior as measured by an eye-tracking device was used to contingently control the gaze behavior of a computer-animated character. Test persons interacted with the virtual other while undergoing fMRI. It was found that in contrast to merely following the other's gaze, actively establishing joint attention by directing the other's gaze was correlated with a differential increase of neural activity in the *ventral striatum*, known to be a part of *reward*-related neurocircuitry (Rolls, Grabenhorst, Parris, 2008). These findings may be interpreted as the neural correlates of an *intrinsic motivation* to engage in triadic intentional relations and of sharing experiences. But a natural question to ask is what allows infants to move forward to triadic forms of intentionality at the end of their first year of life, apart from this natural inclination to *share* something with someone. In the following, the aim is to outline central elements of an enactive approach to cognition and transfer them to the social domain, to show that it provides a plausible account of the capacities needed for this cognitive development. Along the way, additional empirical support from developmental psychology and the neurosciences will be integrated.

2. Enactive Cognition

As has been pointed out above, an embodied-embedded and enactive approach to cognition in general is recommended by a proper understanding of the subject being engaged in intentional relations as being an embodied agent. Such agents are in possession of a number of capacities that allow them to be intentionally directed towards objects of all kinds. It is claimed here that such an agent's cognitive intentional relations are grounded in her motor intentional activities. Motor intentionality is systematically, phylogenetically and ontogenetically prior to cognitive intentionality. What this claim amounts to can be illustrated by referring to essential sources that feed into the enactive account: Husserl and Heidegger. Both of them criticized Brentano for giving too much

prominence to the cognitive intentionality of beliefs and desires, and in general to the problem of how it is possible for our mental states to be about or directed to non-existent objects. In contrast, they claimed that "the manner in which things are given initially is not theoretically, disinterestedly, neutrally to our sight, as it were, rather things are given as items involved in our various tasks and practical engagements, our 'comportments'" (Moran 1996, p.58). That is, according to these phenomenologists, we are primarily directed towards existing objects in practical, embodied and sensorimotor ways.

Embodied sensorimotor skills. This central phenomenological idea has been revived in the so-called 'enactive' approach to cognition, according to which the whole embodied organism embedded in its environment is the fundamental subject of experience and intentionality (Thompson 2007, Hutto 2008). One central claim of enactive accounts is that cognition is not merely achieved by neural activity alone, but to some extent by bodily and environmental factors, which play not only a causal but constitutive role in cognition (Clark 1997; Noë 2004, 2009; Wheeler 2005; Thompson 2007). On this view, cognition is an activity, enabled by the exercise of skillful know-how in the agent's active exploration of and coupling with its environment.

The enactive approach to perception emphasizes the importance of sensorimotor skills exercised in the dyadic interaction with objects. This can be illustrated in an analysis of perception: Husserl already argued that a perceived object is never given in its full detail. Since we always perceive it from some point of view, we always only perceive some specific profile of it. We see the side facing us, while the other sides are hidden. Yet, although we do not directly see these other sides, phenomenologically speaking we have a distinctly perceptual sense of their presence in our actual experience of the side facing us (Hua 16, 176). For example, when you see a yellow lemon, a yellow round object is presented to you; and the correct description of your phenomenal content is not that of a flat two-dimensional screen, although you are only presented with exactly that from where you are standing. What you perceive is a round voluminous object. When you encounter this object for the first time and explore it, then you have to perform certain actions, e.g. eye- or head-movements, in order to make the hidden profiles visible. For example, in order to see the reverse side of the lemon, you must either go around it, or grasp it and turn it around. In this way, in comprehending an objects' complete profile you draw on your know-how, i.e. on a set of sensorimotor skills you are equipped with and which you can refine in your ongoing exploration of the world. Alva Noë (2009, 60) puts this central idea of the enactive approach to perception this way: "Seeing involves moving the eyes and head and body. ... Movements of your eyes or your head or your body actively produce changes in sensory stimulation to your eyes. Or, put differently, how things look, depends, in subtle and fine-grained ways, on what you do. Approach an object and it looms in your visual field. Now turn away: it leaves your field of view. Now shut

your eyes: it is gone. Walk around the object and its profile changes. ... There are patterns of dependence between simple sensory stimulation on the one hand and your own bodily movement on the other. ... Seeing is a kind of skillful activity."

Affordances. In all these activities necessary for perception, your body plays a constitutive role. For one thing, spatial objects can only be experienced by embodied subjects, which are situated and embedded in their environment. Moreover, your body constitutes the point of view from which you perceive objects in the environment, and thus functions as an egocentric principle of experience; and finally, as the analysis above has revealed, every perception of an object is mediated and made possible by the body. Your body is first and foremost not experienced as one object among others but with respect to its potential for action as an experiencing organ. Thus, the kinesthetic experience of your body is correlated with your object experience and, moreover, it presents objects as providing you with various possibilities for action. Thus, new emergent properties arise from the sensorimotor coupling with the environment: affordances (Gibson 1979). These are opportunities for perception and action offered by objects in the environment. A surface, say, may be horizontal and rigid such as to allow you to walk on it. That makes it 'walk-on-able'; it may also be 'sit-on-able' and 'stand-on-able' etc. At the same time, the features of the surface may prevent other actions and they may provide organisms of a different kind with yet other affordances. That is, such possibilities for action are not fixed properties, but vary as a function of the successful coupling between this specific agent and its environmental niche. They may differ for other organisms. Quite often, we even perform certain actions and use tools to change environmental structures in order for them to afford various other actions. In this respect, the coupling between agent and environment displays a certain dynamics.

Online intelligence. All this is especially plausible developmentally, since an infant's primary encounter with objects in the world is characterized by what they can do with objects rather than what these objects are exactly. Experiments by Sommerville and Woodward (2005) suggest that active experience also modulates an infants' *understanding* of simple actions. One of their studies shows that active experience using tools may enable infants to build motor representations of tool use events that subsequently guide action perception and support action understanding. Children can more easily detect and understand actions they have performed themselves than actions they have only observed being performed by someone else. Their understanding of the intentional actions of others may be facilitated by sensorimotor action representations that have been produced during their own performance of the same or similar actions. In this sense, Husserl was right to claim that in our dealings with the world, the practical *I can* is more fundamental than the cognitive *I know* (or the *I think*). And it is in this sense that one should understand the claim that cognitive intentionality is grounded in motor intentionality.

Another way to put this point is by emphasizing the important function of perceptual experience of enabling successful navigation in the environment. Wheeler (2005, p.12f) calls this *online intelligence*: “A creature displays online intelligence just when it produces a suite of fluid and flexible real-time adaptive responses to incoming sensory stimuli”. Online intelligence is to be contrasted with *offline intelligence*, exhibited when pondering on a mathematical problem or deliberating about whether to move to another city. The present framework argues for the primacy of online intelligence over offline intelligence.

To sum up, the enactive account to cognition emphasizes the foundational and constitutional role of embodied *sensorimotor skills* for cognitive acts like perception. The corresponding kind of knowledge that is brought to bear in these situations is not propositional knowledge-that but rather a skillful *know-how* to cope with the environment in online cognition. Such know-how is implicit rather than explicit and can seldom be spelled out by those who possess it (Ryle 1949). A paradigm example is knowing-how to ride a bicycle. *Affordances*, the final notion that has been emphasized, are properties that emerge from the successful *coupling* of agent and environment and change in accordance with their *dynamic* relationship. In the next section, these ideas are applied to the social domain.

3. Enactive Social Cognition

Although it is easy to see how these ideas translate to the social domain, there is as yet no comprehensive account of enactive social cognition, apart from some noteworthy yet sketchy attempts (De Jaegher & DiPaolo 2007; Thompson 2007; Hutto 2008). Consider first the *primacy of embodied and sensorimotor skills*: Due to the dominance of theory-theory and simulation-theory, social cognition has often been interpreted in a very sophisticated way, based on the passing of false-belief tasks at around the age of four or five years. Everything that goes on before that age has (unjustifiably) been considered as a mere precursor to the real thing (cf. the modules distinguished by Baron-Cohen 1995, Ch. 4). According to the enactive approach, not only object perception is essentially embodied in the way specified. Social cognition is also fundamentally embodied and embedded, since the most intimate and basic encounter between two subjects is that in direct social interaction where gestures and facial expressions play a dominant role. Many critics have recently suggested that when we are actively and directly engaged with another, we do not need to draw theoretical inferences or engage in mental simulation. Instead, we have more basic and simple means for getting a grip on other minds: Once we drop the questionable separation between an inner (meaningful mental) and an outer (meaningless behavioral) realm and reject the premise that mental states are abstract entities hidden in someone’s mind, there is room for the alternative view that we can often *directly perceive* other people’s mental states, e.g. feelings and intentions, since mental states are not abstract theoretical entities,

but essentially embodied and revealed to others in expressive behaviors like gestures and facial and other bodily expressions (Gallagher 2001, Ratcliffe 2007). Not only do we ourselves convey our feelings to others through facial expressions, we also use their bodily expressions as cues to what they feel and intend to communicate. Video-replay studies demonstrate that young infants have a good sense for appropriate bodily and facial responses from the caregiver to her own communicative signals since they respond when they are out of synchrony.

Moreover, my own eye- and head-movements are not only crucial for my own perceptual states. They also play an important role as cues for another subject to find out where I am looking and/or to establish joint attention with me. Consequently, Corkum and Moore (1995) found that it was easier for infants to locate a target if this was activated on the same side as an adult model’s head turn than when it was activated on the side opposite to the adult’s head turn. They also investigated the origins of the gaze-following response necessary for joint attention and found that head orientation information is more important for infants below twelve months than eye orientation information. Only at eighteen months gaze following is reliably produced when eye movement is the only cue. Thus, it seems that such bodily cues are important to different degrees in the course of development.

Earliest forms of social understanding are proto-conversations and dyadic emotional engagements between infant and caregiver. They are clearly based on embodied practices, which the infant can engage in from the very beginning. In numerous studies, Meltzoff & Moore (1977) as well as Kugiumutzakis (1998) have established that neonates can imitate simple facial expressions. This has been interpreted as demonstrating an intimate connection between proprioception of one’s own bodily actions and one’s perception of the bodily actions of others, mediated by an innate body schema (Gallagher & Meltzoff 1996). But it also demonstrates an early form of social coupling, i.e. the fact that adult and infant can form a conversational unit from the beginning.

Partly, the spectacular finding of mirror neurons may also be interpreted in support of the claim that we can detect intentional states with a kind of immediacy, since perceiving other’s actions activates one’s own motor program responsible for that particular action (Rizzolatti & Sinigaglia 2008). Mirror neurons also fire differentially depending on which action chain a bodily movement is embedded in. Interestingly, they fail to be activated for observed actions that are not part of the observer’s own motor repertoire (Buccino et al. 2004). I take it that these sensorimotor neurons support and enable the perceptual understanding of intentional action, and that the activation of one’s own motor system reflects the foundational role of motor intentionality for cognitive intentionality. This interpretation is anticipated in Merleau-Ponty’s phenomenological claim that one can *see* one’s own possible bodily actions *in* the actions of the other (Merleau-Ponty 1964, p.117).

That infants take pleasure in directing the attention of the caregiver to oneself or to one’s actions can be seen in the

still-face procedure: Between two and three months they already actively seek to re-engage a parent's attention when it has been disrupted (Murray & Trevarthen, 1985). Reddy (2003) argues that infants acquire an understanding of attention already in the first few months of life, primarily on the basis of the caregiver's attention towards some aspects or actions performed by the infant or the infant as a person. That is, the infant is first confronted with attention to the self and then to some aspect of the self or the self's actions. She argues that in scenes of *dyadic* mutual attention infants already demonstrate a *capacity for* and an interest in dealing with other's attention and that this provides the infant with the experience required for *further developing* her intentional repertoire. In the context of joint attention, attention is best characterized as an *act* of attending rather than an information-bearing mental state that arises passively. Focal attention is a continuous process *executed by the human agent*. The infant's alternation of attention on the object and the other subject (which is constitutive for joint attention) is essentially active and embodied since it involves head and eye movements, and possibly pointing gestures as communicative signals to direct the others' attention.

Gaze and Engagement with other agents. Direct interaction with another agent in joint attention also modulates our own processing of that object. Becchio et al. (2008) found that objects under the gaze of others "acquire properties that they would not display if not looked at", namely the gaze "enriches that object of motor, affective and status properties that go beyond its chemical or physical structure" (2008, 254). The authors call this "intentional imposition". – Other studies have shown that by twelve to fourteen months of age infants can use the gaze of others to predict a person's subsequent actions (Phillips, Wellman, Spelke 2002), can interpret a person's emotional expressions as being about the object at which she gazes (Repacholi 1998), and can interpret the words a person utters as naming the object at which she directs referential behaviors (Woodward 2003). Finally, Moll et al. (2007) demonstrated that one-year olds can attribute knowledge and ignorance to others but that such knowledge-ignorance understanding strongly depends on the joint engagement between infant and adult. Such knowledge could not be demonstrated independently of such engagement. These data support the interplay between object perception and social interaction. They also support the notion that embodied practices and active engagement with another agent plays a crucial role for (social) cognition.

Reciprocity and social affordances. Primary intersubjectivity in direct face-to-face social interaction between infant and caregiver displays an important dynamics and reciprocity that is crucial for *online* social cognition quite generally. Understanding others is typically not a unidirectional process: My own efforts to engage with the other prompt reactions feeding into a communication 'loop' characterized by *reciprocity* (Frith 2007, p.175). The importance of this is underestimated by theory-theory and simulation theory: Since they presuppose a detached observational stance towards the other (*offline* social cognition) instead of a more engaged

interaction, they fail to account for this reciprocity. Basic social understanding is based on a sensitivity to "expressions of intentional and affective attitudes, as revealed in another's gaze, gesture, facial comportment" etc. (Hutto 2008, p.117). But in addition, perceiving the *meaning* of another's bodily expression requires processing the *social affordances* (Costall 1995) provided by them, analogous to the affordances provided by objects we perceive. The coupling between two agents in direct interaction is even more complex than the coupling between agent and environmental object. Due to the general flexibility and unpredictability of others in social interaction and a higher degree of uncertainty, social affordances are richer and more complex than affordances provided by objects. But they can prompt appropriate actions and reactions in a conversational context, culminating in the maintenance and extension of reciprocal relations. And healthy human beings can distinguish and pick up deliberate as well as inadvertently emitted communicative signals and to intuitively grasp the communicative context in which to make sense of another's behaviour (Senju & Csibra 2008). The studies mentioned earlier suggest that infants already possess this skill.

Autism. All this is crucial for the interpretation of autism as a social cognitive impairment. The enactive approach offers an interpretation of autism different from the traditional diagnosis as a lack of theory of mind based on a failure in false-belief tasks (Baron-Cohen 1995). It has recently been demonstrated that autistic patients can indeed pass such tasks when prompted to do so explicitly. Yet, this does not improve their social skills in direct interaction. As Senju et al. (2009) conclude from their study, patients with Asperger's are impaired in the "automatic online computation of others' mental states". They are not impaired in mindreading generally, but lack the more basic social skill to spontaneously encode socially relevant information and understand gestures and facial expressions *as* expressions of emotions (see Lee, Meyer, Hobson 1997). Thus, if autism is seen as a more general deficit in the sensorimotor, embodied and implicit *know-how to deal with other people*, this account can also explain other peculiarities significant for autism that have nothing to do with social cognition, e.g. the problems in lying, righting, sitting, crawling, and walking (Gallagher 2001).

4. Conclusion

In accordance with the enactive approach, it has been argued that cognition is based on sensorimotor skills executed by the organism as a whole in its exploration of objects in the immediate environment. It has been shown how central ideas from enactive cognition can be transferred to the social domain. The *primacy of embodied sensorimotor skills* is obvious in online social cognition when two agents are directly engaged in social interaction. *Social affordances* emerge from the *coupling* between two agents. Picking them up can prompt appropriate reactions, which in turn culminate in the *dynamics and reciprocity* characteristic of online social cognition. Displaying and perceiving bodily expressions of feelings, intentions etc. allows for a *skillful know-how* to deal

with other people, a spontaneous social understanding below and before mindreading which is impaired in autistic subjects. Direct engagement in online interaction also modulates object cognition. In this sense, it has been demonstrated that motor intentionality is more basic than cognitive intentionality both for object cognition and social cognition. Thus, if this foundational role can be spelled in more detail, then it promises to lead to a comprehensive account of intentionality.

Abstract

Naturalistic observations of infant/caregiver social attention have yielded rich information about human social development. However, observational data are expensive, laborious, and reliant on fallible human coders. We model interactions between caregivers and infants using a three dimensional simulation environment in order to gain greater insight into the development of infant attention sharing, specifically gaze following. Most models of infant cognition have been only abstractly linked to the detail of a real life environment and to the perception-and-action physicality of human infants. Our simulation uses human data from videotaped infant/caregiver interactions and a rich 3D environment to model the development of gaze following. Initial tests suggest that infant gaze following can be learned in our simulation using parameters derived from behavioral data.

Keywords: embodiment; infancy; joint attention; simulation; social learning.

Human communication is a dauntingly complex system to model. Consider a seemingly simple system like an infant and caregiver playing together: even with language pared away, infant/caregiver social interactions feature a wide range of behaviors. These take place across many time scales in a complex environment. Moreover, the infant is a moving target; its brain and behavior change rapidly, and this requires caregivers to adapt to the infant's changing skills. Thus it is difficult to generate a powerful model of infant social behavior and learning.

Developing such a model is important because there is ample evidence that early social development has long term effects on (and likely serves as a foundation for) later social cognition, language, and even cognitive style and exploratory behavior [1]. In this paper we describe a modeling approach that is unique in two key areas, extending the approach introduced in [2]. First, we model both the learning agent (in this case the infant) and the agent's environment. Many models of infant learning use an abstract symbolic environment with little relation to the dynamic world infants experience. Ideally, simulations are comprised of both a biologically plausible learning model, and a physically and socially realistic environment [3]. The latter requirement is problematic because detailed data on the structure of infants' learning environment only exist in bits and pieces. Our second innovation is to directly tie behavioral data collected by our lab into our

simulation environment, creating rich and realistic stimuli for our learning agent.

In the following subsections we will review the theoretical issues relevant to this work.

Embodied Modeling The goal of developmental modeling is to test theories of learning processes as they take place within organisms undergoing gross changes. Valid tests of these theories require additional theories as to the information patterns found in realistically structured environments [3]. Currently, however, we do not possess the computational resources to model human perceptual and neural systems, and our technological ability to simulate real, multi-modal environments is still primitive. The key, then, is to gradually converge on a set of biological traits that capture key properties of learning, as well as some key ecological patterns that can be simulated at a level of detail that is appropriate for the theoretical question at hand. This typically requires consideration of the physicality of the organism and the environment. That is, to test our theories with greater validity we must incorporate the embodiment of our models [4]. To the degree that we can embody simulations, we improve our tests of the motivating theory of development and learning.

Robotic studies are one way to achieve embodied simulations, and there are a growing number of good examples [5, 6, 7]. Robots can be placed in the same environments as infants and presented with identical stimuli. Unfortunately robotic studies are expensive, and they introduce tangential methodological issues—they require solving mechanical and computational problems simply to begin testing learning theories. Solving these problems is certainly important for some theoretical questions, but it is not currently necessary to address basic questions about infant social development. Additionally, robotic models cannot be run faster than real time, and they require active supervision. In many cases, current theories can realize faster progress by using simulations that retain elements of embodiment while greatly simplifying implementation and reducing cost.

Gaze Following We have been investigating the development of attention sharing behaviors in human infants. Attention sharing is a behavioral cornerstone of all social learning. In general it means one or more agents changing their fo-

cus of attention because they have observed another individual attending to some stimulus or area. A common example is following the line-of-gaze of another person. There is an extensive literature on the development of infants' attention sharing skills. This literature has focused on the development of gaze following, which is defined as reorienting one's direction of gaze to intersect with that of another person, based on encoding the other's head pose and/or eye direction.

Infants begin following other people's gaze between 6 and 12 months of age, and their ability to follow more and more subtle cues, to a wider range of their environment, increases significantly between 9 and 18 months of age [8, 9]. It is unknown by what mechanism infants develop more powerful gaze-following skills.

We have hypothesized [10] that infants' gaze following skills might emerge as the byproduct of a "basic set" of perceptual, learning, and affective traits that are in place within the first 2 to 3 months of age, well before fully developed gaze following can be observed. The basic set theory states that the following elements are sufficient (though not necessary) for joint attention:

- A set of motivational biases, in particular a preference for social stimuli such as human faces.
- Habituation as a basic reward attenuation mechanism.
- A learning mechanism such as temporal difference learning [11], to learn the temporal structure of predictable, contingent interactions between infant and caregiver.
- Early emerging perceptual traits such as attention shifting, face processing and sensitivity to motion, contrast, and color.
- A structured environment providing strong correlation between where caregivers look and where interesting things are.

This basic set of infant traits might be sufficient to generate new attention sharing skills. However, this requires that the infant learn on a regular regimen of well structured social input, as provided by an organized caregiver [10]. Our modeling efforts are meant to prove the plausibility of this theory. If they are unsuccessful, then perhaps additional mechanisms, such as special-purpose modules, are necessary for an agent to learn gaze following skills during the first 6-9 months of human social experience. The question, then, is how to generate valid simulations of this social learning process. We must imbue the simulated infant with biologically plausible perceptual, learning, and motivational traits, and we must imbue its environment with a reasonable facsimile of a natural social environment.

Naturalistic Social Coding The fine-grained structure of infant social environments is difficult to quantify. Although it is possible to derive gross patterns from previous observational and ethnographic behavioral studies, these tend to be sparse in details, and coded at such a low sampling rate

that there is no information about caregivers' meaningful moment-by-moment action patterns. In most experimental studies of infant social responses, the social input from the adult is controlled and extremely artificial (e.g. [9]). Although these experimental studies are critical for establishing developmental "benchmarks" that a simulated infant should replicate, they do not provide information about real infant learning environments, which can be abstracted for simulation.

Our approach to solving this problems starts by generating a dense, rich video dataset of minimally directed interactions between infants and caregivers. Figure 1 shows one frame of these interactions from two separate viewpoints. By coding these interactions at 30fps in the manner described below, we generate a temporally detailed dataset that opens a new window into infant/caregiver interaction in a natural setting.

In the following sections we will explain our methodological workflow, describe the machine learning and computer vision techniques driving our simulated infant, present results from the simulation environment, and finally discuss the impact this work has on the modeling of infant social interaction.

Workflow

Our lab takes an end-to-end approach to infant social modeling (see Figure 2)—we start in the lab and in the homes of our subjects by collecting hours of audiovisual data from infant/caregiver interactions. These data consist of both semi-naturalistic free play sessions and scripted lab sessions. In the free play sessions caregivers are instructed to play with their infants using a supplied set of toys while the infant is seated in a tray chair. In lab sessions an experimenter performs a series of gaze and point maneuvers to salient objects in the room while holding the infant's attention. In both cases the interactions are recorded with audio from multiple camera angles. The lab has amassed many terabytes of this audiovisual data, which is passed off to a team of undergraduate research assistants who perform a detailed frame by frame coding of relevant events (e.g. gaze shifts, manual actions, environmental and toy-generated noise). These codes are stored in a database in order to facilitate an automated analysis of infant/caregiver behavior using custom software written in C# and Python. The automated analysis derives information from the coding such as the probability of the infant or caregiver to transition from one state to another (e.g. from looking at a toy to looking at a social partner), the duration of their actions, and extended events where the infant and caregiver move through a specified series of states within a restricted time window [12].

Our simulation environment can operate in two modes. In the first, it simply replicates caregiver behavior from a particular experimental session using the codes in the database. If the real-life caregiver started off looking at the infant and then switched to looking at a toy after 2.3 seconds, the simulated caregiver will do the same. In the second mode, the care-

Figure 1: Still picture from naturalistic study, from which the simulated caregiver behavior is derived.

giver behaves probabilistically based on the transition probabilities and timings derived from the automated analysis. In this way, the caregiver behaves realistically without replicating the steps of any particular subject; the simulation can run indefinitely. For example, if our data indicate that caregivers transition from holding an object to holding and moving an object 20% of the time that they change what they are doing, then our simulation likewise will make that transition 20% of the time. In addition, this mode allows our caregiver to (in principle) respond contingently to previous actions of the infant. Our simulation environment is implemented in C++ and we use hardware-accelerated OpenGL for the 3D rendering. Unfortunately, to our knowledge there is no open software for human simulation, so we use Boston Dynamics’ DI-Guy platform for rendering and animating our caregiver and props. Finally, at the end of the chain, our infant learning agent processes rendered frames of the simulation using the OpenCV computer vision library [13]. At each time step of the simulation the *only* information the infant agent receives about its environment are these rendered frames—it extracts a reward signal and high level information about the environment using the computer vision techniques described in the next section.

Methods

There are three primary components to our simulation, the caregiver and environment, the infant agent’s visual processing system, and its learning system. In this section we will detail the three components, starting with the caregiver and environment.

Caregiver and Environment Our simulation environment is set in the interior of a room containing a table and a chair. The caregiver is seated at the chair and interacts with toys placed on the table (see Figure 3, top). The caregiver is capable of interacting with more than one toy, but for our initial simulations we used just one toy, a red bus, for simplicity. The simulated caregiver occupies several different attention

Figure 2: A flow chart depiction of the data collection, analysis and modeling work in our lab, annotated with relevant technologies.

and action states. It can be: waving or not waving its arm, looking at the infant or the toy, and holding the toy or not. These states correspond to codes for caregiver motion, caregiver gaze target, and caregiver held object status in our empirical data. Because our caregiver is simulated as an actual body, these discrete behavior states manifest to the infant as a wide range of visual stimuli. For example while waving an object the caregiver’s arm can be in many positions. Similarly, when looking to an object the caregiver’s head pose varies over time as the motion is undertaken and the final head pose is based on the actual position of the object in the room.

From these data we also estimate the probability of transitioning between any of the states, and the simulated caregiver chooses its actions probabilistically based on these estimates (the caregiver is operating in the second mode de-

scribed above, not off a script). The caregiver uses two transition matrices: the first governs behavior with respect to the toy (holding and waving) and the second governs looking target. The interval between state transitions is based on the observed interval between separate caregiver behaviors (every 2.18 seconds) plus some uniform noise (± 1 second).

The infant also has a body in the environment (unseen from its perspective), with its head at about high-chair height. Changes in infant gaze target are accomplished by tying the position and orientation of a camera to the position and orientation of this body's head.

The objects in the environment are part of the DI-Guy package, which has a nice variety of (mostly military themed) props. A text configuration file specifies the props to load at the start of the simulation as well as their location, orientation and scale. Similarly, the text file specifies the initial location, orientation and appearance of human agents. In this way we can quickly modify the appearance of the simulation, add agents, and rearrange props.

Visual Processing In order for the infant agent to learn from its raw visual input, it needs to extract high level information about its environmental state as well as determine the reward value of the state that it is in. Since we are interested in gaze following, we extract the caregiver head position from the raw image, estimate head pose and use the discretized pose state as the infant agent's environmental state. To do this we first localize the caregiver's head by calculating the probability that each pixel in the raw image came from the known distribution of pixel properties in caregiver head pixels, running a Gaussian blur over that probability map, and then centering a head position rectangle over the maximum probability point on the blurred map. Technically, this is an application of `cvCalcBackProject` (to calculate the back projection of our face color histogram), `cvSmooth` (the Gaussian blur) and `cvMinMaxLoc` (to find the location of maximum probability in the image) from the OpenCV library. Pragmatically, we're only assuming the infant knows broadly what its caregiver's face looks like.

To calculate the head pose, we break the detected head region up into a left and a right segment then perform a color histogram comparison between the observed segments and model segments of left and right facing heads (using `cvCompareHist`). From the histogram distances we can calculate the probability that the caregiver is looking left or right by seeing how close the observed segments are to the models. If the segments are distant from both models we can infer that the caregiver's head pose is center. Again, the only assumption is that the infant knows generally what left and right facing heads look like. Finally we discretize the head pose probability into three states: left, center, and right. A visualization of this head position and pose detection can be seen in Figure 3, middle. The box represents the head position and the handles represent the pose probability.

To compute the reward for the current frame of input, we first calculate a salience map over the entire frame. The

Figure 3: From top to bottom: the raw visual input to the infant agent, head detection and pose estimation output, salience and reward visualization.

saliency map has three components: motion, contrast, and saturation, and it is similar to salience-based visual processing approaches such as the one in [6]. The components are summed to represent overall saliency. Motion is calculated by comparison with the previous input frame (`cvAbsDiff`), contrast is derived from an edge detection routine (`cvSobel`), and saturation is extracted naturally

from the color values of the pixels. Reward is then calculated by averaging the saliency values within the agent’s center of vision (see Figure 3, bottom—the reward area is inside the rectangle). Since the agent only chooses looking direction on the horizontal axis, the center of vision is defined to be taller than it is wide.

Learning The agent uses a reinforcement learning [11] paradigm to choose its actions and learn from the consequences. Its state-action space is a cross of the discretized caregiver head poses and a set of five looking directions: left, near left, center, near right, and right. Every time the agent shifts gaze position, it updates its expected reward for the previous state-action pair using the following formula

$$er(i, j)_{new} = er(i, j)_{old} - \eta(er(i, j)_{old} - ar)$$

where $er(i, j)$ is the expected reward given caregiver head pose i and gaze action j , η is a learning rate parameter (set to 0.1 in our simulation) and ar is the average reward obtained since the last action j in state i . The agent changes gaze pose after a period of time derived from observed infant behavior (every 2.43 seconds) plus some uniform noise (± 1 second—a more complex but more realistic approach would be to draw fixation duration from an estimate of the fixation duration probability density function from actual infants).

It would be straightforward to increase the number of states and actions (e.g. by giving caregiver and infant looking direction a vertical degree of freedom) and add bells and whistles to the reward estimation process, but the purpose of this work is not to showcase machine learning techniques. Rather, we are investigating whether gaze following can be learned given a simple learning mechanism, data-driven caregiver behavior, and a complex simulated environment. The results of this endeavor are summarized and discussed in the next section.

Results

We ran our simulation for approximately 500 seconds (enough time for the infant to shift gaze about 200 times) with the infant agent watching a simulated caregiver interact with a single toy. The agent’s expected reward over its state-action space is detailed in the table below. Looking at a location in the room with background (i.e. smallest) saliency results in a reward around 6.0, so that quantity is subtracted from the below numbers.

CG Pose	Looking Direction				
	left	near left	center	near right	right
left	1.30	1.54	3.58	2.62	1.79
center	1.09	2.62	8.50	3.20	1.97
right	1.56	1.72	1.71	1.43	0.76

Table 1: The final state/action reward space of the infant learning agent.

The course of learning over time is shown in Figure 4. The agent quickly learns that congruent gaze shifts result in higher

reward and the advantage in expected reward generally increases over time.

Discussion

After a fairly short period of training, the agent expects more reward when its looking direction is congruent with the caregiver’s head pose than when its looking direction is incongruent. For example, if the caregiver is looking to its left, then if the infant looks to the right it expects more reward (the infant and caregiver are facing each other and thus their looking directions to the same location are opposite). Both the near and far looking directions show this effect. Looking right in general is privileged because the caregiver is left handed (it only picks up objects with its left hand), and thus during time periods where the caregiver is holding the toy it is more likely to be near or far right than near or far left (from the infant’s perspective).

Looking center is always very rewarding since the caregiver is at center. When the caregiver holds an object it will often be at center, and when it moves the object it generally is at center or near right. Motion is highly rewarding, and the caregiver is normally looking at center during motion, so the center/center expected reward is quite high. The caregiver also has a naturally higher contrast than other parts of the environment.

This general pattern of results fits other recent findings. It seems that infants in everyday setting are highly attentive to caregivers’ manual actions [12], and this might bootstrap infants’ learning of caregivers’ head pose (because adults often look at what they are manipulating). It is also known that infants are attracted to faces, and the simulation results are consistent with that. Since the head pose and position estimation are not used in calculating reward, the infant agent learns that looking center (where the caregiver’s head is) is valuable independent of the general knowledge about head appearance that it has.

These first results show that with a limited set of assumptions, a simple learning model, and a complex data-driven environment, gaze following can be learned. More importantly, this work sets the stage for even more detailed simulation of infant/caregiver interaction—such as interaction between more than two agents (a sibling agent, perhaps), reaching and grasping capability for the infants, and realistic audio cues. Further, since the infant agent no longer receives knowledge about its environmental state other than through visual processing, its input will degrade meaningfully and realistically. For example, if the infant picks up an object that occludes the caregiver, its head position and pose estimates will degrade realistically.

In the greater context of understanding infant social development, from modeling to robotics to experimental work, we see this as occupying a productive niche between disembodied and discretized 2D models and robotic agents. We open computer simulations up to state and action space complexities that mirror those in the real world, but our learning

Figure 4: The sum reward expected from highly congruent gaze shifts (red, top right and bottom left of Table 1) and incongruent gaze shifts (blue, top left and bottom right) over the training period.

simulations are more convenient and we can have complete control over the agent and environment. Moreover, our simulations do not require the expensive and complicated hardware of robotic simulations; nor do they force us to address interesting but difficult and peripheral questions about motor control.

Abstract

To understand the development of infant comprehension of visual obstructions and perspective-taking, this study tested the ability of $N = 28$ infants at 14, 16, and 18 months to adapt attention-sharing to visual constraints. An experimental task investigated how infants modify gaze following behaviors when an adult's line of sight is obstructed by a barrier. From 14 to 18 months, infants gradually learned to modify their search behavior when an adult looked toward a referent hidden behind a barrier from the infant's perspective. This suggests development of perspective-taking during this period. It also reveals age-related changes in infants' understanding of contextual effects on others' referential gaze in visually complex environments. Furthermore, the results address debates about "rich" versus "lean" theories of shared attention and intentionality.

Keywords: Perspective-taking; referential gaze following; visual obstruction; intentionality; cognitive development; social cognition.

Introduction

Infants learn socio-cultural routines and communicative patterns by sharing attention with adults. As they move into early childhood, 1- and 2-year-old infants gradually learn how another's attention can differ from their own; that is, they learn to take other people's visual perspectives in a shared environment. A critical component of this ability is *attention-following*, whereby infants follow the direction of attention of a more experienced person (e.g., a parent) to shift focus to interesting features of the environment. The clearest manifestation of this is referential gaze following, a type of triadic interaction which involves at least two people and a common referent. Referential gaze following is a two-part process: 1) one person directs her own attention toward a referent by orienting her eyes and usually her head, and 2) another person sees this behavior and consequently shifts attention in the direction of that referent (Butterworth & Jarrett, 1991; Scaife & Bruner, 1975). It is well established that referential gaze following plays a critical role in social learning, communication, and mental-state inferences (Argyle & Cook, 1976; Deák et al., 2008; Kleinke, 1986).

A question that has generated interest is how attention-following in general, and gaze following in particular, supports our inferences and predictions about the mental states of others. When one person subjugates her current interest to follow another person's attention, it may be assumed that the former is taking the latter's visual perspective. This implies that the follower imputes a mental or physiological state to the "looker." Indeed, adults

attribute another person's direction of gaze to an internal state—their attention. However, it is difficult to tell what inferences infants make, or mental states they attribute to the people whose gaze they follow. Because infants cannot articulate their inferences, we can only observe their behavioral responses to other people's behavior (i.e., gaze-shifts). More generally, we do not know whether and how infants understand "seeing." Thus, the manner in which infants come to understand the "mental experience of seeing something" in others remains controversial (Caron, Butler, & Brooks, 2002).

"Rich" versus "Lean" Interpretations

One controversy about how children understand another person's looking behavior focuses on two distinct developmental interpretations. At one end, "rich" interpretations of gaze following assume that the follower explicitly represents the looker's intention to look in a particular region (Baron-Cohen, 1995; Woodward, 2003). At the other end, "lean" interpretations assert that gaze following emerges from simpler perceptual and learning processes, and structured social information (D'Entremont, 2000; Nagai et al., 2003; Triesch et al., 2006). Yet other positions focus on the transition from lean to rich inferences about others' gaze (Butterworth, 1998).

The rich interpretation refers to evidence that infants understand adults' gaze following behind visual obstructions (Brooks & Meltzoff, 2002, 2005). It also considers evidence that by 2 years, toddlers use adults' patterns of looking and emotional display to interpret their intentions (Tomasello, 1999). By contrast, the lean interpretation refers to evidence that infants' gaze following is modulated by factors such as target salience and the salience of an adult's head turn (Deák, Flom, & Pick, 2000). Also, earlier studies showed that infants follow an adult's head angle, but not eye direction (Corkum & Moore, 1998; Triesch, Jasso, & Deák, 2007). This is noteworthy because if infants do not know that the eyes mediate visual attention, then they do not grasp the basic mechanics of *seeing*. However, this conclusion has been challenged (Brooks & Meltzoff, 2002, 2005), as we review below. Given the diversity of evidence, we must consider the task paradigms used to test infants' knowledge. Since people eventually develop rich beliefs about looking and seeing, the controversy is inherently developmental. The question is at what age, and by what process, do children make mentalistic inferences about looking? Such inferences relate to the

origins of perspective-taking (Flavell, 1977). We now consider research evidence for age-related changes in infants' responses to looking and visual perspective-taking.

Age of Emergence

Recent studies have debated the age at which referential gaze following and perspective-taking emerge. Between 6 and 12 months of age, infants begin following an adult's direction of gaze (Adamson & Bakeman, 1991; Butterworth & Cochran, 1980; Butterworth & Jarrett, 1991; Corkum & Moore, 1998; D'Entremont, Hains, & Muir, 1997; Morissette, Ricard, & Décarie, 1995).

However, the age at which infants develop *referential* gaze following (i.e., knowing that someone's gaze is directed toward a percept, by virtue of seeing) is disputed. Brooks and Meltzoff (2005) reported that infants as young as 10 months start to realize that others are "'visually connected' to the external world." However, this is the only study showing such early ability, and the data are equivocal. There is more convergent evidence that referential gaze following emerges sometime between 12 and 18 months (Brooks & Meltzoff, 2002; Butler, Caron, & Brooks, 2000; Caron et al., 2002; Dunphy-Lelii & Wellman, 2004; Moll & Tomasello, 2004). For example, Deák et al. (2000) found that under optimal conditions, 12-month-olds follow gaze to targets located behind them. This is evidence of referential gaze following since it entails the representation that the looker is behaving in a way "toward" something, which the infants cannot detect. However, computer simulations show that this ability can be learned without high-level mental representations (Triesch et al., 2007).

By 18 to 24 months, there is substantial evidence for robust referential gaze following, particularly to targets that are visually occluded. That is, infants infer the existence of unseen objects and make inferences about others' visual perspectives. Notably, this is the same age that they begin to make inferences about other's mental states (Dunham & Dunham, 1995; Tomasello, 1999; Wellman, 1993).

The most active debate, then, centers on 12 to 18 months: if infants show referential gaze following by 12 or 14 months, it will suggest that gaze following is perhaps the earliest form of inferring others' mental states. If, however, referential gaze following does not emerge until 18 months, it will suggest that multiple forms of mentalistic inference emerge around the same time.

Problematic Occlusions

Many studies of referential gaze following in infants use large, distal occlusions (e.g., screen-like barriers) to obstruct either the infant's or adult's direct line of sight to a referent (Dunphy-Lelii & Wellman, 2004; Moll & Tomasello, 2004). Butler et al. (2000) compared infants' responses to transparent versus opaque barriers that were placed between a target referent and the experimenter. They found that 18-month-olds responded to the presence of an opaque barrier, whereas 14-month-olds did not reliably infer whether or not the adult could see the target through the barrier.

However, Dunphy-Lelii and Wellman (2004), who also used transparent and opaque barriers, found no change from 14 to 18 months. Infants by 14 months followed the experimenter's gaze more often when the barrier was transparent than when it was opaque.

In addressing this divergence of results, Moll and Tomasello (2004) charged that the task was too unnatural. They therefore used a different paradigm in which the target was placed behind a barrier from the infant's perspective. If the infant followed the experimenter's gaze, she would only see a boring opaque barrier. However, if the infant understood that the adult was looking at something, she would move around to peer behind the barrier. Results suggested that this behavior starts to emerge in some 12-month-old infants, and is more robust in 18-month-olds. This goes beyond Butler et al.'s (2000) results to suggest that 12-month-olds do basic referential gaze following.

Goals of the Current Study

We sought to resolve uncertainties about the development of referential gaze following in the second year. Since no study has examined the *process* of emergence, we tested infants at 14, 16, and 18 months, as a part of a longitudinal study. By testing at 3 bi-monthly ages, we might resolve conflicting results from previous studies of widely differing age groups. We can also test the stability and predictability of individual differences in development, which has not yet been studied.

Similar to Moll and Tomasello (2004), we used opaque barriers in a distal barrier paradigm, but added some improved controls. With a barrier on each side, one barrier occluded a target from the infant while the other displayed a target to both infant and adult. By making one target visible, we assessed each infant's baseline gaze following. We compared this to each infant's tendency to move and peer around the blank barrier when the adult looked toward it. This verified that the infant could visually orient to the experimenter's head and eye direction, thus making interpretable the "more demanding response" (Moll & Tomasello, 2004) of peering around when the adult's looking behavior was ambiguous. That is, in actively leaning forward or moving to look around a barrier to an occluded object, the infant's behavior signals her awareness of the implications of the adult's looking behavior.

In sum, the current investigation seeks to: 1) establish age-related trends in infants' acquisition of referential gaze following when the physical environment suggests that another person has a different visual perspective; and 2) relate the results to prior, simpler gaze following skills. Therefore, the goal of this study is to establish the validity of referential gaze following tasks and examine their implications for perspective-taking.

Method

Participants

Twenty-eight infants (17 males, 11 females) participated at 14 months (mean age = 427 days, $SD = 7$), 16 months ($M =$

491 days, $SD = 13$), and 18 months ($M = 550$ days, $SD = 8$). All infants were walking independently by 12.3 months ($SD = 1.4$). Infants were primarily of middle-class households from the San Diego area.

Materials

Two featureless, rigid brown barriers (92 cm x 58 cm) were placed side-by-side 1.2 m apart. Two 2D foam shapes (10.2 cm x 10.2 cm) were used as target stimuli. The control target was a red circle and the experimental target was a red duck. A researcher (“cue-giver” or CG) interacted directly with the infant in a quiet, controlled testing room (4.0 m by 3.6 m). A second researcher (“observer” or OB) monitored and recorded the infant’s behavioral responses from an adjacent room. Target cues and locations were given by the OB to CG using a two-way radio and earpiece. A metronome was used to accurately time cue-length and inter-trial intervals. To control the visual scene, the CG wore a gray sweatshirt and tied her hair in a ponytail. Both the CG and parent were seated on the floor on cushions.

Procedure and Design

All infants participated in three sessions at 14, 16, and 18 months of age. Before each session, informed consent was obtained from the parent. Each session consisted of eight 10-second test trials.

Before the session, the barriers were placed on either side of the CG and the infant, who sat facing one another approximately 61 cm apart. Targets were attached to the middle of each barrier 46 cm above the floor. The control target was placed on the front of one barrier and the experimental target on the back of the other, relative to the infant. Barriers were angled so that both targets were visible to the CG, but only the control target was visible to the infant (Figure 1). The parent sat with the infant in her lap such that the infant could freely rise to walk around at will. The parent was instructed to provide no cues, and the infant remained seated between trials. The CG sat with her hands in her lap and displayed an open friendly expression.

To orient the infant to the target locations, the CG first held the control target at eye-level and said “[infant’s name], look!” As she placed the target on the front of one barrier, she said “I’m going to put it there.” The CG then held up the experimental target, saying “[infant’s name], look!” She then placed the target on the back of the second barrier, saying “I’m going to put it here.”

In each trial, OB gave the CG the onset cue, and the CG began the trial with an open-mouth smile. She called the infant’s name until eye contact was made, and after two seconds said, “[infant’s name], look!” The CG immediately turned to look directly at the target for four seconds. Then, CG looked back to the infant, establishing eye contact if possible, and said “Can you get it for me?” while executing another gaze cue to the target for four seconds.

After four trials (2 experimental, 2 control) in one left-right configuration, the barriers were switched between sides and the last four test trials were given. Between

sessions the barrier sides were counterbalanced. Across trials, condition (control, experimental), direction (left, right), and target (circle, duck) were also counterbalanced.

Figure 1: One configuration of the experimental setup.

Each session was recorded at 30 fps with four video cameras placed in the corners of the room at infant eye-level. The cameras recorded onto on-board hard drives, and simultaneously pushed video to be time-stamped and captured on a Level 5 RAID. In addition, a video camera with a fisheye lens was mounted above the infant’s head, and was time-stamped and captured in the same manner.

Coding

Videos of infant behaviors were examined frame-by-frame. The infant’s first look after each cue by the CG were coded (i.e., anticipatory looks were not examined). Furthermore, trials were coded only if the infant saw the CG’s cue. Possible visual directions included looks to the correct target, incorrect target, front of the barrier that hid the target in experimental trials, CG, and “other” (i.e., anything else in the room). Success in referential gaze following was defined as the infant looking to the correct target location (i.e., specified by the CG’s cue versus looking to the other target location or not looking at all). In a control trial, this meant looking toward the visible target after the CG’s cue. In an experimental trial, this meant leaning or moving forward to peer around the back of the appropriate barrier.

An *incorrect* look was coded if the infant looked at the wrong target or to the front of the appropriate barrier in the experimental condition. A *non-look* was coded if the infant did not look to any target, but instead looked at the CG or at an irrelevant feature of the room.

Results

Proportions of correct looks were submitted to a 3 (age: 14, 16, 18 months) x 2 (condition: experimental vs. control) analysis of variance (ANOVA) within subjects. There was a significant main effect of age $F(2, 25) = 2.56, p < .09$; 18-month-olds looked proportionately more ($M = 0.55, SD = 0.39$) to the correct targets than 14- ($M = 0.41, SD = 0.44$) or

16-month olds ($M = 0.48$, $SD = 0.40$). There was also a significant effect of condition $F(1, 25) = 147.70$, $p < .001$. Infants looked more to the correct targets when they were visible in the control condition ($M = 0.75$, $SD = 0.31$) than when they were hidden behind barriers in the experimental condition ($M = 0.20$, $SD = 0.29$). However, there was no significant effect for the age \times condition interaction, $F(2, 25) = 0.46$. Separate Student's t -tests were used to compare the factors of age and condition in looking behaviors (see Table 1). As expected, there was a significant difference between the control and experimental conditions for correct looks and non-looks ($p < .001$) at each age.

Table 1: t -tests comparing conditions across age.

Age	Correct Looks				Nonlooks			
	t	df	SD	p -value	t	df	SD	p -value
14	-7.43	27	0.39	$p < .000$	7.55	27	0.34	$p < .000$
16	-10.87	27	0.29	$p < .000$	9.53	27	0.24	$p < .000$
18	-7.03	27	0.38	$p < .000$	5.13	27	0.36	$p < .000$

Longitudinally, 71% of the infants performed steadily well in the control condition, while 4% of infants performed similarly well in the experimental condition. Comparatively, 14% of infants in the control condition and 21% of infants in the experimental condition improved in their performance from 14 to 18 months. Across all 3 age groups, 11% of infants in the control condition and 25% of infants in the experimental condition showed mixed abilities.

In addition to significant effects of age and condition, as well as longitudinal performance, there were subtler developmental changes that occurred between 14 and 18 months. Generally, infants at 14, 16, and 18 months looked to the correct target in the control condition; this showed a trend of increasing consistency, with mean proportions of 0.69 ($SD = 0.40$), 0.77 ($SD = 0.27$), and 0.80 ($SD = 0.25$) at the three ages, respectively. In the experimental condition, the mean proportions of looks to the correct target also increased from 0.14 ($SD = 0.27$), to 0.18 ($SD = 0.26$), and 0.29 ($SD = 0.34$), respectively (Figure 2).

Figure 2: Mean proportions of success in looking behavior (with SE) in experimental and control conditions across age.

To understand these trends more fully, we examined the looking behaviors in each trial, distinguishing between correct looks, non-looks, and incorrect looks. Figure 3

displays these mean proportions at 14 months as a function of condition and looking behavior to illustrate the general pattern. While the general trends remained the same from 14 to 18 months, there was a decrease in the proportion of incorrect looks in the experimental condition from 0.52 ($SD = 0.31$) to 0.42 ($SD = 0.32$). Within the incorrect looks, looks to the front of the appropriate barrier in the experimental condition decreased from 0.39 ($SD = 0.25$) to 0.30 ($SD = 0.29$), and looks to the wrong target decreased slightly from 0.13 ($SD = 0.18$) to 0.12 ($SD = 0.16$).

Figure 3: 14 month mean proportions of looking behavior.

However, one concern about these parametric data is that nothing compels infants to rise and peer around the barrier—especially after having done so once, since they may not be motivated to continue looking at such simple targets. To address this, we considered a less demanding measure of infants' understanding that the experimenter might be looking at something they could not see. The "1 Trial Pass" criterion defined an infant as "passing" if she looked to at least one correct target by moving or leaning forward to look behind a barrier. Since the active movement of searching for an unseen target indicates intentionality, this seems to show some basic level of understanding of visual obstructions and referential gaze. (In support of this, infants virtually never got up to look around the barrier in control trials.) Results showed a steady increase with age in the proportion of infants who looked to the correct target. In the control condition, 82% of the infants at 14 months, and 96% of the infants at 16 and 18 months, passed at least one trial (i.e., followed gaze to the visible target). In the experimental condition, 25%, 43%, and 54% of the infants, respectively, passed at least one trial. Thus, twice as many infants at 18 months followed blocked gaze successfully than at 14 months.

Discussion

The results show that some infants at 14 months are starting to develop an understanding of visual barriers and perspective-taking in referential gaze. This development goes beyond the ability to merely follow gaze, since infants were clearly able to do so by 14 months, as shown by the results in control trials. In the experimental trials, however,

infants must determine that the adult is looking at a referent that the infants cannot see. At 14 months, some infants looked behind the barrier to the correct target, but did so much less than they looked to the front of the barrier. Yet at 18 months, infants peered behind the barrier to the correct target just as often as they looked to the front of the barrier. In addition, the “1 Trial Pass” analysis suggests that by 18 months, more than half of infants develop some Level 1 visual perspective-taking (Flavell, 1977), inferring an unseen target on at least one trial.

A longitudinal analysis suggests that a sizeable minority of infants improved in the experimental condition. Thus, there is some sort of learning from 14 to 18 months. However, there was also some within-infant variability between sessions, suggesting sources of unidentified situation-specific variability.

These results support Butler et al.’s (2000); 18-month-old infants respond significantly more than 14-month-olds to an adult looking behind barriers at hidden targets. Yet, possibly due to our more “natural” experimental design with multiple barriers and targets (inspired by Moll & Tomasello, 2004), our results showed a stronger effect than Butler et al. (2000). In their experiment, only 33% of 18-month-olds and no 14-month-olds leaned forward to look behind a barrier that obstructed a target. Thus, they concluded that infants at 18 months understand referential gaze and visual obstructions, whereas infants at 14 months do not. In the current investigation, 54% of the infants at 18 months and 25% of the infants at 14 months leaned forward to look behind the barrier. This demonstrates that visual perspective-taking develops considerably, and is clearly established, by 18 months, but it remains unclear whether 14-month-old infants have any functional capacity for visual perspective-taking. The current results suggest that some 14-month-olds are starting to develop an incipient understanding, as suggested by Dunphy-Lelii and Wellman (2004). However, we cannot say whether, for example, providing 14-month-old infants with additional training or reinforcement would increase their rate of responsiveness to an adult looking behind a barrier.

In order to better understand the developmental trajectory of referential gaze following, and to establish more precisely the age at which this understanding emerges, we considered results from a prior session in the longitudinal study. A subset of the infants ($N = 18$) who had performed simpler gaze following tasks at 12 months was compared to their performance at 14 months in the current task. Overall, the infants at 12 months occasionally followed gaze to visible targets ($M = 0.43$, $SD = 0.19$), but seldom followed gaze to targets located behind them ($M = 0.11$, $SD = 0.27$). This can be considered a “first step” towards referential gaze following. Furthermore, when subjected to the “1 Trial Pass” criterion, only 16% of the infants successfully looked to at least one target out of their direct view. By comparison, the same infants at 14 months made a similar proportion of successful looks to targets behind barriers ($M = 0.14$, $SD = 0.25$), but a higher proportion of them met the “1 Trial Pass”

criterion (28%) in the experimental condition. Generally, infants at 12 months seldom followed gaze to unseen targets located behind them, therefore failing to show referential gaze following ability. Somewhat more infants showed at least minimal referential gaze perspective-taking at 14 months. Thus, our results do not support claims that infants even younger than 12 months have a concept of intentional behavior (Brooks & Meltzoff, 2002). Rather, our data suggest a shift from a leaner interpretation of gaze following in most 12-month-old infants, to a richer interpretation in most 18-month-old infants. Given this shift, we favor a learning-based account (in which gaze following begins perceptually, and then becomes referential as well as intentional), over accounts that assume strictly either a maturational onset of perceptual processes or an inherent understanding of the referential nature of gaze following.

Between their first and second birthdays, most infants develop the understanding that there may exist some object of interest at which an adult is looking, and that adult visual perspectives, in general, offer useful information. From 14 to 18 months, infants learn that acting on that information, via referential gaze following, can be rewarding. Even if that information consists of a referent that is visually occluded, infants will deliberately move to a proper viewing perspective to search for the inferred referent. Notably, the gradual differentiation of performance in the experimental and control conditions of the current investigation offers some insights into infants’ growing capacity for detecting cues of others’ perceptual states. This capacity is based in, and demonstrated by, their active search patterns, which for unseen targets might serve as an interim “trial and error” strategy that allows infants to test or verify the objective underlying adult looking behavior. However, this strategy is minimal at 14 months of age.

It is worth noting that the behavioral measures used in our study assess infants’ performance and emerging ability, rather than level of competence. Indeed, all of the infants were capable of walking independently or crawling to look behind the barrier. This demonstrates that any possible differences in motor capabilities were not the primary source of divergence in the data between 14 and 18 months. As an additional factor, the manipulation of infants’ motivational states highly influences competence, and may impede performance.

Finally, little is known about how infant gaze following skills relate to other spatial representational skills. However, referential gaze following provides a unique arena for studying how infants develop skills for simultaneously processing social and spatial information, and using these processing skills to support inferences about non-obvious events and ecological relations. Referential gaze following offers a new ability to synthesize information about other people’s embodied actions in a shared environment to infer unperceivable states. This ability may be critical for impending changes in social and communicative knowledge.

The current study confirms developmental trends in

referential gaze following from 14 to 18 months of age. Together with previous studies, this contributes to our understanding of infants' referential gaze following, perspective-taking, vision comprehension, and ultimately, theory of mind.

Acknowledgments

The authors thank the mothers and infants who participated in the study. We also thank Ana Ramundo, Corrine Zavala, Katy Brecht, and members of the Cognitive Development Laboratory for assistance with data collection and coding. This project was supported by NSF award HSD 0527756 to G. Deák.

Joint Perception: Gaze and Beliefs about Social Context

Abstract

The way that we look at images is influenced by social context. Previously we demonstrated this phenomenon of *joint perception*. If lone participants believed that an unseen other person was also looking at the images they saw, it shifted the balance of their gaze between negative and positive images. The direction of this shift depended upon whether participants thought that later they would be compared against the other person or would be collaborating with them. Here we examined whether the joint perception is caused by beliefs about shared experience (looking at the same images) or beliefs about joint action (being engaged in the same task with the images). We place our results in the context of the emerging field of *joint action*, and discuss their connection to notions of group emotion and situated cognition. Such findings reveal the persuasive and subtle effect of social context upon cognitive and perceptual processes.

Keywords: vision; joint action; eye movements; social cognition, situated cognition

Introduction

Cognition is enveloped by social context. It is rare that we use our cognitive or perceptual faculties outside of the world of social influence, what Allport (1954/1979) described as the real or imagined presence of other people. Yet in cognitive and perceptual laboratories, we typically place participants in experimental quarantine away from the confounds of social interaction. The risk of this strategy is that we overlook the ways in which cognitive and perceptual processes interact with social context.

It is now well demonstrated that social cues such as eye contact and gaze direction are attended to in fundamentally different ways from non-social stimuli, both in terms of higher-level attentional selection (e.g. Birmingham, Bischof & Kingstone, 2008a, b, 2009; Frischen, Bayliss & Tipper, 2007; Senju & Johnson, 2009) and their different neurological subsystems (e.g. Greene et al., 2009; Itier & Batty, 2009; Ristic, Friesen & Kingstone, 2002). These studies, and many others, show how perceptual processing differs for social and non-social stimuli (Cacioppo, Visser & Pickett, 2005).

In studies of *joint perception*, this relationship is turned on its head; we keep the stimuli constant and examine how different social cues exert an influence on perceptual processing. The first demonstration (Richardson, Hoover & Ghane, 2008) presented participants with a set of four images on screen for eight seconds. On different trials, participants either believed that in a cubicle next door another participant was looking at the same images, or that the person next door was looking at a set of unrelated

symbols. In each set of images, there was one picture with a negative valence (such as crying child), one with a positive valence (a smiling couple) and two neutral images with no strong valence. When participants believed that they were the only ones currently looking at the images, they looked more at the unpleasant ones. When they thought they were looking jointly with another, they looked more at the pleasant images.

Participants in this experiment could not see or interact with each other. Yet their gaze was systematically shifted if they imagined that another person was looking at the same stimuli. There have previously been similar demonstrations of the influence of social context on social or affective responses, for example, that people will smile and laugh more if they imagine that a friend elsewhere is currently watching the same comedy clip as themselves (Fridlund, 1991). However, the joint perception result showed that, on a trial-by-trial basis, social context can shape a low level perceptual/cognitive process.

The original experiment was carried out at UC Santa Cruz in the US. A replication was soon performed at University College London in the UK (Richardson et al., 2009). The same pervasive effect of social context was found. Gaze patterns shifted in response to joint perception. However, in this case, when participants believed that they were looking together, they looked more at the negative images. The contrasting US and UK data is shown in the top panel of *Figure 1*. What is depicted is the total fixation duration for the positive and negative images during joint and alone looking. Each study found a significant interaction between picture valence and social context, and between the two experiments there was a significant three way interaction, showing that the direction of the effect changed.

Though there were many differences between the laboratories' set up and the participant populations, we hypothesised that an important determinant might be how participants construed that task. One criticism of the first study was that participants did not know why they were looking at the images, and why the person next door was (sometimes) doing the same thing. So, in subsequent research in London (Richardson et al., 2009), we repeated the experiments but told pairs of participants either that we would be comparing their picture preferences (comparison task), or that they would be collaborating on a memory task afterwards (collaboration task). As *Figure 2* shows, we found a pattern of results that mimicked the US / UK differences, and also produced a significant three way interaction. People who thought they were being compared to each other tended to look at the negative and positive images equally in the joint condition, like the US participants. People who thought that they were

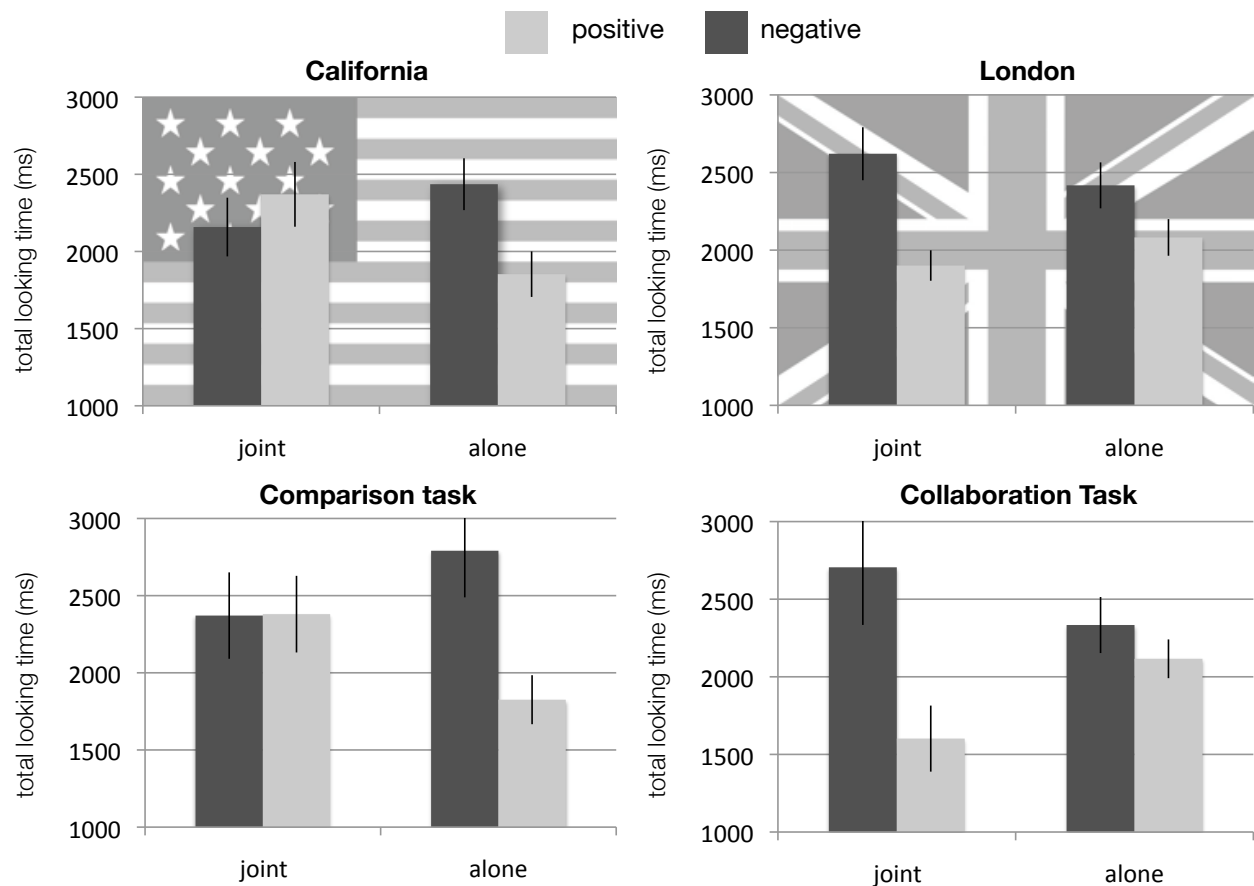

Figure 1. Results from Richardson, Hoover and Ghane (2008) and Richardson *et al.* (2009).

collaborating looked more at the negative images in the joint condition, like the London participants who did not get task instructions. There could be other reasons, of course, why the US and UK participants differed, but one plausible reason appears to be that in the absence of instructions, they interpreted the task in opposite ways. We can only speculate as to the reason the US participants might felt that they were being compared (they are academically evaluated more frequently than UK students), or it might have been that the physical setup of the lab (two adjoining cubicles, rather than one big room) engendered a feeling of being contrasted.

These previous studies have shown that gaze patterns can be systematically influenced by beliefs about social context, and that the direction of this influence is sensitive to differences in how participants construe their task. In the current experiment, we zoom in to this concept of looking at something 'together'.

For the joint perception effect to occur, is it enough to *experience* a set of stimuli at the same time as another person? Or do participants have to believe that they are engaged in the *same task* as the other person? In this experiment, unlike those described above, the participants always believed that they were looking at the same images as each other. What changed, trial-by-trial, was the task that they were doing, and the task that they believed their partner was doing. Inspired by the seminal work on *joint action* (Sebanz, Bekkering & Knoblich, 2006) that we discuss below, we predicted that joint perception effects would be strongest when participants believed that they were not just passively sharing an experience, but acting jointly.

Methods

Participants

32 University College London students (9 male) participated voluntarily or for course credit. Data from 4 participants were unusable due to equipment calibration problems.

Note that although we actually ran pairs of participants simultaneously in the lab, their experiments were run and their data analysed independently from each other. This is because participants could not see or interact with each other during the experiment. In effect, they acted as a mute social context for each other.

Procedure

Participants provided informed consent and then sat in opposite corners of the laboratory with their backs to each other, facing their display monitor. They could not see each other or each other's display. A brief 9-point calibration was carried out for each, and then task instructions were presented on screen. Two tasks were defined for the subjects. In the memory task they had to remember as many of the pictures as possible for a later test. In the search task, they had to look for a translucent X superimposed on one image, and press the mouse button that they held in one hand if they detected it. They were informed that their task could change from trial to trial, but that their partner would always be looking at the same pictures as them.

Figure 2. Trial schematic

Design

At the start of each trial, participants were told their task for the upcoming presentation. A large icon at the top of the screen showed their task (visual search or memory), and a smaller icon below that showed their partner's task (Figure 2). They also heard a voice say "You will be [memorising/searching]. Your partner will be [memorising/searching]".

Participants then saw one negative, one positive and two filler images in random positions in a 2x2 grid (see Figure 2). They were presented for eight seconds, during which

time their gaze was tracked. There was a 1 second interval, and then the instructions for the next trial began.

There were 40 trials. In half the participant was told that they were to memorise the stimuli and in half they were told that they were searching for an X. Similarly, they were told that their partner performed the memory task half the time, the search task the other half. These task conditions were counterbalanced so that half the time the participant and their partner were doing the same task, half a different task. On eight trials (spread evenly across conditions), an X appeared at a random location on one of the images.

Stimuli

Images were taken from the International Affective Picture System (IAPS), a set of photographs that have been extensively normed on a range of attributes (Lang, Bradley & Cuthbert, 2005). We chose 40 negative items with valence ratings from 1.6 to 2.4 and a mean of 2, 40 positive items from 7.6 to 8.3 and a mean of 8, and 80 filler items from 4.8 to 5.2 and a mean of 5. For each trial, stimuli were chosen at random from these categories.

Apparatus

The stimuli were presented on 19" LCD screen at a distance of approximately 60cm. Beneath each display was a Bobax3000 remote eye tracker that sampled fixations at 100 Hz. iMac computers behind a partition presented the stimuli, calculated gaze position, and collected the data.

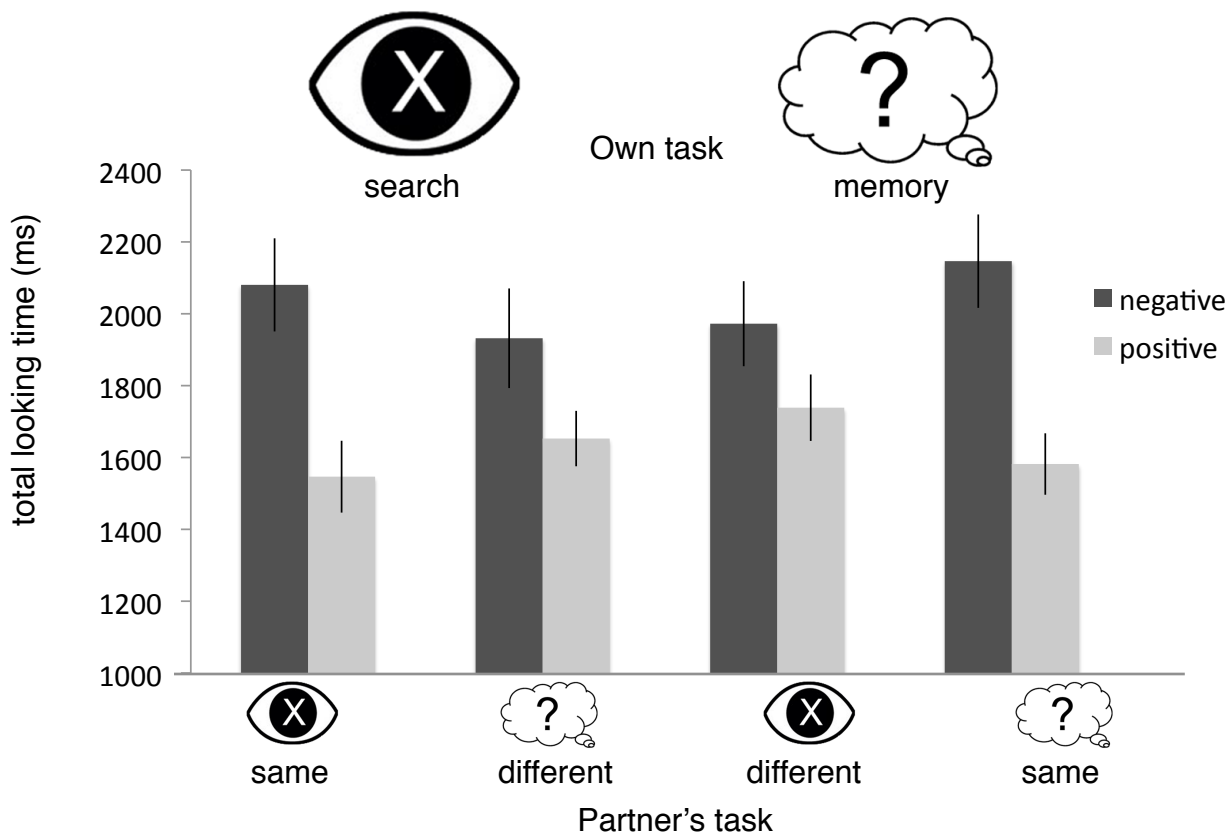

Figure 3. Looking times showed a significant interaction between valence and whether or not the participant's partner was believed to be doing the same or a different task

Results

Participants looked more towards the negative images when they believed that their partner was doing the same task as them, regardless of what the task was. We did not analyse the 20% of trials when there was an X present, as X and participants' responses to it would interfere with how they allocated their attention to each image. We calculated the total amount of time spent looking at the critical negative and positive images on trials where there was not X present. A 2 (valence: negative/positive) x 2 (own task: memory/search) x 2 (other's task: same/different) ANOVA was performed, and the means for each cell are displayed in *Figure 3*. There was a significant two way interaction between valence and other's task ($F(1,27)=10.08, p=.004$). Post hoc tests show that the difference between positive and negative images was significant when the participants believed they were doing the same task (using Tukey's at 0.01), but did not reach significance when they were doing a different task. There was also a main effect of valence ($F(1,27)=19.19, p<.0001$), but all other main effects and interactions were non significant (all F s <1).

General Discussion

The effects of joint perception do not occur simply when someone believes that another person is experiencing the same stimuli as themselves. We have shown that it is necessary that they believe that the other, unseen person is engaged in the same task as themselves. This task could be to memorise the pictures, which presumably would engage processing something of the meaning of an image, or the task could just be to search for a visual feature, which requires only superficial processing: regardless, the effect of joint perception arises whenever these tasks are believed to be done together. In each case, the effect of this co-engagement is to fixate the negative images more than the positive. Below, we discuss other areas of research that throw light on joint perception, and the direction of its effects in this situation.

Joint Action

Though the standard cognitive model marginalises social context, there have been notable exceptions. Studies of situated cognition (Barsalou, Breazeal & Smith, 2007; Robbins & Ayded, 2009) show that cognition 'in the wild' is intimately linked not only to representations of the external world, but also to the cognitive processes of others. Hutchins (1995) observed the ways that navy navigators distribute cognitive processes between themselves by using external tools and representations, such as maps and notations.

Recently, experimental methods are starting to reveal the mechanisms involved in such joint action (Galantucci & Sebanz, 2009; Sebanz, Knoblich & Bekkering, 2006). Social context can modulate even the simplest of tasks. For example, in a traditional stimulus-response compatibility task, participants make a judgment about one stimulus property (color) and ignore another stimulus property (location). If there is an incompatibility between the irrelevant property and the response (such as different

spatial codes) then reaction times increase (Simon, 1969). Sebanz, Knoblich & Prinz (2003) divided such a task between two people. The participants sat next to each other, and each person responded to one colour: in effect, each acting as one of the fingers of a participant in Simon's (1969) experiment. Though each person had only one response to execute, they showed an incompatibility effect when acting together. There was no incompatibility effect when performing the same single response task alone. When acting jointly, participants represented their partners' actions as if they were their own.

Joint action effects do not occur if the participant is simply sat next to another person (Tsai et al., 2006), or if that person's button pressing actions are not intentional (their finger is moved by a mechanical device). Also, if the participant is acting jointly, but with a computer program (Tsai et al., 2008) or a marionette's wooden hand (Tsai & Brass, 2007) there is not a stimulus-response incompatibility effect. Therefore, participants only form representations of another when that person's genuine, intentional actions are engaged in the same task.

Our results fill out this picture. We have shown that a participant's perceptual process is changed when they believe that another person is co-acting with them: they do not have to see the person (c.f. Tsai et al., 2008), and the 'actions' do not have to be overt behaviour. If the participant thinks that the other person is memorising or scanning the images together with them, then that mutual cognitive process will shape their gaze patterns.

Focal Images

The term 'focal image' comes from Schelling (1960) who found that people were very good at guessing what images others would find salient. Schelling realised that everyday cases of verbal reference are often ambiguous. We say, 'Hand me the fork,' in the presence of many such items, yet listeners unproblematically infer the same referent. For example, when presented with a page full of items, such as watches from a catalog, participants agreed with each other which one was most likely to be referred to as 'the watch' (Clark, Schreuder & Buttrick, 1983).

When we enter into any joint activity, such coordination is all important (Clark, 1996). When we talk, we implicitly agree upon names for novel objects (Clark & Brennan, 1991), align our spatial reference frames (Schober, 1993), use each others' syntactic structures (Branigan, Pickering & Cleland, 2000), sway our bodies in synchrony (Shockley, Santana & Fowler, 2003; Condon & Ogston, 1971) and even scratch our noses together (Chartrand & Bargh, 1999). We also coordinate our gaze patterns with each other (Richardson & Dale, 2005), taking into account the knowledge (Richardson, Dale & Kirkham, 2007) and the visual context (Richardson, Dale & Tomlinson, 2009) that we share. Perhaps participants in our experiment, anticipating a future discussion of the stimuli, attempted to coordinate gaze patterns with their partner when they believed they were acting jointly. In other words, they looked at the pictures they thought another person would look at: the focal image.

Responses to Negative Stimuli

Our discussion so far has not touched upon one question: why is it that the effect of joint perception is sometimes to increase looks to the negative pictures, and sometimes to the positive images? It seems plausible that participants who thought that they were being compared to each other might want to look equally at the positive and negative images, since they may feel that ogling a disturbing image might not reflect well upon them. However why is it that in the collaborative memory task and the joint visual search tasks, the participants looking together tend to look at the negative images?

We are generally very responsive to unpleasant or threatening things. Negative images are considered more potent than equivalently-valenced positive images, so much so that when combinations of equivalent positively and negatively valenced stimuli are presented simultaneously participants rate the overall set as unpleasant (for reviews, see Baumeister et al., 2001; Lewicka, Czapinski & Peeters, 1992; Rozin & Royzman, 2004; Skowronski & Charlston, 1989). Negative stimuli are likely to receive attention more quickly (Norris et al., 2004, Smith et al., 2003) and for longer (Hajcak & Olvet, 2008). But why might this bias towards negative images be amplified during joint perception?

Emotion and Social Interaction

When people collaborate in groups, they tend to align with the group emotion (Barsade, 1998; Hatfield, Cacioppo & Rapson, 1993; Wageman, 1995). That emotion arises from the majority's personal disposition for positive or negative mood states (George, 1990). Since, as we've seen, negative stimuli are usually attended to more by individuals, when they cooperate together this would serve to amplify the negativity bias (Taylor, 1991). Affect can influence behaviour without necessarily having to personally experience the emotion (Winkielman, Berridge & Wilbarger, 2005). In this light, our joint perception phenomenon could be seen as a form of minimal, imagined cooperation that is sufficient to produce an alignment of group emotional biases.

Conclusion

How we move our eyes is swayed by a belief that others are looking at the same scene and thinking the same thing. These results broaden the notion of joint action to include perceptual processes, unseen collaborators and mental actions such as remembering and visual search. They also suggest a possible experiment to perform at a poster session. Sidle up to another conference attendee gazing over the results of an experiment. If our results generalise, a slight cough will alert them to your presence, engage their feeling of joint perception and perhaps sway their gaze towards more negative aspects of the poster, demonstrating that an effect of social context can even be found at a cognitive science conference.

Abstract

For self-regulated learning to be effective, students need to be able to accurately assess their own performance on a learning task, and to select an appropriate new learning task in response to that self-assessment. This study investigated the use of video-based modeling examples to teach self-assessment and task-selection skills. Students in both the experimental and control condition observed the model performing a problem solving task; students in the experimental condition additionally observed the model engaging in self-assessment and task selection. Results show that students in both conditions acquired problem-solving skills from the examples, as indicated by a substantial pretest to posttest knowledge gain. Moreover, students in the experimental condition also acquired self-assessment and task-selection skills from the examples: they demonstrated higher self-assessment and task-selection accuracy on the posttest than students in the control condition.

Keywords: Example-based learning; self-assessment; task selection; self-regulated learning.

The Role of Self-Assessment and Task-Selection Skills in Self-Regulated Learning

A major aim of many contemporary educational programs is to foster students' self-regulation skills. It is often assumed that this aim can be achieved by providing learners with the opportunity to self-regulate their learning processes. In the Netherlands, for example, a nationwide innovation was implemented in secondary education in 1999 that relies heavily on self-regulated learning (i.e., the 'study house'; <http://www.minocw.nl/english/education/293/Secondary-education.html>). Self-regulated learning is also assumed to result in personalized learning trajectories, in which instruction is adaptive to the individual student's needs. Such personalized instruction is expected to enhance students' motivation and learning outcomes compared to non-adaptive, fixed instruction that is the same for all students.

Unfortunately, there is little evidence for both assumptions. First of all, research has shown that students do not acquire self-regulation skills merely by engaging in

self-regulated learning, rather, they need additional training or instructional support (e.g., Azevedo & Cromley, 2004; Van den Boom, Paas, Van Merriënboer, & Van Gog, 2004). Secondly, although the assumption is correct that adaptive, personalized instruction can foster learning compared to non-adaptive instruction (e.g., Camp, Paas, Rikers, & Van Merriënboer, 2001; Salden, Paas, Broers, & Van Merriënboer, 2004), it is questionable whether self-regulated learning actually results in adaptivity to students' needs.

In adaptive instructional systems, learning tasks are chosen for each individual student based on an assessment of their current level of knowledge and skill (based on several aspects of students' performance, e.g., Anderson, Corbett, Koedinger, & Pelletier, 1995; Koedinger, Anderson, Hadley, & Mark, 1997; or on a combination of their performance and invested mental effort, e.g., Camp et al., 2001; Corbalan, Kester, & Van Merriënboer, 2008; Kalyuga, 2006; Salden et al., 2004). The assessment of performance and the selection of an appropriate new learning task (i.e., based on that assessment) is conducted by the system. For self-regulated learning to be equally adaptive and effective, students themselves should be able to accurately assess their own performance and to recognize what an appropriate new task would be. Unfortunately, there is quite some evidence that students, and especially novices who lack prior knowledge of the learning tasks, are not very accurate self-assessors. Humans seem prone to several biases that affect accuracy of self-assessments (for a review, see Bjork, 1999), such as hindsight bias (i.e., once an answer or solution procedure is known, e.g., after feedback, students are more likely to think that they could have produced it themselves), or availability bias (i.e., answers that come to mind easily are not only more likely to be provided but are also more likely to be assumed to be correct). Moreover, accurate self-assessment also seems to require some domain expertise (Dunning, Johnson, Erlinger, & Kruger, 2003). Individuals with higher levels of prior knowledge are more accurate self-assessors, presumably because their experience not only provides them with more

task knowledge, but also with more knowledge of the criteria and standards that good performance should meet (Dunning et al., 2003). In addition, their experience also lowers the cognitive load imposed by the task, allowing them to devote more cognitive resources to monitoring their task performance, which likely provides them with a more accurate memory representation on which to base their assessment (Van Gog & Paas, 2009).

Support for our assumption that novice students' lack of self-assessment skills leads to ineffective self-regulated learning, comes from studies that have shown that providing novice students with control over their learning process may have beneficial effects on their motivation or involvement, but often has detrimental effects on learning outcomes (see e.g., Azevedo, Moos, Greene, Winters, & Cromley, 2008; Niemic, Sikorski, & Walberg, 1996). When positive effects on learning outcomes are found, this tends to be mostly for students with higher levels of prior knowledge in the domain (e.g., Niemiec et al., 1996; Moos & Azevedo, 2008), who, as mentioned above, are also likely to be more accurate self-assessors. In addition, Kostons, Van Gog, and Paas (2010) investigated differences in self-assessment accuracy between secondary education students who differed in the amount of knowledge gained from studying in a learner-controlled instructional environment that contained heredity problems with varying levels of support at different levels of complexity. They found that the students who had gained more knowledge, had also more accurately assessed their own performance during learning.

Without accurate self-assessment, selecting an appropriate new learning task will also be very difficult. Given the central role that self-assessment and task-selection skills seem to play in self-regulated learning, an important question is whether we can teach novice students to become more accurate self-assessors and task selectors. We decided to investigate this question, using modeling examples to teach those skills.

Learning from Examples

Learning from examples is known to be a highly effective instructional strategy. Research inspired by cognitive theories such as ACT-R (Anderson, 1993) or Cognitive Load Theory (Sweller, Van Merriënboer, & Paas, 1998) has extensively investigated the effects on learning of instruction consisting of studying *worked examples*, which provide students with a written worked-out didactical solution to a problem. These studies have consistently shown that for novices, studying worked examples is more effective and/or more efficient for learning (i.e., equal or higher learning outcomes attained with lower or equal investment of time and/or effort) than (tutored) problem solving, which is known as the 'worked example effect' (Sweller et al., 1998; for further reviews, see Atkinson, Derry, Renkl, & Wortham, 2000). Studies on the worked example effect have mainly used highly structured cognitive tasks, such as algebra (e.g., Cooper & Sweller, 1987; Sweller & Cooper, 1985), statistics (e.g., Paas, 1992),

geometry (e.g., Paas & Van Merriënboer, 1994), or physics (e.g., Van Gog, Paas, & Van Merriënboer, 2006), although recent studies have shown the same effect with less structured tasks such as learning to recognize designer styles in art education (Rourke & Sweller, 2009).

Research inspired by Social Learning Theory (Bandura, 1986) has mostly focused on *modeling*, that is, learning by observing another person (the model) perform a task. Models can be either adults (e.g., Schunk, 1981) or peers (e.g., Braaksma, Rijlaarsdam, & Van den Bergh, 2002; Schunk & Hanson, 1985), and they can behave didactically or naturally (i.e., possibly skipping steps, or making and/or correcting errors). Moreover, modeling examples can consist of a video in which the model is visible (e.g., Braaksma et al., 2002), a video consisting of a screen capture of the model's computer screen in which the model is not visible (e.g., McLaren, Lim, & Koedinger, 2008; Van Gog, Jarodzka, Scheiter, Gerjets, & Paas, 2009), or an animation in which the model is represented by a pedagogical agent (e.g., Atkinson, 2002; Wouters, Paas, & Van Merriënboer, 2009). Like worked examples, modeling examples have also been used to teach highly structured cognitive tasks such as math (e.g., Schunk, 1981) or chemistry (e.g., McLaren et al., 2008), but they have also been widely applied with less structured tasks such as writing (e.g., Braaksma et al., 2002; Zimmerman & Kitsantas, 2002). In addition, they have been used for teaching *metacognitive* skills such as self-regulation (e.g., Kitsantas, Zimmerman, & Cleary, 2000; Zimmerman & Kitsantas, 2002). For a more in-depth review of research on worked examples and modeling examples, see Van Gog and Rummel (in press).

This study investigated whether video-based modeling examples consisting of screen-recordings could be successfully applied for teaching secondary education students self-assessment and task-selection skills.

Method

Participants and Design

Participants were 39 Dutch secondary education students (age $M = 15.08$, $SD = 0.48$; 26 female) in the fourth year of pre-university education (the highest level of secondary education in the Netherlands, which has a duration of six years). They were novices on the content domain of the examples (heredity problems), which had yet to be taught in the formal curriculum. Participants were randomly assigned to the experimental ($n = 20$) or control condition ($n = 19$).

Materials

Pretest and Posttest The pretest and posttest consisted of 5 paper and pencil heredity problems, at five levels of complexity (see Figure 1), presented in random order. The students were informed at what level of complexity each problem was. These heredity problems could be solved by going through the following five steps: (1) translate the

phenotypes (expression of genetic trait) described in the cover story into genotypes (a pair of upper and/or lower case letters representing genetic information); (2) put these genotypes into a hereditary diagram; (3) determine direction of reasoning and number of Punnett Squares; (4) fill in Punnett Square(s); (5) extract final solution from Punnett Square(s). The posttest problems were equivalent but not identical to the pretest problems; they had similar structural features and were of similar complexity, but the surface features (cover stories) differed. On both tests, participants were instructed to write down the steps they took to reach their solution.

Complexity Level	Support Level	Learning Tasks				
Complexity 1 - 2 generations - 1 unknown - 1 solution - Deductive	Completion 3 steps worked out	Eye color	Hair structure	Shropshire cat fur	Japanese Apple tree	Depression
	Completion 2 steps worked out	Eye color	Hair structure	Saddle cell / Anemia	Curved chicken beak	Cornish Hens
	Conventional 0 steps worked out	Eye color	Hair structure	Huntington	Milk Allergy	Cleft Lip
Complexity 2 - 2 generations - 1 unknown - Multiple solutions - Deductive	Completion 3 steps worked out	Eye color	Hair structure	Flower color	Widow's peak	P.T.A.
	Completion 2 steps worked out	Eye color	Hair structure	Shropshire cat fur	Albinism	Pea plant
	Conventional 0 steps worked out	Eye color	Hair structure	Tongue Curling	Japanese Apple tree	Fruit flies
Complexity 3 - 2 generations - 1 unknown - Multiple solutions - Inductive	Completion 3 steps worked out	Eye color	Hair structure	Fruit flies	Curved Chicken beak	Wolfram syndrome
	Completion 2 steps worked out	Eye color	Hair structure	Dog tail length	Japanese Apple tree	Milk allergy
	Conventional 0 steps worked out	Eye color	Hair structure	Frodoes	Flower Color	Elastosis
Complexity 4 - 3 generations - 1 unknown - Multiple solutions - Both ways	Completion 3 steps worked out	Eye color	Hair structure	Albinism	Shropshire cat fur	Fruit flies
	Completion 2 steps worked out	Eye color	Hair structure	Fruit flies	Tongue Curling	Flower color
	Conventional 0 steps worked out	Eye color	Hair structure	Pea plant	Dimples	Depression
Complexity 5 - 3 generations - 2 unknowns - Multiple solutions - Both ways	Completion 3 steps worked out	Eye color	Hair structure	Milk Allergy	Depression	Huntington disease
	Completion 2 steps worked out	Eye color	Hair structure	Dog tail Length	Wolfram syndrome	Flower color
	Conventional 0 steps worked out	Eye color	Hair structure	Cystic Fibrosis	Fruit flies	Ear lobe

Figure 1: Overview of the task database.

Mental effort rating After each problem in the pretest and posttest, participants rated how much mental effort they invested in solving that problem on a 9-point rating scale (Paas, 1992).

(Self-)assessment After the mental effort rating, participants self-assessed their performance on a 6-point rating scale ranging from 0 (none of the five steps correct) to 5 (all steps correct). After the experiment, participants' performance was scored by the experimenter on the same scale (i.e., max. problem: 5; max. test: 25).

Task selection After self-assessment, students indicated on an overview of the task database (Figure 1) what problem they would select next. At each of five complexity levels (left column), there were three levels of support: completion problem, 3 steps worked-out (white row); completion problem, 2 steps worked-out (light gray row); conventional problem, no steps worked-out (dark gray row). At each level of support within each complexity level there were 5 tasks to choose from, which had equal structural features but

different cover stories. Participants knew the complexity level of the problem they had just worked on. They did not actually get the problem they selected to work on next; test problems were the same for all students.

Modeling examples The four modeling examples consisted of a recording of the model's computer screen along with a spoken explanation by the model of what s/he was doing. The gender of the models was varied: two examples were by two different male models, and two examples were by two different female models (see Table 1). In the experimental condition, the modeling examples consisted of three "phases":

(1) *Problem solving*: The model performed the problem solving task. Two models worked on problems of complexity level 1, and two models worked on problems of complexity level 2 (i.e., of the five complexity levels present in the task database and in the pretest and posttest; see Table 1). The quality of the models' performance varied between the examples: one example showed a model accurately solving the problem, but in the other three examples the models made one or more errors (see Table 1). This was done to create variability in phases 2 and 3 of the examples, that is, in the model's self-assessment scores and task selections (i.e., if the model would not make any errors or would detect and correct them immediately, they would always have the highest possible self-assessment score).

Table 1: Overview of modeling example characteristics.

Example	Model	Performance	Complexity
1	Male 1	0 errors	Level 1
2	Female 1	2 errors	Level 1
3	Male 2	4 errors	Level 2
4	Female 2	1 error	Level 2

(2) *Self-assessment*: Following task performance, the model rated invested mental effort on the 9-point rating scale and assessed their performance on the 6-point rating scale, assigning themselves one point for each correct step. The models' self-assessment was always accurate.

(3) *Task selection*: Then, the model selected a new task based on a combination of the performance score and the mental effort score. The models used a table (see Figure 2) in which the relationship between performance and mental effort scores was depicted, which could be used to infer a recommended 'step size' for task selection (e.g., performance of 4 and mental effort of 3 means a step size of +2). A positive step size means a recommendation to select a more challenging task (i.e., less support or higher complexity level), a step size of 0 means repeating a comparable task (i.e., same level of support and same complexity level), and a negative step size means a recommendation to select a simpler task (i.e., higher level of support or lower level of complexity). This kind of task selection algorithm based on performance and mental effort scores has proven to lead to an effective learning path in

studies on adaptive, personalized task selection (e.g., Camp et al., 2001; Corbalan et al., 2008; Kalyuga, 2006; Salden et al., 2004). The models' task selection was always accurate.

Participants in the control condition observed only the model's problem solving (phase 1). In the time in which the participants in the experimental condition observed the model's self-assessment and task selection, participants in the control condition were instructed to indicate whether the model made any errors during task performance, and if so, what the errors were and what the correct step would have been.

Performance 4-5	+2	+1	0
2-3	+1	0	-1
0-1	0	-1	-2
	1, 2, 3	4, 5, 6	7, 8, 9 Effort

Figure 2: Determining task selection step size.

Procedure

The experiment was conducted in a computer room at the participants' school. First, all participants completed the pretest on paper. Participants were given four minutes to complete each problem, followed by one minute for assessing their performance (a previous study had shown this to be sufficient time for solving the problem; Kostons et al., 2010). Participants were not allowed to proceed to the next problem before the time was up; time was kept by the experimenter using a stopwatch. After completing the pretest, participants studied the modeling examples on the computer; each participant had a head set for listening to the model's explanations. In the experimental condition, the modeling examples showed participants the task performance, self-assessment, and task selection by the model. In the control condition, participants only observed the task performance by the model and then indicated whether errors were made and if so, what the correct step was. This part was computer-paced, participants had to view the examples in the order in which they were offered and could not pause, stop, or replay the examples. Finally, all participants completed the posttest on paper, according to a similar procedure as the pretest.

Data Analysis

Self-assessment accuracy on each posttest problem was determined by computing the absolute difference between participants' objective performance score and their self-assessment of their performance. The lower this difference, the more accurate participants' self-assessment was (i.e., 0 = 100% accurate). We did not compute or analyze self-assessment accuracy on the pretest, because participants managed to solve very few problems on that test. When one is not able to perform a task at all, it is not very difficult to

assess one's own performance as 0. This would be highly accurate, but would have led to a substantial overestimation of participants' self-assessment accuracy, as it is not very indicative of self-assessment accuracy on tasks that they were—at least partly—able to solve.

Task selection accuracy on the posttest was determined by computing the absolute difference between the complexity level that would be recommended based on the objective performance assessment and the complexity level participants chose.

Results

For all analyses, a significance level of .05 was used, and Cohen's *d* is reported as a measure of effect size, with 0.2, 0.5, and 0.8 corresponding to small, medium, and large effect sizes, respectively (Cohen, 1988).

Acquisition of Problem-Solving Skills

Participants' mean performance score on the pretest was 2.08 (*SD* = 3.58), and on the posttest it was 14.31 (*SD* = 6.43), so all students acquired procedural skills for solving heredity problems from the modeling examples. A *t*-test showed no significant difference between the control condition (*M* = 12.05, *SD* = 7.12) and the experimental condition (*M* = 12.40, *SD* = 6.40) in the knowledge gain from pretest to posttest, *t*(37) = 0.16, *ns*.

Acquisition of Self-Assessment Skills

A *t*-test on the mean self-assessment accuracy scores on the posttest, showed that participants in the experimental condition were more accurate (i.e., lower score; *M* = 0.70, *SD* = 0.53) than participants in the control condition (*M* = 1.26, *SD* = .85), *t*(37) = 2.51, *p* = .016 (two-tailed), *d* = 0.79.

Acquisition of Task-Selection Skills

Data from 1 participant in the experimental condition were excluded from this analysis because of too many missing values. A *t*-test on the mean task-selection accuracy scores on the posttest, showed that participants in the experimental condition were more accurate (i.e., lower score; *M* = 0.81, *SD* = 0.60) than participants in the control condition (*M* = 1.21, *SD* = 0.54), *t*(36) = 2.15, *p* = .038 (two-tailed), *d* = 0.70.

Discussion

This study showed that students can not only acquire problem solving skills from studying modeling examples, but also self-assessment and task selection skills, which are considered to play an important role in the effectiveness of self-regulated learning.

We chose modeling examples as a means to teach self-assessment and task-selection skills, because research has shown that example-based learning is a powerful instructional strategy. Thus far, in educational settings, examples have mostly been used for teaching cognitive

skills, and this study adds further evidence that they are useful for teaching metacognitive skills as well (see also Kitsantas et al., 2000; Zimmerman & Kitsantas, 2002). We did not, however, compare whether teaching self-assessment and task-selection skills via modeling examples was more effective than teaching those skills in some other way (e.g., via practice after having been explained the assessment and selection 'rules', i.e., how to come to a performance assessment score and how to combine performance and mental effort scores to select a new task), so the effectiveness of examples compared to other means of teaching self-assessment and task-selection skills might be explored in future research.

Our control condition received no self-assessment and task-selection training at all, but engaged in a filler task (finding and fixing errors) which may have been relevant for the acquisition of problem solving skills (see Große & Renkl, 2007) and which we expected to direct students' attention towards assessment of performance (of the model) to some extent. Further analysis of data from the control condition was beyond the scope of this paper but could be interesting in its own right. For example, one might expect that students with better ability to find and correct errors would have better self-assessment skills and/or would show more knowledge gain. In addition, it might be interesting to establish whether the errors made by the models had any effects on students' test performance (especially for those students who were not able to find and fix errors).

A question we cannot address based on our data that would be interesting to address in future research concerns the relationship between students' levels of task knowledge and the accuracy self-assessment and task-selection skills. Even though there was some variability in pretest scores, these were in general very low. Problem-solving skills did increase from pretest to posttest. We cannot rule out that the increase in problem-solving skills might have increased students' self-assessment and task-selection accuracy in the control condition, we only know that the training in the experimental condition led to significantly higher accuracy than attained in the control condition. A problem that occurs in trying to establish gains in assessment and task selection accuracy is that it is hard to establish the level of these skills at pretest, because –as mentioned above– it is easy to rate performance as 0 when one is not able to perform a task at all. Although this is a highly accurate self-assessment, it probably does not reflect a high level of self-assessment skill. Therefore, a design in which students have lower and higher levels of prior knowledge at the start of the experiment would be required to address this question.

Other important questions for future research in this area concern whether training either self-assessment or task-selection skill would automatically lead to improvements in the other skill or whether both need training as in our experimental condition, as well as whether acquired self-assessment and task selection skills can transfer to other tasks in the same domain or even to other domains. We assume that spontaneous transfer is not very likely or would

not be very effective, as assessment criteria and standards will differ for different types of task. However, we do expect that experience with self-assessment and task selection through training in one task or domain may facilitate acquisition of those skills for other tasks or domains (i.e., transfer in the sense of preparation for or accelerated future learning; Bransford & Schwartz, 1999).

Last but certainly not least, the most important question for future research is whether students can apply the self-assessment and task selection skills they acquired from modeling examples in a self-regulated learning environment in which they are allowed to select which problems to work on. If so, one would expect training self-assessment and task-selection skills to improve learning outcomes attained as a result of self-regulated learning.

Confidence without Competence in the Evaluation of Scientific Claims

Andrew Shtulman (shtulman@oxy.edu)

Department of Psychology, Occidental College
1600 Campus Rd., Los Angeles, CA 91106

Abstract

Scientific entities like X-rays and black holes defy firsthand observation and everyday intuition, yet most people outside the scientific community still believe in their existence. Upon what kind of epistemic foundations do such beliefs rest? The present study explored this question by comparing students' scientific beliefs to their supernatural beliefs along four dimensions of epistemic import: confidence, perceived consensus, means of justification, and openness to revision. Participants' scientific beliefs were strongly differentiated from their supernatural beliefs along the dimensions of confidence and consensus but only weakly differentiated along the dimensions of justification and revision. Moreover, participants' confidence in both types of beliefs was predicted by their consensus estimates but not their ability to cite evidence in support of, or potentially in conflict with, those beliefs. These findings imply that students' scientific beliefs are no more epistemologically sound than their supernatural beliefs, despite self-perceptions to the contrary.

Keywords: Belief; testimony; naïve epistemology; intuitive theories; science education; conceptual development

Introduction

Research in cognitive science has informed the goals and methods of science education in a number of ways. Research on intuitive theories, for example, has clarified the nature of students' pre-instructional conceptions and the process by which those conceptions may be replaced by more accurate, scientific ones (Carey, 2009; Vosniadou, 1994). Research on knowledge representation has highlighted strategies effective at promoting conceptual change in the science classroom (Ohlsson, 2009; Slotta & Chi, 2006). And research on causal inference has shed light on how our theoretical commitments influence, and are influenced by, the interpretation of empirical data (Chinn & Brewer, 2001; Schulz, Goodman, Tenenbaum, & Jenkins, 2008).

To date, such research has focused mainly on the *understanding* of scientific claims, yet an equally important issue in the realm of science education is the *acceptance* of such claims as true. What, for instance, leads a student to accept the existence of electrons given that electrons are neither observable (with the naked eye) nor intuitive (with respect to our everyday conceptions of matter)? This issue is particularly important in domains where scientific explanations compete with supernatural explanations of the same phenomena, like explanations for the origin of species or explanations for the origin of the universe.

Various attempts to articulate the difference between scientific explanations and supernatural explanations have focused on differences in evidential structure (e.g., only scientific explanations generate testable hypotheses) or

evidential support (e.g., only scientific explanations are supported by observation and experimentation), yet, from the perspective of how scientific explanations are *learned*, these criteria are not particularly salient. Students of science are not, after all, practitioners of science, and it is thus unlikely that most students appreciate differences in the *derivation* of scientific and supernatural explanations when simply presented with the explanations themselves.

Indeed, the *products* of science and religion – i.e., concepts, theories, explanations, and assertions – share many commonalities even if the *practices* of science and religion do not (McCauley, 2000). Both provide frameworks for interpreting everyday observations and experiences. Both posit unobservable entities as the causes of various observable phenomena. And both extend, or even defy, early-developing intuitions about the kinds of entities that exist and the kinds of interactions those entities engage in.

Given such similarities, it is unclear how well students differentiate the epistemic status of scientific claims from that of supernatural claims. Although no studies have addressed this question directly, extensive research on students' understanding of scientific inquiry provides reason to suppose that most students are not equipped to make such a differentiation (Lederman, Abd-El-Khalick, Bell, & Schwartz, 2002; Schauble, Glaser, Duschl, Schulze, & John, 1995; Smith, Maclin, Houghton, & Hennessey, 2000). This research has shown that students typically conceive of science as problem solving, rather than inquiry, and typically conceive of experiments as means of confirming, rather than testing, one's ideas. Even individuals who hold doctorates in the humanities tend to believe (a) that scientists abide by a single, deterministic method of inquiry, (b) that scientists conduct experiments in order to prove (rather than support) their ideas, (c) that scientists deduce (rather than infer) their ideas from the data at hand, and (d) that scientists who study the same data will inevitably arrive at the same conclusions (Lederman et al., 2002).

The present study attempted to extend this literature by exploring students' epistemic commitments regarding the products of science, rather than its methods. These commitments were assessed in relation to commitments regarding beliefs with ostensibly inferior evidential support – i.e., supernatural beliefs. Four dimensions of students' epistemic commitments were measured: (1) confidence in the validity of one's beliefs, (2) perceived consensus surrounding the endorsement of one's beliefs, (3) means of justifying one's beliefs, and (4) openness to revising one's beliefs. Of primary interest was the extent to which the first dimension (confidence) was related to the other three (consensus, justification, and revision).

Method

Participants

One-hundred and forty college undergraduates participated in the study for course credit in an introductory psychology class. Approximately half were recruited from a large, urban university in the Northeastern US and half from a small, urban college in the Southwestern US. Preliminary analyses revealed no significant differences between the two groups on any of the findings reported below, so they were pooled.

In the course of the study, participants rated their belief in the existence of six scientific entities and twelve supernatural entities. Although all participants endorsed the existence of at least three scientific entities, 31 participants did not endorse the existence of at least three supernatural entities. Those 31 were excluded from the analyses presented below, as they provided no internal metric against which to compare their scientific beliefs. The final sample thus consisted of 106 participants who endorsed the existence of supernatural entities at a frequency similar to the general public (Moore, 2005; Winseman, 2004).

Procedure

Participants completed a questionnaire that probed their beliefs about black holes, electrons, evolution, fluoride, genes, X-rays, angels, fate, ghosts, God, Heaven, Hell, karma, precognition, reincarnation, Satan, souls, and telepathy. Pilot data confirmed that, given this selection, college students tended to endorse an equal number of scientific and supernatural entities (i.e., all six scientific entities and around six of the twelve supernatural ones).

For each entity, participants were asked five questions: (1) whether they currently believed in the entity's existence; (2) how confident they were of that belief (on a scale from 1 to 7); (3) how many other Americans (out of 7) hold the same belief; (4) why they believed the entity exists; and (5) what evidence might persuade them to change their mind. Responses to these questions will henceforth be referred to as "existence judgments," "consensus estimates," "belief justifications," and "belief refutations," respectively.

Participants' belief justifications and belief refutations were analyzed using coded schemes described below. These schemes were constructed via a bottom-up process in which one-third of the data were sorted into numerous, fine-grained categories closely resembling the data themselves. Those categories were then collapsed into eight "basic-level" categories, which, in turn, were collapsed into three "superordinate" categories. These coding schemes were then applied to the entire dataset by two independent coders: the author, who created the coding schemes, and a research assistant, who was instructed on how to apply the coding schemes but was not involved in their creation. Among basic-level categories, agreement between coders was 90% for belief justifications and 89% for belief refutations. Among superordinate categories, agreement was 95% for belief justifications and 94% for belief refutations. Disagreements were resolved through discussion.

Results

Existence Judgments

The first question participants answered about each entity was whether or not they believed in its existence. "Yes" responses were assigned 1 point, and "No" responses were assigned 0 points. Participants' mean existence judgments are displayed in Table 1. On average, participants endorsed the existence of 5.9 scientific items (or 98%) and 7.6 supernatural items (or 63%). Item for item, these judgments were highly similar to those obtained in national surveys of supernatural belief (e.g., Moore, 2005; Winseman, 2004).

It should be noted that subsequent analyses were conducted *only* on responses connected with entities judged existent by the responder. Responses connected with entities judged nonexistent were excluded from the dataset, as they were not directly relevant to the question of how the *acceptance* of scientific claims compares to the *acceptance* of supernatural claims. Thus, the mean confidence ratings and mean consensus estimates reported in Table 1 represent only those participants who judged the target entity existent.

Table 1: Mean existence judgments (range = 0 to 1), confidence ratings (range = 1 to 7), and consensus estimates (range = 1 to 7) for the six scientific entities (top) and twelve supernatural entities (bottom).

Item	Existence	Confidence	Consensus
X-rays	1.00	6.9	6.4
Genes	.99	6.8	6.4
Electrons	.99	6.4	5.9
Fluoride	.98	6.7	6.3
Evolution	.95	6.3	4.7
Black holes	.94	5.7	5.1
Souls	.97	6.0	5.4
God	.83	5.9	5.2
Karma	.78	5.6	4.0
Heaven	.75	5.6	5.2
Angels	.66	5.4	3.9
Fate	.66	5.4	4.5
Ghosts	.56	4.6	3.6
Hell	.52	5.1	4.7
Precognition	.51	4.9	3.0
Telepathy	.44	4.7	3.0
Satan	.41	5.8	4.5
Reincarnation	.40	4.9	3.0

Confidence Ratings

Participants rated their confidence in the existence of each entity on a scale from 1 ("no confidence") to 7 ("100% confident"). Participants tended to be highly confident, selecting "7" significantly more than any other rating (33% of all selections, binomial $p < 0.001$). They also exhibited greater confidence in their existence judgments for scientific items than those for supernatural items, as shown in Table 1. Not only was the mean rating for the scientific items

significantly greater than that for the supernatural items when averaged across entities ($M = 6.5$ vs. $M = 5.3$, $t(108) = 11.30$, $p < 0.001$), but the mean ratings for individual scientific items were almost always greater than the mean ratings for individual supernatural items. Interestingly, the more often an entity was judged existent by the group, as a whole, the more confident any individual participant was in his/her judgment. Indeed, the correlation between mean existence judgments and mean confidence ratings (i.e., columns 2 and 3 of Table 1) was highly significant ($r(18) = 0.85$, $p < 0.001$), implying that participants' confidence in their existence judgments may have been influenced by their perception of how frequently others would agree with them.

Consensus Estimates

After selecting a confidence rating, participants estimated the number of Americans who would agree with their existence judgment on a scale from 1 ("1 out of 7") to 7 ("7 out of 7"). Mean consensus estimates for each entity are displayed in Table 1. Similar to the confidence ratings, consensus estimates for the scientific items were, on the whole, significantly greater than those for the supernatural items ($M = 5.8$ vs. $M = 4.3$, $t(108) = 16.80$, $p < 0.001$). Participants' mean consensus estimates were also correlated with their mean existence judgments, when compared on an item-by-item basis ($r(18) = 0.84$, $p < 0.001$), indicating that their estimates were at least partly veridical.

Belief Justifications

Participants provided a total of 1458 justifications for their existence judgments (639 for scientific items and 819 for supernatural items). These responses were sorted into the various categories and subcategories described below.

Evidential Justifications These justifications referenced objectively verifiable facts that support the existence of the entity in question. Evidential justifications came in two forms: appeals to direct evidence and appeals to indirect evidence (which accounted for 4% and 13% of all justifications, respectively). Appeals to direct evidence described an observable property or causal effect of the target entity (e.g., evolution must exist because "there are fossils for past species that have similar characteristics to present day animals;" genes must exist because "they can be sequenced and manipulated"). Appeals to indirect evidence referenced facts about the world consistent with the existence of the target entity but *not inconsistent* with other explanations (e.g., genes must exist because "children look like their parents;" God must exist because "some force must explain the Universe"). It should be noted that while it was not possible for participants to cite direct evidence of supernatural entities, it was possible for them to cite indirect evidence, and many did. It should also be noted that evidential justifications were the only justifications that could be considered epistemologically sound, as they were the only justifications that provided a *warrant* for belief rather than merely a *reason* for belief.

Deferential Justifications These justifications referenced the source of one's belief without referencing any factual or conceptual considerations relevant to the legitimacy of that source. These justifications came in three forms: appeals to unspecified evidence, appeals to authority or instruction, and appeals to a preexisting worldview or commitment (which accounted for 15%, 13%, and 23% of all justifications, respectively). Appeals to unspecified evidence differed from appeals to direct or indirect evidence in that they lacked any description of the evidence itself (e.g., X-rays must exist because "there is scientific evidence proving their existence;" souls must exist because "aspects of the concept have been sort of proven"). Appeals to authority/instruction referenced a trusted source of information without providing any details regarding the content of that information (e.g., black holes must exist because "I trust my physics teacher Mr. Murray;" Hell must exist because "it's in the Bible"). Finally, appeals to a worldview/commitment referenced some preexisting philosophy or creed consistent with the existence of the entity in question (e.g., fluoride must exist because "I'm a chemistry major;" angels must exist because "I'm Muslim; angels exist by default"). Like appeals to authority/instruction, appeals to a worldview/commitment contained no factual information from which the belief could be inferred by someone who did not share the participant's same cultural or educational background.

Subjective Justifications These justifications referenced considerations predicated on a participants' own experience or point of view. They included appeals to intuition or volition, appeals to a personal experience or encounter, and appeals to definitions or clarifications (which accounted for 15%, 11%, and 6% of all justifications, respectively). Appeals to intuition/volition referenced the sensibility, plausibility, or desirability of the target entity without referencing considerations that actually bear upon its existence (e.g., electrons must exist because "they make rational sense;" Heaven must exist because "I like to think that my loved ones are going there"). Appeals to experience/encounters took the form of autobiographical events whose interpretation presupposed the existence of the entity in question (e.g., fluoride must exist because "it has been used on my teeth;" telepathy must exist because "my sister and I used to have it a lot when we played 21 questions"). Finally, appeals to definitions/clarifications were intended to refine the scope or certainty of one's belief, which, like the other two subtypes, provided no objectively persuasive reasons for belief (e.g., "I believe that organisms adapt to their environment, but not that we all come from one common being;" "I believe in the presence of those who have passed away, and I suppose this is what you would call an angel").

Justifications Frequencies by Domain The proportion of justifications that fell into each of the above categories are displayed in Table 2. Paired-samples *t* tests revealed that participants provided significantly more deferential

justifications for scientific items than for supernatural items ($t(108) = 2.61, p < 0.05$) and significantly more subjective justifications for supernatural items than for scientific items ($t(108) = 8.02, p < 0.001$). Participants also provided significantly more evidential justifications for scientific items than for supernatural items ($t(108) = 6.75, p < 0.001$), but the magnitude of this difference was small (0.16), especially considering the fact that one subtype of evidential justifications – appeals to direct evidence – could be provided only for scientific items.

In sum, participants provided similar, yet non-identical, justification profiles across the two domains of belief. Although participants provided significantly more evidential justifications for their scientific beliefs than for their supernatural beliefs, they provided relatively few evidential justifications overall. Instead, they relied predominantly on deferential justifications in both domains, appealing to a trusted source of information (e.g., “my teacher,” “my textbook,” “my religion,” “scientists,” “the Bible”) rather than the information itself.

Table 2: Mean proportion of justifications in each domain representative of each justification type (+ *SE*).

Justification type	Scientific	Supernatural
Evidential	.28 (.02)	.11 (.02)
Deferential	.54 (.02)	.47 (.03)
Subjective	.18 (.01)	.42 (.03)

Belief Refutations

The final question participants answered for each entity was what evidence would persuade them to change their mind about its existence. These responses are described below.

Evidential Refutations Refutations of this nature cited substantive facts or ideas that challenged the belief in question. Two subtypes were observed: anomalous data and alternative explanation (which accounted for 7% and 13% of all refutations). Participants who cited anomalous data described findings or phenomena that, if discovered, would be inconsistent with the target entity’s existence (e.g., one’s belief in electrons would be challenged “if an atom was found without them;” one’s belief in karma would be challenged “if bad people started experiencing good things”). Participants who cited alternative explanations described situations in which the target entity would no longer be needed to explain the phenomena it was intended to explain (e.g., one’s belief in fluoride would be challenged “if a new scientific model was heavily endorsed that could explain the building blocks of life without using the elements in the periodic table;” one’s belief in souls would be challenged “if science could find a way to explain why there is life at all and how individuality is created in terms of thinking and feeling”). Just as evidential justifications were the only epistemologically sound type of justification, evidential refutations were the only epistemologically sound type of refutation.

Deferential Refutations These refutations fell into the same categories as deferential justifications: appeals to unspecified evidence, appeals to authority or instruction, and appeals to a preexisting worldview or commitment (which accounted for 22%, 6%, and 3% of all refutations, respectively). Appeals to unspecified evidence acknowledged that one’s belief was revisable in light of new evidence but did not specify the content of that evidence (e.g., one’s belief in genes would be challenged by “scientific evidence that can prove genes do not exist;” one’s belief in precognition would be challenged by “proof that it’s genuinely impossible”). Appeals to testimony/education cited an informant, or group of informants, whose change of mind was sufficient to incite a personal change of mind (e.g., one’s belief in X-rays would be challenged “if a bunch of scientists got together and proved they didn’t exist;” one’s belief in Satan would be challenged “if the Church said it did not exist”). Finally, appeals to a worldview/commitment cited the possibility of changing a fundamental belief, or system of beliefs, that would result in a change to the specific belief at hand (e.g., one’s belief in evolution would be challenged by “becoming extremely religious;” one’s belief in reincarnation would be challenged by “more exposure to alternative beliefs”). All three categories cohered in their privileging of information sources over the information itself.

Subjective Refutations These refutations referenced considerations relevant only to the participant. They included appeals to a personal experience or encounter, appeals to ignorance or uncertainty, and denials of the premise itself (which accounted for 9%, 10%, and 30% of all refutations, respectively). Participants who appealed to a personal experience/encounter described hypothetical events that, if experienced, would call the target entity’s existence into question (e.g., one’s belief in X-rays would be challenged “if I found out all the X-rays I underwent were staged;” one’s belief in Hell would be challenged “if I died and wasn’t punished for all my sins”). Participants who appealed to ignorance/uncertainty explicitly claimed not to know what would constitute counterevidence to the entity’s existence (e.g., “I don’t know if you could ever prove it or disprove it;” “it is a personal belief, so I am not sure”). Finally, some participants denied the premise that their mind could be changed altogether, asserting that target entity’s existence was irrefutable (e.g., “there is no evidence that could effect my belief in fate;” “Nothing at this point can dissuade me from the idea of evolution”). While denying the possibility of counterevidence is, of course, different from identifying counterevidence contingent on one’s own experience, such responses were still fundamentally subjective in that they focused on personal predilections rather than external information (evidential refutations) or information sources (deferential refutations).

Refutation Frequencies by Domain Table 3 displays the mean proportion of evidential, deferential, and subjective

justifications to total justifications in each domain. Similar to the findings regarding belief justifications, participants provided significantly more deferential refutations for scientific items than for supernatural items ($t(108) = 4.80, p < 0.001$) but provided significantly more subjective refutations for supernatural items than for scientific items ($t(108) = 8.06, p < 0.001$). Participants also provided significantly more evidential refutations for scientific items than for supernatural items ($t(108) = 4.38, p < 0.001$), but the magnitude of this differences was, once again, quite small (0.11). Thus, just as participants tended to cite non-evidential considerations in justifying their scientific beliefs, they tended to cite non-evidential considerations when contemplating the revisability of those beliefs.

Table 3: Mean proportion of refutations in each domain representative of each refutation type (+ *SE*).

Refutation type	Scientific	Supernatural
Evidential	.29 (.02)	.19 (.02)
Deferential	.39 (.03)	.21 (.02)
Subjective	.32 (.02)	.59 (.03)

Interrelations among the Four Indices of Belief

The analyses presented thus far indicate that the epistemic foundations of participants' scientific beliefs are not identical to those of their supernatural beliefs. As a group, participants (a) exhibited greater confidence in their scientific beliefs; (b) perceived greater consensus surrounding their scientific beliefs; (c) cited more evidence in support of their scientific beliefs; and (d) identified more counterevidence to their scientific beliefs. This pattern of results appears, on its surface, to imply that participants' scientific beliefs were more epistemologically sound than their supernatural beliefs. Nevertheless, three additional findings militate against this interpretation.

First, the degree of differentiation between participants' scientific and supernatural beliefs was much greater along some dimensions than others. Cohen's *d* for the difference between scientific and supernatural beliefs was 1.41 for the confidence ratings and 1.64 for the consensus estimates, but was only 0.61 for participants' tendency to provide evidential justifications and 0.36 for participants' tendency to provide evidential refutations. Apparently, participants' sensitivity to differences between scientific and supernatural beliefs influenced their appraisals of confidence and consensus much more than it influenced their ability (or proclivity) to cite evidential considerations relevant to those beliefs.

Second, differences in confidence were not warranted by differences in the quality of participants' justifications or refutations. This finding emerged from a hierarchical regression analysis in which participants' confidence ratings for the scientific items were first regressed against their consensus estimates (Model 1) and then regressed against their tendency to provide (a) evidential justifications and (b) evidential refutations (Model 2). While the first model

explained a significant amount of the variance in participants' confidence ratings ($R^2 = 0.12$; F -change (1,637) = 89.63, $p < 0.001$), the second model did not ($R^2 = 0.13$; F -change (2,635) = 1.75, *ns*). Thus, participants' confidence in their scientific beliefs was linked to their perception of how widely those beliefs are shared but was not linked to their ability to support those beliefs with evidence.

Third, the ability to provide evidential justifications and evidential refutations was not widespread. Only 13 participants (or 12%) provided evidential justifications as their modal justification type, and only 19 participants (or 17%) provided evidential refutations as their modal refutation type. Moreover, participants' tendency to provide evidential justifications was significantly correlated with their tendency to provide evidential refutations, as shown in Table 4. These tendencies were linked not only within the same domain but across domains as well, implying that they represent a domain-general disposition to reflect upon the validity of one's beliefs, similar to those documented in the domains of argumentative reasoning (Kuhn, 1991), inferential reasoning (Stanovich & West, 1998), and modal reasoning (Shtulman, 2009).

Table 4: Correlations between evidential justifications (JUS) and evidential refutations (REF) for both scientific items (SCI) and supernatural items (SUP).

Measure	JUS_SCI	JUS_SUP	REF_SCI	REF_SUP
JUS_SCI	1.0	.26**	.44**	.25*
JUS_SUP		1.0	.20*	.23*
REF_SCI			1.0	.43**
REF_SUP				1.0

Discussion

The evidential support for scientific claims is quantitatively and qualitatively superior to that for supernatural claims, yet it is unclear whether students appreciate this difference in light of the fact that both types of claims are conveyed in similar ways (through testimony) and perform similar functions (explaining observed phenomena in terms of unobservable entities). The present study addressed this issue by comparing students' scientific beliefs to their supernatural beliefs along four dimensions of epistemic import: confidence, consensus, means of justification, and openness to revision. Although participants were almost always more confident in their scientific beliefs than their supernatural beliefs, they were rarely able to identify evidence that might bear on the validity of those beliefs, either in the form of justification or refutation. Moreover, participants' confidence was related to their perception of how likely other people would agree with their beliefs but was *not* related to their ability to cite evidential considerations relevant to those beliefs.

Two features of the data were particularly notable. First, participants' modal form of justification was deference to the opinions and conclusions of others. That is, participants

were more likely to reference the *proximal* source of their beliefs (i.e., the testimony of an accepted authority or the tenets of an accepted worldview) than to reference its *distal* source (i.e., reasons for accepting the testimony/tenets as true), both for scientific beliefs and supernatural beliefs. Although it could be argued that deference to “more knowledgeable others” is a generally rational course of action (Keil, Stein, Webb, Billings, & Rozenblit, 2008), this claim is undermined, at least in the present study, by the fact that participants deferred to unsubstantiated sources of information (i.e., those propounding supernatural claims) as often as they deferred to substantiated ones (i.e. those propounding scientific claims). Moreover, participants who provided deferential justifications for their scientific beliefs, rather than evidential ones, also tended to claim that these beliefs were indefeasible, which clearly indicates a non-rational view of the nature of science. Indeed, the majority of participants (55%) denied that *anything* could dissuade them of the existence of at least one scientific entity.

Second, the findings obtained here with adults who had had multiple years of science instruction strongly mirror those obtained by Harris, Pasquini, Duke, Asscher, & Pons (2006) with individuals who had had little to no science instruction: 5- to 6-year-old children. In that study, children not only endorsed the existence of scientific entities, like germs and oxygen, more often than they endorsed the existence of supernatural entities, like God and the Tooth Fairy, but also claimed that more people, in general, believe in the existence of the former than the latter. They did *not*, however, provide different types of justifications for their judgments. Instead, they tended to appeal to generalizations that presupposed the target entity’s existence in both cases (e.g., germs exist because “animals can have germs;” the Tooth Fairy exists because “she visits you when you lose a tooth”). While it is unclear how the justification categories used in Harris et al. (2006) relate to those used in the present study, it is telling that even young children appear to be more sensitive to the amount of consensus surrounding various extraordinary claims than to the conceptual and/or evidential status of those claims.

Taken together, these findings imply that students’ understanding of science as a body of knowledge is not much better than their understanding of science as a method of inquiry (Lederman et al., 2002; Schauble et al., 1995; Smith et al., 2000). Just as students conceive of science as problem solving rather than inquiry, they justify their scientific beliefs with appeals to intuition and authority rather than evidence. And just as students think that scientists are in the business of “proving their ideas true,” they think that certain scientific entities have been proven to exist beyond a shadow of doubt. These findings not only complement existing findings on students’ scientific epistemologies but also point to the possibility that misconceptions about the *process* of science may actually be responsible for misconceptions about the *products* of science. Still, the question of whether, and how, such misconceptions are related awaits further research.

Individual Differences as Predictors of Learning and Engagement

Abstract

We investigated the possibility of predicting students' engagement and learning gains during a tutoring session from trait measures of motivation, engagement, burnout, cognitive ability, prior knowledge, and task related measures. Participants completed a multiple choice pretest, a learning session, a posttest, and a battery of individual differences tests and questionnaires. Multiple regression and exploratory factor analyses indicated that the individual differences measures yielded medium sized effects at predicting learning gains as well as engagement levels that were self-reported during the tutorial session. In general, self-reported interest in the task and confidence in learning from a computer tutor coupled with working memory capacity and attentional abilities were the major predictors of both engagement and learning.

Keywords: learning, engagement, individual differences, cognitive abilities, motivation, burnout, ITS

Introduction

There is no one-size-fits-all approach when it comes to promoting student engagement and learning. Engagement and learning are affected by a number of factors such as, the learning environment (classroom, human tutor, high stakes learning), the task (acquiring shallow facts versus obtaining a deeper conceptual understanding), and characteristics of the learners themselves (e.g., visual versus verbal learners, performance versus mastery-oriented learners) (Ackerman, Sternberg, & Glaser, 1989; Jonassen & Grabowski, 1993; Schmeck & Geisler-Brenstein, 1989). Therefore, understanding how a particular student will be engaged in and benefit from a learning session requires an analysis of how the learning environment, the task, and the characteristics of the learner (i.e. individual differences) interact and influence learning outcomes.

For a given learning activity (e.g., learning conceptual physics from a human tutor), the context and the task are fixed, however the individuals involved in the activity vary. Hence, it is important to discriminate learners that actively engage and benefit from a learning session from others who passively attend the session and do not demonstrate dramatic improvements in their knowledge levels. Consequently, individual differences research has been a long standing and valuable tradition in the fields of psychology and education (Ackerman et al., 1989; Jonassen & Grabowski, 1993). Although research efforts along this front have yielded some important insights, there is little

data on how individual differences influence engagement and learning within the context of intelligent learning environments such as Intelligent Tutoring Systems (ITSs). Understanding how individual differences impact learning sessions with ITSs is important, because ITSs are emerging as effective alternatives to deliver individualized instruction to large numbers of students (Corbett, Anderson, Graesser, Koedinger, & VanLehn, 1999; Graesser, Person, & Magliano, 1995; Koedinger & Corbett, 2006).

It is generally acknowledged that all students do not benefit equally from learning sessions with ITSs (VanLehn et al., 2007). Some learners show dramatic improvements in learning gains from pre to post tests, while tutoring has a negligible impact on others. Some learners actively attend the session by carefully listening to the tutor, taking initiative by asking questions, and providing verbose responses to the tutor's questions (Graesser et al., 1995). However, other non-critical learners, socially attend the session, and are comfortable being passive information receivers rather than active problem solvers. Who are these learners? Can they be discriminated from standard individual difference measures? What are the individual differences that are predictive of engagement and learning gains? These are the questions that motivated the present study.

The present study investigated whether trait measures of individual differences in (a) motivation, engagement, and burnout, (b) cognitive abilities, and (c) task related measures, could predict state measures consisting of engagement levels and learning gains in a one-on-one tutoring session with an ITS. Our focus on trait measures of motivation, engagement, and burnout is motivated by numerous studies that have related these measures to engagement and learning (Bartels & Magun-Jackson, 2009; Pekrun, Elliot, & Maier, 2006). For example, learners with mastery-approach motivation orientations are expected to be absorbed in the learning process (i.e., more engaged) and process the material deeply, presumably resulting in higher learning gains (Elliot & McGregor, 2001). In contrast, learners with performance-approach characteristics process the material at relatively shallow levels and do not demonstrate impressive learning gains. Similarly, some research has linked trait measures of engagement and burnout to performance outcomes (Schaufeli, Martinez, Pinto, Salanova, & Bakker, 2002).

Individual differences in cognitive abilities have previously been related to a variety of outcomes, hence, we expect them to be predictive of both engagement and learning with ITSs. For example, working memory capacity has been linked to performance on tests of fluid intelligence (Yuan, Steedle, Shavelson, Alonzo, & Oppizzo, 2006). Sustained attention has been related to academic achievement in school contexts (Steinmayr, Ziegler, & Träuble, 2010). In general, existing research has empirically demonstrated interactions between affect, working memory capacity, attention, intelligence, and performance outcomes (Linnenbrink, Ryan, & Pintrich, 1999; Steinmayr et al., 2010; Vergus & Boeck, 2002; Yuan et al., 2006). Hence, the present study focused on working memory capacity, selective and sustained attention, and general intelligence as predictors of engagement and learning gains.

In addition to the motivation, engagement, burnout, and cognitive variables, there is reason to suspect that individual differences pertaining to the learning task itself might be predictive of both engagement and learning gains. For example, task interest is likely to trigger curiosity and promote engagement (Berlyne, 1978), while prior knowledge is expected to be predictor of learning gains (VanLehn et al., 2007). More interestingly, there is some recent evidence that suggests that students' confidence of learning from a computer can be a better predictor of learning gains than other variables (e.g., initial motivation, prior knowledge) (Jackson, Graesser, & McNamara, 2009).

The present study investigated whether engagement and learning gains from a tutoring session in biology could be inferred from the aforementioned individual differences measures. More specifically, our analyses focused on (a) comparing the predictive power of three banks of predictors (motivation/engagement/burnout *versus* cognitive *versus* task), (b) assessing the predictive power of combined models that simultaneously include predictors from all three banks, (c) deriving principal components from the individual difference measures, and (d) correlating the derived components with engagement and learning gains.

Methods

Participants

Participants were 90 college students (non biology majors) who participated for course credit.

Description of Learning Environment

The study used a dialogue-based ITS that tutored students on eight topics in biology (e.g., cellular respiration, mitosis, ecological succession) via natural language dialogues. The ITS was designed to mirror the pedagogical and motivational strategies of lectures delivered by expert human tutors (D'Mello et al., in review).

Participants were randomly assigned to one of three versions of the ITS. In the *dialogue* version, the tutor primarily transmitted information (68% of the time) but occasionally provided cues for acknowledgements (e.g.,

"Right?", "ok?"), asked comprehension gauging questions (e.g., "Do you understand?"), and prompted the student for answers (e.g., "X is a type of what?"). Alternatively, in the *monologue* version, the tutor did all the talking and the student was a passive recipient. The third version consisted of *vicarious dialogues*, where the discourse patterns were structurally similar to the dialogue condition, but with one important exception. Here, it was a virtual student, instead of the learner, that answered the tutor's comprehension gauging questions and prompts. The virtual student always provided the correct answer (via simulated keystrokes) and the human learner simply watched the interaction.

The lectures were delivered via a simple conversational interface that consisted of an animated conversational agent that delivered the content of the lectures by means of synthesized speech, a media panel that displayed images relevant to the lectures, and an input box for students to type their responses for the dialogue condition. In the vicarious dialogue condition, the virtual student's responses were provided in the input box with simulated keystrokes. The simulated keystrokes were carefully calibrated in order to mirror the temporal dynamics of actual typing (i.e., onset delay, variable interstroke delay, and delay before hitting enter key to submit response).

Dependent Measures

Engagement Measures. Participants' engagement levels were tracked at multiple points in the tutorial session with the affect grid (Russell, Weiss, & Mendelsohn, 1989) and through post-lecture questionnaires. The affect grid is a validated single item affect measurement instrument consisting of a 9×9 (valence \times arousal) grid. Valence and arousal are the primary dimensions that underlie affective experiences. The arousal dimension ranges from sleepiness to high-arousal, while the valence dimension ranges from unpleasant feelings to pleasant feelings. Participants indicate their affective state by marking an X at the appropriate location on the grid.

The post-lecture questionnaire asked participants to self-report their engagement levels after each lecture. There were three questions which asked the participant to rate their engagement at the beginning, middle, and end of each lecture. Participants indicated their ratings on a six-point scale ranging from *very bored* to *very engaged*.

Knowledge Tests. The knowledge tests (used to measure prior knowledge and learning gains) were 24-item multiple-choice tests with three questions for each lecture. *Prompt* questions tested participants on content for which the tutor explicitly prompted the student in the dialogue and vicarious conditions. Although there were no explicit prompts in the monologue condition, we verified that the content of the prompts was explicitly covered in the monologue. *Assertion* questions tested participants on content that the tutor explicitly asserted to the student via direct instruction. Finally, there were *deep reasoning* questions that required causal reasoning, inference, etc. rather than recall of shallow

facts. Participants completed alternate test versions for pretest and posttest that were counterbalanced across participants.

Individual Difference Measures

Motivation, Engagement, and Burnout. These measures consisted of: the Achievement Goals Questionnaire (AGQ) for motivation, the Utrecht Work Engagement Scale for Students (UWES-S) for trait engagement, and the Maslach Burnout Inventory Student Survey (MBI-SS) for burnout (Elliot & McGregor, 2001; Schaufeli et al., 2002).

The AGQ, a validated 12 item questionnaire, was used to classify participants' motivation levels as *performance-approach*, *performance-avoidance*, *mastery-approach*, and *mastery-avoidance* (Elliot & McGregor, 2001).

The UWES-S is a validated 14-item self-report measure of three dimensions of student engagement: *vigor*, *dedication*, and *absorption* (Schaufeli et al., 2002).

The MBI-SS is a validated 15-item self-report measure of three dimensions of student burnout: *exhaustion*, *cynicism*, and *professional efficacy* (Schaufeli et al., 2002).

Task Related Individual Differences. These measures consisted of pretest scores as a measure of *prior knowledge* in biology (see above) and a locally created Perceptions of Learning Biology Questionnaire (PLB). The PLB consisted of three questions that were designed to gauge participants' *interest* in learning biology, their perceived *usefulness* of learning biology, and their *confidence* that they could learn biology from a computer tutor.

Cognitive Measures. The cognitive measures consisted of: self-reported ACT or SAT scores as a measure of aptitude (these are standardized tests required for admission to universities in the US; SAT scores were converted to ACT scores in the present study), the validated Reading Span test (RSpan) to measure working memory capacity (Daneman & Carpenter, 1980), and the validated Ruff 2 and 7 Selective Attention test (Ruff 2 and 7) which measures selective and sustained attention (Ruff, Neimann, Allen, Farrow, & Wylie, 1992).

In each trial of RSpan, participants are presented with a logical or nonsensical sentence and an arbitrary letter that appears at the end of the sentence. They have to read the sentence out loud, determine if it was logical or nonsensical, and try to remember the unrelated letter. At recall, the participant typed the letters from the current set of trials in the correct order. The set sizes ranged from 2 to 5 letter strings (there were 3 trials of 2 character strings, 3 trials of 3 character strings, 4 trials of 4 character strings, and 2 trials of 5 character strings).

The measures from the RSpan include the *absolute span*, which is the highest set size (i.e., 2, 3, 4, or 5) that the participant recalled correctly, the *weighted span* (i.e., a score computed by weighting set size and items recalled), and the *total recalled* (i.e., the total number of items that the participant recalled correctly).

The Ruff 2 and 7 is a measure of selective and sustained attention (Ruff et al., 1992). It is a five-minute timed task with 20 trials (each trial is 15 seconds). For each trial, 30 targets (2's and 7's) were embedded in either a string of alphabetical capital letters (known as the automatic detection trials), or among strings of digits (known as the controlled search trials). Participants are required to spot the 2's and 7's from the distracters and click on them.

Selective attention was measured by the *automatic detection speed* and *accuracy* (the 10 letter trials) and by the *controlled search speed* and *accuracy* (the 10 digit trials). Sustained attention is measured by the *total speed* and *total accuracy* in the 20 trials.

Procedure

Participants were tested individually over a two hour session. They first completed an informed consent followed by the pretest and the Perceptions of Learning Biology questionnaire. Next, they read instructions on how to use the affect grid. On the basis of random assignment, participants then completed a tutorial session with either the monologue, dialogue, or vicarious version of the tutor. There were 30 participants in each condition. The tutoring session consisted of eight lectures that were randomly ordered for each participant. Random ordering was permissible because there was no major content overlap across lectures. Participants completed the affect grid and the post-lecture questionnaire after each lecture. They completed the posttest after the completion of all eight lectures. Finally, they completed the battery of individual difference measures after which they were fully debriefed.

Results and Discussion

We analyzed the data with multiple regression (MLR) and exploratory factor analysis techniques. The goal of the MLR analyses was to assess the predictive power of the three banks of predictors by comparing each bank separately, as well as building combined models that collectively considered all three banks. The factor analysis was used to extract principal components from the individual difference measures and to correlate the extracted components to the dependent measures (engagement and learning gains).

It is important to highlight some important points before describing the results. First, there were seven dependent variables: four learning gains measures and three engagement measures. The four learning gains measures were the corrected learning gains $[(\text{post} - \text{pre}) / (1 - \text{pre})]$ for the prompt, assertion, and deep-reasoning questions, and an overall learning gains score (gains computed on all the items without segregating them into the different categories).

The three measures for engagement consisted of valence and arousal scores from the Affect Grid and a *composite engagement* score, which was the average engagement from the post lecture questionnaire (i.e., mean for each lecture of beginning engagement, middle engagement, and end engagement). Since the Affect Grid and post lecture questionnaires were administered eight times, once after

each lecture, an aggregate value for valence, arousal, and composite engagement was computed for each participant by averaging the scores across lectures.

It is important to emphasize that the goal of the present paper is to identify the individual difference measures that predict learning and engagement and not to assess the impact of the tutor version (i.e., dialogue, monologue, vicarious). Previous analyses have compared our dependent measures as a function of tutor type (D'Mello et al., in review). Hence, the present analyses collectively analyzed all participants without considering tutor version.

Comparing Individual Predictor Banks

The goal of this analysis was to compare the predictive power of the different banks of predictors. This was accomplished by constructing 21 multiple regression models for the seven dependent variables and the three predictor banks. There were ten motivation and engagement predictors, four task related measures, and ten cognitive predictors.

Prior to constructing the regression models, we performed a correlational analysis to identify the most diagnostic set of predictors. In particular, any predictor that marginally-significantly correlated ($p < .10$) with at least one of the seven dependent measures was preserved for the subsequent analyses. This reduced the predictor set to four motivation and engagement predictors (performance-approach, performance-avoidance, vigor, and exhaustion), three task related predictors (prior knowledge, confidence, and interest), and seven cognitive predictors (ACT; absolute span, weighted span, total recalled from the RSpan test; automatic detection speed, controlled search speed, and total speed from the Ruff 2 and 7). Multicollinearity problems among these predictor sets were diagnosed and corrected with tolerance analyses prior to constructing the regression models.

Space constraints preclude an extensive discussion of the regression models constructed by examining each predictor set independently. Hence, the current discussion is limited to comparison of the predictive power of the three feature sets (coefficients will be examined in the subsequent analysis). R^2 adj. values as a measure of goodness of fit for regression models are presented in Table 1.

It appears that on average the cognitive predictors explained 10.2% of the variance for the learning gains measures, which is consistent with a small to medium sized effect (Cohen, 1992). Variance explained by the cognitive set was also quantitatively greater than the variance explained by the motivation/engagement/burnout and task related predictors, which were on par with each other (mean R^2 adj. = .044 and .053, respectively). In contrast, the three predictor sets were equally effective in predicting the engagement measures.

Multiple Predictor Sets

The next set of regression models were constructed from the predictors that were significant in the previous set of

analyses. Here, predictors from all three feature sets were simultaneously considered and the significant predictors were identified via stepwise regression.

Table 1. R^2 adj. for regression models

Dependent Measure	Individual Banks			Combined
	<i>M,E,B</i>	<i>Task</i>	<i>Cog</i>	
Learning				
Prompt	0 ^c	0 ^c	.085	.113
Assertion	.111	.027 ^b	.039	.122
Deep	0 ^c	.053	.129	.194
Overall	0 ^c	.062	.156	.149
<i>Mean</i>	.028	.036	.102	.145
Engagement				
Valence	.047	.030	.067	.082
Arousal	.066	.111 ^b	.061	.197
Composite	.081	.086	.136	.169
<i>Mean</i>	.065	.076	.088	.149

Notes. All models significant at $p < .05$ unless noted otherwise. ^b significant at $p < .10$, ^c not significant ($p > .10$). *M,E,B* = motivation, engagement, burnout. *Cog* = Cognitive.

Learning Gains. There were statistically significant models for learning gains on prompt questions, assertion questions, deep reasoning questions, as well as for total learning gains (see Table 1). On average, the combined feature sets explained .145 of the variance, which approaches a medium sized effect (Cohen, 1992) and represents a 43% improvement in the variance explained by considering the best feature set independently (i.e., cognitive features).

Turning our focus to the significant predictors of the regression models (see Table 2), it appears that students with higher working memory abilities performed well on prompt questions. Surprisingly, self-reported exhaustion scores positively predicted performance on assertion questions; this finding warrants further analysis.

Deep reasoning questions, however, were predicted by a combination of self-reported interest in learning biology as well as a high ability to sustain attention. Total learning gains, however, were predicted by a combination of working memory capacity and sustained attention, indicating that the cognitive variables are the most relevant.

Table 2. Direction (+, -) of significant predictors

Predictor	Learning Gains				Engagement		
	<i>P</i>	<i>R</i>	<i>D</i>	<i>O</i>	<i>A</i>	<i>V</i>	<i>C</i>
Perf-Approach						+	
Exhaustion		+					
Interest			+		+	+	+
Absolute Span	+				+		
Weighted Span						+	
Total Recalled				+			+
Total Speed			+	+			
Contrl. Srch. Speed							+ ^a

Notes. ^a $p = .056$; $p < .05$ for other predictors; *P*, *R*, *D* = gains for prompt, assertions, and deep questions, respectively. *O* = overall learning gains. *A*, *V*, *C* = arousal, valence, and composite engagement, respectively.

Engagement. Statistically significant models were obtained for arousal, valence, and the composite engagement score. These models explained an average of 14.9% of the variance, which is consistent with a 70% improvement over the best individual model (cognitive features; see Table 1).

An examination of the significant coefficients of the regression models for engagement indicated that task interest and working memory capacity were the most diagnostic predictors (see Table 2). In particular, arousal was predicted by task interest and absolute span. Valence was predicted by task interest, weighted span, and with a performance-approach motivational orientation. Finally, composite engagement was predicted by task interest, total items recalled during the RSpan test, and controlled search speed (an important characteristic of selective attention). Simply put, being interested in the learning session and having the requisite cognitive ability (working memory span and attention) to handle the difficulties and demands of the session were the major predictors of engagement.

Factor Analysis

We analyzed the individual differences with an exploratory factor analysis (principal components analysis with varimax rotation and Kaiser normalization). The analysis was conducted on 18 out of the 24 predictors because the inclusion of some of the predictors from the RSpan and Ruff 2 and 7 tests posed problems with respect to the factorability of the data. Specifically, only the absolute span measure from the RSpan test and the total speed and total accuracy scores from the Ruff 2 and 7 test were included.

Several indicators of factorability on the model with 18 predictors indicated that the data were in fact factorable. In particular, (a) the Kaiser-Meyer-Olkin measure of sampling adequacy was .72, which is above the recommended value of .6, (b) Bartlett's test of sphericity was significant ($\chi^2(153) = 287.16, p < .05$), (c) the diagonals of the anti-image correlation matrix were all above .5, which supports the inclusion of each item in the factor analysis, and (d) the commonalities were above .3, which indicates that each item shared a degree of common variance with the other items.

The analysis yielded six components with eigen values greater than 1 that collectively accounted for 63.4% of the variance (see Table 3). It appears that Component 1, which consists of a combination of predictors from the UWESS-S, MBI-SS, and AGQ represents highly engaged, low burnout, and mastery-approach oriented learners. This component accounted for 18.9% of the variance. In contrast, Component 2 (10.3% variance) represents learners with mastery and performance-approach tendencies. Component 3 (9.5% variance) represents learners that have some prior knowledge in biology and they find it interesting and useful, while Component 4 (9.4% variance) is consistent with learners that are intelligent and have high attention abilities. Component 5 (8% variance) represents learners have a large working memory and are confident that they can learn biology from a computer tutor. Finally, Component 6 (7.2%

variance) consists of learners that are absorbed, but have a performance-avoidance motivational orientation.

Our analyses proceeded by correlating the individual difference measures with the six extracted components (see Table 4). As evident from the table, components 4 and 5 are the major predictors. In particular, component 5 correlates with six out of the seven dependent measures, thereby indicating that confidence in learning biology from a computer tutor coupled with large working memory capacity and attentional ability is the individual difference component that predicts engagement and learning.

General Discussion

The present study investigated the possibility of predicting students' engagement and learning gains during a tutoring session with an ITS on the basis of individual differences in motivation, engagement, burnout, cognitive abilities, and task related measures. The results supported the conclusion that the cognitive factors reigned supreme when it comes to predicting learning outcomes; however, all three predictor banks were equivalent for predicting engagement. When

models were combined, the individual difference measures explained 15% of the variance in engagement and learning gains, which is consistent with a medium effect (Cohen, 1992). In general, interest in the task, confidence in learning from a computer tutor, large working memory capacity, and heightened attentional abilities were the major predictors of both engagement and learning.

Our findings have important implications for the design of ITSs that aspire to be dynamically adaptive to individual learners. These ITSs construct sophisticated student models and utilize them to tailor the instruction to each student's zone of proximal development (Koedinger & Corbett, 2006). The models are usually constructed on the basis of how students' knowledge in a particular domain meshes with the material that the tutor is expected to cover. In our view, a brief pretesting session on some of the individual difference measures coupled with the existing student modeling approaches will yield more accurate models that can guide individualized instruction. How these models are utilized to heighten engagement and enhance learning gains awaits further research and technological development.

Abstract

Research has established that tutors often have difficulty with accurately assessing a tutee's understanding. However, it is a completely open question which characteristics of tutors might affect their assessment. In an empirical study with $N = 22$ tutor-tutee dyads, we used a methodology developed by Chi, Siler, and Jeong (2004) to examine the influence of the tutors' content knowledge and beliefs about learning on their assessment accuracy. Results replicated previous research in showing that tutors overestimated a tutee's correct understanding and underestimated a tutee's incorrect understanding. In addition, more accurate assessments were positively related with tutees' learning. Finally, content knowledge had a positive impact on assessment accuracy, whereas beliefs about learning were not strongly associated with assessment accuracy. Thus, assessing a tutee's understanding seems to be important for the effectiveness of human tutoring. Moreover, the results suggest that the tutors' assessment accuracy is largely influenced by their content knowledge.

Keywords: assessment accuracy; beliefs about learning; content knowledge; human tutoring

Introduction

In educational psychology, it is widely acknowledged that for learning to be effective instruction should be tailored to a learner (Kalyuga, 2007). However, such learner-tailored instruction makes it necessary to assess a learner's individual understanding. Therefore, the ability to collect diagnostically relevant information about a learner is a central component that constitutes teaching competence (Wittwer & Renkl, 2008).

One-to-one tutoring is a form of instruction where tutors can make intensive use of the possibility of freely interacting with a tutee in order to assess a tutee's understanding. Accordingly, tutors can be expected to have a detailed "model of the student" (Putnam, 1987). However, research has shown that tutors often have difficulty with

gleaning diagnostically relevant information about a tutee. For example, Chi, Siler, and Jeong (2004) examined tutoring in biology and found that tutors appeared to be relatively accurate in knowing the tutees' correct understanding but they failed to assess the tutees' incorrect understanding including their false beliefs and flawed mental models. The researchers interpreted this finding as evidence that tutors mainly used their own normative perspective as a basis for estimating what the tutees did and did not know. Similar findings were obtained by Graesser, Person, and Magliano (1995), who showed that tutors rarely diagnosed a tutee's incorrect understanding. Instead, their actions were largely based on a curriculum script that determined which skills and concepts were to be learned by the tutees (see also Putnam, 1987).

In light of these findings, the question arises as to what influences the tutors' assessment of a tutee's understanding. In this article, we shed light on two characteristics of tutors that might impact their assessment of tutees. Specifically, we look at the tutors' content knowledge and beliefs about learning. To theoretically elucidate the role of these tutor characteristics, we draw on research in the field of human tutoring and classroom teaching.

Tutors' Content Knowledge

There is widespread agreement that having a deep understanding of a subject matter is an important condition for effective teaching. Research has shown that teachers with higher content knowledge show, for example, a greater understanding of important concepts in a domain and of the relationships among them (e.g., Borko & Putnam, 1996).

However, the question as to how content knowledge specifically affects the assessment of learners in the process of teaching has not been the object of much research (cf. Baumert & Kunter, 2006). For example, Krauss et al. (2008) found that teachers with higher content knowledge tended to

have more knowledge about a learner's misconceptions. The influence of this knowledge on the teachers' practices in classroom, including their assessment of the learners, was, however, not examined.

Similarly, in the context of tutoring, little is known about the relationship between the tutors' content knowledge and their assessment of tutees. For example, Schmidt et al. (1993) found that tutors with higher content knowledge were generally more effective in promoting tutees' learning when compared to tutors with lower content knowledge. The researchers attributed this finding to the fact that tutors with more content knowledge engaged in content-related activities that helped tutees to acquire knowledge. Even so, the role of the tutors' assessment practices for the tutees' learning was not investigated in this study.

Overall, the findings suggest that tutors with higher content knowledge might assess a tutee's individual understanding more accurately than tutors with lower content knowledge. This is assumed to be because tutors with more content knowledge normally have a deeper understanding of the concepts to be learned by a tutee (Borko & Putnam, 1996). Accordingly, tutors can be expected to show a more differentiated understanding of a tutee's conceptual knowledge (Nickerson, 1999). For example, tutors with higher content knowledge might be more likely to think at a deeper level about the conceptual aspects of a tutee's comprehension difficulties (Chi, Feltovich, & Glaser, 1981). Similarly, tutors with higher content knowledge might more likely infer from a tutee's particular misunderstanding which related misunderstandings and misconceptions can occur (Person et al., 1994).

Tutors' Beliefs About Learning

Apart from the teachers' content knowledge, their beliefs about how learners learn might also influence their teaching (Borko & Putnam, 1996). These beliefs can be roughly divided into two different views of learning: a transmission view of learning and a constructivist view of learning. A transmission view of learning focuses on the contents to-be-learned and emphasizes the role of transmitting knowledge to the learner. In contrast, a constructivist view of learning places a learner's own knowledge-construction activities at the center of instruction and emphasizes the role of supporting a learner's learning.

Research has provided evidence that such beliefs have an impact on teaching and learning. For example, Staub and Stern (2002) found that teachers with a constructivist view of learning were more successful in enhancing a learner's problem solving. In addition, Dubberke et al. (2008) showed that the teachers' beliefs strongly guided their teaching practices. For example, teachers with a transmission view of learning less often engaged in activities to support the learners' knowledge acquisition than teachers with a constructivist view of learning.

Despite these findings, there is also research showing that the teachers' beliefs are not necessarily associated with their

pedagogical activities observed in classroom (e.g., Leuchter et al., 2006). It can be assumed that this is because teachers might not be completely accurate in self-assessing their beliefs about learning. Another explanation is that the teachers' beliefs might be too distal to strongly shape their teaching practices.

In the context of tutoring, it is a completely open question as to how the tutors' beliefs about learning influence their assessment of tutees. In line with the findings obtained in research on classroom teaching, it can be assumed that a constructivist view of learning supports the accuracy with which tutors assess a tutee's understanding. This is because tutors with a constructivist view of learning as opposed to tutors with a transmission view of learning see tutees as being actively involved in learning. Thus, it is supposed that tutors with a constructivist view of learning provide tutees with opportunities to be active and constructive on their own. As a result, the tutors should get insights into the tutees' understanding and learning progress during the course of tutoring.

Research Questions

We present an empirical study in which we examined human tutoring in biology to shed light on the role of the tutors' content knowledge and beliefs about learning in assessing a tutee's conceptual understanding. We addressed the following research questions:

- 1) How accurately do tutors assess a tutee's correct understanding and a tutee's incorrect understanding?
- 2) Is the tutors' assessment accuracy positively associated with the tutees' learning?
- 3) Does the tutors' content knowledge positively influence their assessment accuracy?
- 4) Does the tutors' orientation towards a constructivist view of learning positively influence their assessment accuracy?

Method

Sample and Design

A total of $N = 22$ dyads of tutors and tutees participated in the empirical study. Tutors were university students of biology. Of the tutors, 18 were female and 4 were male. Their mean age was 22.64 years ($SD = 2.79$). Tutees were K-7 students from Realschulen (i.e., schools from the middle track of the German school system). Of the tutees, 9 were female and 13 were male. Their mean age was 12.64 years ($SD = 0.49$). The tutors and the tutees did not know each other before tutoring.

We examined the accuracy with which the tutors assessed a tutee's individual understanding. We also analyzed the impact of their assessment accuracy on tutees' learning. Finally, we investigated the influence of the tutors' content knowledge and beliefs about learning on their accuracy at assessing a tutee's individual understanding.

Materials

Textbook (Tutee and Tutor) In the tutoring session, the tutor and the tutee engaged in a dialogue on the basis of a passage about the human circulatory system, which was previously used by Chi et al. (2001). We adapted this passage for the present study by deleting and reformulating some sentences. Each of the remaining 59 sentences of the passage was printed on a separate sheet of paper. The sentences were presented to the tutor and the tutee in a ring binder.

Content Knowledge Test (Tutor) The test consisted of 18 multiple-choice items. Each correct answer was assigned 1 point. The test measured not only the tutors' knowledge about basic concepts to be discussed in tutoring, but also their knowledge about advanced concepts of the human circulatory system, about the relationships among these concepts, and about the relevance of these concepts for life processes. Hence, answering the test required different levels of knowledge. Accordingly, item difficulty ranged from .41 to .95 ($M = .64$, $SD = .16$).

Beliefs About Learning Questionnaire (Tutor) The questionnaire was adapted from Staub and Stern (2002). On a 4-point Likert scale ranging from 1 (= *strongly disagree*) to 4 (= *strongly agree*), the tutors indicated their agreement with 19 statements. Agreement with 9 out of the 19 statements indicated a constructivist view of learning. The agreement with the remaining 10 statements indicated a transmission view of learning. The statements indicating a transmission view of learning were reversed so that the mean agreement with a constructivist view of learning could be computed, with higher scores showing a more constructivist view of learning.

Misconceptions Test (Tutee and Tutor) The test consisted of 25 multiple-choice items that addressed concepts about the human circulatory system at the local level of propositions (cf. Chi et al., 2004). The items were adapted from tests originally developed by Sungur and Tekkaya (2003) and by Michael et al. (2002) or constructed on the basis of the literature on misconceptions of the human circulatory system (e.g., Pelaez et al., 2005). The items covered concepts about the human circulatory system that were explicitly or implicitly mentioned in the textbook. A correct answer indicated a scientifically correct understanding of the concept. Each of the incorrect answers indicated a specific type of incorrect understanding of the concept.

Drawings of the Human Circulatory System (Tutee and Tutor) On a sheet of paper, the outline of a human body was displayed. The tutees were asked to draw the blood path of the circulatory system into the human body and to explain the blood path. The explanations were audiotaped. By using this methodology, which was originally developed

by Chi et al. (2004), we assessed a tutee's conceptual understanding at the global level of mental models.

To code the tutees' and the tutors' drawings and explanations of the human circulatory system, we adapted a classification scheme originally developed by Azevedo, Cromley, and Seibert (2004). On the basis of this classification scheme, the drawings were assigned to one of twelve categories. The categories reflect distinguishable types of correct and incorrect mental models with categories 0 to 9 indicating different types of incorrect mental models and with categories 10 to 11 indicating a correct mental model.

Procedure

Each tutoring session was divided into three phases: pre-test phase, tutoring phase, and post-test phase. It lasted about 3 hours.

Pre-Test Phase In the pre-test phase, the tutors completed the content knowledge test. The tutees completed the misconceptions test. In addition, the tutees were asked to draw the blood path of the human circulatory system in the outline of a human body and to explain the blood path as they knew it. Afterwards, both the tutors and the tutees individually read the passage about the human circulatory system.

Tutoring Phase The dyads of tutors and tutees read each sentence of the passage about the human circulatory system and engaged in a dialogue about each sentence. After the 33th sentence, tutoring was interrupted and the dyads were separated. The tutees were asked to draw and explain the blood path of the human circulatory system. To measure what the tutors thought that the tutees would know about the blood path, the tutors were required to draw and explain the tutees' mental model of the human circulatory system. After accomplishing this task, tutoring was continued.

Post-Test Phase After completing the tutorial dialogue, the dyads of tutors and tutees were separated again and asked to draw and explain the blood path of the human circulatory system. Afterwards, the tutees completed the misconceptions test. The tutors also received the 25 items of the misconceptions test and were asked to indicate how the tutee would answer each of the items. Finally, the tutors filled in the beliefs about learning questionnaire.

Results

The following results concerning the tutors' assessment accuracy and the tutees' learning are based on the data collected in the post-test phase.

Tutors' Assessment Accuracy

In a first step, we examined the accuracy with which the tutors assessed what the tutees did and did not know at the level of propositions (i.e., misconceptions test) and at the

level of mental models (i.e., drawings of the circulatory system).

Misconceptions Test On average, the tutees had a correct understanding of 49% ($SD = 11\%$) of the concepts and an incorrect understanding of 43% ($SD = 13\%$) of the concepts¹.

Generally, the tutors assumed tutees to have a correct understanding of 58% ($SD = 12\%$) of the concepts and to have an incorrect understanding of 26% ($SD = 5\%$) of the concepts. Hence, the tutors significantly overestimated the tutees' correct understanding of the concepts, $t(21) = -2.43$, $p = .02$, $\eta^2 = .22$ (strong effect), and significantly underestimated the tutees' incorrect understanding of the concepts, $t(21) = 6.10$, $p = .01$, $\eta^2 = .64$ (strong effect).

When we specifically looked at whether the tutors knew how the tutees would answer each of the items of the misconceptions test, we found that the tutors knew the tutees' precise answers for 43% ($SD = 11\%$) of all items.

Drawings Of the tutees, 64% drew and explained an incorrect mental model, whereas 36% drew and explained a correct mental model.

The tutors assumed the tutees to have an incorrect mental model in 18% of all cases and assumed the tutees to have a correct mental model in 82% of all cases. Thus, the tutors tended to assume the tutees to have more often a correct mental model than the tutees actually had and to have less often an incorrect mental model than the tutees actually had, $\chi^2(1, N = 22) = 2.79$, $p = .09$, $\phi = .36$ (medium effect).

When we further looked at the categories into which the drawings of the tutees and the tutors fell, we found that, on average, the tutees' mental models were assigned to category 7 ($M = 7.36$, $SD = 3.19$). The tutors' drawings of the tutees' mental models were, on average, assigned to category 10 ($M = 10.27$, $SD = 0.88$). The difference between the average category of the tutees' mental models and the average category of the tutors' drawings of the tutees' mental models ($M = -2.91$, $SD = 3.25$) was significant, $t(21) = -4.20$, $p = .01$, $\eta^2 = .46$ (strong effect). Hence, the tutors largely overestimated the tutees' understanding at the level of mental models.

Tutors' Assessment Accuracy and Tutees' Learning

In a next step, we examined the importance of the tutors' assessment accuracy for the tutees' learning. To do so, we computed the correlation between the tutors' assessment accuracy at the level of propositions and the tutees' understanding at the level of mental models. The correlation was significant, $r = .59$, $p = .01$. Hence, the tutors' assessment accuracy was substantially associated with tutees' learning.

¹To reduce the probability of guessing the correct answer in the misconceptions test, the tutees were asked to check the option "don't know" in case of uncertainty. Thus, correct and incorrect answers do not add up to 100%.

Tutors' Content Knowledge, Beliefs About Learning, and Assessment Accuracy

In a last step, we determined the relation between the tutors' content knowledge and beliefs about learning on the one hand and their assessment accuracy on the other hand. To measure the assessment accuracy at the level of propositions, we used the number of answers that the tutors correctly assumed the tutees to give to each of the items of the misconceptions test. To measure the assessment accuracy at the level of mental models, we used the difference between the category number of a tutee's mental model and the category number of a tutor's drawing of the tutee's mental model. Content knowledge and beliefs about learning were not significantly related with each other, $r = .25$, $p = .26$.

Content Knowledge In the content knowledge test, the tutors answered, on average, 64% ($SD = 21\%$) of the items correctly. The number of correctly answered items was positively and significantly correlated with the accuracy with which the tutors assessed the tutees' understanding at the level of propositions, $r = .47$, $p = .03$. It was also positively and significantly correlated with the accuracy with which the tutors assessed the tutees' understanding at the level of mental models, $r = .48$, $p = .02$. Hence, the tutors with higher content knowledge were clearly more accurate in assessing the tutees' understanding.

Beliefs About Learning When answering the beliefs about learning questionnaire, the tutors achieved a mean score of 2.76 points ($SD = 0.44$). Hence, the tutors, on average, tended to show a constructivist view of learning. The correlation between the tutors' beliefs about learning and their accuracy at assessing what tutees knew at the level of propositions just failed to reach the 10%-level of statistical significance, $r = .35$, $p = .11$. The correlation between the tutors' beliefs about learning and their accuracy at assessing what tutees knew at the level of mental models was not significant, $r = .12$, $p = .59$. Obviously, the tutors' beliefs about learning were not generally associated with the accuracy with which the tutors assessed the tutees' understanding.

Discussion

The present study examined the accuracy with which tutors assessed a tutee's understanding of the human circulatory system. We found that the tutors significantly overestimated the tutees' correct understanding of important concepts related to the human circulatory system and significantly underestimated the tutees' incorrect understanding of these concepts. A similar pattern of results was obtained when we looked at the tutors' assessments of the tutees' mental models of the human circulatory system. Again, the tutors assumed the tutees to have a more complete understanding than they actually had. Overall, our findings replicate the results of Chi et al. (2004) and suggest that tutors seriously fail to take into account a tutee's alternative understanding.

As already discussed by Chi et al. (2004), tutors appear not to carefully assess what tutees do and do not know. Instead, they seem to exhibit a bias towards imputing their own normative perspective to the tutees (Hinds, 1999; Nickerson, 1999).

However, our results also show that the accuracy with which the tutors assessed a tutee's understanding largely depended on their content knowledge. In other words, tutors with more content knowledge were more accurate in assessing a tutee's conceptual understanding both at the level of propositions and at the level of mental models. It can be argued that this is likely to be because tutors with more content knowledge assess and categorize a tutee's understanding of concepts at a deeper level (Nickerson, 1999). This might allow the tutors to discriminate a tutee's understandings and misunderstandings more accurately (Chi et al., 1981).

In addition, we found that the tutors' beliefs about learning seemed to be less important for their assessment accuracy. This finding, however, has to be interpreted with caution. In our study, nearly all tutors showed an orientation towards a constructivist view of learning. Therefore, the variance of this tutor characteristic apparently was too small to yield any significant result.

Even though we observed differences in the accuracy with which the tutors assessed a tutee's understanding, we do not know yet which assessment strategies they used to collect diagnostically relevant information about a tutee. Prior research has already provided evidence for differences in tutorial actions between more experienced tutors and less experienced tutors. For example, Cromley and Azevedo (2005) found that more experienced tutors more often engaged in cognitive scaffolding. Less experienced tutors, in contrast, more often delivered information to the tutees. Following Chi et al. (2001), it is plausible to assume that these tutorial moves might help or hinder tutors in assessing what a tutee knows. For example, when asking questions (i.e., asking for information) instead of providing explanations (i.e., generating information on one's own), tutors might have more cognitive resources left for assessing a tutee's understanding (see also Wittwer, Nückles, & Renkl, 2010). Thus, to shed light on the question which moves of tutors positively and negatively influence their assessments of tutees, we are currently analyzing the tutoring protocols collected during the tutoring sessions.

Related to this is the question how the tutors in our study adjusted their tutorial moves on the basis of their assessments. Our results show that the tutors' assessment accuracy was positively associated with the tutees' learning. This suggests that the tutors might have used their assessments of what a tutee does and does not know in order to individualize instruction. It can be conjectured that the assessments, for example, influenced the tutors in deciding to move on to the next sentence of the textbook or to ask a question in order to elicit knowledge-construction activities from a tutee. Again, our content analysis of the tutoring

protocols could clarify how the tutors adapted their moves to a tutee's specific understanding.

What are the implications of our study and what are the directions for future research? First, our findings suggest that it seems to matter who serves as tutor. Obviously, tutors with higher content knowledge can more accurately assess what a particular tutee does and does not know. As a result, these tutors acquire knowledge about a tutee's knowledge which they can use to support the tutee's learning². Hence the concrete effectiveness of human tutoring might vary, amongst other things, as a function of tutor characteristics such as a tutor's content knowledge and tutoring experience (Cromley & Azevedo, 2005; though tutoring has generally been shown to be effective: Cohen, Kulik, & Kulik, 1982).

Second, our study seems to indicate that, in general, tutors with lower content knowledge have more difficulty with taking into account a tutee's particular understanding. At first glance, this finding might contradict the notion that peer tutors who normally do not possess considerably more knowledge than their tutees can also be responsive to their tutees' needs. However, such responsive behavior might not primarily result from the tutors' accurate assessments of the tutees' knowledge. Instead, it can be argued that tutors in peer tutoring share with their tutees a similar understanding of the learning task and, thus, might encounter the same comprehension difficulties. As a result of this common ground (Chi et al., 2004), the tutor and the tutee are more likely to "automatically" possess a mutual understanding. Hence, peer tutors might not be required to deliberately assess a tutee's understanding at all.

Third, our results show that, on average, the tutors largely overestimated a tutee's understanding. It was assumed that this finding can be attributed to the tutors' bias to impute their own normative perspective to the tutees. Although our study suggests that having more content knowledge reduces the risk of overestimating a tutee's understanding, there might be a trade-off between the tutors' content knowledge and their assessment accuracy under some circumstances. For example, Nathan and Petrosino (2003) found that pre-service teachers with higher content knowledge had problems with correctly estimating the difficulty of mathematical problems for learners. This was assumed to be a result of the pre-service teachers' discipline-specific perspective on the mathematical problems. Accordingly, it might well be that tutors who have, due to their high content knowledge, a more discipline-oriented view of the subject matter are particularly prone to an egocentric bias. In this case, it can be expected that tutors with such knowledge are less accurate instead of more accurate in assessing a tutee's understanding.

²In a mediation analysis, we found that the tutors' content knowledge influenced the tutees' learning. This effect was significantly mediated by the tutors' assessment accuracy.

Acknowledgments

We would like to thank our research assistants Julian Etzel, Tatjana Scharping, Anika Schoneville, and Raoul Zimmermann for their help with many practical aspects of the project. This research was supported by grants from the German Science Foundation DFG (WI 3348/2-1).

Risk attitude in decision making: A clash of three approaches

Abstract

We evaluate the consistency of different constructs affecting risk attitude in individuals' experiential decisions across different levels of risk. Three major views concerning the psychological constructs that underlie risk attitude are contrasted. The first is the classical economic approach which views risk as the sensitivity to differences in variance. The second is the latent components approach suggesting the importance of sensitivity to losses and diminishing sensitivity to marginal increases in payoffs. The third approach, risk acceptance, relates to the willingness to accept probable outcomes over certainty. The results of three studies indicate that: (1) Individuals do not exhibit consistency in their sensitivity to variance (2) Across domains individuals are consistent when deciding between constant versus probable outcomes, refuting the prediction based on diminishing sensitivity. (3) Risk acceptance entails different psychological constructs when the decision involves co-occurring gains and losses. The results are modeled with a quantitative index of subjective risk.

Keywords: risk; choice; individual differences; cognitive style.

Introduction

A dominant view of the psychological construct of sensitivity to risk (or risk attitude) suggests that it in fact represents the consistent sensitivity to different latent components. The most prominent example of this idea is prospect theory (Kahneman & Tversky, 1979) which explains contingent risk taking in different domains by the assumption that subjective values (or utilities) are based on relative judgments reflecting the effect of two main constructs: (a) Loss aversion – the idea that losses loom larger than equivalent gains, and (b) Diminishing sensitivity to marginal changes in payoff – the assertion that the subjective impact of a change in the absolute payoff decreases with the distance from zero. Recent cognitive models of individual choice in decisions from experience (see Hertwig et al., 2004) have adopted this view by implementing these factors as two core components of subjective utility: (a) loss sensitivity – the assumption that individuals weigh gains and losses in a consistent fashion (e.g., Busemeyer & Stout, 2002; Worthy, Maddox, & Markman, 2007), and (b) diminishing sensitivity – the assertion that people are consistent in discounting payoffs magnitudes with the distance from zero (e.g., Ahn et al., 2008).

We contrast this “latent constructs” approach with two alternative views. The first is the classical economic approach that addresses risk attitude as sensitivity to differences in payoff variances (e.g., Pratt, 1964; Preuschoff, Bossaerts, & Quartz, 2006). The second is a recent view which suggests that “risk acceptance,” the tendency of people to prefer (or avoid) risk over certainty is a single primitive construct that cannot be further dissected into the effect of gains and losses and the effect of diminishing sensitivity, but does not necessarily reflect sensitivity to variance (e.g., Brachinger & Weber, 1997). There are different formulations of the risk acceptance approach. For simplicity purposes we chose to focus on a simplified interpretation, referring to risk acceptance as the individual's sensitivity to certain versus probable outcomes. Thus, the risk acceptance hypothesis can be viewed as an extreme case of the sensitivity to variance hypothesis. That is, it suggests that the difference in variance is a necessary but insufficient condition of individual sensitivity to risk. The other necessary condition for risk sensitivity is a condition activating the individual's preference for certainty versus uncertainty.

The three aforementioned approaches are related but have distinct predictions that, surprisingly, have not been previously contrasted. The first such prediction involves the consistency between risk taking propensities in the gain and loss domain. Under the latent construct approach, supposing that indeed diminishing sensitivity underlies risk taking between domains, then a negative association is expected between risk taking in the gain and loss domains as implied by the reflection effect (Kahneman & Tversky, 1979). For example, if an individual discounts \$1200 to a higher degree than she discounts \$600 and is consistent in this diminishing sensitivity then she should be risk averse while choosing between a sure win of \$600 and a bet with equal chances to win \$1200 or nothing, but should be risk seeking when these values are framed as losses. In contrast, models based on the sensitivity to variance, as well as models of risk acceptance would predict a positive correlation between risky choices in the two domains, as individuals would either seek or avoid variance in both domains. However, the risk acceptance approach will have this prediction only when the choice alternatives also differ in their levels of certainty. These contrasting predictions are examined in Experiment 1.

The second prediction, which is the focus of Experiment 2, involves the consistency of the weighting of gains and losses. Under the latent construct model's assumption of weighting of gains and losses, a positive correlation should appear between choice problems differing in the magnitudes of gains and losses regardless of factors like variance or certainty. In contrast, the sensitivity to variance model predicts that the largest consistencies would appear between problems where the alternatives have the same levels of variance. The risk acceptance approach predicts choice consistency mostly when there are distinguishable differences in levels of certainty, such as in the choice between fixed and probabilistic outcomes. Experiment 3 focuses on the argument that risk acceptance involves a single primitive construct, even when gain domain problems are contrasted with choice problems involving both gains and losses.

Our comparison of different potential accounts for individual consistency in risk taking across tasks is closely related to previous studies of consistency in risk taking (Schoemaker, 1990) and to studies that compared models of risk taking (e.g., Battalio, Kagel, & Jiranyakul, 1990; Wakker et al., 2007). There are two major differences from these previous studies: First, these studies have tended to focus on the latent construct approach and did not systematically investigate alternative approaches to the psychological constructs underlying risk sensitivity. Secondly, these studies have focused on one-shot choices between described prospects, whereas we focus on risk taking in decisions from experience (Hertwig et al., 2004). In such decisions, Individuals do not get explicit information about the distributions that underlie the alternatives they face (e.g., the probabilities and payoff sizes). However, by choosing repeatedly between the different alternatives, and realizing the outcome of each choice (which is drawn from the relevant distribution) they can learn the potential outcomes associated with each alternative and their likelihoods. Previous studies have demonstrated that experience-based decision tasks have many attractive features for studying individual risk taking. It has been shown, for example, that such tasks have high external validity in assessing individual differences in decision making and that they are also relatively more resistant to social desirability than descriptive gambles (see review in Koritzky & Yechiam, 2010).

Experiment 1

The main purpose of our first study was to contrast the “diminishing sensitivity” assertion (appearing in latent component models such as prospect theory) with the “sensitivity to variance” hypothesis, and the “risk acceptance” assertion, by focusing on the main implication of the diminishing sensitivity construct, namely the contingent risk taking in the gain and loss domains. Each participant was presented with four repeated choice tasks, as described in Table 1. Each task included two alternatives and one (referred to as “L”) was always associated with

lower variance payoffs than the other (“H”). The main within-subject manipulation pertained to the domain in which choices were made. In the Gain condition choice alternatives yielded positive outcomes, whereas in the Loss condition outcomes were negative.

In order to differentiate between the “sensitivity to variance” and the “risk acceptance” hypotheses, the tasks were also distinguished with respect to the difference in the levels of uncertainty. In two of the tasks selecting the safer option eliminated probabilistic outcomes. We refer to these tasks as the “Avoidable Uncertainty” (AU) condition. In the other two tasks uncertainty could not be avoided since both alternatives included probable outcomes. These tasks are referred to as the “Unavoidable Uncertainty” (UU) condition.

The diminishing sensitivity assertion implies negative association between both domains in both the avoidable and the unavoidable uncertainty conditions because high diminishing sensitivity leads to risk seeking in the loss domain and risk aversion in the gain domain. Notice that this assertion also implies positive correlations between the two gain problems, and between the two loss problems. The risk acceptance assertion, however, suggests a positive association between the two avoidable uncertainty problems, and no association between the two unavoidable uncertainty problems. In the avoidable uncertainty problems there are clearer environmental signals concerning the differences in uncertainty level, which supposedly trigger risk acceptance tendencies. Finally, the sensitivity to variance model predicts positive association between all four choice problems due to one option being higher in variance than the other, even in the unavoidable uncertainty problems.

Forty undergraduates (20 males and 20 females) participated in the experiment. The participants' average age was 24 (ranging between 19 and 27). Payoffs ranged between NIS 14 and NIS 26 (NIS 1 = \$4.5).

Each participant made 100 choices in each of the four choice problems. The participants were informed that they would be playing different games in which they would operate “computerized money machines” which include two unmarked buttons, and that their final payoffs would be sampled from one of the “machines” but received no prior information about the payoff distributions or the number of trials. Their task was to select one of the machine's two unmarked buttons in each trial. The payoffs in each task were contingent upon the button chosen and were randomly drawn from the relevant distributions described in Table 1. Final take-home amounts were determined according to the accumulating score in one choice problem that was randomly selected at the end of the experiment. The performance score was converted into cash money at a rate of 0.01 agora per 1 point (1 agora = 0.24 cents). The final payoff was then determined by summing this amount with the participation fee (NIS 25).

Two types of feedback immediately followed each choice: (1) the basic payoff for the choice, which appeared

on the selected button for two seconds, and (2) an accumulating payoff counter, which was displayed constantly, but was initialized at the beginning of each task. The order of the Gain and Loss conditions was counterbalanced, and the order of the two problems within each condition was randomized. The location of alternatives L and H was randomized across different participants. The measure used in each task was simply the proportion of choices of H across trials. There are therefore four variables in this study (and subsequent ones) conforming to the rate of H choices in each of the four choice problems.

Table 1: Payoff schemes of the four experimental conditions of experiment 1.

Domain	Condition	Payoff	P(H)
Gain	Avoidable	L: win 600	0.26
	Uncertainty	H: 50% to win 1200, 50% to win 0	
Gain	Unavoidable	L: 50% to win 500,	0.31
	Uncertainty	50% to win 400 H: 50% to win 890, 50% to win 10	
Loss	Avoidable	L: lose 600	0.45
	Uncertainty	H: 50% to lose 1200, 50% to lose 0	
Loss	Unavoidable	L: 50% to lose 500,	0.49
	Uncertainty	50% to lose 400 H: 50% to lose 890, 50% to lose 10	

Table 2: Spearman correlations between risk-taking in the different tasks in Experiment 1 (AU = Avoidable Uncertainty; UU = Unavoidable Uncertainty).

		AU		UU	
		Gain	Loss	Gain	Loss
AU	Gain	1.00			
	Loss	.45*	1.00		
UU	Gain	.63*	.22	1.00	
	Loss	.17	.35*	.03	1.00

* $p < .05$

Results

The choice proportions under the different conditions are summarized in the rightmost column of Table 1. The findings at the aggregate level show that people took more risk in the loss domain than in the gain domain ($t(39) = 3.98, p < .001$). There were no significant differences in risk taking between the AU and the UU conditions ($t(39) = 1.41, NS$).

The consistency of individuals' risk taking across the different tasks is presented in Table 2. The results show that in the AU condition there was a positive association between the gain and loss domains ($r = .45, p < .01$), which stands in contrast to the diminishing sensitivity hypothesis,

and supports the risk acceptance assertion. Taking the UU condition into account, the results show that in this condition there was no association between the loss and gain domains ($r = .03, NS$), which further supports the risk acceptance assertion, since in the UU condition the probabilistic outcome could not be avoided (or accepted). In addition, participants were consistent between the two Gain problems ($r = .63, p < .0001$) and between the two Loss problems ($r = .32, p < .02$), suggesting that individuals might exhibit diminishing sensitivity to a certain degree.

Therefore, it seems that the reflection effect, implied by the diminishing sensitivity assertion, was not observed at the individual level. Instead, participants exhibited a consistent preference between a constant outcome and a probable outcome across the gain and loss domains. This suggests that risk acceptance modulates the consistency across the gain and loss domain and that diminishing sensitivity alone cannot account for it.

Additionally, the suggestion that the consistent sensitivity to risk is due to mere variance differences cannot account for the null correlations between gain and loss domain problems in the Unavoidable Uncertainty condition. Still, the variance difference in this condition was somewhat smaller than in the Avoidable Uncertainty condition (and thus it could be argued that this produced lower correlations in this condition). In the next experiment we examine problems that have the same exact differences in variance.

Experiment 2

The second experiment was designed to examine whether loss sensitivity indeed modulates risk taking behavior in problems involving gains and losses, or whether its effect are due to risk acceptance (or sensitivity to variance) as well. This was accomplished by contrasting two conditions involving losses and gains: A condition with strong differences in uncertainty level (i.e., the participants could opt for not selecting the gamble and get a sure outcome of zero) and a condition where the differences in uncertainty were smaller (i.e., selecting the safer option decreased the magnitude, but not the frequency of losses). We examined whether participants would still be consistent in their response to losses (across two choice problems) in the latter condition.

Under the latent component approach the loss-sensitivity construct involves pure sensitivity to the magnitude of losses compared to gains. Therefore, consistency is expected to be maintained regardless of the differences in uncertainty. Similarly, under the sensitivity to variance approach a positive correlation is expected to emerge as long as the alternatives maintain the same difference in variance. However, under the risk acceptance approach consistency is only expected to emerge in the condition where there are substantial differences in the level of uncertainty.

Each participant was presented with four repeated choice tasks, as described in Table 3. The tasks involved two conditions differing in the capacity of decision makers to avoid probabilistic outcomes. In two of the tasks selecting

the safer option eliminated the probability of losing. We refer to these tasks as the “Avoidable Uncertainty” (AU) condition. In the other two tasks uncertainty differences between alternatives were smaller and both alternatives included possible losses occurring with the same frequency (but differing in magnitude). Accordingly, these tasks are referred to as the “Unavoidable Uncertainty” (UU) condition. A second within-subject manipulation pertained to the level of variance associated with the riskier option. In condition “Low Variance” the standard deviation associated with alternative H (SD = 100) was one fifth of that associated with the corresponding alternative in condition “High Variance” (SD = 500). This enabled us to evaluate the consistency across different levels of variance and compare the consistency in the AU and UU conditions.

Thirty (15 males and 15 females) undergraduate students participated in the experiment. Their average age was 24 (ranging from 20 to 27). Payoffs varied between NIS 25 and NIS 33. The procedure was as in Experiment 1 except that the experiment focused on the tasks described in Table 3, and the conversion rate was 1 agora per 1 point.

Table 3: Payoff schemes of the four experimental conditions of Experiment 2.

Condition	Variance	Payoff	P(H)
Avoidable Uncertainty	Low	L: win 0	0.64
		H: 50% to win 100, 50% to lose 100	
Avoidable Uncertainty	High	L: win 0	0.61
		H: 50% to win 500, 50% to lose 500	
Unavoidable Uncertainty	Low	L: 50% to win 50, 50% to lose 50	0.52
		H: 50% to win 150, 50% to lose 150	
Unavoidable Uncertainty	High	L: 50% to win 250, 50% to lose 250	0.51
		H: 50% to win 750, 50% to lose 750	

Table 4: Spearman correlations between risk-taking in the different tasks in Experiment 1 (AU = Avoidable Uncertainty; UU = Unavoidable Uncertainty).

		AU		UU	
		Low var	High var	Low var	High Var
AU	Low var	1.00			
	High var	.54*	1.00		
UU	Low var	.07	-.08	1.00	
	High var	.20	.13	.13	1.00

* $p < .05$

Results

The choice proportions under the different conditions are summarized in the rightmost column of Table 3. At the

aggregate level it seems that the participants tended to take more risk in the AU than in the UU condition ($t(29) = 3.15$, $p < .01$). Additionally, in both conditions participants did not appear to exhibit loss aversion, consistent with previous findings in experience-based tasks (e.g., Erev et al., 2008).

Table 4 presents the consistency of individuals’ risk taking across tasks. The results reveal that despite showing no loss aversion on average, participants were highly consistent between the AU problems, in which risks could be avoided ($r = .54$, $p < .01$) but not in the UU problems, where risks could not be avoided ($r = .13$, NS).

Also, the participants did not show consistency across the two High-Variance and Low-Variance tasks, inconsistently with implication of the risk as variance. The correlations within each of the two pairs of High and Low variance tasks were small ($r = .07$, $.13$) and insignificant. This suggests that what makes participants respond consistently to high and low variance alternatives is not their mere variance.

This pattern suggests that the consistency in risk taking with losses is not driven by an accounting balance that inflates gains or losses (e.g., a weighted average of gain and loss amounts) nor is it driven only by sensitivity to variance. Rather, the participants were only consistent when a risky alternative involving losses and gains was contrasted with a safe alternative offering a fixed outcome. This indicates that the consistent construct in the mixed domain involves risk acceptance. Without strong signals of differences in risk level in the form of constant versus probabilistic outcomes, the correlation appears to disappear.

Experiment 3

From the results of Experiments 1 and 2 one can conclude that the main construct modulating people’s responses is risk acceptance. Yet an alternative suggestion is that while risk acceptance consistently affects people’s responses, this is limited to situations involving no explicit comparisons between gains and losses. Under the latent construct model, in the latter situation risk taking (i.e., selecting the high variance option) is solely due to the weighting of gains and losses and not due to diminishing sensitivity (because diminished sensitivity is balanced for gains and losses). While the pure weighting of gains and losses hypothesis was rejected in Experiment 2, it can still be argued that risk acceptance is an independent psychological construct when gains and losses are explicitly compared. The goal of Experiment 3 was therefore to examine whether risk acceptance is a single psychological construct or whether it implicates a second construct when the outcomes involve frequently appearing gains and losses. This was examined by comparing the consistency of risk taking across Gain and Mixed domain problems (as shown in Table 5). A second within-subject manipulation pertained to the level of risk. In Condition “Low Variance” alternative H was associated with a standard deviation smaller by half than in condition “High Variance” (SD = 1000, 2000, respectively).

Fifty (25 males and 25 females) undergraduate students participated in the experiment. Their average age was 24

(ranging from 21 to 28). Payoffs varied between NIS 20-30. The procedure was as in Experiment 1 except that the experiment focused on the tasks described in Table 5. The conversion rate was 1 agora per 1 point.

Table 5: Payoff schemes of the four experimental conditions of Experiment 3.

Condition	Variance	Payoff	P(H)
Mixed	Low	L: win 0 H: 50% to win 1000, 50% to lose 1000	0.55
Mixed	High	L: win 0 H: 50% to win 2000, 50% to lose 2000	0.56
Gain	Low	L: win 1000 H: 50% to win 2000, 50% to win 0	0.28
Gain	High	L: win 2000 H: 50% to win 4000, 50% to win 0	0.30

Table 6: Spearman correlations between risk-taking in the different tasks in Experiment 3.

		Mixed		Gain	
		Low var	High var	Low var	High Var
Mixed	Low var	1.00			
	High var	.57*	1.00		
Gain	Low var	.06	.11	1.00	
	High var	.14	.14	.55*	1.00

* $p < .05$

Results

The choice proportions under the different conditions are summarized in the rightmost column of Table 5. The results show that people took more risk on average in the Mixed condition than in the Gain condition under relatively low risk ($t(49) = 4.71, p < .01$) and also under higher risk ($t(49) = 2.93, p < .05$). This pattern is again inconsistent with loss aversion. It does replicate previous results in experience-based tasks (e.g., Erev et al., 2008).

The consistency of individuals' risk taking across the different tasks is presented in Table 6. The results reveal that participants were highly consistent between the two Mixed problems ($r = .57, p < .01$) and between the two Gain problems ($r = .55, p < .01$). However, participants were not consistent across the two problems: the association between the proportions of H choices in the two domains was small (average $r = .11$) and insignificant. These results suggest two separate construct for gains and losses of similar magnitudes. Another interpretation rests on the special case of a constant outcome of zero. It might be that the mixed condition was dissociated from the gain condition because participants have a special psychological tendency to respond to the absolute zero.

A quantitative index of subjective risk

The results of the current studies support the "risk acceptance" approach although suggesting that the psychological construct of risk acceptance could be different in a domain with both gains and losses. Yet a more challenging goal is to use these findings in an attempt to develop a quantitative index for what makes people respond consistently to risk. Individual differences studies indicate that a trait should be measured in a situation when it is relevant, which therefore involves a decision between a non-trivial amount of risk and a very low amount of risk. Therefore, the subjective difference in the risk of the alternatives is expected to lead to increased behavioral consistency in risk taking levels. We evaluated two quantitative indices for the emergence of consistency based on such subjective differences. A simple index was based on the idea that variance differences lead to consistency. According to this idea, the larger the differences in variance, the better a person differentiates between alternatives; and is thus more consistent in his or her risk taking behavior.

An alternative account involves the assumption that differences in subjective risk level (and therefore individual consistency) increase as a function of differences in variance but also decrease as a function of the distance from zero. This actually incorporates the two constructs that received only limited support in the experimental studies (sensitivity to payoff variance and diminishing sensitivity to marginal returns) into one construct that was largely supported by the experimental data (risk acceptance). This account can lead to a following index for subjective risk differences:

$$S = S_{diff} / \sum(|p_i x_i|) \quad (1)$$

Where S is the Risk-Difference Signal (RDS), S_{diff} is the difference in standard deviation of the two distributions, p_i is the probability for each outcome i and x_i is its size.

Under both accounts the risk differences in a problem pair are assumed to aggregate as follows:

$$C = S_1 \cdot S_2 \quad (2)$$

This yields a parameter-free index C (of predicted consistency). The problems of Studies 1-3 were re-arranged into 18 pairs (representing all possible pairs within each study), and the risk difference in each pair was determined according to the two alternative indices. Then, the predictive ability of the two indices was determined by calculating the correlations between the predicted consistency of each pair and its actual consistency in risk level. The variance based index produced a correlation of 0.23, while the RDS index produced a correlation of 0.37 when predicting the consistency across all 18 comparisons.

A post-hoc version of the RDS, which differentiates non-mixed (gain or loss domain) from mixed (gain and loss) problems and is otherwise identical to the original index was also examined. It yields an average correlation (between predicted and actual consistency) of 0.80 for 14 relevant pairs: $r = 0.68$ for non-mixed problems ($n = 7$) and 0.91 for mixed problems ($n = 7$). For the variance-based

index the correlations are only 0.47 and 0.63, respectively.

Thus, the results of the current three studies cannot be interpreted by a parsimonious model resting just on variance differences. Rather, two additional assumptions must be made: (a). Subjective risk differences decrease as a function of the distance from zero, and (b). Two constructs of risk acceptance should be assumed: one for gain or loss domain problems and a unique construct for mixed outcomes.

Discussion

The main purpose of the current study was to shed light on the constructs leading to internal consistency in individuals' risk taking in experience-based decisions. Three approaches were contrasted: One suggesting that loss-sensitivity and diminishing sensitivity are the main factors that underlie individual differences in risk taking (see Busemeyer & Stout, 2002; Ahn et al., 2008), the other suggesting that the acceptance or the rejection of uncertainty is the principle factor modulating people's risk taking (Brachinger & Weber, 1997), and the third suggesting that sensitivity to differences in variance guides risk preferences (e.g., Pratt, 1964). To our knowledge, no previous studies have systematically evaluated the contrasting predictions of these approaches for the consistency of individual predispositions.

The findings of the three studies have important implications for the definition of subjective risk. Throughout the paper, and following the common convention in experimental studies of risky decisions in general and decisions from experience in particular, we have associated risk taking behavior with choices of the option with the higher variance as our point of departure. Nevertheless, our findings show that differences in variances alone do not drive individual consistencies in choosing the risky (higher variability) option. Rather, we have highlighted a second necessary condition: the presence of certainty. We view this finding as an example of a more general factor modulating individual consistencies, involving the extent to which the alternatives differ in their level of (un)certainly, with the case of certainty versus uncertainty being an extreme contrast along this axis. It appears that such a contrast is necessary in order to obtain consistency in risk taking even in problems that are relatively similar in terms of their payoff domain (e.g., the mixed domain problems of Experiment 2).

Additionally, the results of Experiment 1 confirmed the predictions of the risk acceptance construct for the consistency across domains (gains versus loss outcomes). In particular, this construct indicates positive consistency across domains, implying that people who take risks with gains also take risks with losses. This pattern contradicts the prediction based on diminishing sensitivity, which implies a negative correlation across domains (as explained above). It appears that the more consistent construct is risk acceptance.

In conclusion, as in previous examinations of individual risk taking, this construct was found to be consistent only in limited settings. Only in 6 out of 18 possible comparisons between simple experiential decision tasks did the

participants exhibit consistency in their risk taking levels. Yet the current analysis also shows that the consistencies found are far from being coincidental, and it sheds light on the factors that modulate this behavioral consistency. A construct that seems to trigger the consistent tendency to take risk is the "risk acceptance" factor denoting individuals' sensitivity to differences in risk level when such differences are clearly perceived (such as in a decision between a constant outcome and a riskier prospect). When differences in risk level are less clear, lower consistency between different decision problems is observed.

Making Assessments While Taking Sequential Risks

Avishai Wershbal (wershbal@msu.edu) & Timothy J. Pleskac (pleskact@msu.edu)

Department of Psychology,
Michigan State University,
East Lansing, MI 48824

Abstract

This study utilized inter pump response times on a laboratory gambling task, the BART, to examine cognitive aspects of response selection during sequential risky decision making. Findings suggest a response procedure that utilizes multiple levels of processing. Amount of task exposure as well as the distance to the goal both affect the rate at which assessments are made, with task exposure decreasing assessment rate, while target distance increases assessment rate. Several alternative models are fit to the data, to determine if the behavioral results can be informative of a model that more accurately reflects differences in processing.

Keywords: Psychology, Decision Making, Mathematical Modeling, Cognitive Decision Theory

Introduction

People take sequential risks every day. Drivers repeatedly choose to talk on the cell phone, or text while driving each time they get in their car. People every day choose to eat at their favorite fast food establishment. Smokers of all ages repeatedly choose to smoke a cigarette. In all of these situations, our choice is not a one-shot deal rather our choices occur many times sequentially over the course of a day, a week, a month, etc. Often we are even presented with the same or similar choices on multiple occasions. Sometimes these choices may even change as a function of time or even as a function our previous choices (Busemeyer & Pleskac, 2009).

Despite the many instances of sequential risks in the real world, most of the laboratory analogs of risky decision making only ask participants to make one single choice (e.g., Hertwig, Barron, Weber, & Erev, 2004; Kahneman & Tversky, 1979). However, a number of laboratory-based gambling tasks have now been developed that require people to take sequential risk, such as the Iowa Gambling Task (Bechara, Damasio, & Anderson, 1994); the Balloon Analogue Risk Task (BART; Lejuez et al., 2002); or the Angling Risk Task (Pleskac, 2008). These tasks also appear to have some construct validity with real world risk taking. Risk taking in the BART, for example, correlates with smoking and drug abuse, as well as safety issues including seatbelt usage and safe sex (Lejuez et al., 2002; Lejuez, Aklin, Zvolensky, & Pedulla, 2003; Pleskac, Wallsten, Wang, & Lejuez, 2008).

The overall decision making processes for these sequential risk taking tasks are also reasonably well understood. In fact, the processes have been formalized in terms of cognitive models (Busemeyer & Stout, 2002; Wallsten, Pleskac, & Lejuez, 2005). However, the processes

postulated within the components of the model have received less direct attention. In this study, we focus on the BART and test some of the processing implications of its respective cognitive model. In particular we use inter pump times to better understand the response selection process that decision makers use to take sequential risks during the BART.

Balloon Analogue Risk Task (BART; Lejuez et al., 2002)

During the BART participants are presented with a computerized balloon, a pump button, and a stop button. Pressing the pump button inflates the balloon, and also puts money in a temporary bank. Balloons in the BART explode after a randomly predetermined amount of pumps are made. An explosion terminates the trial and all money in the temporary bank is lost. Clicking the stop button, transfers the temporary points into the permanent bank and also terminates that trial. The participant's goal in the BART is to earn as much money as they can, but they need to take into account the chance that the balloon could pop. Participants typically complete 30 independent balloon trials.

Participants are given no information about the design of the task, other than the basic reward and punishment rules, and the fact that the balloon will explode before it fills the entire screen. It is up to the participant to determine the amount of risk they are willing to incur for a given reward. Though the BART may seem simple at first, there are many processes that take place within the course of completing the task. The processes have been formally defined in the Bayesian Sequential Risk Taking model (BSR; Wallsten et al., 2005).

Bayesian Sequential Risk Taking (BSR) Model

We briefly review the general processes of this 4 parameter model (for a formal derivation see Pleskac, 2008; Wallsten et al., 2005). The BSR model consists of three sub processes. The first process is a reward evaluation process. During this process, participants select a target pump number to pump the balloon towards. The target selected is a function of the participant's subjective value of a reward and their perceived chance that an explosion will occur for any pump. Participants who value the reward more will increase their target amount of pumps to be made, while an increase in the perceived chance of an explosion occurring decreases this pumping target.

The second process in the model is a response selection process. This process describes how participants use their target to determine whether to select a pump or a stop response at each pumping opportunity. In particular, the probability of pumping is assumed to be a function of the participant's current distance to the pumping target that they derived in the reward evaluation component. According to the model, the probability of pumping decreases as the current number of pumps taken approaches and passes the target number of pumps. Some participants are more consistent in pumping to their targets. A topic of interest in this paper is if in fact participants appear to be making a distance calculation, as the model seems to assume, at every pump opportunity.

The final process in the BSR model describes how participants learn from their experience. This process describes how participants arrive at their belief of the probability that the balloon will explode (used in the reward evaluation process described previously). The model assumes participants use a Bayesian learning process to integrate their prior beliefs with the observed data from each balloon trial (# pumps and if it exploded or not). Their new belief is used to evaluate rewards and select a target during the next balloon trial.

The model has been formally specified and tested (see Pleskac, 2008; Pleskac et al., 2009; Wallsten et al., 2005) with previous studies being by and large centered on the reward evaluation process and learning components of the BART. Little focus, however, has been allocated to the response selection component of the model. Recall the BSR model implies that on every pump opportunity of every balloon participants engage in some sort of distance-to-target calculation. If they are far from the target they are almost certain to pump and as they approach the target they become more and more likely to stop pumping. This raises the question whether participants perform a distance calculation at every pump opportunity? Our hypothesis is that instead of performing this calculation on every pump opportunity, there are instead two different types of pumping behavior being utilized. One pump type is a relatively automatic pump, while on other pump opportunities, decision makers pause and take an assessment of how far they have gone and how far they want to go. To test this hypothesis we examined the inter-pump times (the amount of time taken between responses).

Assessments

Cognitive psychologists have long known that due to limitations in working memory capacity an increase in the amount of information to process leads to an increase in the time it takes to process that information (Atkinson, Holmgren, & Juola, 1969; & Schneider & Schiffman, 1977). This means that an action that occurs following a complex calculation should have a slower response time than if that action were preceded by an easier calculation. This cognitive principle implies the distance calculation the BSR assumes to take place when selecting a response should take

some observable amount of processing time over and above motor time.

However, we also know that these sequential risk taking situations require choices on multiple trials. This high exposure to the task and task structure may lead to a routinization of the decision making process (Betsch, Haberstroh, Glöckner, & Fiedler, 2001) and perhaps even eventually approaching the automaticity properties of a habit (Aarts, Verplanken, & van Knippenberg, 1998). This routinization of decision making would imply less and less demands on working memory and thus lead to fairly quick inter-pump times.

Our hypothesis though is that there is some mix between fairly routine almost automatic pumps and other pumps where the decision maker pauses to take an assessment of where they are in the balloon trial. Our hypothesis is very much motivated by analogous findings from the animal learning literature where rats make a series of sequential decisions while traversing a maze. In particular, rats when learning a maze will at some decision points pause and appear to orient themselves toward potential options (Tolman, 1938 & Tolman 1948). Then after orienting themselves make a decision. This behavior has been termed vicarious trial and error (VTE), and has several interesting characteristics (Gallistel, Fairhurst, & Balsam, 2004). It was found that these VTEs occur fairly frequently during the early learning trials, and decreases with exposure to the task. This decrease in VTE's means that after enough exposure to the task environment, rats upon reaching a decision point (a fork where they have to go either right or left), eventually stop orienting themselves towards both potential options before making a decision, and instead simply immediately take the correct turn. It was also shown that this decrease in VTE's takes a non-linear shape.

These results prompt the question whether our postulated assessments follow the same pattern as VTEs. To test this we examined inter-pump times. Our hypothesis was that the inter-pump intervals in which a distance calculation was performed should take longer than those intervals in which no calculation was performed. And the inter-pump times for non-calculation intervals should not differ from baseline pumping speed.

To determine baseline inter-pump times, participants first completed a task in which only one option is presented to them: a pump option. Participants were instructed to pump each balloon as quickly as possible until they exploded. Participants neither received nor lost money for these trials. The inter-pump times from this were averaged together to estimate a baseline inter-pump time for each participant, as well as the standard deviation of their baseline pumping speed.

An assessment pump was operationalized as any pump for which the respective inter-pump time was 3 standard deviations or greater than the mean baseline time. Our hypotheses are as follows.

Hypothesis 1: Assessments will only occur periodically throughout a given balloon trial. The remaining trials will

reflect relatively routine almost automatic choices due to the frequency of their occurrence.

Hypothesis 2: Another testable prediction comes out of the hypothesis that the assessment points found in the BART reflect the same type of learning as the VTE's in rodent maze learning. As in the VTE's we expect that over balloon trials assessments will decrease in a non-linear fashion so that the observed assessment rate will decrease as exposure to the BART increases.

Hypothesis 3: Within a balloon trial, as participants approach their targeted stopping point their assessment rate should increase. This hypothesis is derived from the following reasoning. First, we assume that as participants pump they form an association between pump opportunities and the difficulty of making a choice (to pump or not). For example, participants will tend to associate the 4th pump trial with an easy decision (pump), but later pump opportunities (e.g., 48th opportunity) will present the participant with a more difficult choice. The prediction that follows from this hypothesis is that participants should be more likely to make an assessment on later pump opportunities for a given balloon.

Finally, we were interested whether the actual magnitude of the inter-pump times on routine pumps (non-assessed) would change over the course of pumping any given balloon. If we think of reaching the target pump as the main goal and the assessment points as sub-goals in reaching the target then we form a goal hierarchy. We know from goal activation models (Altmann & Trafton, 2002) that respondents often track their distance from previous sub goals and this leads to a slowing in response times as they progress. One might expect that participants are somehow implicitly tracking their distance from the last assessment. This would imply that inter-pump times of non-assessed pumps should increase as the distance from the last assessment increases. Next we test these predictions using data from two studies. Then we propose modifications based on these results to the BSR model.

Methods

The data examined comes from two experiments conducted in the Laboratory for Cognitive Decisions at Michigan State University during spring of 2008 and spring of 2009. These studies were designed to look at the effect of individual differences in various executive functions on BART performance. Both a standard version of the BART and a

response time BART were included in these studies as well as a number of other executive function tasks, however we will limit descriptions of the tasks to just those relevant to this paper. Participants were college age undergraduates. A total of 104 students participated in the 2008 study and 108 in the 2009 study. There were no substantial differences between the two studies so we report their results together.

Baseline BART

The first task that every participant completed in both data sets was a baseline BART. The baseline BART is a simplified version of the BART that was created to measure average response time for pumping behavior. This version has only a pump button and participants are instructed to pump each balloon until it explodes. The balloons in the baseline BART were programmed to explode with the same statistical distribution that the normal BART balloons utilize. Participants completed ten trials of the baseline BART in order to establish a baseline non-fatigued measure of pumping motor time.

Manual BART

The regular BART task that we used is based on the task used in previous studies (see Lejuez et al., 2002; Pleskac et al., 2009). The task consists of a virtual balloon that is inflated by pressing a button. Participants were awarded 10 points for each successful pump. The popping point for each trial was randomly chosen out of 128, and pairings for each random trial were included to assure the same optimal distribution as in the original BART paper (Lejuez et al., 2002). Each trial ends with either a popped balloon (participants earn no points), or the participant clicking the stop button in which case the participant keeps all of the earned points for that balloon trial. Either way a fixation cross then appears in the center of the screen to prepare the participants for the onset of the following trial. To obtain more accurate response time data, our version of the manual BART was programmed in E-Prime 2.0. Furthermore, participants entered their pump and stop choices with separate keyboard buttons.

Results

Behavioral

In both studies, participants' risky behavior was consistent with past studies. On non-exploding balloons, they pumped an average of 39 (SD = 16.03) and 34.3 (SD = 18.01) pumps

Figure 1: Inter Pump Time on a Single Trial for Participant 55 in study 2.

in studies 1 and 2, respectively. The average baseline inter-pump time in both studies was 181.38 ms (SD = 58.4) and 178.47 ms (SD = 54.22). The average within-subject standard deviation of inter-pump times on the baseline task was 53.91 ms (SD = 32.14) and 55.38 ms (SD = 40.66).

Recall we defined an assessment as any pump during the BART for which its respective inter-pump time exceeded 3 standard deviations above the baseline inter-pump time. With that definition, 11.1% of the pump opportunities from study 1 and 16.35% from study 2 would be classified as assessments. This yields an average assessment rate of 4.3 and 5.6 assessments per trial respectively. A plot of inter-pump times from a single subject and balloon trial is shown in Figure 1.

In terms of Hypothesis 2, to test whether there was a change in assessment behavior as participants become more familiar with the task, we regressed assessment rate onto trial number. Assessment rate was calculated by dividing the number of assessments in a given trial by the length of that particular trial. The results of this regression showed the same pattern for both studies, which is a decrease in assessment rate as trial number increases. Averaging across participants, the data seemed to best fit a logarithmic decreasing curve, with study 1 significant at $R^2 = .876$ and $p < .001$, and study 2 significant at $R^2 = .935$ and $p < .001$ (Figure 2). Thus, assessment rate was high on the first few trials (approximately a 40% assessment rate on average) and then decreased at an increasing rate as participants experienced more balloon trials.

Hypothesis 3 focused on whether the probability of an assessment changes within a balloon trial. Pump number itself cannot be used as the predictor for this regression, due to the fact that the length of each trial is entirely dependent on the participant's own pumping behavior. Instead a count of how many non-assessment pumps was taken between each assessment point, and then that count was divided by the length of that trial. This number is the proportion of pumps within that trial that preceded each assessment point (excluding the initial pump opportunity). Assessment points that are immediately followed by another assessment point were only counted as a single assessment. These proportions were then averaged across trials and across participants to give us a proportion score. A regression was run with assessment point number as the predictor and the proportion score as the dependant measure. Results of this regression also had a logarithmic fit, with $R^2 = .652$ and $p < .001$ for study 1, and $R^2 = .675$ and $p < .001$ for study 2. This is similar to the shape as for trial number, but the interpretation is that assessment rate increases as a factor of pump number.

Along with determining the factors that influence the probability of a distance to target assessment occurring, it is also important to identify characteristics of the non-assessed pumps as they approach the next assessment point. To characterize the changes in response times of the non-assessed pumps, Goodman-Kruskal Γ rank order correlations were ran to determine if there is generally an

Figure 2: Change in Assessment Rate by Trial Number

increase, decrease, or no change in the response times the non-assessed pumps that were made between assessment points (hypothesis 4). A Γ coefficient was calculated for every string of non-assessed pumps that occurred. When the gamma coefficients were averaged (2615 coefficients in study 1 and 2887 coefficients from study 2), the results indicate an increase in inter-pump times time for the non-assessed pumps as they approach the next assessment point, with an average gamma coefficient of .108 for study 1 and .135 for study 2. While small, this result indicates a small but systematic increase in inter-pump times the further one gets from an assessment.

These results suggest that choice behavior during the BART is a bit more complex than that which is depicted in the BSR model. In particular, we have shown that in two studies on some trials participants pause and perhaps take an assessment of their situation. On the other trials the inter-pump times are quick enough to suggest a routine or perhaps even an almost automatic pumping behavior. Next we examine how to best modify the BSR model to incorporate these findings.

Proposed Changes to BSR Model

One possible way to account for these observed pauses in the BSR model is to modify the response selection process. Figure 3 illustrates this proposed change. The idea is that in the original response selection process participants either pumped or stopped and each response followed an assessment. Instead we propose that not every pump opportunity involves a distance to target assessment. That is with some probability participants stop to make an

Figure 3: One possible modification to the BSR model.

assessment and only then do they choose between pumping and stopping. On other trials they make what we call a non-assessed pump which has an inter-pump time that is close to baseline. Several different functional forms of this modification were examined to determine if the inclusion of non-assessed behaviors improves the model fit.

The changes to the model are based off of the predictions from the new hypotheses. We tested four modifications. The first model assumed a static assessment rate, μ , which estimates the probability of making an assessment before the response is selected.

The second model assumed assessment changed as a function of balloon trial (h),

$$P(\text{assess}) = \frac{1}{1 + \exp(\mu(h - \lambda))} \quad (1)$$

Where λ is a biasing factor that controls the starting point of the assessment rate and μ now controls the rate of change in the assessment rate.

The third model incorporates the idea that assessments change as a function of pump opportunity i ,

$$P(\text{assess}) = \frac{\exp(\mu(i - \lambda))}{1 + \exp(\mu(i - \lambda))} \quad (2)$$

The parameters serve much the same role as in Equation 2, but now assessment rate changes as a function of pump opportunity and λ controls the starting assessment rate for each balloon.

The fourth model incorporates both an assessment rate that changes as a function of balloon trial h and pump opportunity i ,

$$P(\text{assess}) = \frac{\exp(\mu(\frac{h}{i} - \lambda))}{1 + \exp(\mu(\frac{h}{i} - \lambda))} \quad (3)$$

Preliminary Model Fitting & Comparisons

The modifications were incorporated into the BSR model. Then each model was fit at the individual level with maximum likelihood procedures using the Nelder-Meade numerical optimization routine. Several different starting points were used to try and guard against local maxima issues. A Bayesian Information Criterion (BIC) was calculated for each model, and was used to determine the best fitting model overall (where lower BIC means better fit). The BIC is a goodness of fit measure which penalizes models for the number of parameters they have.

Table 1: Average BIC scores for Alternative Models

	Ave (Std) BIC	Ave (Std) BIC
Baseline	740.32 (358.85)	758.86 (428.15)
Static Assessment Rate	733.06(360.15)	746.54 (434.73)
Assessment rate changes as a function of balloon trial	718.74 (325.78)	734.20 (397.82)
Assessment rate changes as a function of pump opportunity	728.57 (358.84)	747.88 (442.52)
Assessment rate is a function of both trial and pump opportunity	741.62 (338.5)	733.60 (410.01)

The models were also compared against a statistical baseline model. The baseline model simply uses the observed proportion of assessed pumps, non-assessed pumps, and stops over the thirty balloons and estimates the likelihood of the data by utilizing those proportions.

The average BICs are shown in Table 1. They show that the best fitting model is one in which assessment rate changes as a function of balloon trial. It is of note that there is some variability in this conclusion at the individual level. In particular, while nearly all the participants exhibited some form of assessment behavior, there was individual variability in the relationship between assessment rate and balloon trial. Some (~40%) showed a very weak relationship between balloon trial and assessment rate. For these individuals, the constant assessment model and the baseline model provided better fits.

Discussion

This study aimed to better understand the response selection process in sequential risk taking situations. Using the BART as an analog to these situations, we found that nearly all participants engaged in a behavior we call assessment. That is, within a given sequence of risky choices, generally decision makers would make very quick choices, but periodically (about every 4 to 5 pumps) they would take very long pauses. We interpret this behavior as a time of assessment when the decision maker gauges how many risks they have taken and how many more risks they plan to take. We also found the following behavioral properties of an assessment rate.

First, across balloon trials the assessment rate was on average higher for early balloon trials and then diminished at an increasing rate. This idea is consistent with previous decision making literature with rodents, showing that as task exposure increases, learning takes place, which leads to automated decision evaluations (Tolman, 1938 & Tolman 1948). The second, property of assessment rate, was the change within a single balloon trial, where assessment rate increases towards the end of the trial. One possible explanation is that the assessment rate increases relative to the level of perceived risk. It would be interesting to see if this is reflected in self reported risk taking measures. Lastly, there was a small but significant increase in inter-pump times between assessments. This suggests an increasing taxing of cognitive resources, which may be due to a buildup of interference, so that eventually the participants need to reassess their location relative to their pump target

Assessments and the change in assessment rate over balloon trials may be analogous to the distinction between exploration and exploitation in sequential decision making (Schumpter, 1934 & Holland, 1975). This idea of exploration versus exploitation holds that in order to maximize gains, one should initially explore the structure of the environment to create a good approximation of the distribution of rewards. Once a good approximation of the environmental structure is obtained, then one should begin exploiting it in a manner that maximizes their gains.

Assessments in sequential risk taking may afford the decision maker with an opportunity to explore different risk options and then exploit the options.

Acknowledgments

We thank David McFarlane for his help in programming the BART in E-Prime.

Testing Two Explanations for the Disjunction Effect in Prisoner's Dilemma Games: Complexity and Quasi-Magical Thinking

Abstract

The paper explores the disjunction effect in the Prisoner's dilemma game using behavioral experiments with eye-movement recordings. An experiment was designed to explore the complexity hypothesis about the appearance of the disjunction effect. The results show that in games with payoffs which are simpler to perceive and compare, the disjunction effect disappears, while it is present when more complex payoffs are used. In a second experiment, the participants were told that the moves of the computer opponent had been made before the game session. This manipulation led again to the disappearance of the disjunction effect even. We interpret this result as a suppressing of a possible quasi-magic reasoning by stressing the fact that participants' own moves cannot influence the move of the opponent. The results from the experiments point to information processing complexity as a major factor for the disjunction effect contrary to the conclusions in some previous research.

Keywords: disjunction effect, eye-tracking, Prisoner's Dilemma, decision making

Introduction

The Prisoner's dilemma (PD) game is one of the most extensively studied social dilemmas. PD is a two-person game. The payoff table for this game is presented in Figure 1. In the PD game the players simultaneously choose their moves – C (cooperate) or D (defect), without knowing their opponent's choice.

In order to be a Prisoner's dilemma game, the payoffs should satisfy the inequalities $T > R > P > S$ and $2R > T+S$. Because of this game structure a dilemma appears – there is no obvious best move. On one hand, the D choice is dominant for both players – each player gets larger payoff by choosing D than by choosing C no matter what the other player chooses. On the other hand, the payoff for mutual defection (P) is lower than the payoff if both players choose their dominated C strategies (R for each player).

As PD game is used as a model for describing social dilemmas and studying the phenomena of cooperation, there is a great interest in the conditions that could promote or diminish cooperation. The *cooperation index* (CI), computed as $CI = (R-P)/(T-S)$ (see Rapoport and Chammah, 1965) is assumed to indicate the degree to which a player can be motivated to cooperate (choose move C).

The disjunction effect in Prisoner's Dilemma has attracted considerable interest and has been investigated in several

experimental and theoretical studies without reaching consensus about its explanation (e.g. see Shafir & Tversky, 1992; Croson, 1999; Busemeyer et al. 2006; Li, Taplin & Zhang, 2007; Hristova & Grinberg, 2008). The disjunction effect can be summarized as follows: experiments with one-shot PD games show that players choose move D more often when they know the move of their opponent whatever it is (C or D) than when they don't know it. The logical expectation is that if participants choose a particular strategy for any of the two possible moves of the opponent, they should have the same strategy when they don't know their opponent's move. However, people do not act as expected and cooperate more in the latter situation, i.e. when the opponent move is uncertain.

		Player II	
		C	D
Player I	C	R, R	S, T
	D	T, S	P, P

Figure 1: Payoff table for the PD game. In each cell the comma separated payoffs are the Player I's and Player II's payoffs, respectively.

Several explanations for the disjunction effect have been put forward in the PD literature. Shafir and Tversky (1992) are accounting for the disjunction effect using their theory for reason-based choice: people need a reason in order to make a choice. Thus, when they know that their opponent will play C, they defect to get the higher payoff; and if they know that she will play D, they defect in order to avoid the lowest payoff and punish the opponent (see Figure 1). But when the move of their opponent is not known, they don't have a particular reason to make a move and this changes the situation contributing to the disjunction effect. Additional explanations, discussed in the same paper, claim that people cannot account properly for all alternatives of the game, or if they do, due to the uncertainty about the opponent's move, they cannot establish clearly their own preferences. Thus, depending on what outcome they focus on, they can choose to cooperate or defect. When people are made aware of their choices the disjunction effect disappears (Tversky & Shafir, 1992).

An alternative explanation is related to the change of participant's perspective (individualistic vs. collectivistic) about the PD game (see Shafir & Tversky, 1992). When

their opponent's move is known, people can be tempted to defect as the outcome of the game depends only on their choice and they have to consider only one column in the game matrix (see Figure 1). In this case, they adopt an individualistic point of view and defect. On the other hand, when the opponent's move is unknown, they have to consider the whole game matrix, the outcome depends on their and their opponents moves, and the collectively optimal decision of mutual cooperation becomes more attractive. This is supported by the fact that the CC outcome (payoff R) is better than the DD outcome (payoff P) for both players (as $R > P$; see Figure 1).

Experiments show that sometimes participants act as if they believe that their moves can influence the game outcome, although they know this is impossible. In Shafir & Tversky (1992), this is called quasi-magical thinking. Quasi-magical thinking, applied to PD, would imply that if people cooperate more when they are uncertain about the other player move, this means that the CC outcome is preferred by them, and by playing C they expect to elicit the same choice in the other player.

In the account of Shafir & Tversky (1992), the possibility of complexity to be an explanation of the disjunction effect is discarded and it is claimed that 'the failure to reason consequentially may constitute a fundamental difference between natural and artificial intelligence.' Croson (1999) tested the complexity explanation and the conclusion was that complexity plays no role and the reason-based choice explanation should hold. However, the test was performed using games which are not dilemmas as the PD game. Recently, inspired by the above conclusions, alternative explanations have been put forward even involving quantum probability theory and logic (see Busemeyer et al., 2006).

Li et al. (2007) used the so-called 'equate-to-differentiate' approach to explain the disjunction effect. This approach seems to involve the complexity hypothesis by assuming that when people have ambiguous alternatives concerning their own payoffs, they can equate them and take the perspective of their opponent. Moreover, the eye-tracking study of Hristova & Grinberg (2008), has shown longer information acquisition in PD games when the opponent's move is uncertain than when it is known by participants, reflecting the difference in the complexity of the task in the two cases.

One of the goals of the present study is to explore to what extent the complexity of decision making can lead to the disjunction effect in PD games. The approach adopted here, is different from the one followed in Croson (1999). Instead of using games with different structure, in our experiments we manipulated the payoffs by keeping their ratio and cooperation index the same. Participants in one experimental condition played PD games with payoffs which were two digit numbers with the second number *different* from zero. Participants in another experimental condition, played games with two-digit numbers with the second digit *equal* to zero. The idea was that, while equivalent from a game-theoretical point of view, the payoffs from the first condition are more difficult to

perceive and compare than the numbers in the second condition. Thus, the complexity of the former case was assumed to be higher than the complexity of the latter case.

The second goal was to try to evaluate the influence of quasi-magical thinking discussed above on the disjunction effect in PD games. This has been done by using exactly the same experimental design as the one described above but with an additional manipulation – a sentence in the instruction which says that the computer program, playing against the participants, had chosen its moves before the beginning of the game session.

In both experiments eye-movements have been recorded in the hope to discern differences in the four conditions which could shed additional light on information processing involved based on the experience of Hristova & Grinberg (2008).

Experiment 1 – Testing the complexity explanation

Goals and hypothesis

The goal of the present experiment is to test the complexity explanation for the disjunction effect, namely that the effect appears because of the complexity of the game. When the opponent's move is not known, the situation is complex and the players are not able to analyze it well and to choose the appropriate move. To test this, in the current experiment we manipulate the complexity of the payoffs that are presented. The prediction is that if we make the game simpler (by using simple round payoffs) the disjunction effect will be smaller.

Stimuli

A set of 6 Prisoner's dilemma games was used in the experiment (see Table 1). Although the payoffs were different, the cooperation index of all the games was equal to 0.7 (as discussed above, cooperation index is an important predictor of the cooperation rate). Three of the games were with simple round payoffs, and 3 games were with 'complex' payoffs.

Table 1: PD games used in the experiment

	T	R	P	S
simple payoffs	100	90	40	30
	90	80	30	20
	80	70	20	10
complex payoffs	106	94	41	32
	91	83	34	22
	83	75	24	12

Each of the 6 PD matrices was presented 3 times during the game playing: the computer move is not known yet, the computer move is known to be cooperation, the computer move is known to be defection. These 18 payoff matrices that are later used in the analysis were intermixed with 62 other games resulting in a total of 80 games. The 18 PD games were pseudo-randomly distributed between the 4th and the 78th game.

. Care was taken as one and the same PD game to appear in the first, second, and third part of the game sequence. Playing games with different strategic structure was used to introduce the PD games as one-shot games and prevent subjects for using strategies applicable in the repeated play of PD.

Eye Movements Recordings

Eye movements were recorded using the Tobii 1750 remote binocular eye-tracker with 50 Hz sampling rate. The accuracy of the gaze position record is about 0.5 degrees visual angle. The game was presented on the Tobii monitor (17", 1280x1204 pixels). Each box containing payoffs or moves occupied about 1 degree visual angle on the screen. The distance between two adjacent boxes was at least 1 degree visual angle to ensure stable distinction between eye-fixations belonging to respective zones. The schematic game interface is presented in Figure 2.

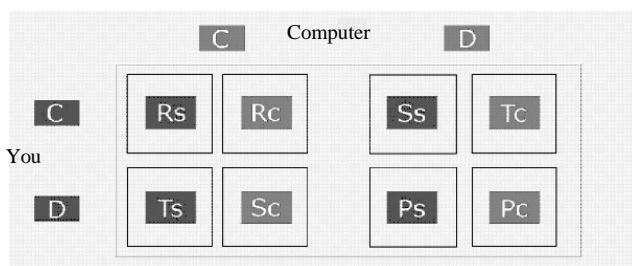

Figure 2: Schematic representation of the game interface. During playing, the actual payoffs and moves are presented. The superscript 's' refers to the subject, and 'c' to the computer opponent.

Procedure

After the eye-tracking calibration, subjects received instructions and were tested for understanding the instructions. Then each subject played 5 training games, and next the 80 games described above.

The game was presented in a formal and a neutral formulation. On the interface, the cooperation move was labeled '1' and the defection move was labeled '2'. However, further in the paper, for convenience, we will continue to use *cooperation* instead of move '1' and *defection* instead of move '2'.

Subjects were instructed to try to maximize their payoffs and not to try to 'beat' the computer. After each game the subjects got feedback about their and the computer's choice and payoffs in the current game. This information was visible for 3 seconds and then the next game automatically appeared. To ensure that players are following the instruction, three participants that got most points were promised and given a reward. In such a way we were trying to emphasize the importance of getting more points (and not trying to get more points than the opponent). Participants were not told their total number of points until the end of the game.

It is explained to the participants that the computer makes its choices trying to maximize the payoff in each game. They were also told that the computer is not aware of the participant's

choice. In fact the computer's moves were randomly generated in advance and were the same for all participants.

Participants

33 subjects with normal or corrected to normal vision took part in study. Playing behavior of all subjects was analyzed, however, due to technical difficulties, eye-tracking data of only 22 of the subjects were analyzed.

Playing results

The number of cooperative choices for PD games was used as a dependent variable characterizing the participants' playing and choices. If the disjunction effect is present, the cooperation rate in the unknown move condition will be higher than either the defect (D) or cooperate (C) known move condition. If no disjunction effect is observed, the cooperation rate for the unknown move condition is expected to be equal or between the cooperation rates for D and C. This is the reason to compare the unknown move condition against the known D and C conditions separately and not against the aggregated data.

For the games with *complex* payoffs the expected pattern for a disjunction effect appeared in the data (see Figure 3). Participants cooperated in 27 % of the PD games in which the computer move was not known, in 11 % of the games that the computer move was known to be cooperation, and in 12 % of the games that the computer move was known to be D defection. Cooperation rate when the computer move is not known is significantly different ($p < 0.05$) from the cooperation rates when the computer move is known to be cooperation or defection.

Figure 3: Mean cooperation (%) in Experiment 1 for *complex* and *simple* PD games when the computer's move is not known (*unknown*); the computer's move is known and it is cooperation (*move C*); the computer's move is known and it is defection (*move D*). Error bars represent standard error of the mean.

For the games with *simple* payoffs the disjunction effect was not so prominent (see Figure 3). Participants cooperated in 20 % of the PD games in which the computer move was not known, in 16 % of the games that the computer move was known to be cooperation, and in 6 % of the games that the computer move was known to be defection. Although the trend is present, there is no significant difference in the cooperation rates when the computer move is unknown or

when the computer move is known to be cooperation. Cooperation rate when the computer move is known to be defection is significantly different ($p < 0.05$) from the cooperation rates when the computer move is not known or is known to be cooperation.

In summary, when the payoffs were complex, a clear disjunction effect appeared. However, the effect was not statistically significant when the payoffs were simple. It seems that these results support the complexity explanation for the disjunction effect because change in the complexity of the payoffs changes the participants' choices and the disjunction effect diminishes.

Eye-movements results

We defined several areas on the screen that are interesting in studying information acquisition during PD game playing. Each Area of Interest (AOI) contains the box in which the information is presented and a small region around it. Here we present the analysis of the eye-tracking data for the four AOIs containing the subject's possible payoffs. These AOIs are referred to as T_S , R_S , P_S , and S_S (see Figure 2). We used the gaze-time (sum of all fixation durations on each AOI) as a measure of attention devoted to it (Rayner, 1998).

We expect that when the computer's move is known, the subject's attention will be directed to the possible payoffs corresponding to the computer's choice. So, for each game we computed the aggregate gaze-times in the zones containing subject's possible payoff if the opponent cooperates (R_S and T_S) and in the zones containing subject's possible payoff if the opponent defects (S_S and P_S). These data are analyzed in a repeated-measures analysis of variance with the computer's move (not known, known to be cooperation, and known to be defection) as a within-subject factor. Two such analyses were performed: for the PD games with complex payoffs and for the PD games with simple payoffs.

For the games with *complex* payoffs when subjects knew that the computer's move was defection they attended less to the AOIs denoted as T_S and R_S compared to the games when the computer's move was not known ($p = 0.018$) or it was known to be cooperation ($p = 0.055$) (see Figure 4). When subjects knew that the computer's move was cooperation they attended less to the AOIs denoted as P_S and S_S compared to the games when the computer's move was not known ($p = 0.004$) or when it was known to be defection ($p = 0.002$) (see Figure 4).

For the games with *simple* payoffs when subjects knew that the computer's move was defection they attended less to the AOIs denoted as T_S and R_S compared to the games when the computer's move was not known ($p = 0.018$) or it was known to be cooperation ($p = 0.02$) (see Figure 4). When subjects knew that the computer's move was cooperation they attended less to the AOIs denoted as P_S and S_S compared to the games when the computer's move was not known ($p < 0.001$) or when it was known to be cooperation ($p < 0.001$) (see Figure 4).

In summary, the eye-tracking data show that when the opponent's move is known, the eye-movement patterns are

changed in both types of games (*complex* and *simple*). When the computer's move is D, the subject's possible payoffs are S_S or P_S and they do not pay attention to the other payoffs (R_S and T_S). When the computer's move is C, the subject's possible payoffs are R_S or T_S and they do not pay attention to the other payoffs (S_S and P_S).

Figure 4: Average gaze-time for AOIs containing subject's possible payoffs (T_S , R_S , P_S , and S_S) when the computer's move is not known (*unknown*); the computer's move is known and it is cooperation (*move C*); the computer's move is known and it is defection (*move D*). Error bars represent standard error of the mean.

Another measure analyzed is the total gaze-time in the four AOIs containing the subject's possible payoffs. The analysis shows that when the payoffs are complex players spend more time looking at their them (mean 2270 ms) than when the payoffs are simple (mean 1880 ms), $p = 0.04$. This result indicates that *simple* payoffs are indeed easier to process than the *complex* payoffs.

Summary and discussion for Experiment 1

All these results are in accordance with the complexity explanation of the disjunction effect. When complexity of the PD game is reduced (by using payoff that are easy to process) the disjunction effect is reduced. Eye-movements data also support this explanation. When the computer's move is known, the eye-movement patterns are changed – players are paying less attention to the payoffs that are not relevant for the already revealed opponent's move. Eye-movement data also give evidence that the intended reduction in complexity of the game is successful.

Experiment 2 – Testing the quasi-magical thinking explanation

Goals and hypothesis

The goal of this experiment is to test the explanation that the disjunction effect arises due to the so called 'quasi-magical thinking'. The explanation is that the players behave as if they believe that their choices could influence the other

player's choices (although they know that in fact the other player is not aware of their choice while making his).

To test this explanation in this experiment we use a novel manipulation consisting in telling the subjects that the computer's moves are determined in advance. When this fact is known the above stated 'quasi-magical beliefs' should be diminished and the disjunction effect should disappear.

Stimuli and Procedure

Game and procedure were the same as in experiment 1. Change was made only in the information given to the participants in regard to the computer's move. It is said not only that the computer tries to maximize its payoff in each game but also that the computer has determined all of its moves in advance, before the start of the sequence of 80 games.

Participants

27 subjects with normal or corrected to normal vision took part in study. Playing behavior of all subjects was analyzed, however, due to technical difficulties, eye-tracking data of only 16 of the subjects were analyzed.

Playing results

For the games with *complex* payoffs participants cooperated in 21 % of the PD games in which the computer move was not known, in 12 % of the games that the computer move was known to be cooperation, and in 7 % of the games that the computer move was known to be defection (see Figure 5). Cooperation rate when the computer move is not known is significantly different ($p < 0.05$) from the cooperation rate when the computer move is known to be defection. All other differences are non-significant. Although the trend is present, there is no significant difference in the cooperation rates when the computer move is unknown or when the computer move is known to be cooperation.

Figure 5: Mean cooperation (%) in Experiment 2 for *complex* and *simple* PD games when the computer's move is not known (*unknown*); the computer's move is known and it is cooperation (*move C*); the computer's move is known and it is defection (*move D*). Error bars represent standard error of the mean.

For the games with *simple* payoffs no disjunction effect was found (see Figure 5). Participants cooperated in 14 % of the PD games in which the computer move was not known, in 16 % of the games that the computer move was known to be cooperation, and in 10 % of the games that the computer move was known to be defection. There is no significant difference between these three cooperation levels.

In summary, when the players know that the computer moves are determined before the start of the sequence of games, the disjunction effect is smaller or absent. Especially when the PD games payoffs are easy to be processed and compared, no such effect is observed.

Eye-movements results

For the games with *complex* payoffs when subjects knew that the computer's move was cooperation they attended more to the AOIs denoted as T_S and R_S compared to the games when the computer's move is not known ($p = 0.009$) and it is known to be defection ($p = 0.003$). They also attended less to the AOIs denoted as P_S and S_S compared to the games when the computer's move is not known ($p < 0.001$) and it is known to be defection ($p < 0.001$) (see Figure 6).

For the games with *simple* payoffs, when subjects knew that the computer's move was D, they attended less to the AOIs denoted as T_S and R_S compared to the games when the computer's move was not known ($p = 0.044$) and when it was known to be C ($p = 0.08$). They also attended less to the AOIs denoted as P_S and S_S compared to the games when the computer's move was not known ($p = 0.001$) and when it was known to be C (< 0.044) (see Figure 6).

Figure 6: Average gaze-time for AOIs containing subject's possible payoffs (T_S , R_S , P_S , and S_S) in Experiment 2 when the computer's move is not known (*unknown*); the computer's move is known and it is cooperation (*move C*); the computer's move is known and it is defection (*move D*). Error bars represent standard error of the mean.

In summary, the eye-tracking data show that in both types of games (*complex* and *simple*) the eye-movement patterns are changed. When the computer's move is known, the subjects pay more attention to their possible payoffs in the corresponding column and they don't pay attention to the other payoffs.

Again we analyzed the total gaze-time in the four AOIs containing the subject's possible payoffs. The analysis shows that when the payoffs are complex players spend more time looking at their payoffs (mean 1525 ms) than when the payoffs are simple (mean 1309 ms), $p = 0.036$. Total gaze time in these four AOIs is less in Experiment 2 (mean 1417 ms) than in Experiment 1 (mean 2079 ms), $p = 0.034$.

Summary and discussion for Experiment 2

As expected, when the subjects are told that the computer moves are already decided, the disjunction effect is reduced and even disappears when games with lower complexity are played. These results are in accordance with the quasi-magical thinking explanation of the disjunction effect and also give further support for the complexity explanation.

Discussion and Conclusions

The paper presents an experimental study of the disjunction effect in PD games based on behavioral experiments with eye-movement recordings. The experiments were designed to explore the complexity hypothesis about the appearance of the disjunction effect which seems to have little support in the literature. However, our study showed that without changing the structure of the game (and its cooperation index), but by just using payoffs which can be easily processed, the disjunction effect can disappear. We interpret this result as an indication that despite the arguments and evidences that have been discussed in the literature (see Shafir & Tversky, 1992; and Croson, 1999) the role of complexity should not be underestimated and deserves further attention and exploration.

One possible interpretation of the findings from Experiment 1 can be that participants have difficulties in the comparison of alternatives in the complex payoff condition and cannot come out with clear preferences. In the simple payoff condition, outcome comparison is simpler and participants can choose their move in a similar way as when the move of their opponent is known.

In the second experiment, the participants were told that the moves of the computer opponent had been made before the game session. Such a manipulation hasn't been used before. This manipulation led again to the disappearance of the disjunction effect even in the complex payoff condition. We interpret this result as a suppressing of a possible quasi-magical reasoning by stressing the fact that participants own moves cannot influence the move of the opponent. Interestingly, the manipulation led also to considerable decrease in the payoff processing time which deserves further exploration.

The results from the two experiments point to information processing complexity as a major factor for the disjunction effect contrary to the conclusions in previous research.

The eye-movement data support the complexity explanation described above. They show a change in the dynamics of the information acquisition in relation to the experimental manipulations of the complexity of the

payoffs, and of the information about the opponent's move. As has been suggested in Bussemeyer et al. (1993), the deliberation process can play a crucial role in decision making, especially when participants cannot attend at once to the full information available but can compare alternatives based on selected features.

A further systematic experimental and theoretical investigation of the results presented in this paper is under way and will be presented in the future.

Mentalizing in games: A subtractive behavioral study of Prisoner's Dilemma

Antonio Napoli (antonio.napoli@phd.units.it)

via S. Anastasio, 12, I-34134 Trieste, Italy

Abstract

Economists and neuroscientists often explain game playing by assuming that humans try to predict the opponent's behavior on the basis of her past choices. We try to question this assumption in a Prisoner's Dilemma Game by using a methodology which we call the "subtractive behavioral method". Our aim is to investigate which task features make participants attend to the opponent's behavior or, on the contrary, make them take into account only their own choices and received payoffs. We find a critical effect of contextual information and we derive some suggestions about the methodology of brain imaging and behavioral game theory experiments.

Keywords: Game Theory; Brain Imaging; Theory of Mind; Social Dilemmas; Prisoner's Dilemma

Introduction

Game Theory (Von Neumann & Morgenstern, 1944) is a branch of applied mathematics focused on describing and predicting the behavior of "players" involved in strategic interactions in which the result of every player's "move" is contingent on the move(s) made by the other player(s). One of the critical assumptions of the theory is that games are played by completely rational agents whose strategies could be precisely calculated. In recent years the Game Theory formalism has been adopted to develop models that try to account for the fact that people often behave differently from what the theory predicts. This approach has been named "Behavioral Game Theory" (Camerer, 2003).

Behavioral Game Theory models make the assumption that people learn during the interaction, i.e., that they change their behavior according to the efficacy of their past choices. Among these models there are some, like those based on Reinforcement Learning (Erev & Roth, 1998; Sarin & Vahid, 2001), which take into account only the player's own choices and received payoffs while others, like so-called sophisticated (Camerer, Ho, & Chong, 2002) and belief learning (Cheung & Friedman, 1997) models, consider also (or only) the opponent's choices and payoff history. We will refer to the former as "partial information models" and to the latter as "full information models".

Even if Behavioral Game Theory does not make any assumption about the internal mechanisms involved in game playing, from a cognitive perspective it is possible to find a difference between partial information and full information models. Partial information models obey to a strictly behaviorist rule: the more you get from a choice, the more you will choose it in subsequent trials. These models

completely ignore the opponent's behavior and only manipulate representations about chosen moves and obtained payoffs. They may also be applied to situations of playing without opponents (one-person games); in fact, they have been proposed by Sutton and Barto (1998) to model the performance in multi-armed bandit tasks in which participants make repeated choices among different options which are followed by a numerical reward that depends on the choice being made.

On the other hand, full information models manipulate representations about the opponents' moves and payoffs to anticipate their behavior and obtain thus a strategic advantage. These models address the opponent's beliefs, intentions, and strategies, and therefore mimic a Theory of Mind (henceforth: ToM) or "mentalizing" mechanism.

Neuroscientist have recently begun to study the cortical circuits involved in game playing through neuroimaging. Krueger, Grafman, and McCabe (2008), after reviewing the literature on the topic, propose that two cognitive mechanisms are specifically involved in game playing.

The first one is a "shared affect system" located in the Anterior Insula. This area is only activated in non-zero sum games in which cooperation between players is possible, and therefore feelings of trust, reciprocity and collaboration could be developed. The area seems responsible of two main effects: it makes people feel disgust towards uncooperative behavior and react to it (for example, rejecting unfair offers in a Ultimatum Game: Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003) and it makes people reciprocate by distinguishing between cooperative and non-cooperative opponents (Singer, Kiebel, Winston, Dolan, & Frith, 2004).

The second mechanism is a "shared intentions system", which is located in the Medial Prefrontal Cortex (MPFC). This area is activated both in zero and non-zero sum games, because it has the function of representing the opponent's beliefs, desires, and intentions, i.e. it seems to constitute the neural substrate of the ToM. Several brain imaging studies (see Krueger et al., 2008, for a comprehensive review) have shown MPFC activation during game playing and, therefore, it seems plausible that people mentalize while playing these games.

There are two other circuits which are not specifically involved in game playing but seem to be engaged in all kinds of learning tasks: a reward-based mechanism situated in a broad network of cortical and subcortical areas (see Lee, 2005 for a review), and a system concerned with the

prediction of complex behavior independently of its source, which is located in the Posterior Superior Temporal Sulcus (Frith & Frith, 2003).

Studies about mentalizing in game playing usually rely on the comparison between a condition in which people play against a computer and one in which they play against a human opponent on the presumption that mentalizing could be promoted by the latter. However, it is not clear whether and when people adopt a “mentalizing stance” and which task features could promote this activity. In fact, some studies show that a computer opponent could elicit activity in MPFC (Rilling, Sanfey, Aronson, Nystrom, & Cohen, 2004), while others claim that not all game situations against humans make people mentalize (Sally, 2003).

It is also unclear how mentalizing affects behavior, or, in other words, how decision making is affected by a ToM. For example Hill, Sally and Frith (2004) report that autistic adults behave in the same way as healthy participants in the Prisoner's Dilemma game, even if the autistic participants are severely impaired in other ToM tasks. Also, most neuroimaging studies lack a comparison between participant's behavior while playing against a human and a computer opponent.

We are convinced that the study of the ToM mechanisms would benefit from experiments which analyze participant's behavior. Two questions are important to us: 1) Which task feature make people mentalize? 2) Which effect does mentalizing have on people's behavior? In the present paper we try to address the first question by investigating some of the task features which could promote mentalizing during game playing.

Previous work

We have already started to explore the behavioral effects of mentalizing (Napoli & Fum, 2009) in playing a computer version of Rock, Papers, and Scissors (henceforth: RPS).

We had three groups of participants play 100 turns of RPS. In the first group, the computer was presented as an opponent, and the game was explicitly described as RPS. In the second group, the computer was presented as a neutral device. Participants saw three geometric figures which they should choose among at each trial; they received a payoff after each choice, and they could see the payoffs they could have obtained by making the alternative choices. Thus, this condition was equivalent to a multi-armed bandit task (Sutton & Barto, 1998) with the indication of foregone payoffs. In the third group, the computer was presented as an opponent. The game was played with the same rules of RPS but the choices were represented by geometric figures and the hierarchy of the moves (what beats what) had to be discovered during the game. This condition served as a control for the effect of the knowledge of the payoff matrix. The algorithm which assigned the payoffs was the same in all groups; the conditions differed therefore only for the setting induced in the participants (and the user interface).

We did not find any behavioral difference between the conditions, and we were able to model the behavior of all

the groups by using a Reinforcement Learning algorithm based on ACT-R's utility learning mechanism (Anderson, 2007). This corroborates the idea that people did not use any information about foregone payoffs in the second condition and did not use any information about the opponent's moves or payoffs in the first and third condition. In summary, participants did not seem to mentalize at all during the experiment.

There are many possible explanations for this “failure to mentalize”. Maybe people did not mentalize because they played against a computer; maybe they did not mentalize because the game was a mixed-strategy equilibrium game in which no move was better than the others and a simple behaviorist strategy could efficiently cope with the game; maybe people did not mentalize because no cooperation was possible in playing a competitive game. Or it may be a combination of all the three.

In this paper we try to clarify the findings of our previous work by making participants play a non-zero sum game, the Prisoner's Dilemma, both against what they believed was a human opponent and against a computer. Our aim is to understand which task features make people mentalize in game playing, which features affect game behavior and, possibly, why.

The experiment

Prisoner's Dilemma (henceforth: PD) is a non-zero sum game which has been extensively studied in psychology (Rapoport & Mowshowitz, 1966), classical game theory (Bo, 2005), behavioral game theory (Camerer, 2003), and neuroimaging studies (Singer et al., 2004). The payoff matrix used in our experiment is presented in table 1.

Table 1: Our experiment's payoff matrix

	Cooperate	Defect
Cooperate	60 60	100 0
Defect	100 0	20 20

PD can be thought of as a paradigmatic situation for any social dilemma in which the selfish interest contrasts with the common one. Classical game theory states that, independently of the choice made by the opponent, the most rational move for a player is to defect. In fact, if the opponent chooses to cooperate, defection gets 100 points and cooperation only 60 while, if the opponent defects, defection gets 20 points and cooperation 0. The result is that the optimal strategy for both people is to defect.

The most intriguing aspect of this game is that, even if the most rational move is defection, experiments show a substantial amount of cooperation between the players when the game is played in the iterated version (Bo, 2005). Another finding is that players learn to cooperate more and more during the experiment (Rapoport & Mowshowitz, 1966).

In order to understand what makes people mentalize, we adopted a “subtractive behavioral method” by assigning people to four different conditions in a repeated PD decision-making task in which the points earned by the participants were converted into play money.

The conditions differed according to the task features present in them which are summarized in Table 2.

Table 2: Features present in the experimental conditions

Features	Conditions			
	N	CB	HB	HPD
Repeated decision making	Y	Y	Y	Y
Opponent	N	Y	Y	Y
Believed Human Interaction	N	N	Y	Y
Explicit social scenario	N	N	N	Y

In the first condition, named “Nature” (N), participants played the PD disguised as a binary decision task: in each trial they had to choose between two options receiving a reward after each choice. It should be noted that in this condition the PD is presented as a repeated decision making one-person game, or a game against nature, in which no opponent is involved.

In the second condition, named “Computer Bet” (CB) participants were told that they would play a game against the computer. The instructions, however, presented the PD as a betting task: in each trial, the participants and the computer should bet on one of two alternatives and, depending on the combination of their choices, they would receive a given reward.

The third condition, named “Human Bet” (HB), was similar to the previous one (CB) except for the fact that participants were made to believe that they would play against a human opponent while in fact they were engaged by the computer.

In the fourth condition, named “Human Prisoner's Dilemma” (HPD), participants played PD against what they believed was a human opponent, just as in CB condition. There was, however, a substantial difference in the instructions provided for this condition and the two betting ones: the game was introduced by a story which illustrated a classical PD scenario (see Procedure for more details) and the two choices were labeled as “Cooperate” and “Defect”.

In CB, HB and HPD conditions the instructions stressed that the goal of the participants was to gain as much money as possible independently of the money gained by the opponent, and that their opponent had the same objective.

According to results of neuroimaging research discussed in the Introduction, there are four cognitive processes which may influence participants' behavior in this task: the reward-based system, the complex behavior detecting system, the shared intentions system, and the shared affect system.

It is known that the reward-based system plays a role both in individual learning tasks and in game playing (Lee, 2005) by integrating the information received during the task in order to calculate the expected utility of different

choices. Thus, this system should be active in all conditions, because of the repeated nature of the task.

It has been shown that the complex behavior detecting system is active during game playing against both computer and human opponents (Gallagher, Jack, Roepstorff, & Frith, 2002; Haruno & Kawato, 2009), and thus it should be activated in all conditions except Nature.

The shared intentions system is the main concern of this article. This area is always activated during game playing against humans, but it has been shown to be activated also during game playing against computer opponents, even if it is unclear which effect it exerts on people's behavior. If we find any difference between the CB and HB conditions, we can argue that mentalizing has a behavioral effect only in the case of a human opponent.

Finally, the shared affects system has been shown to be active when game playing involves the possibility of pro-social behavior, reciprocity, or fairness, and therefore we expect it could influence people's behavior only in the HPD condition. In this case the instructions promote empathizing with the opponent both because of the explicit social scenario and because of the labels attributed to the choices, which have a strong moral connotation. Therefore, every difference between the HB and HPD conditions should be attributed to this system.

Method

Participants and design. Sixty-four students (38 males) enrolled at the University of Trieste, Italy, were recruited as participants. Their age varied between 18 and 29 years ($M=21.2$, $SD=3.4$). Participants played two PD rounds, each one against a different algorithm (see below) whose order was counterbalanced between rounds. The experiment followed therefore a 4x2 mixed design with Setting as between-subjects and Algorithm as within-subjects factors.

Materials. Two algorithms were used in the experiment. The first one, Tit for Tat, cooperated in the first interaction and then replicated the opponent's previous choice. The second one, named Biased, made his moves by randomly sampling from a distribution of 60% Cooperate and 40% Defect moves.

Procedure. The experimental sessions were held in groups of 10-12 participants convened in a computer laboratory. Each participant was randomly assigned to one of the four conditions taking care that participants assigned to the same condition were not sitting next to each other. Participants were told that they would play different versions of the same game and received the instruction according to the condition to which they were assigned. Then, they were engaged in two PD rounds lasting eight minutes each.

The interface was kept as similar as possible in the four conditions. Participants made their choices by clicking on one of two circles displayed in the upper part of the screen. After a random lag time, in the Nature condition participants received a feedback about the money gained in the trial,

while in the other conditions they received a feedback about the opponent's choice, the money gained by themselves and by the opponent. The length of a bar representing their running total was updated and they were allowed to make another choice. In all conditions the two circles were labeled as "Yellow" and "Blue" except for the HPD condition, in which they were named as "Cooperate" and "Defect".

The main differences between the conditions relied in the amount of information and the kind of instructions provided to participants. In the N condition it was stated that they would play a binary decision task. After the first round participants were told that the computer would change the rule according to which it assigned the money. In the other three conditions participants had the payoff matrix in front of them from the beginning of the game. In the CB condition instructions stated that they would play a betting game with the computer, and after the first round they were told that the computer would change its strategy. In the HB and HPD condition participants were told they would play the game with one of the other participants in the room, and that the opponent would change after the first round. In the HB condition the task was presented as a betting game while in the HPD condition the game was introduced through a bargaining scenario in which Cooperate meant to respect the contract by delivering the promised goods and valuable money, respectively, while Defect meant to give the other player an empty bag. The instructions explicitly underlined this aspects of moral obligation and contract infringement involved in the game.

All groups played against the same algorithms with the Yellow and Blue circles equated to Defect and Cooperate, respectively.

At the end of the experiment we had informal interviews with the participants to assess the possibility that they had some doubts about having played against a computer and not a mate. Subjects who reported doubts were discarded from data analysis. Finally, a collective debriefing session ensued in which the nature of the opponent was discovered to all participants and the reasons for always adopting a computer as opponent were explained.

Results

Since the experiment was self-paced, participants made a variable number of choices in each round. To perform statistic analyses, we took into account their first 50 moves only.

Analysis of Cooperations. Being interested in the quality of participant's behavior more than in their ability to exploit the opponent's algorithm, we concentrated the analysis on the number of Cooperate moves and not on the amount of money gained.

First, we looked for possible differences between the first and second round in order to control for effects of learning (or fatigue). A mixed design ANOVA between the Round and the Setting did not reveal any significant effect for the Round ($p=.55$) or interaction ($p=.93$), while there was a significant effect of the Setting ($F(3,58)=10.1$,

$p < .001$).

We then analyzed the factors manipulated in the experiment. A mixed design ANOVA revealed a significant effect of Setting and Algorithm ($F(3,58)=10.1$, $p<.001$ and $F(1,58)=93.14$, $p<.001$ respectively), while the interaction was not significant ($p=.92$). Table 3 reports Means and Standard Deviations of the participants' total Cooperate moves.

Table 3: Means (and Standard Deviations) of Cooperate per Algorithm in the various Settings

Algorithm	Setting			
	N	CB	HB	HPD
Biased	15.69 (5.41)	11.18 (7.7)	14.23 (10.03)	24.24 (7.09)
TFT	32.6 (9.93)	26 (10.65)	28.8 (17.2)	41.35 (10.6)

Algorithm and Setting seem to have an additive effect in promoting cooperation between participants. While it is evident that the TFT algorithm promotes Cooperation more than the Biased one, it is unclear how Settings exerted its effect. Since there was no main effect of Round and no interaction between Algorithm and Setting, we analyzed separately the participant's performance against the two algorithms.

Two separate one-way ANOVAs for Biased and TFT Algorithms were performed. Both showed a significant effect for Setting ($F(3,58)=8.95$, $p<.001$ and $F(3,58)=4.94$, $p<.01$ respectively). The probabilities associated with post-hoc Newman-Keuls tests to contrast each Setting condition with the others are summarized in tables 4 and 5. For both algorithms a significant difference was found between the HPD and the other three conditions which, on the other hand, did not differ from each other.

Table 4: Probabilities for Post-hoc Newman-Keuls tests for the Biased Algorithm

	N	CB	HB	HPD
N		.24	.6	.0029*
CB	.24		.27	.002*
HB	.6	.27		.0017*
HPD	.0029*	.002*	.0017*	

* = significant

Table 5: Probabilities for Post-hoc Newman-Keuls tests for the TFT Algorithm

	N	CB	HB	HPD
N		.29	.39	.051**
CB	.29		.52	.016*
HB	.39	.52		.0049*
HPD	.051**	.0049*	.016*	

*= significant **=marginally significant

Analysis of conditional probabilities. We ran another analysis in order to understand why there was a difference in the number of Cooperate moves in HPD condition. This analysis was proposed by Rapoport and Mowshowitz (1966) and was also utilized by Erev and Roth (2001) in order to assess the efficacy of their reinforcement learning model.

Rapoport and Mowshowitz analyzed the probability of cooperation in a given trial according to the choices made in the *previous* trial by *both* players. Thus, a participant's strategy can be described by four numbers, C|CC, C|CD, C|DC, and C|DD. In the N condition, these probabilities may be interpreted as an analysis of a “win stay / lose switch” behavior. We can assume that, after a few choices, people get acquainted with the payoffs associated with the various options. Thus, for example, C|CC would be the probability of making the Cooperate/Blue move after receiving the best reward associated with that choice; therefore, a high value of this parameter would be an expression of a “win stay” strategy.

We analyzed the four conditional probabilities separately for the two algorithms to search for possible different strategies used in the different Settings. We ran a total of eight one-way ANOVAs analysis and all post-hoc Newman-Keuls tests for the significant ones.

We found a significant difference in three ANOVAs: C|DC both in the Biased ($F(3,58)=7.94, p<.001$) and in the TFT condition ($F(3,58)=5.21, p<.005$) and C|CC in the TFT condition ($F(3,54)=4.73, p<.006$). Newman-Keuls post-hoc tests showed that: in C|DC / Biased, HPD was different from all the other conditions ($p<.001$ in all cases), which were similar between them; in C|DC / TFT, HPD was different from CB and HB ($p<.001$ in both cases) and only marginally significant respect to N ($p=.055$), and the other three conditions were similar between them; in C|CC / TFT, the only significant difference was between HPD and CB $p<.001$.

Discussion and conclusions

In the experiment, participants played against an algorithm, the Biased one, that chooses its moves by sampling randomly from a given distribution, i.e., independently from the move made by the opponent, and against another algorithm, the TFT, that cooperates only if the opponent cooperated in the previous trial and defects otherwise. This means that the most rewarding strategy for participants was to Defect against the Biased algorithm—in order to exploit the trials in which it cooperates and to defend against the possibility of being exploited when the algorithm defects—and to Cooperate against the TFT—in order to initiate and maintain a virtuous reciprocation loop. The statistical analyses demonstrated that participants made more Cooperate moves against the TFT than against the Biased algorithm, i.e., that they were successful in adapting their strategy to the strategy used by the opponent.

However, we also found some differences between the groups: in the HPD condition participants made a higher number of Cooperate moves against both algorithms. The

conditional probability analysis showed that this difference could be explained by the higher rate of C|DC in both cases. Since the only difference between the HPD and the other groups relied in the use, in the former case, of instructions that explicitly underlined the aspects of moral obligation and contract infringement involved in the game, the most natural conclusion is that this feature made people more prone to regret their defection against a cooperative opponent in the previous trial leading thus to more frequent cooperative behavior.

Interpreting the behavioral results in terms of the cognitive systems framework introduced above, we could safely assume an influence on this task of the reward-based system, being the participants capable of successfully adapting their strategy to the opponent in all conditions. However, we cannot exclude that such a performance could reflect the activation of the complex behavior prediction system too, being the activation of this system not selectively associated with strategic interactions (Frith & Frith, 2003). As for the shared affect system, it could have played a role in both human conditions (HB and HPD). In fact, during the debriefing interviews, some HB participants spontaneously told us about their willingness to cooperate with the opponent, a behavior that is typically associated with the activation of this system (Singer et al., 2004). However it is unlikely that this system played a critical role in the HB group, whose performance was similar to that of the N and CB condition where it is not credible that people could empathize with a computer, being it an opponent or not. Therefore, this system could be active only in the HPD condition.

As for the ToM system, we can exclude that it influenced the participant's behavior in CB and HB groups, which was similar to that of the N group. Therefore, we are left with two systems (ToM and empathizing) as responsible for the difference found in the HPD condition. Because brain imaging studies show that playing against a human opponent activates ToM areas regardless of the specific game (see for example Gallagher et al., 2002) and because, according to the participant's reports, it seems likely that they did in fact mentalize, we think that this area was active in both situations, and suggest two possible explanations for our results: (1) ToM had no behavioral effect in HB situation or (2) ToM had no effect both in the CB and HB conditions, and the difference between the two groups should be attributed to the shared affect system.

We won't take position with regard to this issue, because the limitations of our behavioral method don't permit us to. However we think that, whichever is the real explanation, this study makes some interesting points about both brain imaging and behavioral game theory experiments.

With regard to brain imaging studies, even if it has been shown that ToM areas are active in almost every game played against human opponents, it is not clear when they have a behavioral effect, too. We can speculate that there is some mechanism which prevents ToM from influencing the behavior in some situations. Otherwise, it would seem really

strange that it wouldn't have any effect on behavior *at all*. Therefore, we think that brain imaging studies should always take in account people's behavior, in a similar way to Haruno & Kawato (2009) and Hampton, Bossaerts, and O'Doherty (2008).

As for behavioral game theory, this paper makes a case for Erev and Roth's (2001) proposal of accounting people's behavior in Prisoner's Dilemma by the means of Reinforcement Learning. In fact, in N condition participants did not have any information about foregone payoffs, and nonetheless, their behavior was similar to the other groups. This means that the knowledge of payoff matrix and of the opponent's choices had a limited effect on participant's behavior. On the other side, the paper shows also the importance of contextual information—a variable which is seldom taken into account in game theory. In a more general sense, we think that our paper suggests the utility of having, along experiments in which people play one against the other, some more controlled sessions in which the participants play against an opponent (be it a computer or a human actor) whose strategy was under the control of the experimenter and compare them with individual learning sessions. This could make the experimenter safely exclude in most cases unnecessary believes or sophisticated learning.

Abstract

In recent years, more and more data have come to fore that indicate perception to be inherently prospective (i.e., anticipatory). The purpose of the present symposium is to examine the research of three scholars who investigate prospective perception from three different theoretical perspectives: the Theory of Event Coding, the Action-Specific Perception account, and Ecological theory. Panelists will examine differences between theories and address the extent to which prospective perception affords a means of potentially integrating these theories.

Keywords: Prospective control; sensory-motor learning; ecological psychology; Action-Specific Perception account; affordances; anticipation.

What is Prospective Perception?

In recent years, more and more data have come to fore that indicate perception to be inherently prospective (i.e., anticipatory). The purpose of this symposium is to present research from three scholars who investigate prospective perception. Each will discuss the types of dependent variables they measure, the variables they manipulate, and the theoretical frameworks they use to interpret their data. Emphasis will be placed on differences and similarities between theories, as well as possible means of overcoming such differences. In the end, the panel will address what exactly it means for perception to be prospective, and how this might impact current theorizing in cognitive science.

The Theory of Event Coding

J. Scott Jordan is a cognitive psychologist who investigates the well known finding that the perceived vanishing point of a moving stimulus is displaced beyond the actual vanishing point, in the direction the stimulus was traveling just before it vanished (Hubbard, 2005). Numerous studies have revealed that the magnitude of this forward displacement (FD) varies systematically as a function of stimulus factors such as velocity (i.e., FD increases as stimulus velocity increases), movement direction (i.e., upward moving stimuli give rise to less FD than downward

moving stimuli), and implied friction (i.e., FD decreases as a stimulus appears to move across a surface). Traditionally, such findings are accounted for in terms of representational-momentum, the idea being that the brain evolved to represent dynamic as well as static stimulus properties. Thus, when the moving stimulus vanishes, its representation entails momentum and continues moving, as it were, in the direction of represented motion. In a series of recent papers, Jordan and colleagues have researched an alternative account; namely, that FD is due to the anticipation underlying action control. This interpretation is based on the Theory of Event Coding (TEC; Hommel, Muessler, Aschersleben, & Prinz, 2001) which assumes the following: (1) actions are planned in terms of the distal effects they are to produce, and (2) action-planning and perception share overlapping neural dynamics. According to TEC therefore, FD occurs because the stimulus' movements are perceived in terms of the action plans participants generate as they interact with the stimulus. In one study (Jordan & Hunsinger, 2008) it was discovered that when participants simply observed the movements of the stimulus, FD was larger for observers who had just recently learned to control its movements via key presses on a computer keyboard. According to TEC, when observers were simply observing the movements of the stimulus, they were 'perceiving' those movements in terms of the plans they had learned while controlling it, due to the neural overlap of perception and action-planning. In short, perception entails plans, and these plans render perception inherently prospective.

Action-Specific Perception Account

Jessica Witt is a cognitive psychologist who also studies perception, and does so in terms of a framework known as the action-specific perception account. According to this framework, perception is scaled to the abilities and intentions of the perceiver. For example, when participants intend to reach with a tool to targets that are just beyond their reach, the targets look closer than they do when participants intend to reach without the tool or when the participants hold the tool but never intend to reach (Witt,

Proffitt, & Epstein, 2005). As another example, targets on the ground look farther away to participants who intend to throw a heavy ball to them compared with participants who intend to throw a light ball (Witt, Proffitt, & Epstein, 2004). However, after throwing a heavy ball, targets only look farther away for participants who intended to throw again, but not to participants who intended to walk (Witt et al., 2004). Only effort for the action-about-to-be-performed influences perception. In addition, as was reported in Jordan & Hunsinger (2008), performance of a task and the plans one generates during such performance, can influence later perception. For example, softball players who were hitting better selected a larger circle as matching the size of the softball used during the game (Witt & Proffitt, 2005), and golfers who are putting better select a larger circle as matching the size of the hole (Witt, Linkenauger, Bakdash, & Proffitt, 2008). This implies that better athletic performance led players to perceive the target as larger.

Collectively, these findings are consistent with the action-specific perception account, and support the assertion that perception is scaled relative to the behavioral possibilities of anticipated actions. Again, as was the case with Jordan, this implies that perception is inherently anticipatory.

Ecological Theory

While on the one hand, the notion that perception takes place in terms of behavioral possibilities might seem new to cognitive science, the idea has been a foundational concept in Ecological Psychology, where perception is argued to take place in terms of *affordances*. That is, ecological theory assumes we perceive the environment in terms of the behaviors it affords. Michael Riley is an ecological psychologist who studies affordance perception during action perception. That is, he and his colleagues investigate the patterns of environmentally-available information generated by body-object systems and the ways perceivers use such information. In one study (Ramenzoni, Riley, Shockley, & Davis, 2008) he and his colleagues asked both short and tall participants to indicate maximum overhead reaching capabilities for both themselves and another participant. The available perceptual information was manipulated by changing the participants' optically specified eye-height. Participants were able to accurately perceive the maximum overhead reach for both the 'self' and the 'other'. However, when the perceiver's eye-height was increased, the perceived maximum overhead reach increased for both judgments about both self and other. Riley and his colleagues interpret these results as revealing a rich source of environmentally-available information that perceivers use when perceiving action possibilities. Given these perceived possibilities refer to possible *future* behaviors, they are, by definition, prospective.

Discussion

Common to the Theory of Event Coding (TEC), the Action-Specific Perception account (ASPA), and Ecological Theory (ET), is the notion that perception is prospective. The theories do differ, however, with TEC focusing on overlapping neural structures, ASPA focusing on task specificity, and ET focusing on information structures available in the optic array. While these may seem to reduce to an internal versus external difference, the members of the panel will address the issue of whether or not this common notion of prospective perception might constitute a means of overcoming the computational-ecological divide that has plagued cognitive science for decades.

Constructing Spatial Concepts from Universal Primitives

Abstract

Spatial terms such as *on* and *in* are found in every language, and psychologists have suggested that the meanings of these terms may be constructed from a universal set of spatial primitives. We develop a computational version of this idea and explore whether the primitives typically proposed are sufficient to account for the meanings of spatial terms across languages. We compare a model where spatial terms correspond directly to primitives with models that represent spatial terms as discrete or weighted combinations of primitives. Our results suggest that combinations play an critical role, and we find limited evidence for weighted combinations.

Keywords: spatial cognition; cross-cultural; semantics; computational model.

Every documented language includes some machinery for describing spatial relationships. For example, an English speaker might say that the cup in Figure 1b is *on* the table and that the spoon is *under* the cloth. Spatial terms like these are acquired relatively early by children (Antell & Caron, 1985) and are used so frequently that they may come to seem unremarkable. Researchers have found, however, that it is surprisingly difficult to specify the meanings of spatial terms (Brown, 1994), and that different cultures make use of very different spatial concepts (Levinson & Meira, 2003; Levinson & David, 2006). This paper presents computational models that explore how spatial concepts might be constructed from more basic components, and that help to establish whether spatial concepts across cultures are constructed from a universal set of spatial primitives.

Many previous researchers have discussed the idea that spatial concepts might be constructed as combinations of primitive notions such as “support”, “contact” and “containment”. (Piaget & Inhelder, 1956; Jackendoff, 1983; Feist, 2000) For example, Figure 1b suggests that *on* in English may be roughly defined as the conjunction of “support” and “contact”. Although this basic proposal is very familiar, there have been few sustained attempts to evaluate how well it can account for cross-linguistic data. Here we focus on primitives gathered from the existing literature and ask whether the distinctions that they capture are sufficient to account for spatial concepts across 25 different languages. Future work in this area can compare different sets of candidate primitives and compare how well they account for the data.

Any attempt to study semantic primitives must include some proposal about how these primitives combine to create spatial concepts. Here we compare proposals that vary along three dimensions. One of these dimensions specifies whether combinations of primitives are or are not allowed. A

simple baseline approach assumes that every concept in every language corresponds to one of the semantic primitives, and we compare this approach to alternatives which assume that concepts correspond to combinations of primitives. In Figure 1b, for example, “on” is defined as the conjunction of support and contact. A second dimension specifies whether primitives are differentially weighted. In Figure 1b, all combinations are assumed to be conjunctions, and we compare this approach with an alternative that relies on weighted combinations. The final dimension specifies whether or not negations of primitives are allowed—for example, whether “no contact” is included in addition to “contact.” Our three dimensions produce a collection of eight possible models, and we explore the five most interesting cases (Table 1). Comparing the performance of these models suggests that combinations of primitives are important, but we find only limited evidence for weighted combinations. None of the models we consider is rich enough to capture the true complexity of spatial cognition, but these simple models are a useful starting point for the computational approach that we advocate.

Our work is inspired in part by several recent studies of cross-cultural spatial cognition (Feist, 2000; Bowerman & Choi, 2001; Levinson & Meira, 2003; Feist, 2008; Khetarpal, Majid, & Regier, 2009). A consistent theme in the previous literature is that spatial concepts correspond to regions in some kind of similarity space. To mention just two examples, Bowerman and Choi (2001) suggest that scenes described using “on” and “in” by English speakers can be arranged along a similarity gradient, and that different languages carve up this similarity space in different ways. Levinson and Meira (2003) propose that spatial terms correspond to attractors in a similarity space, and use multidimensional scaling to support their proposal. Approaches like these have helped to illuminate the basis of spatial cognition, but they rely on a notion of similarity that is rarely made precise, and are unable to explain exactly how humans recognize similarities between spatial configurations. Our work is compatible with many of the insights that have emerged from these previous approaches, and could be viewed as an attempt to ground the notion of similarity in terms of concrete spatial primitives. We prefer, however, to treat similarity as an epiphenomenon, and expect that similarity will play no explanatory role once the building blocks of spatial concepts are understood.

We begin by introducing the semantic primitives that we will consider and the cross-linguistic data that we will attempt to explain. We then evaluate five simple models which

Figure 1: (a) A computational framework for exploring how spatial primitives (P) combine to create the meanings of spatial terms (T). Given information about which primitives characterize a set of scenes (S), the framework predicts which terms apply to which scenes. (b) An illustration of the framework in (a). English “on” is a combination of “support” and “contact,” and applies to scenes (like cup on table) where both primitives are present.

make different assumptions about how spatial concepts are constructed from semantic primitives. Each successive model includes one or more previous models as a special case, and we explore whether the additional assumptions made by each model help to account for the cross-linguistic data.

A Computational Approach to Spatial Cognition

Our formal approach is summarized by the graphical model in Figure 1a. Suppose that P represents a set of spatial primitives and that S is a matrix of scene vectors, where column s_i is a binary vector that indicates which primitives apply to scene i . In Figure 1b, for example, the scene vector for “cup on table” indicates that this scene is characterized by “support” and “contact” but not “hanging.” Let T be a matrix of term vectors, where vector t_j indicates which primitives contribute to the meaning of term j . In Figure 1b, the term vector for “on” indicates that the meaning of this term is based on the “support” and “contact” primitives. Finally, let D be a

Table 1: A brief description of the five models and their abbreviations. The two columns on the right compare model scores on the real data to the mean scores on the random sets discussed in Results. D_1 is data from the authors and Levinson and Meira (2003). D_2 is data collected by Feist (2000).

Model	Abbrev.	$S(D_1)$	$S(D_2)$
Singleton	BS+	.61 : .39	.61 : .50
Singleton with negations	BS−	.62 : .41	.66 : .53
Conjunction	BC+	.66 : .46	.70 : .58
Conjunction with negations	BC−	.79 : .57	.83 : .68
Weighted combination	WC−	.79 : .54	.80 : .65

binary matrix where entry d_{ij} indicates whether the spatial relationship in scene i can be described by term j .

The graphical model in Figure 1a can capture at least three kinds of inferences. If asked to decide whether term j applies to scene i , a native speaker can use scene vector s_i and term vector t_j to decide whether $d_{ij} = 1$. When interpreting a description of an unobserved scene i , a native speaker can use term vector t_j along with the information that $d_{ij} = 1$ to predict the scene vector s_i . When learning the meanings of spatial terms, a learner given P , S , and D can infer the term vectors in T . We will address this third problem and the nodes for P , S , and D are shaded in Figure 1a to indicate that these variables are observed for all cases we consider.

We report results for two cross-linguistic data sets. The first is based on a triple (P_1, S_1, D_1) that combines data reported by Levinson and Meira (2003) with new data that we have collected. Our second data set is based on a triple (P_2, S_2, D_2) that is taken from the work of Feist (2000). The next sections describe these triples, and we then describe how we used these triples to explore the meanings of spatial terms.

Spatial primitives. The first set of primitives (P_1) is shown in Table 2, and includes 19 primitives that capture position along the vertical axis, position with respect to the observer, and various notions related to contact and inclusion. These primitives were collected from several previous authors, and the set is intended to capture most of the concepts that have previously been proposed as candidate primitives. The second set of primitives (P_2) is based on a set proposed by Feist (2000), and includes primitives like “above,” “contact,” and “support.” The complete set of primitives is shown at the top left of Figure 2b.

Scenes and scene vectors. The scenes we consider are taken from the *Topological Relations Picture Series* designed by Melissa Bowerman. This picture set is composed of 71 different line drawings of a wide range of spatial scenes. Each scene in the picture set represents a spatial relationship between a designated *figure* (indicated by an arrow in the drawing) and a *ground* object. Figure 1 shows a few examples of these drawings. Scene matrix S_1 includes all 71 pictures. We asked three English speakers to code these pictures using the

19 primitives in Table 2. Each primitive was described using a short phrase, and summaries of these descriptions are shown in Table 2. Matrix S_1 was created by merging the three sets of responses using a majority vote, and a subset of this matrix appears in Figure 2a. Scene matrix S_2 includes information for 27 scenes from the picture series. Feist coded each scene in terms of the primitives in her set, and matrix S_2 is based on her codes. A subset of S_2 is shown in Figure 2b.

Scene-term mappings. Matrix D_1 includes results for all 71 scenes. Levinson and Meira (2003) reported data for 4 languages, and we built on this data set by asking one speaker for each of 21 additional languages to label the set of 71 scenes. The languages included are listed in Table 2. Participants were asked to provide a single spatial term for each picture and were allowed to use as many different terms as they liked across the set of 71 scenes. In cases where they were not sure, we asked them to choose the term that seemed best to them. Feist (2000) asked speakers of 16 languages to label the scenes represented in S_2 , and the results are collected in data matrix D_2 .

Modeling the meaning of spatial terms

The information in a triple (P, S, D) can be used to explore the semantics of spatial terms. We consider a family of five models that make different assumptions about the spatial term representations T and the way in which scene representations (S) and term representations (T) combine to generate the term-scene mappings (D). All of the models assume that spatial term j is represented as a term vector t_j , but the models vary along three dimensions which determine the nature of the entries in each vector.

One of these dimensions—binary (B) or weighted (W)—indicates whether primitives can be differentially weighted. Binary models use term vectors t_j where 0 indicates that a primitive makes no contribution to the meaning of t_j , and 1 indicates that a primitive must be present in order for term j to apply. Weighted models use vectors where each entry is a real number between -1 and 1 inclusive. Weights near 1 indicate that a primitive should be present in order for a term to apply, and weights near -1 indicate that a primitive should be absent. A second dimension—singleton (S) or combination (C)—indicates whether terms correspond to single primitives or combinations of primitives. Singleton models assume that each term vector has exactly one non-zero entry, but combination models allow term vectors to have multiple non-zero entries. The final dimension—positive (+) or negative (-)—indicates whether spatial terms can be defined using negations of primitives. For binary models with negation, we expand the set of primitives so that it includes negated versions of each primitive in Table 2. For weighted models with negation, we keep the original set of primitives and capture negation by allowing term vectors to include negative weights. The three dimensions just introduced generate 8 models in total, and we will focus on the five models in Table 1.

Although some of our models allow term vectors t_j to contain real-valued entries, scene vectors s_i are always repre-

sented as binary vectors which specify which primitives apply (1) or do not apply (0) to each scene. Given a scene vector s_i and a term vector t_j , all of our binary models determine whether spatial term j applies to scene i as follows:

$$d_{ij} = \begin{cases} 1, & \text{if } s_i^T t_j = |t_j| \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where $|t_j|$ is the number of non-zero entries in term vector t_j . Equation 1 states that term i applies to scene j (i.e. $d_{ij} = 1$) only if all of the constraints specified by term vector t_j are consistent with the scene. Weighted models use a soft version of Equation 1:

$$d_{ij} = \begin{cases} 1, & \text{if } \sigma(s_i^T t_j) > p \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

where $\sigma(\cdot)$ is a sigmoid function (e.g. $\sigma(x) = \frac{1}{1+\exp(-x)}$) which maps its argument into a probability (i.e. a number between 0 and 1). The parameter p is a threshold that will be learned from the data sets that we consider.

The models in Table 1 make contact with previous ideas from several fields. The singleton model is based on an idea proposed by Piaget and Inhelder (1956) who claims that there exists a common topology in which spatial languages build on concepts such as proximity and contiguity. Jackendoff (1983) further suggests that spatial semantics are composed of simple primitives such as “on” and “in”, which are directly encoded in languages. We expect, however, that the singleton model is unlikely to prove adequate. Levinson and others (Levinson & Meira, 2003; Levinson & David, 2006) have argued that there is great variation in spatial concepts across cultures, and the singleton model cannot account for this variation without an explosion in the number of primitives.

The combination models are also related to previous work. The discrete combination model captures the familiar proposal that meanings can be represented as conjunctions of primitive concepts, and psychologists have also proposed that spatial terms are represented as sets of weighted attributes (Feist, 2000). The weighted model in Equation 2 is known to statisticians as a logistic regression model, and is equivalent to a single-layer neural network, where the input (s_i) is mapped to the output (d_{ij}) via a layer of weights (t_j) and the sigmoid function.

Inferring term vectors

Our goals can now be precisely formulated. Given a triple (P, S, D) and one of the five models in Table 1, we wish to infer a term matrix T and decide how well S and T account for the data D . For both the singleton and conjunction models, we use a greedy algorithm to infer the term matrix T . For each spatial term we begin with a term vector t_j that includes only zeros, then greedily flip elements to improve a standard precision-recall F-score

$$F = \frac{2 \times \sum_i I(\hat{d}_{ij} = d_{ij} = 1)}{\sum_i I(\hat{d}_{ij} = 1) + \sum_i I(d_{ij} = 1)} \quad (3)$$

Table 2: Lists of author-collected languages (alphabetical), spatial primitives and their descriptions. “*” indicates negatable primitives. “F” and “G” stand for figure and ground.

Language	Primitive	Description
Arabic	above	F higher than G
Bengali	below	F lower than G
Cantonese	vertical equality*	F and G of equal height
Croatian	support*	F supported by G
English	horizontal support*	F supported horizontally by G

Vietnamese		

where \hat{d}_{ij} is a prediction based on the term vector t_j and d_{ij} indicates whether term j actually applies to scene i . The F-score will be high if most of the $\hat{d}_{ij} = 1$ entries predicted by t_j are correct (high precision), and if these predicted 1-entries include most of the actual 1-entries for term j (high recall).

For the weighted combination model, instead of inferring binary vectors we must learn a vector of weights for each term. Choosing the weights to maximize the F-Score is possible in principle (Jansche, 2005), but instead we fit a standard L1 regression model which is equivalent to a Bayesian logistic regression (Genkin, Lewis, & Madigan, 2004) with a Laplacian prior on the weights. For each spatial term, this approach searches for a weight vector t_j such that Equation 2 accurately predicts which scenes can be described by term j . The Laplacian prior captures the idea that term vectors t_j should be as simple as possible, and encourages small entries in t_j to end up as zero weights. In addition to this prior, we use the number of non-zero entries inferred by the conjunction model as an upper bound on the number of non-zero weights for the weighted model. Allowing many of the entries to be non-zero gives the weighted model more flexibility, but enforcing a sparsity constraint enables a direct comparison between the conjunction and weighted combination models. After learning the weights in all of term vectors t_j , we finish by choosing threshold p in Equation 2 to maximize the F-score (Equation 3).

Results

We applied the five models just described to the two triples (P, S, D) mentioned previously. In each case we computed the term matrix T that best accounts for the data. Term vectors for some languages are shown in Figure 2, and are discussed towards the end of this section.

The extent to which each model captures each data set can be captured using the F-score in Equation 3. Scores for the five models are shown in Table 1. To assess whether these scores are better than chance-level performance, we compared them with baseline scores achieved on random data sets. We used three randomization strategies. A *randomized D* set is created by randomizing all entries in D so that the sparsity is preserved (i.e. the number of “1” entries remains the same but all other structure is lost). A *shuffled D* set is created by randomly reordering the rows in D and leaving the scene vectors in S fixed. Finally, a *shuffled S* set is created by permuting the rows in S and leaving D fixed. Note that both shuffled sets leave the columns in D and S unchanged and therefore preserve many characteristics of these matrices, including the extent to which scenes (i.e. columns) tend to fall into clusters. For each triple, we created 20 random sets for each randomization strategy and computed the model scores. We then used t-tests to evaluate the hypothesis that performance on the real sets was significantly higher than performance on the random sets. In all cases we obtained highly significant results with truncated $p < 0.001$ after correction for multiple tests (first five rows of Table 2). These results suggest that all of our models were able to capture the structure in the observed data better than chance.

Although all models appear to capture some structure in the data, it is natural to ask which model performs best. The scores for the individual models do not address this question directly—for example, since the singleton model is a special case of the conjunction model, the conjunction model will always achieve a higher score regardless of whether it is actually the better approach. We therefore compared pairs of models by exploring whether the difference between their scores was significantly above chance level. For each pair, we compared the difference in prediction scores on the real data set against the differences achieved on the three random sets. The results appear in the final five rows of Table 2. Rows 6 and 7 suggest that the conjunction models perform better overall than the singleton models. Rows 8 and 9 suggest that allowing negated primitives leads to a significant improvement in performance. Finally, row 10 suggests that the weighted combination model does not perform better than the conjunction model with negations. Note, however, that we also evaluated an alternative weighted model where the sparsity of the weight vectors was not constrained by the conjunctive solution, and where all of the entries in each vector were allowed to be nonzero. This model performed significantly better than the conjunction with negation model on three of the six randomized tests across the two data sets, suggesting that weighted combinations may capture some aspects

Table 3: Significance of model performances and pairwise comparisons from t-tests. The model scores on the real data sets are compared to those on the random sets (1 – *randomized D*, 2 – *shuffled D*, 3 – *shuffled S*). D_1 is data from the authors and Levinson and Meira (2003). D_2 is collected by Feist (2000). For each pairwise comparison, the model on the left scores higher than the model on the right (e.g. BC+ outperforms BS+). “**” indicates statistical significance at $p < 0.05$.

of spatial semantics. Future work can explore this issue in more detail and determine which sparsity assumptions allow weighted models to provide the best account of spatial terms.

Our analyses so far suggest that the primitives in P_1 and P_2 are able to account for much of the structure in data sets D_1 and D_2 . It is important, however, to consider whether our models combine the primitives in psychologically meaningful ways. Figure 2 shows the definitions learned by our models for three languages, and focuses on a subset of 10 scenes that were used in both data sets. Figure 2a shows term vectors and predictions for our data set. Note that the conjunction model captures important aspects of meaning that the singleton model misses. For example, Figure 2a.ii shows that “contact” is included in the meaning of *on* by the conjunction but not the singleton model. The plots also illustrate how negations allow the conjunction model to improve its predictions. Figure 2a.xi shows that the conjunction model makes several predictions about “qian mian” that do not match the true scene-term mapping in Figure 2a.x. “Qian mian” corresponds roughly to the phrase “in front of,” and including “no contact” in the definition of this term allows the negated conjunction model to successfully predict that it will not apply to scenes like “handle on cupboard” or “stamp on letter.”

For our second analysis the term vectors T_1 (Figures 2b.iii and b.iv) can be compared against a gold standard, which is the set of term vectors manually assigned by Feist (Figure 2b.ii). The vectors learned by our model are similar to those specified by Feist, and the predictions that follow from Feist’s representation (Figure 2b.vi) do not appear more accurate overall than the predictions generated by our automatically learned term vectors (Figure 2b.vii).

Conclusion

We presented computational models that explore whether spatial concepts can be constructed by combining a set of universal primitives. Our results suggest that a large proportion of the information in two cross-linguistic data sets can be captured by models that begin with the primitives typically discussed in the literature and combine them using simple operations such as conjunctions and weighted sums. Our general framework (Figure 1a) can be used to address many questions in spatial cognition and we mention just two directions for future work. First, we fit our models to the cross-linguistic data by learning definitions for each spatial term, and future work can use our approach to explore how humans learn spatial concepts. Second, all our analyses used primitives that were specified *a priori*, but it is conceptually straightforward to develop models that learn the primitives that best account for a given data set. Uncovering the nature of spatial primitives presents many challenges, but computational approaches can help address some of these challenges.

Abstract

In 1969, Berlin and Kay proposed that there exist cross-cultural universals in the form of basic color terms. To test this hypothesis, the World Color Survey (WCS) collected color naming data from 110 non-industrial societies, identifying regularities in the structure of languages with different numbers of terms. This leaves us with the question of where these universals come from. We use a simple model of cultural evolution known as “iterated learning” to explore the hypothesis that universals emerge from human perceptual and learning biases. We conducted an experiment simulating the process of cultural transmission in the laboratory, and compared the results to the systems of color terms that appear in the WCS data. Our results show that cultural evolution results in convergence of systems of color terms towards a form consistent with the WCS, supporting the hypothesis that universals are the result of perceptual and learning biases.

Keywords: basic color terms; iterated learning model; color term universals; cultural evolution; Bayesian inference.

Introduction

Linguistic universals – properties that seem to hold across all human languages – have the potential to provide unique insight into the nature of human cognition. Universals in systems of color terms are among the best documented of these properties. Berlin and Kay (1969) proposed that color naming systems across different cultures are based on one or more of eleven focal colors corresponding to the English color terms *black, white, red, green, yellow, blue, brown, purple, pink, orange, and gray*. Kay and McDaniel (1978) and Kay and Maffi (1999) later refined this model to emphasize the six Hering primary colors (*black, white, red, green, yellow, and blue*) (Hering, 1964), and to characterize the process by which societies might transition from one system of color terms to another as new terms are introduced.

The World Color Survey (WCS) was initiated in the late 1970’s to provide a more comprehensive empirical test of the universality hypothesis (Kay, Berlin, & Merrifield, 1991; Kay, Berlin, Maffi, & Merrifield, 1997). In the WCS, a total of 330 color chips, comprised of 40 equally spaced Munsell hues at 8 levels of lightness and achromatic chips at 10 levels of lightness (see Figure 1), were presented to speakers of 110 different languages in non-industrial societies. Those speakers were asked to name each color chip, and also to point out the most representative chip for each color term. Later analysis of the WCS data showed that the universality hypothesis was by and large confirmed (Kay et al., 1997). Recently, several statistical analyses of the WCS data have also been conducted

in an attempt to resolve the debate over the universality of color naming. For example, Kay and Regier (2003; Regier, Kay, & Cook, 2005) showed that the focal colors in the WCS data largely fall in similar regions to those seen in English; in another study they defined a statistical measure of “well-formedness”, and used this measure to show that observed systems of color terms correspond to a near-optimal partition of color space (Regier, Kay, & Khetarpal, 2007).

The consistent cross-linguistic structure highlighted by the WCS raises a new question: Where do these universals come from? They may be a result of cultural universals that may arise from the homogeneity of biological traits and evolutionary paths across cultures that constrain people to consider only a limited range of color categories when learning language, thus forcing color term systems to conform to a limited range of universal types (Hawkins, 1988). However, if we view language as a system culturally transmitted from generation to generation, a simpler hypothesis is that these universals may arise directly from biases that cause learners to prefer some color categorizations over others, but that do not place absolute constraints on the types of color categories that are learnable. One way to explore this hypothesis is using the *iterated learning* model, a simple model of cultural transmission in which a sequence of agents each learns from the behavior of the previous agent in the sequence (Kirby, 2001). In an iterated learning model of the transmission of systems of color terms, each agent learns a system of color terms from examples provided by another agent, and then generates examples which are provided to the next agent in the sequence. Mathematical analyses of iterated learning show that as this process continues, the information being transmitted gradually changes to become consistent with the learning biases of the agents involved (Griffiths & Kalish, 2007; Kirby, Dowman, & Griffiths, 2007). If systems of color terms similar to those seen in the WCS emerge from a process of cultural

Figure 1: The World Color Survey stimulus array.

transmission by iterated learning, then the biases of individual learners may be sufficient to explain the regularities seen across human societies.

Previous work has used computer simulations to demonstrate that iterated learning with simulated agents can produce systems of color terms similar to those seen in the WCS (Dowman, 2007, 2009). In this paper, we test the hypothesis that color naming universals may be a result of the perceptual and learning biases of human learners by conducting a large-scale laboratory experiment based on iterated learning. In our experiment, human learners acquire and transmit novel systems of color terms, providing a human simulation of the process of cultural evolution. We examine how these systems of color terms change over time, comparing the results to the WCS. We show that, consistent with the hypothesis that perceptual and learning biases are the source of color-naming universals, the systems of color terms generated by our iterated learning chains converged over time to become more consistent with the WCS.

The plan of the paper is as follows. The next section provides further details of the iterated learning model and its predictions about the influence of learning biases on the outcome of cultural transmission. We then present our experiment, which used human learners to simulate the cultural transmission of systems of color terms. Analyzing the results of this experiment raises some technical challenges, which we address by introducing a novel method for quantifying the correspondence between the languages produced by our participants with those in the WCS. We conclude the paper by discussing the implications of our results, and consider some of the potential limitations of our analysis.

Iterated Learning

Much of human knowledge is not learned from the world directly, but from other people. When we learn languages, we learn them from the utterances of existing speakers, and our utterances inform the next generation of speakers. A simple way to model this process of cultural transmission is in terms of “iterated learning”, as illustrated in Figure 2. We imagine a sequence of learners, each of whom observes data, forms a hypothesis about the process that produced those data, and then generates data for the next learner based on that hypothesis.

We can analyze the process of iterated learning by assuming that our learners are rational Bayesian agents. In this framework, learners come up with the *posterior* probability $P(h|d)$ of a hypothesis h given the observed data d by applying Bayes’ rule,

$$P(h|d) = \frac{P(d|h)P(h)}{\sum_{h'} P(d|h')P(h')} \quad (1)$$

where $P(d|h)$ is the *likelihood*, indicating the probability of observing d if h were true, and $P(h)$ is the *prior* probability, indicating the extent to which the learner was willing to accept h prior to observing d . The prior encodes the learner’s

Figure 2: Iterated learning. (a) Each learner sees data produced by the previous generation, forms a hypothesis about the process by which those data were produced, and uses this hypothesis to produce the data that will be supplied to the next generation. (b) In iterated learning with Bayesian agents, each learner sees data d , and uses Bayes’ rule to compute the posterior probability of each hypothesis h , $p(h|d)$. The learner samples a hypothesis from this distribution, and then generates data from the distribution $p(d|h)$.

inductive biases, being a factor that combines with the observed data to yield a conclusion.

In the cultural transmission process, data are passed along a chain of learners. Assume that the same Bayesian inference process happens repeatedly at each generation, with each learner sampling a hypothesis from their posterior distribution and generating data by sampling from the likelihood function associated with that hypothesis. This process can be analyzed as a Markov process: The probability each learner selects a particular hypothesis depends only on the data produced by the previous generation. Griffiths and Kalish (2005, 2007) showed that when learners share a common prior distribution, the probability a learner selects a hypothesis converges to the prior probability of that hypothesis as the process of iterated learning continues. Likewise, the probability of generating data d converges to the prior predictive distribution, being the average of the likelihood over the prior, $p(d) = \sum_h p(d|h)p(h)$.

The convergence of iterated learning to the prior potentially provides an explanation of linguistic universals, including universals in color naming. Languages are constantly being passed from speaker to speaker via a process of cultural transmission similar to iterated learning. If this process provides a way for perceptual and learning biases of the kind captured by a prior distribution to have an effect on the structure of languages, we should expect languages to demonstrate properties that are consistent with human biases. If this hypothesis is correct, we should expect to see systems of color terms transmitted via a process of iterated learning to change over time to resemble those that appear in the WCS. To test this idea, we ran a series of iterated-learning chains among an English-speaking population in our laboratory, comparing the systems of color terms produced by those chains to those seen in the WCS.

Color Term Transmission in the Lab

Methods

Participants Participants were 390 members of the community at the University of California, Berkeley, receiving either course credit or approximately \$10/hr for taking part in the experiment.

Stimuli Each participant learned a system of color terms by being provided with examples of colors and the terms that were associated with them, and then generalized those terms to new colors. The color stimuli were presented on an Apple iMac computer by a Java program, and the monitor was calibrated using a ColorVision Spyder2 colorimeter/color calibrator on regular basis. A total of 330 colors were used as stimuli, corresponding to the computer screen analogues of the 330 Munsell color chips used in the WCS. Each term was a randomly-allocated pseudo word (from Rastle, Harrington, & Coltheart, 2002), and varied across participants.

Procedure We simulated a total of 30 iterated learning chains, each with 13 “generations” of learners. Each chain varied in the number of terms that were allowed in the “language” being transmitted, with two, three, four, five or six terms per language. The first learner in each chain received data generated from one of three types of initial partition of the WCS color space: hue, lightness, and random. The “hue” and “lightness” partitions were approximately equal vertical and horizontal partitions of the color space into the relevant number of categories; the “random” partitions were a truly random partition of the color space, generated uniquely for each chain. These three kinds of initial partitions were used as a means of checking the convergence of iterated learning: by starting the chains with very different systems of color terms, we could easily establish when the influence of the initial partition had disappeared. The following generations of learners all received data generated from the responses of the previous generation, as detailed below. We ran a total of 20 random chains, four for each number of terms, and five hue and five lightness chains, one for each number of terms.

Each participant was trained on the system of color terms by being shown a set of chips together with the corresponding terms. The total number of observed chips was six times the number of terms in the language. These chips were chosen at random from the 330 chips making up the full array, and then provided labels according to either the initial partition (for the first learner) or the responses of the previous learner (for subsequent learners). These training examples remained on the screen while the participant went on to label all 330 color chips from the WCS array. On every trial, they were presented a color chip and asked to select one of the terms to label the color chip. No feedback was given during this phase of the experiment. The responses of each participant thus produced a partition of the set of 330 chips, and this partition was used to generate the labels given to chips for the next learner in the chain.

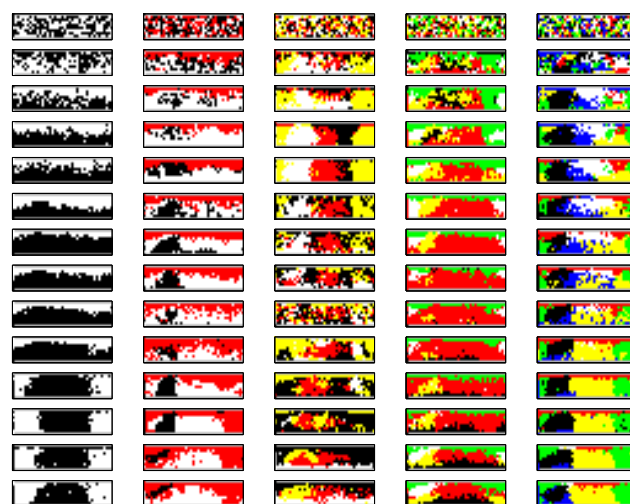

Figure 3: Representative examples of the data produced by simulating iterated learning of systems of color terms in the laboratory. Each panel shows one system of color terms, with arbitrary colors indicating the term assigned to each chip in the World Color Survey array. Each column is one chain with a particular number of terms, each row shows a different generation. The first row shows the random partitions used to initialize each chain.

Results

Figure 3 shows one set of chains initialized with random partitions, with the number of terms varying from two to six. Through this simple visualization of the data, we can see that each chain started from an unnatural color term system (a random partition), and that transmission along the chains resulted in a very rapid restructuring towards a more regular form. However, it is not clear how well these laboratory-generated data fit the WCS data. In the next section, we use a measure of the difference between each system of color terms and a randomly selected set of responses from the WCS data to test the convergence of the chains and to compare them to the kinds of systems seen across human languages.

Using Variation of Information to Analyze Color Term Systems

Analyzing the results of our experiment presents a challenge: how can we evaluate whether two systems of color terms are similar? Various methods have been proposed for solving this problem. For example, Kay and Regier (2003) converted the color chips from Munsell space to CIE $L^*a^*b^*$ space so they could compute the centroid for each color term. Centroid distances could then be used to compare clusterings. However, just using centroid measurements may discard important information about the variance of a cluster, and about the locations of boundaries. This method is also dependent on the psychological validity of the CIE $L^*a^*b^*$ representation of colors, which is disputable (Dowman, 2007).

Since our participants’ responses consisted of partitions of

the same set of colors as those used in the WCS, we used a technique that compares the Munsell arrays directly, without referring to another color space. This technique uses an information-theoretic measure known as *Variation of Information* (VI) to compare clusterings of a set of items (Meila, 2003). Given two clusterings C and C' , the VI is

$$VI(C, C') = H(C) + H(C') - 2I(C, C') \quad (2)$$

where $H(C)$ is the *entropy* of C ,

$$H(C) = - \sum_{k=1}^K P(k) \log P(k) \quad (3)$$

where k ranges over the cluster labels and $P(k)$ is the probability of an item being assigned to each cluster, and $I(C, C')$ is the *mutual information* between the two clusterings

$$I(C, C') = \sum_{k=1}^K \sum_{k'=1}^{K'} P(k, k') \log \frac{P(k, k')}{P(k)P'(k')} \quad (4)$$

where $P(k, k')$ is the probability an item belongs to cluster k in clustering C and to k' in clustering C' .

While VI was originally developed for comparing clusterings, a clustering is simply a partition of a set of items, just as our systems of color terms partition colors according to the terms applied to them. The VI value for two systems of color terms is thus calculated by comparing the distribution of the terms in the two systems, as well as the extent to which they agree with one another. A high VI value reflects a larger difference between two clusterings, whereas a small VI value indicates that the two clusterings are more similar. Our primary analytic tool was comparing the partitions produced by our participants with those observed in the WCS data. We did this by randomly selecting one speaker from each of the 110 languages in the WCS data set, and then calculating the VI of the partition produced by our participants with the 110 partitions from the WCS. Finally, we average across all of the languages from the WCS, to give us a single measure of consistency.¹

Testing Convergence

The theoretical analyses of iterated learning outlined above predict that, no matter what language begins a chain, it will eventually converge to a distribution over languages reflecting the prior. We could evaluate this prediction by comparing the chains generated with different initial partitions. A necessary characteristic for convergence is that the VI to the WCS data should not differ between chains, since they should all

¹While it would be desirable to also average over speakers, this was too computationally intensive to be practical in our current analyses. We observed little variation in average VI across sampled sets of speakers. We chose to use a single speaker rather than a composite formed by aggregating across speakers within a language (a “mode map”) on the grounds that this might not produce a system typical of the language of any individual, especially as different speakers of the same language sometimes use different numbers of color words (Kay & Maffi, 1999).

have reached the same distribution over languages. Figure 4 shows the VI values for the three types of initialization in each language system, showing individual chains with two to six terms for the hue and lightness initialization and the average over all chains for the random initialization.

To test for a difference in VI values across chains, we ran a two-way ANOVA at each generation with initialization and number of terms as the two factors. The main effect of number of terms are significant for all generations ($p < 0.05$); while only the initial systems ($F(2, 23) = 196.78, p < 0.0001$) and the first generation ($F(2, 23) = 11.19, p < 0.001$) showed a statistically significant effect of initial partition. These results are consistent with a relatively rapid convergence towards a common distribution. Rapid convergence is to be expected in this experiment, since only a very small proportion of the color chips were labeled in each generation, providing a good opportunity for other factors (such as the learning and perceptual biases of the participants) to influence the resulting systems of color terms. This can be seen in Figure 3, where the initial partitions quickly give way to more systematic responses.

Comparison to the WCS

As described above, to compare our experimental results with the WCS data, VI values were calculated between the responses of each participant and 110 randomly selected WCS systems. Figure 5 shows the VI values for all 20 random chains. A paired t-test on the VI values for the initial and final systems in those random chains showed a statistically significant difference ($t(19) = 11.44, p < 0.0001$), indicating a significant reduction of VI along iterated learning chains, resulting a better fit to the WCS data.

The remaining question is how close our data are to the WCS data: What counts as a low VI score? To address this question, we randomly selected another set of systems from the WCS data, one from each of the 110 languages. Using the same method as used above, we computed the VI between the two sets of WCS data. The average pairwise VI is shown in Figure 5. This average lies close to the mean VI seen in our random chains once they converge. We tested the difference between the VI scores produced by the final participants in each of our random chains and the VI scores for speakers sampled from the WCS using a two-samples t-test. The result was not significant ($t(128) = -0.29, p = 0.78$). These results suggest that the systems of color terms generated from our lab are indeed consistent with the data collected from the WCS.

Rotation Analysis

One potential objection to the conclusion that our chains are moving closer to the WCS could be that the reduction in VI may merely be a result of increasing regularity in the responses. As the systems of color terms in the random chains move towards more regular forms, the VI scores will go down naturally, regardless of whether the actual partition of terms reflects the structure of the WCS or not. To further test the consistency between our experiment results and the WCS

Figure 4: Variation of Information (VI) fit to WCS data for iterated-learning chains with three types of initial partitions and two to six color terms. Results for random initial partitions are averaged over four chains each.

Figure 5: Variation of Information (VI) fit to WCS data for random chains. The dashed line shows the VI for comparing the WCS to itself.

Figure 6: Variation of Information (VI) fit to WCS data for rotations of the final partitions produced by chains initialized with random partitions.

data, we compared the degree of match of each system to the WCS data when it was rotated in the hue dimension by varying amounts. We would expect that the more a partition was rotated out of position, the lower the resulting degree of match would be. This procedure was used by Regier et al. (2007) in connection with their measure of how “optimal” a set of color terms was as a division of the color space into maximally perceptually distinct regions.

Figure 6 shows the mean VI values of the partitions generated by the final participants in our random chains, when rotated from 0 to 20 steps in the hue dimension. Paired t-tests on VI values for no-rotation vs. maximum-rotation ($t(19) = -6.12, p < 0.01$), no-rotation vs. quarter-rotation ($t(19) = -3.66, p < 0.001$), and no-rotation vs. three-quarter-

rotation ($t(19) = -4.61, p < 0.001$) all showed statistically significant differences, indicating that the data from the experiment fits the WCS data significantly better than the rotated systems. This analysis thus confirmed that the iterated learning chains did converge to forms closer to the WCS.

Discussion

We tested the idea that human color-naming universals may be a result of shared learning and perceptual biases, demonstrating that systems of color terms similar to those seen in a variety of non-industrial societies emerge purely as a result of cultural transmission. Using Variation of Information as a measure of the difference between systems of color

terms generated in our experiment and the WCS data, we showed that the VI for systems generated by iterated learning rapidly decreases as the systems moves from unnatural random partitions to more regular forms. Our rotation analysis also showed that this reduction of VI can not be explained as simply a result of the emergence of more regularity, but reflects the adoption of a form consistent with the WCS data.

One objection that could be made with respect to our study is that our English-speaking subjects could have been imposing a system of colour naming reflecting that of English on the languages in our experiments, rather than using pre-linguistic universal biases. As English has 11 basic color terms, many more than the 2 to 6 terms in our experiments, none of the emergent languages could reflect English very closely, which we could expect would minimize the potential for our participants knowledge of language to shape the colour categories formed in the experiment. We take the finding that systems of color terms similar to those seen in the WCS can be produced by cultural transmission by English speakers as supporting our argument that human learning and perceptual biases may be sufficient to explain universals, under the assumption that the English-speaking participants in our experiments share the same learning and perceptual biases as the members of non-industrial societies surveyed by the WCS. This result is less surprising when we take into account previous findings relating the color term categories produced by English speakers with cross-linguistic trends. For example, Boster (1986) found that when English speakers were asked to recursively split a set of color chips into subsets, the partitions they produced corresponded to those seen in other languages with a corresponding number of terms.

Our experiment and subsequent analyses not only demonstrate that iterated learning may provide a valuable experimental method for investigating human inductive biases, but also show that languages formed in the laboratory by English speaking participants seem to converge toward a form consistent with the WCS. These results suggest that the color-naming universals may come from the learning and perceptual biases of human learners, brought out through the process of cultural transmission. In particular, our results supplement previous computational modeling results demonstrating that such properties could be produced by iterated learning with simulated agents. We anticipate that similar pairings of laboratory experiments and computer simulations will be effective in further elucidating how languages and concepts change through cultural transmission.

Abstract

Many theories hold that semantic variation in the world's languages can be explained in terms of a universal conceptual space that is partitioned differently by different languages. Recent work has supported this view in the semantic domain of containers (Malt et al., 1999), and assumed it in the domain of spatial relations (Khetarpal et al., 2009), based in both cases on similarity judgments derived from pile-sorting of stimuli. Here, we reanalyze data from these two studies and find a more complex picture than these earlier studies suggested. In both cases we find that sorting is similar across speakers of different languages (in line with the earlier studies), but nonetheless reflects the sorter's native language (in contrast with the earlier studies). We conclude that there are cross-culturally shared conceptual tendencies that can be revealed by pile-sorting, but that these tendencies may be modulated to some extent by language. We discuss the implications of these findings for accounts of semantic variation.

Keywords: Language and thought; semantic universals; linguistic relativity.

A universal basis for semantic variation?

The semantic systems of the world's languages vary considerably. This observation has suggested two opposed accounts of the relation between language and thought. The Sapir-Whorf hypothesis holds that such cross-language differences cause corresponding differences in cognition, leading speakers of different languages to think about and perceive the world substantially differently (Lucy, 1992; Majid et al., 2004; Roberson et al., 2000). In contrast, many other theories accommodate such variation by positing a universal conceptual space that is partitioned in different ways by different languages (Berlin & Kay, 1969; Croft, 2003:139; Levinson & Meira, 2003; Majid et al., 2008; Malt et al., 1999; Regier et al., 2007). On this view, the significant point about the variation is that many logically possible semantic configurations are never attested – thus, the constrained variation illuminates underlying commonalities in human cognition.

Although the starting point for this debate is linguistic – namely the observation of semantic diversity across languages – a natural means of testing it is by probing non-linguistic cognition. The Whorfian view predicts that speakers of languages with different semantic systems should conceive of the world differently, each group in line with their own language's semantic system. The universal-space view in contrast predicts that speakers of different languages should conceive of the world similarly.

One source of support for the universal-space view comes from *pile-sorting*. In the first large-scale quantitative study of its kind, Malt et al. (1999) asked speakers of English, Chinese, and Spanish to name a set of household containers – e.g. a jar, a juice-box, an ice-cream carton, etc. – and to pile-sort pictures of these items on the basis of their overall similarity. They found that while naming patterns differed substantially across languages, sorting patterns did not.

The same view is indirectly supported by recent studies that explain differing patterns of semantic structure in the world's languages as optimal or near-optimal partitions of an underlying and presumably universal similarity space. Regier et al. (2007) demonstrated that color naming in the world's languages is consistent with this idea, assuming a standard perceptual color space, CIELAB. This account explains universal tendencies in color naming while also accommodating some deviation from those tendencies, as is observed empirically. Khetarpal et al. (2009) showed that the same idea can account for semantic variation in the spatial domain. In the spatial case, however, no standard independent assessment of a universal similarity space exists. Therefore, inspired by the Malt et al. (1999) results, Khetarpal et al. (2009) based their analysis on similarities derived from pile-sorting of spatial scenes by speakers of Dutch and English. Critically, while they assumed that these similarities would be universal or near-universal, and while their results were consistent with that assumption, they did not directly test the assumption. We test it here.

To preview our results, we find that pile-sorting of spatial stimuli, according to the data of Khetarpal et al. (2009), is broadly similar across languages – but does nonetheless

differ as a function of language. These results were obtained using an analysis different from that of Malt et al. (1999) – thus the question arises whether Malt et al.’s (1999) container data would yield similarly mixed results under our analysis. We show that they do. We conclude that on one analysis at least, pile-sorting reveals not just shared cross-language tendencies, but also apparent influence of the sorter’s native language, suggesting an interesting combination of the universalist and Whorfian positions (Regier & Kay, 2009).

Spatial language and cognition

Khetarpal et al. (2009) demonstrated a commonality underlying the diversity of spatial naming in the world’s languages. They based their study on a set of 71 spatial scenes that were originally designed by Melissa Bowerman and Eric Pederson. Figure 1 shows a sample of 10 of these scenes, as categorized in 2 languages.

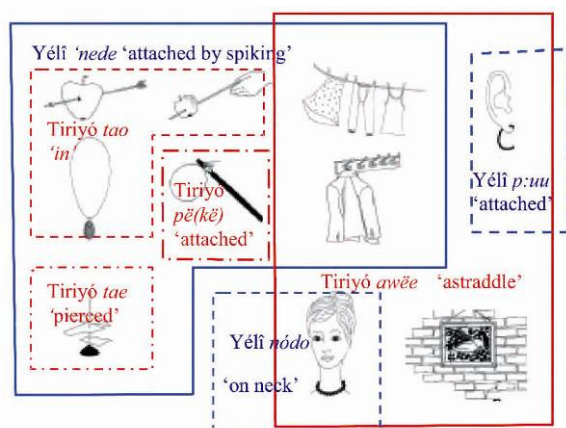

Figure 1: 10 spatial scenes, as categorized in 2 languages: Tiriyo and Yéli-Dnye. Source: Levinson & Meira (2003).

Khetarpal et al. (2009) had native speakers of Dutch and native speakers of American English sort pictures of these 71 spatial scenes into piles on the basis of the similarity of the spatial relation portrayed. Afterwards, they also elicited names for these spatial relations from each sorter in his or her native language. They then derived similarity judgments from sorting behavior: the similarity between any two scenes x and y was taken to be the proportion of all participants (American and Dutch pooled together) who sorted x and y into the same pile. Finally, they assessed the spatial semantic systems of 9 unrelated languages (one language was Dutch but the rest were unrelated to Dutch and English; Levinson & Meira, 2003) relative to these similarities. They found that these 9 attested spatial semantic systems maximized similarity within categories, and minimized it across categories (Garner, 1974), more than did a reasonable set of competitor systems of comparable complexity; in this sense these attested spatial semantic systems are *near-optimal*. This finding is consistent with the assumption that the sorting-derived

similarities are universal – since they help to explain the spatial semantic systems of unrelated languages. But is this assumption in fact correct – or do these similarities reflect the sorters’ native language? A natural means of testing this question is to compare the sorts produced by speakers of English and Dutch to the naming systems of the same two languages.¹ The Whorfian prediction is that speakers of each language should sort in a manner that reflects their native language, more than the other language. The universalist prediction is that speakers of the two languages should sort identically.

Methods

Naming data. For both English and Dutch, separately, we recorded the modal spatial term for each of the 71 spatial scenes — i.e. the spatial term that was used by the largest number of speakers of the language to name that scene. Ties were broken by random choice. The resulting labeling of the 71 scenes was taken to be that language’s spatial naming system.

Sorting data. We analyzed the English and Dutch sorting data in 3 ways. First, we measured the *correlation* of sorting behavior across languages. Second, we measured how well sorts matched the semantic systems of English and Dutch, using *edit distance*. Third, we examined the *height*, or coarse-grainedness, of the sorts and of the English and Dutch semantic systems, since this quantity is helpful in interpreting other analyses, as will be seen below. Here, we describe each analysis in turn.

Correlation analysis. Following Malt et al. (1999), we compared sorts produced by English and Dutch speakers as follows. For each of Dutch and English, for each pair of scenes, we counted the number of times those two scenes were placed in the same pile by speakers of that language. This yielded, for each of the two languages, a vector of $(71 \times 70) / 2 = 2485$ co-sorting counts. We determined the correlation of the Dutch vector with the English vector.

Edit-distance analysis. We took a pile-sort of the 71 scenes to be a *partition* of those stimuli into groups; we similarly took a language’s names applied to those scenes to be a partition of the same set of stimuli into groups. We quantified the dissimilarity between two such partitions by measuring the *edit distance* between them. The edit distance between two partitions A and B is the minimum number of operations required to change A into B, where each operation involves moving a single item from one group to another (possibly empty) group. We computed edit distances via the Hungarian algorithm for bipartite graph

¹ We collected new English data analogous to that of Khetarpal et al. (2009), since their English naming data were incomplete. We report here the comparison of Khetarpal et al.’s (2009) complete Dutch data with our complete English data. Comparison of Khetarpal et al.’s (2009) Dutch and English data yield qualitatively the same results as those we report here.

matching (Deibel et al., 2005).² For each pile sort produced by a speaker of either Dutch or English, we determined its edit distance to the partition defined by the Dutch language, and its edit distance to the partition defined by the English language.

Height analysis. The *height* of a partition is a measure of how coarse-grained it is: greater height indicates coarser grain, while lower height indicates finer grain. Height is defined as the sum, over all groups in a partition, of the number of pairs of items in each group (Coxon, 1999):

$$\text{height} = \sum_i \binom{g_i}{2} = \sum_i g_i(g_i - 1)/2$$

where g_i is the number of items in group i . We measured the height of the partitions corresponding to the English and Dutch naming systems, and the height of each pile-sort.

Results and discussion

Correlation. The correlation of the Dutch and English co-sorting vectors was 0.87. This correlation is fairly high, and is greater than the agreement between halves of the same group (Dutch or English): the mean within-group split-half reliability was 0.80. This result suggests that speakers of the two languages sorted quite similarly.

Edit distance. Edit distance gives us a means of measuring the dissimilarity between pile-sorts and naming systems. Figure 2 shows the average edit distance of sorts produced by Dutch speakers and those produced by English speakers, to the Dutch and English naming systems.

Figure 2: Edit distance of sorts, produced by Dutch and English speakers, to the Dutch and English naming systems.

We analyzed these data as follows. For each sorter from each of the two languages, we created a difference score: the edit distance of that person's pile sort to the English naming

system minus the edit distance of that person's pile sort to the Dutch naming system. The difference scores for both groups were significantly greater than 0 (Dutch: $M=4.5$, $t(23) = 4.83$, $p < .0002$; English: $M=1.92$, $t(23) = 3.81$, $p < .002$), indicating that speakers of both languages sorted more in line with Dutch than with English. The Dutch mean difference score was greater than the English one ($t(46) = 2.44$, $p < 0.05$; all p values Bonferroni-corrected), indicating that Dutch speakers showed this preference for Dutch over English more strongly than English speakers did. Thus there appears to be both a cross-language tendency to sort more in line with Dutch than with English (a universalist finding), and a tendency to sort in line with one's native language (a Whorfian finding); these two forces pull in the same direction for Dutch speakers, but in opposite directions for English speakers.

What is it about the Dutch naming system such that speakers of both languages sort more in line with it than with English? It may be relevant that Dutch appears to be semantically *finer-grained* than English in this domain. For example, the English spatial term *on* covers a broad range of spatial meanings, including a cup on a table, and a picture on a wall – whereas these two spatial configurations are named differently in Dutch (as *op* vs. *aan*, respectively). Thus a possible explanation for the privileged status of Dutch in our results above is that people may tend to sort in a manner that is finer-grained than either language, and therefore more like the finer-grained language – in this case Dutch.

Figure 3 shows that this is the case. The height quantity measures the coarseness of a partition; thus, comparison of the two vertical lines shows that Dutch naming is indeed finer-grained than English naming with respect to these spatial scenes. Moreover, the bulk of sorts produced by speakers of both languages is finer-grained than the finer-grained language, Dutch.

Figure 3: The height (coarse-grainedness) of the Dutch and English naming systems, and sorts produced by speakers of these two languages.

Thus, it seems likely that Dutch emerges as privileged in our edit-distance results at least in part because it is finer-grained than English in this domain. But are these results attributable to fine grain *per se*, or to the particular fine-grained partition that Dutch represents? To test this, we

² See <http://psych.uchicago.edu/~khetarpal/code/edit-distance> for our code, which extends an implementation written by Gary Baker and released under GPLv3.

also compared the pile-sorts to Dutch-like partitions which are as fine-grained as Dutch but group the items differently. The set of Dutch-like partitions was sampled repeatedly ($n=3.5 \times 10^6$) by randomly grouping items such that the total number of groups equaled the number of Dutch spatial terms and the sizes of these groups matched the number of items associated with the Dutch spatial terms. We then measured the average edit distance from English speakers' sorts to each of these sampled hypothetical Dutch-like partitions ($Min=46.79$, $Mean=52.09$, $Max=55.13$), and the average edit distance from Dutch speakers' sorts to each of these sampled hypothetical Dutch-like partitions ($Min=46.04$, $Mean=51.48$, $Max=54.29$). In both cases the average edit distance of the sorts to actual Dutch (shown in Figure 2) was less than to any of the sampled hypothetical Dutch-like partitions of equally fine grain.³ This finding suggests that the privileged status of Dutch in our edit-distance results is a function not just of its fine grain, but also of the similarity relations it captures.

Taken together, these reanalyses of the Khetarpal et al. (2009) spatial data suggest that spatial similarity judgments as gauged by pile-sorting are quite similar and fine-grained across languages – a universalist finding – but that they nonetheless vary in line with the sorter's native language – a Whorfian finding.

Container names and cognition

Our present analysis of the Khetarpal et al. (2009) spatial data revealed a mixed picture, in contrast with the purely universalist results of Malt et al. (1999) on containers. But our result was obtained through an edit-distance analysis that Malt et al. (1999) did not use. This raises the question whether the Malt et al. (1999) data would also exhibit an effect of language if analyzed using edit distance. We sought to test this question.

Malt et al. (1999) based their study on 60 pictures of simple containers, such as cartons, boxes, bottles, and the like. They asked speakers of 3 different languages – American English, Mandarin Chinese, and Argentinean Spanish – to name the containers shown in these pictures and to sort them into piles, on several different bases. Here, we re-examine their data from English and Chinese, for which data were readily retrievable, and we focus on pile-sorting based on overall similarity of the containers, rather than functional or perceptual similarity, which Malt et al. (1999) also probed. Importantly, while the semantic categories for the various containers differed across languages, the overall sorts showed no effect of language in their analyses.

Methods

We analyzed Malt et al.'s (1999) container naming and sorting data from Chinese and English using the same methods we had applied to the spatial data of Khetarpal et

al. (2009). Specifically, we (1) identified each language's semantic partitioning of the space by determining the modal term applied to each stimulus in each language, and conducted (2) correlation, (3) edit-distance, and (4) height analyses of the sorting and naming data.

Results and discussion

Correlation. The correlation of the Chinese and English co-sorting vectors was 0.91, as Malt et al. (1999) had found. This correlation is quite high, and is comparable to the agreement between halves of the same group (Chinese or English): the mean within-group split-half reliability was 0.90. This result suggests that speakers of the two languages sorted quite similarly.

Edit distance. Figure 4 shows the average edit distance of sorts produced by Chinese speakers and those produced by English speakers, to the Chinese and English naming systems.

Figure 4: Edit distance of sorts, produced by Chinese and English speakers, to the Chinese and English naming systems.

We analyzed these data as before. For each sorter from each of the two languages, we created a difference score: the edit distance of that person's pile sort to the Chinese naming system minus the edit distance of that person's pile sort to the English naming system. The mean difference score for Chinese speakers was 0.0 ($SD = 5.99$), indicating that Chinese speakers sorted in a manner equally similar to the Chinese and English naming systems. In contrast, the mean difference score for English speakers was significantly greater than 0 ($M=3.43$; $t(55) = 6.17$, $p < .0002$), indicating that English speakers sorted in a manner more like the English than like the Chinese naming system. The English mean difference score was greater than the Chinese one ($t(36.6^4) = 2.64$; $p < .05$; all p values Bonferroni-corrected), indicating that English speakers sorted in line with English

³ The actual Dutch naming system is also by definition a Dutch-like partition.

⁴ Heteroscedasticity corrected using Welch's method.

more than Chinese to a greater extent than Chinese speakers did. As in the spatial case, a natural interpretation of these data is that there is a cross-language tendency to sort more in line with English than with Chinese, and also a tendency to sort in line with one's native language. For Chinese speakers these two forces cancel each other out, whereas for English speakers they reinforce each other.

Given our earlier discussion, a general tendency to sort more in line with English than with Chinese naming would make sense if English were more fine-grained than Chinese in this domain, and if people sorted more finely than either language. Figure 5 shows that this is the case.

Figure 5: The height (coarse-grainedness) of the Chinese and English naming systems, and sorts produced by speakers of these two languages.

Whereas English was coarser-grained than Dutch in the spatial domain, it is finer-grained than Chinese in the container domain. And the bulk of the sorts produced by speakers of both languages is finer-grained yet. This is consistent with the reasoning proposed above for the apparently privileged status of English in our edit-distance analysis of the container data. Still, as before, we wished to ascertain whether the results are attributable to fine grain *per se*, or to the particular fine-grained partition that English represents. To test this, we also compared the pile-sorts to English-like partitions of the container items which are as fine-grained as English but group the items differently – analogously with our creation of Dutch-like partitions of spatial relations, described above. The set of English-like partitions was sampled repeatedly ($n=3.5 \times 10^6$) by randomly grouping items such that the total number of groups equaled the number of English container terms and the sizes of these groups matched the number of items associated with the English container terms. We then measured the average edit distance from English speakers' sorts to each of these sampled hypothetical English-like partitions ($Min=41.54$, $Mean=45.67$, $Max=48.02$), and the average edit distance from Chinese speakers' sorts to each of these sampled hypothetical English-like partitions ($Min=44.23$, $Mean=48.01$, $Max=50.31$). In both cases the average edit distance of the sorts to actual English (shown in Figure 4) was less than to any of the sampled hypothetical English-like partitions of equally fine grain. This finding suggests that the privileged status of English in our edit-distance

results is a consequence not just of its fine-grainedness, but also of the specific groupings of referents that it represents.

Taken as a whole, these reanalyses of the Malt et al. (1999) container data present a picture similar to the one that emerged from our examination of the Khetarpal et al. (2009) spatial data. Similarity judgments as assessed by pile-sorting are fine-grained and quite similar across languages, but also reflect the sorter's native language to some extent. Thus, there is again evidence both for cross-language and for language-specific forces – and thus for both the universalist and Whorfian positions.

Conclusions

Different languages exhibit different systems of semantic categories. It is often assumed that this semantic variation is constrained by, and can be explained by, a universal conceptual space that is partitioned in different ways by different languages. Malt et al. (1999) found evidence consistent with such a language-invariant space, and Khetarpal et al. (2009) assumed such a space existed. In both cases conceptual similarity was assessed through pile-sorting.

We reanalyzed data from these two earlier studies, with a view to reassessing whether pile-sorting on the basis of similarity does or does not reflect language. In both cases we found the same overall picture: pile-sorting was very similar across speakers of different languages (in agreement with the findings and assumptions of the earlier studies), but it also tended to reflect the sorter's native language (in contrast with those studies). Moreover, pile-sorting tended to be semantically finer-grained than any of the languages we considered. These findings suggest several conclusions.

First, they suggest a particular view of the relation of language and thought, namely that: (a) there is a set of fine-grained and potentially cross-cutting conceptual distinctions that may be made, and some languages will happen to mark more of these distinctions than will other languages; (b) distinctions that are unmarked in a language are nonetheless conceptually available to speakers of that language – this is suggested by the fine-grained sorting; and (c) a distinction becomes more salient if it is marked linguistically in one's native language (Hespos & Spelke, 2004) – this is suggested by the effect of language we find. This interpretation is consistent with the general view that “Whorf was half right” and correspondingly half wrong, as has been argued elsewhere (Regier & Kay, 2009).

Second, our results are compatible with the possibility that language may influence cognition in relatively subtle ways that are detectable by some analyses and not by others. Edit distance applied to pile-sorting may be a useful analytical tool, when used in tandem with others, in pursuing this question more generally.

Finally, our results suggest that caution is needed when basing accounts of semantic variation on an ostensibly universal similarity space derived from pile-sorting (e.g. Khetarpal et al., 2009) – because universality cannot be assumed. Similarity judgments are likely to be similar but

not identical across languages, as was the case in our analyses. This highlights an unavoidable tension. A universal conceptual space is a useful theoretical construct for explaining semantic variation, but we have no guarantee that such a thing actually exists – nor, if it does, do we have a completely reliable means of assessing it. Instead, we have somewhat language-colored approximations to such a space, and these should be treated as such. A reasonable treatment may be to average together similarity judgments obtained from speakers of different languages in an attempt to better approximate a universal similarity space, as Khetarpal et al. (2009) did. But any interpretation of results based on such an approximation should be tempered by the awareness that it is merely an approximation.

At the same time, our results leave a number of questions open. The first concerns the contrast between our findings and those of Malt et al. (1999). They found that language was not reflected in sorting by overall similarity, and we found that it was, based on the same data. One possibility, as mentioned above, is that our edit distance analysis is more sensitive than some others, such that it picks up on differences that are missed by other analyses. Is this conclusion correct? Or is our analysis itself inappropriately biased in some respect? Which set of results should be believed? Answering this question is critical to placing our present findings in their proper context.

A second question raised by our findings is the extent to which they generalize to other languages. If we were to examine a new language that partitions semantic space more finely than the languages we have examined here, we would expect to find that pile-sorts produced by people of all backgrounds tend to align more closely with this new fine-grained language than they do with the more coarse-grained languages we have already examined. Is this the case? This question provides a straightforward means of further testing these ideas.

There is also the question of whether these results generalize to other semantic domains. While we have restricted ourselves to the two domains of spatial relations and containers, this was simply a matter of convenience, as the data were readily available. The reasoning behind these ideas however is general in scope, and we would expect to find supporting evidence in other semantic domains as well.

Finally, while these results demonstrate a correlation between language and sorting behavior, they do not demonstrate the causal link claimed by the Whorf hypothesis. It remains an open question whether the observed correlation is attributable to an effect of language on cognition, or to other factors, such as culture influencing both language and cognition.

Regardless of how these questions are eventually answered, we hope that our present initial findings help to make plausible the central idea we have promoted here: a fine-grained conceptual space, largely shared in structure across speakers of different languages, but nonetheless also reflecting the speaker's native language.

Adults' self-directed learning of an artificial lexicon: The dynamics of neighborhood reorganization

Abstract

Artificial lexicons have previously been used to examine the time course of the learning and recognition of spoken words, the role of segment type in word learning, and the integration of context during spoken word recognition. However, in all of these studies the experimenter determined the frequency and order of the words to be learned. Here we ask whether adult learners choose, either implicitly or explicitly, to listen to novel words in a particular order based on their acoustic similarity. We use a new paradigm for learning an artificial lexicon in which the learner, rather than the experimenter, determines the order and frequency of exposure to items. We analyze both the temporal clustering of subjects' sampling of lexical neighborhoods during training as well as their performance during repeated testing phases (accuracy and reaction time) to determine the time course of learning these neighborhoods. Subjects sampled the high and low density neighborhoods randomly in early learning, and then over-sampled the high density neighborhood until test performance on both neighborhoods reached asymptote. These results provide a new window on the time-course of learning an artificial lexicon and the role that learners' implicit preferences play in learning highly confusable words.

Keywords: spoken word recognition; phonological neighborhoods; word learning; artificial lexicon

Introduction

Since the pioneering work of Marslen-Wilson (1987) on the role of acoustic/phonetic similarity in on-line spoken word recognition, there has been debate over the structure of phonological neighborhoods in the mental lexicon. In the cohort model, lexical items were neighbors—and, thus, competitors—if and only if their sound-forms overlapped from the beginning of the word, such as in “pat” and “pack”. The Neighborhood Activation Model (Luce, Pisoni & Goldinger, 1991; Luce & Pisoni, 1998) quantified neighborhood similarity as a combination of factors: the frequency of the single item in question, neighborhood density (also describable as confusability), and overall neighborhood frequency. Neighbors as defined by NAM can include rhyme words (e.g., “pat” and “rat”) and words with other one-segment differences, such as “pat” and “past”.

A series of studies by Creel, Aslin, and Tanenhaus (2006) employing an artificial lexicon (Magnuson, Tanenhaus,

Aslin, & Dahan, 2003) further revealed another intricacy of neighborhood structure, specifically by asking whether all segment differences, regardless of type (i.e., consonant vs. vowel) have an equal influence on confusion of newly learned words. Two CVCV items with matching consonants are more often confused with each other than two CVCV items with matching vowels; in other words, segment type matters. Furthermore, the position of the consonants played a role: VCVC items with matched consonants did not elicit such confusions.

One outstanding question concerning neighborhoods is how they develop. After a pre-lexical infant learns its first word (e.g., “no” or its own name), how does acoustic/phonetic similarity affect the learning of new words? Do infants acquire words based solely on frequency of occurrence in the ambient linguistic environment, or do they systematically avoid attending to novel words that are similar in sound-structure with known words? Based on corpus analyses, Charles-Luce and Luce (1990, 1995) made just such a prediction, but others have provided conflicting evidence (Coady & Aslin, 2003; Dollaghan, 1994). More direct evidence comes from word-learning studies with toddlers. Swingley and Aslin (2007) taught young children new words that were either neighbors to words they already knew (e.g., “tog” vs. “dog”) or non-neighbors (e.g., “meb”). Neighbor items were more difficult than non-neighbors for the children to learn. However, conflicting evidence from toddlers exists (Newman, Samuelson & Gupta, 2008), suggesting that with more exposure they can learn a novel item from a high-density neighborhood as well as from a very low-density neighborhood.

This same question of neighborhood effects on word learning applies to adults, who are constantly acquiring new words in their lexicon (e.g., “locavore”, “staycation”). Perhaps more relevant to the growing adult lexicon is the case of learning words in a second language. Here there is both a neighborhood effect *within* the L2 lexicon and interference effects *between* the L1 and L2 lexicons. There is conflicting evidence of between-language neighborhood effects (Spivey & Marian 1999; Ju & Luce, 2004) in spoken word recognition, but virtually no evidence for such effects in word *learning*. One reason for this limited evidence is that studies of L1 and L2 lexicons are extremely difficult to control, and L2 often provides the learner with phonetic and

phonological cues that clearly mark the lexical item as a member of only one language.

Another approach to the study of neighborhood effects in word learning is to create new words that are designed to compete with known words. Gaskell & Dumay (2003) present evidence of competition development in English-speaking adults who learn a non-English word that competes with an English word that lacks neighbors. For example, “cathedral” has no English neighbors, but listeners were exposed to the meaningless word-form “cathedruke” over the course of an experiment. The novel item immediately leads to facilitatory effects on the English item. However, after sleeping, subjects’ behavior reflected lexical competition between the two forms. These results suggest that new words compete with old words during spoken word recognition, but they do not bear directly on the time-course of *learning* new words. Importantly, Magnuson et al. (2003), using an artificial lexicon, found no significant evidence that the native language (English) interfered with the processing of neighbors from the artificial lexicon, at least not after only 2 hours of training. Thus, in the early phase of training, even with 90% or better accuracy in learning the names for novel objects, adults do not seem to show between-language neighborhood interference.

Here we describe a study of adult learners using an artificial lexicon. The rationale for using an artificial lexicon, as in Magnuson et al. (2003) and Creel et al. (2006), is that we can carefully control all the parameters of the lexicon (density, frequency, phoneme inventory, meaning) that are very difficult to balance using natural language materials. Our key innovation is creating a learning paradigm in which adults choose how they listen to the entire set of novel words. They must map 16 novel word-forms onto 16 novel visual shapes. Across a series of learning blocks, subjects sample the sound-object pairs by selecting a shape on a touch screen and hearing that shape’s name. A testing phase after each training block assesses the accuracy and speed of word recognition using the same touch screen. By varying the neighborhood structure within the set of 16 words, we can determine whether adult learners choose to sample from high or low density neighborhoods during the process of learning novel word-object mappings.

Overview of Design

The learning environment was simplified by presenting each subject with an array of 16 novel shapes on a touch screen display. We selected a touch-screen monitor rather than a computer mouse because it lends itself to ease of use for children or other special populations who have limited mouse experience. Subjects are instructed that they should learn the names of the shapes by touching them and hearing that shape’s name. They are told that they can touch shapes in any order and that they have 64 touches per block. After each block, they will be tested for their knowledge of shape names by hearing a name and completing a 16-AFC task. This alternation of training blocks and testing blocks allows us to describe any changes in how subjects allocate their

exploration of the lexicon and its relation to how well subjects have learned the lexicon.

Method

Participants

A total of 41 subjects from the University of Rochester participated in the study and consented per the guidelines of the University of Rochester human subjects review board. Each subject received \$10 for one session of approximately 45 minutes. They were told that they would be listening to words and selecting pictures on a touch screen, to learn the names of the pictures, and subsequently tested on what they have learned. All subjects reported normal hearing, normal or corrected-to-normal vision, and were native speakers of English.

Stimulus Materials

The lexicon was created to vary in neighborhood density and type of acoustic/phonetic similarity. It consisted of 16 items in total: a high-density cohort neighborhood (baga, bagi, bago, bagu), a high-density rhyme neighborhood (dido, kido, pido, tido) and 8 low-density items (gobu, dupi, poti, toku, kuba, tupa, gota, puki). Items were recorded as WAV files by a graduate student with linguistics training. The speaker read each item at a natural rate, yielding an average word length of 745 milliseconds. Items were paired with 16 novel black and white images (Hunt & Aslin, 2009). Three different list conditions of random pairings of words and pictures were used, counterbalanced to avoid any item effects that may have arisen from particular word-image pairings. Subjects were randomly assigned to conditions.

Environment

The experiment was run on MathWorks Matlab and the Matlab Psychophysics toolbox (Brainard, 1997; Pelli, 1997) on a Dell Dimension desktop PC running Windows XP with an NEC touchscreen monitor. Images were randomly presented in a 4x4 grid on the screen., as seen in Figure 1. Subjects listened to words over Sennheiser HD 570 headphones set at a comfortable volume level. The study was conducted in a sound-attenuated booth.

Figure 1: An example screen

Task

Training and testing were alternated in a session, with 6 blocks of each, for a total of 12 blocks. Participants were told to select the items (i.e., touch a shape) in any order they desired to learn the words that named each of the 16 images on the screen. They were not told that they would be trained on the same 16 images and corresponding words in future blocks. Rather, they were told that each testing block would correspond to the preceding training block. During each training block, an on-screen counter marked off the number of remaining training trials the subject had, from 64 to 0, until a test block would begin. If the subject had evenly distributed their touches in a block, they would hear each word 4 times, which was deemed sufficient for a minimal level of familiarity but not full mastery after the initial block. The location of each image was randomized four times during training blocks: once at the beginning of the block, then once after each 16 trials. This precluded the possibility that subjects made associations between item location and name, rather than the desired effect of item image (shape) and name.

A test block consisted of two passes through the list of lexical items, for a total of 32 trials, in random order. Subjects pressed a GO button image on the screen to start a test trial, then heard a word corresponding to one of the 16 images on the screen. They were free to select any of the items present on the screen, in a 16-AFC task. Instructions specified that they should respond as quickly and accurately as possible. If they correctly selected an image, the image turned green. If they selected an incorrect image, the image turned red; they were not informed of the correct image. Thus feedback provided the subject with only minimal information about each decision—whether it was correct—but not information as to which image was the correct item if they made an error. Allowing the participant to start each trial provided the opportunity for short rests as needed during the testing blocks.

Results

Training data

An analysis of variance was performed to determine the effect of density (high versus low) on overall proportion of selection of training items; the result was not significant. Within high density items, a two-factor ANOVA with replication was performed, comparing the number of selections of items from the high density cohort neighborhood to those from the high density rhyme neighborhood, across blocks. Cohort items were chosen more frequently than rhyme items, $F(1,84) = 15.69, p < .001$ (see Figure 2). Block was also a significant factor $F(5,420) = 2.52, p < .05$ and there was an interaction of neighborhood type and block, $F(5, 420) = 3.60, p < .01$.

Figure 2: Training selections of high density items

Training sequences were then analyzed for the likelihood that a subject, having selected an item from a particular neighborhood, would next select an item from the same neighborhood. The blue line in Figure 3 shows, across all subjects, the proportion of item selections that, on the immediately following trial, were drawn from the same high density neighborhood. Error bars represent standard errors of the mean. The pink line represents the eight low-density items grouped into random pseudo-neighborhoods of four items, to provide a baseline comparison for the likelihood of selecting within any group of four items.

Figure 3: In-neighborhood probability

A two-factor ANOVA with replication was performed. This revealed a main effect of density, low versus high, $F(1,5) = 37.86, p < .001$, and a significant interaction of density x block, $F(1,5) = 5.92, p < .001$. Within the high-density neighborhoods, a single factor ANOVA examined whether there was an effect of block on probability of successive same-neighborhood selections. A significant effect of block was found, $F(5,252) = 2.94, p < .05$.

Test data:

Figure 4 shows that for both high and low density items, the accuracy of responding on the 16-AFC test blocks rose rapidly from 50% correct (chance=6.25%) to asymptotic performance within the 6 testing blocks. A two-factor ANOVA with replication examining accuracy across test blocks revealed a significant effect of block $F(5,504) = 98.19, p < .001$. There was also an effect of density $F(1,1) = .10, p < .05$, but no interaction of density with block $F(5,504) = .36, p > .05$.

Figure 4: Proportion of test trials correct

A single-factor ANOVA of reaction times for correct trials across test blocks, collapsed across densities, showed a significant effect of block $F(5,252) = 8.03, p < .001$.

Figure 5: Reaction times in test

Figure 5 shows reaction times in the initial and final test blocks, as a function of neighborhood density. A two-factor ANOVA with replication revealed highly significant effects of block $F(5,492) = 14.50, p < .001$ and density $F(1,1) = 18.36, p < .001$.

Discussion

The present experiment is the first that we know of to assess how human learners allocate their attention by selecting novel words for association with novel visual objects in a word-learning paradigm. By having subsets of words that share acoustic/phonetic properties (lexical neighbors), we could ask whether learners seek or avoid repetitive samples of words from low- or high-density neighborhoods as they acquire new word-object associations.

Training data

Throughout the six training blocks, more high density cohort items were selected than high density rhyme items. Subjects concentrated their selections on cohort items, presumably because of the perceived phonological similarity among these items.

For high density items, there was a significant effect of block on the likelihood that subjects selected an item from one neighborhood and then on the subsequent touch selected an item from the same neighborhood. (This includes pressing the same item twice in a row.) In the initial trials, selection was nearly random. As the session continued, however, the probability that subsequent selections were within the same neighborhood significantly increased, then decreased to initial levels as mastery of the items was achieved and concentrated training on neighbors was no longer beneficial. When the low density items were randomly grouped into two groups of four and the selection data from those were compared to the high density selections, there was a significant effect of density and an interaction with blocks. Subjects were more likely to select two high-density items within a neighborhood (of four), one after another, than to select any two low-density items out of a random grouping of four. A regression model (proposed later) may be informative in further analyses of the influence of word-sampling behavior within one training block on the behavior exhibited in subsequent blocks.

Testing data

Subjects achieved 51% accuracy within the first testing block, after hearing each word on average only 4 times; this is significantly above chance (6.25% correct). This minimal exposure was sufficient to achieve significant learning, but performance did not reach asymptotic levels until 5 or 6 blocks of training. Accuracy was affected by density. High density items were correctly identified less frequently than low density items until halfway through the experiment. Their phonological similarity presumably created greater difficulty for the subjects.

As in previous studies, differences in reaction times also occurred as a result of density, with low density items being responded to more rapidly than high density items consistently until the final block, at which point performance on the two densities was equivalent.

Future studies

Numerous ways of examining the development of neighborhoods could provide greater insight into the time course of lexical competition during word learning. One such study would be to successively reveal subsets of neighborhoods to the learner in the paradigm described here. The training sequences would be of particular interest; in contrast to the present study, a different set of items would be present during each training block, and so the subject may adjust training strategies accordingly as overall neighborhood density is revealed across blocks.

Other statistical analyses, in the form of linear regression models, may reveal more about the present study and future designs. One analysis would be whether the performance on one test block influences training patterns in the immediately following block, which the current analyses cannot address well. Finally, our current analyses of within-neighborhood effects of training include pairs of trials in which one of the four items from the same high-density neighborhood is selected, including immediate repeats of the same item. Excluding these identical repeats may be more relevant to the question of lexical competition during learning.

Conclusion

It is well established that words in high-density neighborhoods are more difficult to process than words in low-density neighborhoods. When adults are given control over the frequency of exposure to novel words, they quickly adjust the rate of exposure by over-sampling words in high-density neighborhoods, particularly cohort neighbors more so than rhyme neighbors. The difficulty of learning high density items was revealed in this study as differences in accuracy and reaction time, which persist for the initial blocks of test trials. However, subsequent training yields equivalent learning accuracy for words in high- and low-density neighborhoods.

Our paradigm is likely to be useful for addressing a variety of issues in lexical learning. Perhaps most importantly, the method may be useful for teaching children novel lexical items, either in the laboratory or in the classroom.

Perceptual Advantage from Generalized Linguistic Knowledge

Bożena Pająk (bpajak@ling.ucsd.edu)

Department of Linguistics, UC San Diego
9500 Gilman Drive #108, La Jolla, CA 92093 USA

Abstract

We address the question of how previously acquired linguistic knowledge facilitates perception and learning of a new language. We report results from two experiments showing evidence that participants better discriminate a segmental duration contrast in a novel language if they had some previous exposure to a language that uses duration contrastively. Crucially, the perceptual advantage occurs even when the novel language employs the contrast in entirely different conditions: in novel segmental contexts and for novel segments, including a change from application to vowels to application to consonants. We take these results to suggest that language learners use their knowledge of previously learned languages to make inferences about the ways in which languages are likely to vary, which in turn increases their perceptual sensitivity when languages do in fact vary in the predicted ways.

Keywords: Speech perception; language learning; overhypotheses; cross-linguistic influence; multilingualism.

Introduction

Second language (L2) acquisition and bilingualism have received a lot of attention in the literature over the past few decades (for an overview, see e.g., Ritchie & Bhatia, 2009). Significantly less research has been done on acquisition of more than two languages, but it is now more widely recognized that acquisition of additional languages (L_n) is fundamentally different from L2 acquisition due to more possibilities for between-language interactions (De Angelis, 2007). However, the mechanisms behind these between-language interactions are still very poorly understood.

One specific consequence of this limitation in scope to L2 acquisition has been a lack of systematic research investigating the common intuition that while learning an L2 is often hard, learning each subsequent language becomes easier. We explore this intuition by asking higher-level questions about the learning process, as well as the nature of abstracting and generalizing, with the goal to understand what mechanisms would produce facilitation in L_n acquisition. A convenient framework for asking these questions makes use of Goodman's (1955) notion of "overhypothesis". Goodman's observation was that humans not only learn things that they experience directly, but they also infer abstract knowledge about how the things they experience directly are structured. Imagine a stack of bags that contain colored marbles. You empty a few of them and discover that some bags only have black marbles, while others only have white ones. Now imagine you pick a new bag and draw one marble which turns out to be white. The experience with previous bags makes you hypothesize that this particular bag contains only white marbles. This hypothesis is based on the overhypothesis you formed through your overall experience with this stack of bags that each bag contains marbles that are uniform in color.

Our proposal is to work within the overhypothesis framework to build a model of multiple language learning (MLL). The reasoning behind the model is that with knowledge of only one language, one possesses a limited amount of information about the possible features that languages can have: for example, what sounds they use or what syntactic and morphological features they employ. For a monolingual speaker, the general overhypothesis over how languages are structured, or what linguistic dimensions are relevant to assign meaning, depends entirely on the knowledge of one's single native language (L_1). This means that when learning an L_2 , one is likely to assume that the L_2 features are similar to those of L_1 , a prediction confirmed by a large body of research in L_2 acquisition (Ritchie & Bhatia, 2009). On the other hand, with at least some basic knowledge of two or more languages, one can update the overhypothesis (or, rather, the set of overhypotheses, each related to a specific linguistic dimension) by reevaluating which dimensions are relevant for each language. Structural differences between two or more languages on any given dimension provide a basis for expanding the hypothesis space (i.e., predictions about possible categories) for this dimension. We hypothesize that this conceptually expanded hypothesis space facilitates learning of novel categories along relevant dimensions in an L_n due to the fact that specific predictions about possible categories have already been formed, which in turn accelerates their processing.

When applied at the level of sound, the model makes predictions regarding the ability of bi/multilingual learners to discriminate novel contrasts along familiar dimensions in an L_n . Auditory perception of nonnative contrasts is often initially impaired, but can significantly improve with increased exposure. The explanation for this initial difficulty is that nonnative speech perception is shaped by the L_1 experience, and current theories are successful in predicting which L_2 sounds will be harder to initially perceive by listeners with a given language background (Kuhl & Iverson, 1995; Best, 1995; Flege, 1995). However, these models are not explicit about how the L_1 bias is overcome when nonnative phonological categories are successfully learned. A possible answer is instead provided by the literature on perceptual categorization. When learning phonological categories in L_2 , language learners adjust weights assigned to different phonetic dimensions so that dimensions reliably aiding in proper phoneme categorization in L_2 are given more weight, while dimensions creating phonologically irrelevant variation are given almost no weight (Kruschke, 1992; Strange & Shafer, 2008). Incorporating these theoretical assumption, the MLL model predicts that assigning high weight to a given phonetic dimension based on L_2 input raises the likelihood of this dimension

also being considered as relevant in *Ln*. This, in turn, leads to facilitation in perception and learning of novel *Ln* categories that make use of this dimension.

As an example, consider the phonetic dimension of segmental duration. Imagine a native speaker of English who also speaks Cantonese. In English, segmental duration is used mainly as a prosodic cue (Klatt, 1976), while in Cantonese, vowel duration can be considered a *contrastive* feature (Bauer & Benedict, 1997), which means that words can potentially be distinguished based solely on the duration of a given vowel (short vs. long). The model assumes that this speaker has formed an overhypothesis over the dimension of duration stating that duration of segments can be relevant for assigning meaning in some languages. Crucially, even though the speaker's experience with duration is only based on *vowel* segments, he/she is expected to have formed an overhypothesis over the duration dimension that is not segment-specific, and consequently, to have formed hypotheses (or predictions) regarding the relevance of duration for *any* segment. Now, if this speaker is learning an *Ln* like Polish, which has a *consonant* duration contrast, the model predicts a facilitation in learning this contrast, as compared to a learner who has not had any previous exposure to any duration contrasts, and consequently no opportunity to form an overhypothesis over the duration dimension.

Here we report the results of two experiments, in which the perception of short vs. long consonants was tested. In the first experiment, we tested speakers of American English who had previously learned a language with contrastive consonant duration. We expected to observe a perceptual advantage for this group over English speakers without such experience. Furthermore, we tested whether the perceptual advantage generalizes to novel consonant segments and novel segmental contexts. In the second experiment, we asked the question of whether the feature of contrastive duration can be generalized even further: namely, from vowels to consonants. Specifically, we tested the perception of a consonant duration contrast by speakers fluent in English and Cantonese, which has a duration contrast for vowels, but not for consonants.

Experiment 1

In an AX discrimination task we tested the perception of a consonant duration contrast (short vs. long) by a “bilingual group”: native (or near-native) speakers of American English with previous exposure to another language that uses consonant duration contrastively (e.g., Japanese or Italian). The control “monolingual group” consisted of native speakers of American English with no previous exposure to any language that contrasts duration.¹ Following the assumption

¹American English does not use duration contrastively. Vowel duration varies, but it correlates with the tense-lax distinction (e.g., *beat* vs. *bit*) or depends on the voicing of the following segment (e.g., *cad* vs. *cat*). Long consonants are sometimes attested but only at morpheme boundaries (e.g., *dissatisfied*; Benus, Smorodinsky, & Gafos, 2003). Minimal pairs are rare (e.g., *unnamed* vs. *unaimed*), and for most speakers the contrast is neutralized (Kaye, 2005).

of the MLL model that the bilinguals have assigned a high weight to the duration dimension in their L2, it was predicted that the bilingual group would perform better than the monolingual group. Furthermore, the perception of the duration contrast was tested in different phonotactic environments (here, the position in a word and the adjacent segments). While some theories assume that learning new contrasts is context-specific (Flege, 1995), the proposed model predicts that the abstracted knowledge should allow generalization across different environments. Additional comparisons within the bilingual group were planned in order to investigate more closely the process of generalization from previous knowledge. In particular, it was predicted that the bilingual participants would be able to generalize their perceptual capacity for duration contrasts to novel segments, and – following the underlying principle of the overhypothesis framework – that familiarity with the contrast in at least two different contexts would facilitate generalization to a novel context more than its familiarity in only one context.

Method

Participants 80 undergraduate students at UC San Diego participated in the experiment for course credit: 40 “monolinguals” and 40 “bilinguals”. The bilingual group was largely heterogeneous. It consisted of speakers of a total of 17 different L2s, and varied in their proficiency in L2, as well as the manner of exposure to L2 (school instruction or exposure at home through family members). The bilingual participants were further split in two ways depending on the types of segments possible as long consonants and the positions in which they occur in their L2. The division by “segment” included “[ss] bilinguals” who were only familiar with long [s], and “[ss] & [zz] bilinguals” who were familiar with both long [s] and long [z]. The division by “context” included “intervocalic bilinguals” who were only familiar with long consonants in the intervocalic context, and “intervocalic+ bilinguals” who were familiar with the contrast in the intervocalic context plus in at least one other context (word-medial preconsonantal and/or word-initial prevocalic).

Materials The materials consisted of nonce words constructed around either a long or a short target consonant. The target consonants were placed in four different contexts created by crossing two conditions: word position (medial vs. initial) with following segment (vowel vs. consonant). All the bilingual participants had previous exposure to the contrast in the word-medial prevocalic (or intervocalic) context, while none had previous exposure to the contrast in the word-initial preconsonantal context. Two different types of segments were used: voiceless alveolar fricatives [s]/[ss] and voiced alveolar fricatives [z]/[zz], resulting in a total of eight conditions. The materials are shown in Table 1.

Furthermore, there is evidence that by 18 months of age English-learning infants process duration contrasts differently from infants learning a language that contrasts duration (e.g., Japanese; Mugitani, Pons, Fais, Werker, & Amano, 2008).

Table 1: Materials. (V-vowel, C-consonant, #-word boundary)

		Prevocalic	Preconsonantal
		V_V	V_C
Word-medial	voiceless	asa/assa	asta/assta
	voiced	aza/azza	azda/azzda
Word-initial	voiceless	sa/ssa	sta/ssta
	voiced	za/zza	zda/zzda

The materials were recorded by a male native speaker of Moroccan Arabic since all the words were phonotactically legal in this language. For each test word, 18 repetitions were recorded. The duration of the fricatives was measured, and five tokens with fricatives that approximated mean duration for each condition were selected for use in the experiment. The trials consisted of an equal number of “different” pairs (e.g., asa-assa) and “same” pairs (e.g., assa-assa or asa-asa). Even in the “same” pairs, the first and second words in each pair were always physically different tokens, and were separated by an interstimulus interval of 500ms. Each participant heard 12 “different” pairs and 12 “same” pairs for each of the eight conditions. There was a total of 384 pairs in the experiment: 192 test pairs and 192 fillers.

Procedure The experiment began with a practice session during which participants listened to 16 filler stimuli (8 “different” and 8 “same” pairs) over headphones, and were asked to respond by clicking on one of two answer boxes displayed on the computer screen saying “same word” or “different words”. No feedback was given during the practice session. The test trials followed immediately after the practice session. Participants were presented with six 64-trial blocks. On each trial, a stimulus was presented aurally through headphones, and the participant responded by clicking on one of the two boxes on the computer screen. Each stimulus was played once without a replay option. The response to one stimulus triggered the presentation of the following stimulus with a delay of 500ms. The stimuli order was randomized for every participant. There was a self-terminated break after each block.

Results

We calculated A-prime scores for each participant and each condition (the same results hold for d-prime). A-prime (Grier, 1971) was used to measure the participants’ capacity to perceive the short/long consonant contrast, and is a non-parametric analog of d-prime. Both A-prime and d-prime are measures of sensitivity to a given contrast, and are calculated by taking into account the proportion of Hits (responding ‘different’ when the stimulus is ‘different’) and False Alarms (responding ‘different’ when the stimulus is ‘same’).² A-prime

²The formula used for calculating A-prime was the following: $A' = 0.5 + \frac{(H-FA)(1+H-FA)}{4H(1-FA)}$ (where H = Hits, and FA = False Alarms; Grier, 1971, p. 425). In order to avoid infinite or undefined

Figure 1: Performance on the short/long consonant contrast in different contexts by monolinguals and bilinguals. (Error bars are standard errors.)

yields values between 0 and 1, where 1 means ‘perfect discriminability’ and 0.5 is chance performance.

Monolinguals vs. bilinguals The results are plotted in Fig. 1. We analyzed the scores using a repeated measures ANOVA with the within-participants factors *position* (‘medial’ or ‘initial’), *following segment* (‘vowel’ or ‘consonant’), *voicing* (‘voiced’ or ‘voiceless’), and the between-participants factor *language background* (‘monolingual’ or ‘bilingual’). There was a significant main effect of *language background* [$F(1,78) = 12.8; p < .001$] with the bilingual group performing better ($\bar{A}' = 0.79$) than the monolingual group ($\bar{A}' = 0.72$).

There was also a significant interaction between *language background* and *following segment* [$F(1,78) = 11.4; p < .01$], and a three-way interaction between *language background*, *following segment* and *position* [$F(1,78) = 4.2; p < .05$]. The difference in performance between monolinguals and bilinguals was larger in preconsonantal than in prevocalic contexts, and was especially striking in the word-initial, preconsonantal contexts.

In addition, there were significant main effects of *position* [$F(1,78)=34.6; p<.001$] and *following segment* [$F(1,78) = 64.8; p < .001$] independent of language background. That is, both groups performed better when the contrast was in word-medial (vs. word-initial) contexts, and better when it was prevocalic (vs. preconsonantal).

Bilinguals: segments Two groups of bilinguals were compared depending on the segments that occur as long consonants in their L2. The results are plotted in Fig. 2. We analyzed the scores using a repeated measures ANOVA with the same as before within-participants factors *position* (‘medial’ or ‘initial’), *following segment* (‘vowel’ or ‘consonant’), *voicing* (‘voiced’ or ‘voiceless’), and the between-participants factor *L2-long-consonant-segment* (‘[ss] bilinguals’ or ‘[ss] & [zz] bilinguals’). The two groups of bilinguals were balanced by randomly removing participants from the larger group, leaving a total of 20 participants for this comparison.

No significant main effect of *L2-long-consonant-segment*

values, $H = 0$ was converted to $\frac{1}{2N}$, and $F = 1$ was converted to $1 - \frac{1}{2N}$ (where N = number of trials on which the proportion is based; Macmillan & Creelman, 2005).

Figure 2: Performance on the short/long consonant contrast by bilinguals familiar with both long [s] and long [z] ('[ss] & [zz] bilinguals') and bilinguals only familiar with long [s] but not long [z] ('[ss] bilinguals'). Monolinguals added for comparison. (Error bars are standard errors.)

Figure 3: Performance on the short/long consonant contrast by bilinguals familiar with the contrast in different contexts ('intervocalic+ bilinguals') and bilinguals familiar with the contrast only in the intervocalic context ('intervocalic bilinguals'). Monolinguals added for comparison. (Error bars are standard errors.)

was found [$F < 1$] and no interaction between *L2-long-consonant-segment* and *voicing* [$F < 1$]. Both groups of bilinguals performed the same on both voiceless and voiced contrasts.

There were also significant main effects of *position* [$F(1, 18) = 8.1; p < .05$] and *following segment* [$F(1, 18) = 16.3; p < .001$]. Again, both groups performed better when the contrast was in word-medial (vs. word-initial) contexts, and better when it was prevocalic (vs. preconsonantal).

Bilinguals: context The final comparison involved bilinguals which were grouped depending on the contexts in which long consonants are possible in their L2. The results are plotted in Fig. 3. We analyzed the scores using a repeated measures ANOVA with the within-participants factors again being *position* ('medial' or 'initial'), *following segment* ('vowel' or 'consonant'), *voicing* ('voiced' or 'voiceless'), and the between-participants factor *L2-long-consonant-context* ('intervocalic' or 'intervocalic plus V_C and/or #_V'). The two groups of bilinguals were balanced by randomly removing participants from the larger group, leaving a total of 32 participants for this comparison.

There was a significant main effect of *L2-long-consonant-context* [$F(1, 30) = 5.5; p < .05$] with the intervocalic+ bilingual group performing better ($\bar{A}' = 0.79$) than the intervocalic group ($\bar{A}' = 0.72$).

As in previous comparisons, there were significant main effects of *position* [$F(1, 30) = 18.5; p < .001$] and *follow-*

ing segment [$F(1, 30) = 19.5; p < .001$]. As before, both groups performed better when the contrast was in word-medial (vs. word-initial) contexts, and better when it was prevocalic (vs. preconsonantal).

Discussion

As predicted, the participants performed better on the short/long consonant contrast than monolingual participants. Importantly, the effect was observed despite high heterogeneity of the bilingual group in terms of their L2 background, the shared feature being the presence of the short/long consonant contrast in every L2. All the bilingual participants seemed to be able to use a similar kind of perceptual capacity which emerged from their different backgrounds. This result provides support for the hypothesis that previous exposure to duration contrasts in an L2 improves perception of a similar contrast in a novel language.

Furthermore, better performance by bilinguals was not simply a result of direct incorporation of certain elements from L2 to a novel language, because – as predicted – the bilinguals were able to generalize their perceptual capacity to novel segments (at least across voicing of segments) and novel contexts. Thus, the perceptual capacity was not found to be context-specific, even though some contexts may be perceptually harder than others.

Finally, following the hypothesis, the bilinguals whose L2 made the contrast in at least two different contexts (intervocalic, word-medial preconsonantal and/or word-initial prevocalic) performed better in the novel word-initial preconsonantal context than the group whose L2 only used the contrast intervocalically. This suggests that, while exposure to at least one segmental context of a duration contrast helps with the overall perception (as is the case for the "intervocalic bilinguals"), it is the exposure to at least two different contexts that allows for a real boost in perceptual capacity (as observed for the "intervocalic+ bilinguals"). This result can be interpreted as a supporting piece of evidence for the overhypothesis framework: exposure to a contrast in at least two contexts allows for the formation of an overhypothesis that this particular contrast can occur in many different contexts. Interestingly, the "intervocalic+ bilinguals" also performed better than the "intervocalic bilinguals" in the intervocalic context, to which all the bilinguals had equal exposure. While this result does not directly follow from the hypothesis, it might be that forming the overhypothesis over contexts makes the perceptual system more attuned to the contrast in any context, either novel or non-novel.

Experiment 2

Experiment 2 was designed in order to test whether the feature of contrastive duration can be generalized further than across voicing of segments, namely, from vowels to consonants. The participants were speakers of Cantonese (also fluent in Mandarin) and speakers of Mandarin with no knowledge of Cantonese. Cantonese has vowel duration contrasts, but no consonant duration contrasts, while Mandarin does

not use duration of any segments contrastively. To control for differences in populations, the experiment also included stimuli with a sibilant contrast from Polish, which were chosen because similar consonants form part of the Mandarin consonant inventory. Thus, the two groups of participants (Cantonese/Mandarin and Mandarin) were exposed to two types of stimuli: duration contrasts (short vs. long consonants) and sibilant contrasts (alveolo-palatal vs. postalveolar/retroflex consonants). The MLL model predicted that Cantonese speakers would perform better than Mandarin speakers on the duration contrast due to their experience with the vowel duration contrast in Cantonese. However, both groups were predicted to perform equally well on the sibilant contrast due to their familiarity with a similar contrast in Mandarin (although a slight advantage for the native Mandarin speakers was expected for this contrast).

Method

Participants 40 undergraduate students at UC San Diego participated in the experiment for course credit. 20 were native speakers of Mandarin fluent in English, and the other 20 were native speakers of Cantonese fluent in English and at least competent in Mandarin.

Materials The materials consisted of two types of stimuli, as shown in Table 2.

Table 2: Materials: segmental contrasts.

A. Duration contrasts (short vs. long)							
Sonorants						Obstruents	
[j]/[j]	[w]/[ww]	[l]/[ll]	[m]/[mm]	[n]/[nn]		[f]/[ff]	[s]/[ss]
B. Sibilant contrasts (alveolo-palatal vs. postalveolar/retroflex)							
Voiceless				Voiced			
[ç]/[ç]	[ç̥]/[ç̥]			[ʒ]/[ʒ]	[dʒ]/[dʒ]		

This created 4 conditions by crossing two factors: contrast (duration or sibilant) with language background (Cantonese/Mandarin or Mandarin).

Each contrast was embedded in seven different frames: [pa_a], [pe_a], [po_a], [ta_a], [te_a], [ka_a], [ke_a]. All the words were recorded by a phonetically-trained native speaker of Polish with five repetitions of each word. One token of each stimulus type was chosen as a frame (a short consonant token for duration contrasts and a postalveolar/retroflex token for sibilant contrasts). The target consonants were spliced out from different tokens. Long consonants were created from the short consonants by either doubling their length (for sonorant consonants: [j], [w], [l], [m], and [n]) or elongating it by half its length (for obstruent consonants: [f] and [s]).³ The stimuli were created by pairing words that were “different” (e.g., paja-pajja) and “same” (e.g., paja-paja or pajja-pajja). Unlike in Experiment 1, the “same” words in each pair were physi-

³This difference was introduced in order to account for the fact that intervocalic duration contrasts are perceptually harder for sonorants than for obstruents (Kawahara, 2007).

Figure 4: Performance on the long/short consonant contrast by Cantonese/Mandarin and Mandarin speakers. (Error bars are standard errors.)

cally identical and the “different” words in each pair always shared a physically identical frame (i.e., the words were identical except for artificial lengthening for duration contrasts and a spliced consonant for sibilant contrasts). This was done to ensure that any difference in the participants’ responses resulted only from the manipulation of interest. The words in each pair were separated by an interstimulus interval of 750ms. Each pair was repeated twice throughout the experiment, which yielded a total of 392 pairs: 196 pairs with duration contrasts and 196 pairs with sibilant or other (filler) contrasts.

Procedure The procedure was almost identical to experiment 1. The differences included the number of blocks (seven 56-trial blocks) and the response type: instead of clicking on the screen with a mouse, participants responded by pushing buttons on a game pad.

Results

As in Experiment 1, we calculated A-prime scores for each participant in each condition as a measure of contrast sensitivity (the same results hold for d-prime).

Duration contrast The results from the duration contrasts are plotted in Fig. 4. We analyzed the scores using a repeated measures ANOVA with the within-participants factor *segment* ([j], [w], [l], [m], [n], [f], or [s]), and the between-participants factor *language background* (‘Mandarin’ or ‘Cantonese/Mandarin’). There was a significant main effect of *language background* [$F(1,38) = 12.7; p < .01$] with the Cantonese/Mandarin group performing better ($A' = 0.87$) than the Mandarin group ($A' = 0.81$). There was also a significant main effects of *segment* [$F(6,228) = 5.8; p < .001$], indicating that some segments were overall harder than others.

Sibilant contrast The results from the sibilant contrasts are plotted in Fig. 5. We analyzed the scores using a repeated measures ANOVA with the within-participants factor *segment* ([ç]/[ç], [ʒ]/[ʒ], [ç̥]/[ç̥], [dʒ]/[dʒ]), and the between-participants factor *language background* (‘Mandarin’ or ‘Cantonese/Mandarin’). As predicted for this con-

Figure 5: Performance on the sibilant contrast by Cantonese/Mandarin and Mandarin speakers. (Error bars are standard errors.)

trast, no significant main effects of *language background* [$F(1,38) = 1.6; p = .21$] nor *segment* [$F(3,114) = 1.9; p = .14$] were found. Both groups performed similarly on all sibilant contrasts, as illustrated in Fig. 5. There was, however, a tendency for Mandarin speakers to perform better than Cantonese speakers, at least on one type of contrast ([tɕ]/[tʃ]).

Discussion

This experiment showed that the speakers of Cantonese/Mandarin perform better on the short/long consonant duration contrast than Mandarin speakers without any exposure to Cantonese. It was hypothesized that such a difference between the two groups would be observed due to the fact that Cantonese uses *vowel* duration contrastively. This result suggests that Cantonese speakers were able to generalize their knowledge about a vowel duration contrast to a consonant duration contrast in a way that perception of the latter contrast was facilitated.

Importantly, the better performance of the Cantonese participants was not due to other differences in populations since the two groups performed equally well on the control contrast of sibilants. In this case, both groups were predicted to perform similarly due to the influence of Mandarin, which has a similar contrast between voiceless sibilants.

The combination of these results means that the feature of contrastive duration can indeed be abstracted away from a limited set of segments (e.g., vowels) and applied in novel conditions with a perceptual advantage, thus supporting the predictions of the model.

Conclusion

This paper argued that previously acquired linguistic knowledge can have a facilitative effect on perception and learning of new languages. In Experiment 1, we showed that participants with previous exposure to a language that uses consonant duration contrastively are better at discriminating a similar duration contrast in a novel language. Perceptual advantage was observed even if the contrast was presented in novel segmental contexts and for novel segments. Experiment 2 showed an even stronger result: perceptual advantage on consonant duration contrasts was observed for participants who only had previous exposure to *vowel* duration contrasts. Together, these results support the MLL model and the over-

hypothesis framework, which predict that knowledge of previously learned languages is generalized and leads language learners to make inferences about the ways in which languages are likely to vary. These inferences, or overhypotheses, about dimensions along which languages can differ may in turn increase learners' perceptual sensitivity to contrasts that the overhypotheses predict. Having established that such generalization occurs from previously learned to novel languages, the next step for future work will be to determine the exact conditions under which overhypotheses are made, and in what exact ways they are used in language learning.

Abstract

A model is presented that explains perceptual compensation for context as a consequence of listeners optimally categorizing speech sounds given contextual variation. In using Bayes' rule to pick the most likely category, listeners' perception of speech sounds, which is biased toward the means of phonetic categories (Feldman & Griffiths, 2007; Feldman, Griffiths, & Morgan, 2009), is conditioned by contextual variation. The effect on the resulting identification curves of varying category frequencies and variances is discussed. A simulation case study of compensation for vowel-to-vowel coarticulation shows the predictions of the model closely correspond to human perceptual data.

Keywords: Speech perception; perceptual compensation; rational analysis.

Introduction

A major challenge for models of speech perception is explaining the effect of context on phonemic identification. Depending on their acoustic, phonological, semantic, syntactic, and even socio-indexical contexts, identical acoustic signals can be labeled differently and different acoustic signals can be labeled identically. One of the most investigated types of contextual effects stems from phonemes' phonetic environments. Because of coarticulation, a phoneme's phonetic realization is heavily context-dependent. To understand speech, the listener must take into account context-induced coarticulatory effects to recover the intended message. The term *perceptual compensation* (PC) has often been used to characterize this type of context-induced adjustment in speech perception. For example, the identification of an ambiguous target syllable as /da/ or /ga/ is shifted by preceding /ar/ or /al/ contexts (Mann, 1980): the same /Ca/ token is *less* likely to be heard as /ga/ in /arCa/ context than in /alCa/ context. This effect has been argued to result from perceptual reduction of the coarticulatory fronting effects of /l/ on a following velar consonant: listeners are compensating for the effect of /l/ on /g/. This paper proposes a simple model in which PC effects emerge as an optimal solution to the problem of categorization in the presence of context-induced variation. In this model, listeners behave as if they are compensating because what is optimal differs by context.

PC effects have been observed in many phonetic settings. The fricative /f/ has lower noise frequencies than /s/, and lip rounding lowers the resonant frequencies of nearby segments. Synthetic fricative noises ranging from /f/ to /s/ are more often identified by English listeners as /s/ when followed by /u/ than by /a/ (Mann & Repp 1980; see also Mitterer 2006), presumably because listeners take into account the lowering effect of lip rounding from /u/ on the noise frequencies of /s/ in

natural coarticulated speech. As another example, the perception of a fundamental frequency (f_0) contour can change as a function of vowel height (Hombert, 1978; Silverman, 1987) or consonant voicing (Pardo & Fowler, 1997): /i/ is perceived as lower in pitch relative to an /a/ with the same f_0 , presumably because high vowels typically have higher f_0 than low vowels.

Listeners' language-specific experience crucially affects the degree of perceptual compensation. In a study replicated in part below, Beddor, Harnsberger, & Lindemann (2002) found that English and Shona listeners compensate for the coarticulatory effects of V_2 on V_1 in CV_1CV_2 sequences. That is, listeners identified a continuum of synthesized vowels between /a/ and /e/ more often as /a/ when the following vowel was /i/ than when the following vowel was /a/. Importantly, they observed that Shona listeners compensate more for the vowel contexts that triggered larger acoustic influences in speech production. Compensatory responses can affect listeners' rating judgments as well. English listeners are less accurate in judging vowel nasality in nasal than in non-nasal contexts, with nasal vowels in nasal contexts the most difficult (Beddor & Krakow, 1999; Kawasaki, 1986).
