Following work in other areas of cognition (Braun, Mehring, & Wolpert, 2009; Kemp & Tenenbaum, 2009), we suggest that rapid learning arises from the exploitation of structured knowledge in the form of inductive biases. In particular, our proposal is that humans employ a sparsity bias: the assumption that only one (or a small number) of dimensions (input features) is relevant at any given time for predicting reward. For example, when you are at a stoplight, only the color of the light matters, not its shape, size, etc. In other domains (such as ordering food in a restaurant), you may know that dimensional relevance is sparse, but not which particular dimensions are relevant (does it matter which restaurant it is? which table I am sitting at? who the chef is? who the waiter is?); for this purpose, one requires a learning algorithm that can exploit sparsity. We formalize this idea in terms of rational statistical inference, and present new experimental evidence that human behavior is consistent with such a model.

Central to our analysis is the idea that selective attention is a direct consequence of Bayesian inference with a sparsity

bias: Restricting attention to only a few dimensions is akin to the belief that only those dimensions are relevant for earning reward. This has the effect of reducing the space of possible value functions to a much smaller subspace.

While Bayesian probability theory stipulates the ideal learner, in general it may not be computationally tractable to perform the necessary calculations exactly (Kruschke, 2006; Daw & Courville, 2008). We therefore consider a “hybrid” model that combines the computational efficiency of model-free RL with the statistical efficiency of Bayesian inference. We compare the Bayesian and hybrid models to naive RL (no sparsity bias) and show that models that exploit structured knowledge better capture choice behavior in our experiment.

The Computational Problem

For concreteness, we consider one particular example of the general class of reinforcement learning problems for which the sparsity assumption holds. This example is meant to capture the abstract structure of many problems facing humans in the real world, where they must make choices between several multidimensional stimuli under conditions where most dimensions are unpredictable of reward. This example will also serve as a formal description of the task that we asked human subjects to perform, the results of which we report in a later section.

The subject plays N trials, and observes M stimuli simultaneously on each trial. The i th stimulus on trial n is denoted by a D -dimensional vector \mathbf{x}_{ni} , where each integer-valued component x_{nij} indicates the property of the j th stimulus dimension (for instance, [color = green, shape = triangle, texture = dots]). Each set of trials has a target dimension d (e.g., ‘shape’) and target property f on that dimension (e.g., ‘circle’). The subject chooses a stimulus c_n on each trial and observes a binary reward r_n . The probability of reward given choice and target is

$$P(r_n = 1 | c_n, d, f, \mathbf{X}_n) = \begin{cases} \theta_1 & \text{if } x_{nc_nd} = f \\ \theta_0 & \text{otherwise,} \end{cases} \quad (1)$$

In other words, the subject receives a reward with probability θ_1 if the chosen stimulus possesses the target property on the target dimension, and with probability θ_0 otherwise.

Bayesian Model

Given uncertainty about the target dimension and property, a Bayesian model would use Bayes’ rule to infer the posterior over the target dimensions and property and then calculate the

value of the stimulus by taking the expectation of reward with respect to the posterior:

$$V_n(c) = \sum_d \sum_f P(r_n = 1 | c_n = c, d, f, \mathbf{X}_n) P(d, f | \mathcal{D}_{n-1}, \mathbf{r}_{1:n-1}), \quad (2)$$

where $\mathcal{D}_{n-1} = \{\mathbf{X}_{1:n-1}, \mathbf{c}_{1:n-1}\}$. The intuition behind the Bayesian model is that the model weights the expected reward in each possible state of the world (i.e., target dimension and property) by the probability of the world being in that state given past observations. A key characteristic of this model is that a complete posterior distribution is maintained over states of the world, rather than a point estimate. The posterior distribution used by the Bayesian model is given by Bayes' rule:

$$P(d, f | \mathcal{D}_{n-1}, \mathbf{r}_{1:n-1}) \propto P(\mathbf{r}_{1:n-1} | \mathcal{D}_{n-1}, d, f) P(d, f), \quad (3)$$

where the prior is assumed to be uniform and the likelihood is given by:

$$P(\mathbf{r}_{1:n-1} | \mathcal{D}_{n-1}, d, f) = \prod_{t=1}^{n-1} P(r_t | c_t, d, f, \mathbf{X}_t). \quad (4)$$

Note that although this model describes the optimal learning rule, we shall assume that subjects are “weakly” rational in their decision rule (see the softmax choice function described below).

Reinforcement Learning Models

We now consider several alternative models based on RL. The intuition behind these models is that what ultimately matters for the choice value is the *expectation* under the posterior; so incrementally updating an estimate of this expectation from experience will eventually converge to the optimal choice values, even though these updates do not make optimal use of information on each trial. The various RL models differ principally in their construction of the value function.

Naive RL Model

The naive RL model represents a separate value for every possible stimulus-dimension-property configuration. Specifically, the choice value estimate is given by $V_n(c) = v_n(\mathbf{x}_{nc})$. This estimate is updated according to the learning rule:

$$v_{n+1}(\mathbf{x}_{nc_n}) = v_n(\mathbf{x}_{nc_n}) + \alpha \Delta_n, \quad (5)$$

where α is a learning rate and Δ_n is the *prediction error*:

$$\Delta_n = r_n - V_n(c). \quad (6)$$

Although the optimal solution is learnable by this model, its learning will be very slow, as we describe in the next section.

Function Approximation Models

One reason why the naive RL model may be ineffective in this task is that it lacks the ability to generalize across different configurations of features. Intuitively, if you knew the target dimension and property, then the value of a stimulus should be independent of the properties on the non-target dimension. However, the naive RL model yokes these together, such that learning operates on configurations of properties and hence fails to exploit this invariance. For example, the naive RL model learns a different value for green triangles with dots and for green triangles with waves, although the texture dimension may be completely incidental and not predictive of reward.

A more structured RL model that generalizes across configurations can be obtained by constructing the value function as a linear combination of D basis functions ϕ :

$$V_n(c) = \sum_{d=1}^D w_n(d, x_{ncd}) \phi_d, \quad (7)$$

where the weight matrix \mathbf{W}_n determines how the basis functions are combined, with one weight for each dimension-property pair. This type of model is known as a *function approximation architecture* (Sutton & Barto, 1998). RL is used to update the weights according to:

$$w_{n+1}(d, x_{ncd}) = w_n(d, x_{ncd}) + \alpha \Delta_n \phi_d, \quad (8)$$

where the prediction error Δ_n is computed the same way as in the naive RL model (Eq. 6). This update can be understood as performing gradient ascent on the value function by optimizing the weight parameters (Williams, 1992).

We will consider a family of basis functions parameterized by η :

$$\phi_d = \frac{P_d^\eta}{\sum_j P_j^\eta}, \quad (9)$$

where $P_d = \sum_f P(d, f | \mathcal{D}_{n-1}, \mathbf{r}_{1:n-1})$. The basis function can be thought of as an “attentional focus” that encodes the subject’s beliefs about what dimension is currently relevant. Thus, rather than maintaining the full posterior over target dimension and property (which may be quite computationally expensive), with the function approximation model the subject maintains the *marginal* posterior over target dimension (i.e., the probability of a dimension being the target, averaging over different target properties), which is then used to weight separate value functions, one for each dimension. When reward feedback is received, credit (or blame) is assigned to each value function in proportion to its posterior probability.¹ We refer to this model as the *hybrid* model, because it combines properties of RL and Bayesian inference.

Different settings of η lead to several special cases of interest:

¹Note that the subject need not maintain and update the full posterior; any procedure that estimates the marginal posterior directly is consistent with this formulation.

- $\eta = 0$: uniform weighting of dimensions (diffuse focus).
- $\eta = 1$: exact posterior weighting of dimensions (optimal focus).
- $\eta \rightarrow \infty$: maximum a posterior (MAP) weighting (myopic focus).

Other intermediate scenarios are also possible. Thus, the value of η tells us how much information about the posterior distribution the subject is using to focus attention, with $\eta = 1$ being optimal focus and $\eta = 0$ completely ignoring information from the posterior and attending equally to all dimensions.² When η is larger than 1, the subject discards posterior uncertainty by focusing on the mode of the distribution, and is therefore overconfident in her beliefs about the relevant dimension.

One way to interpret the function approximation model is as a neural network in which the basis functions represent attentional units focusing on different sensory channels, and the weights represent synaptic connections between the attentional units and a reward prediction unit (Figure 1). The synaptic weights are updated using RL (Eq. 8). This interpretation resonates with ideas in computational neuroscience that view the dorsolateral prefrontal cortex as encoding attentional or task-related biases that interact with a striatal reward prediction system (Braver, Barch, & Cohen, 1999; Rougier, Noelle, Braver, Cohen, & O'Reilly, 2005; Todd, Niv, & Cohen, 2009). The prediction error Δ driving the weight updates is thought to be signaled by midbrain dopaminergic afferents to the striatum (Schultz, Dayan, & Montague, 1997)

Figure 1: **Neural network interpretation of the hybrid model.**

Method

We now describe a behavioral experiment designed to quantitatively evaluate these models. Our experiment was inspired

²It is important to note that diffuse focus is not the same as the naive RL model. For all values of η , the function approximation model is still able to generalize across different configurations, unlike the naive RL model.

by the intra-dimensional/extra-dimensional set-shifting task (Dias, Robbins, & Roberts, 1996; Owen, Roberts, Polkey, Sahakian, & Robbins, 1991), in which subjects are asked to discriminate between visual stimuli on the basis of a particular (but unknown) dimension which they must learn from feedback, as well as the Wisconsin card-sorting task (Milner, 1963). We have adapted this task to a multi-armed bandit setting, such as has been used in previous studies of reinforcement learning (e.g., Daw, O'Doherty, Dayan, Seymour, & Dolan, 2006; Schonberg, Daw, Joel, & O'Doherty, 2007).

Participants and Stimuli

Sixteen participants received 12 dollars reimbursement for performing 1800 trials of the task. The stimuli were triplets of stimuli varying along three dimensions: color (red, yellow, green), shape (circle, triangle, square), and texture (waves, dots, lattice). An example triplet is shown in Figure 2.

Figure 2: **Example experimental stimuli.**

Procedure

For each game, the target dimension and property were chosen randomly and with equal probability. On each trial, the subject was presented with a random triplet and asked to choose one of the stimuli. The stimuli on each trial were generated by a random permutation of the property assignments. After making the choice, the subject received feedback about whether or not her choice resulted in a reward. If the subject chose the stimulus with the target dimension/property pair, she received a reward with probability 0.75. Otherwise, reward was delivered with probability 0.25. The targets changed on each game (lasting 20-30 trials), and subjects were informed when a new game was beginning.

Choice Probabilities

To map from values to choices, we define a *policy* π_n that specifies the probability $\pi_n(c)$ of making choice c on trial n . Here we use the “softmax” policy defined by

$$\pi_n(c) = \frac{e^{\beta V_n(c)}}{\sum_a e^{\beta V_n(a)}}, \quad (10)$$

where β is an *inverse temperature* parameter that allows us to model stochasticity in the subject's responses.

Parameter Estimation and Model Comparison

We fit the parameters of each model with MAP estimation using gradient descent and calculated the Laplace approximation (Kass & Raftery, 1995) to the log marginal likelihood

(evidence) for each model m according to:

$$E_m = \ln \int_{\omega_m} P(\omega_m) P(c|\omega_m) d\omega_m \\ \approx \ln P(\hat{\omega}_m) + \ln P(c|\hat{\omega}_m) + \frac{1}{2} G_m \ln 2\pi - \frac{1}{2} \ln |\mathbf{H}_m|, \quad (11)$$

where ω_m is the set of parameters for model m , $P(c|\hat{\omega}_m) = \prod_{n=1}^N \pi_n(c_n|\hat{\omega}_m)$, $\hat{\omega}_m$ is the MAP estimate of the parameters, G_m is the number of parameters (length of ω_m), and \mathbf{H}_m is the Hessian matrix of second derivatives of the negative log-posterior evaluated at the MAP estimate. We then calculated the log Bayes Factor relative to chance (where all choices are equiprobable) according to $E_m - N \ln(1/3)$. A larger Bayes Factor indicates greater support for a model. Note that the chance (null) model has no parameters. In addition to comparing models based on Bayes Factors, we also calculated predictive log-likelihood on a held-out game using a leave-one-out cross-validation procedure.

For all the models, we fit an inverse temperature β , placing on it a Gamma(2,2) prior. This served to ameliorate a well-known degeneracy in models with both a temperature and learning rate, such that these parameters tend to trade-off against each other (inverse temperature becoming very large and learning rate very small). For the RL models, we fit a learning rate α , placing on it a Beta(1.2,1.2) prior, which slightly biases the fits away from the parameter boundaries. We also allowed θ_1 and θ_0 to vary across subjects, since we only told subjects that the target would be rewarding more often than non-targets, placing on θ_1 a Beta(12,4) prior and on θ_0 a Beta(4,12) prior; these priors were chosen to have as their expected value the true—but unknown—values of θ_1 and θ_0 . Finally we placed a Uniform(0,10) prior on η .

Results

Figure 3 presents the log Bayes Factors for each model, summed across subjects, along with the cross-validation results. Zero represents the null (chance) model in both cases. Clearly all the models do better than chance, but the naive RL model appears to perform substantially worse than the others. Overall, the hybrid model appears to best match behavior on this task. Figure 4 displays the distribution of log Bayes Factors for the Bayesian and hybrid models, showing that there are also individual differences in which model is favored for each subject.

Additional insight into these models can be gained by inspecting aggregate learning curves (the probability of choosing the optimal stimulus as a function of trials within a game). As shown in Figure 5, the naive RL model appears to consistently underestimate the speed of learning exhibited by subjects, whereas both the Bayesian and hybrid models hew closely to the empirical learning curve. One peculiarity of the learning curve is that subjects appear to learn faster than the Bayesian model. We believe that this is an artifact of the softmax choice probability function: the inverse temperature parameter appears to be too low early in a game and slightly

too high later in a game. No single value of the inverse temperature would be able to capture this pattern.

	Log Bayes Factor	Held-out log-likelihood
Bayesian	5425	5620
Hybrid	5892	6208
Naive	3307	3312

Figure 3: **Model comparison results.** Highest scores are shown in bold.

Figure 4: **Comparison of Log Bayes Factors for Bayesian and hybrid models.** Points above the diagonal are favored by the hybrid model. The red shaded region indicates the confidence interval outside of which one model is more likely than the other with $p < 0.05$.

Another question we can ask is whether subjects who behave more in accordance with the Bayesian model or hybrid model earn more reward overall. Figure 6 does indeed show this relationship (measured as the correlation between reward earned and the log Bayes Factors for the Bayesian model relative to the hybrid model), suggesting that subjects who more effectively exploit the structure of the task tend to perform better. The correlation is significant at $p < 0.01$. The hybrid model log Bayes Factor relative to the null model also correlates with total reward ($p < 0.02$).

Figure 7 shows the parameter estimates for η on a log-scale, demonstrating that subjects cluster around 0, corresponding to exact posterior weighting (optimal focus). This was supported by a sign test which failed to reject ($p=0.45$) the null hypothesis that $\ln(\eta)$ was drawn from a distribution with 0 median. Thus, within the family of possible basis functions, posterior attentional weighting best describes human behavior on this task.

Discussion

In this paper we have posed a problem that humans face in everyday life: how to learn value functions in high-dimensional state spaces. The crucial assumption that makes this possible

Figure 5: **Learning curves.** Probability of choosing the optimal stimulus as a function of trial within a game. The circles represent the empirical choice probability. Error bars are standard errors of the mean.

Figure 6: **Individual differences in earned reward.** On the x-axis is plotted the log Bayes Factors of the Bayesian model relative to the hybrid model, and on the y-axis is plotted the total reward earned. A least-squares line is superimposed on the scatter plot.

is that only one or a few dimensions is relevant at any given time. By employing this sparsity bias in the machinery of Bayesian inference, the effective dimensionality of the problem is reduced. This can be understood as a kind of selective attention that is learned through experience.

Our experimental results demonstrate that humans can exploit sparsity information when it is available. We compared a Bayesian model and a family of sophisticated RL algorithms against a naive RL model that ignores sparsity information and hence does not generalize across stimulus configurations, the key ingredient to efficient learning. Our computational analysis of behavior on this task suggests that humans combine reinforcement learning with Bayesian inference, rather than using a purely Bayesian strategy. This makes sense if the brain’s learning algorithms are designed to deal with high-dimensional problems for which exact Bayesian inference is

Figure 7: **Boxplot of $\ln(\eta)$ estimates.**

intractable. The hybrid model represents a compromise between the computational efficiency of model-free RL and the statistical efficiency of Bayesian inference.

The idea that selective attention can be framed as the outcome of Bayesian inference has been explored by several authors (Dayan, 2009; Rao, 2005; Yu, Dayan, & Cohen, 2009). Most relevant to our work is the competitive combination model of Dayan, Kakade, and Montague (2000), in which stimuli are assumed to vary in how reliably they predict reward. Dayan et al. (2000) showed that selective attention to particular stimuli falls naturally out of inference over the causal relationships between stimuli and reward in such a model. Our work is conceptually similar, with the main difference that we model inference over dimensions, rather than just stimuli. As emphasized by Dayan et al. (2000), the selectivity of attention in our model is based on processes of statistical inference, rather than resource constraints. This point is particularly important to explaining how attention is *learned*; resource-limitation models, without further elaboration, do not speak to this issue.

The central role of selective attention has been extensively explored in the category learning literature, notably by Nosofsky (1986) and Kruschke (1992). The basic idea is that learned attentional weights amplify or attenuate specific stimulus dimensions in a way that facilitates category discrimination. Recently, Kruschke (2006) has attempted to connect these ideas to a form of approximate Bayesian inference he dubs “locally Bayesian learning” (LBL). Much as in our work, attention arises in LBL as a consequence of weighting different hypotheses about the currently relevant stimulus dimension in response to new evidence. In this sense, LBL is form of hybrid model; here we have attempted to identify a continuum through which Bayesian knowledge can influence RL, and fit this to data to identify where human learners fall on this continuum. At the same time, although our model shares some characteristics with categorization models such as LBL (see also Heller, Sanborn, & Chater, 2009), it is important to note that the problem it is designed to solve

is conceptually different: it does not receive feedback indicating the correct response (as in supervised category learning), but must instead learn from probabilistic reward feedback.

While our work was partly inspired by earlier neural network models (Braver et al., 1999; Rougier et al., 2005), our goal in this paper was to step away from implementational details and interrogate computational- and algorithmic-level concerns. Future work will need to examine more systematically how the algorithmic ideas presented here map onto neural mechanisms. We are currently investigating this question with functional magnetic resonance imaging.

In conclusion, the main theoretical and experimental contribution of this paper is showing that the human RL system is more sophisticated than previous computational models have given it credit for. This may not, after all, be that surprising; many years of machine learning research have shown that the naive assumptions of previous models simply do not scale up to high-dimensional real world problems. It remains to be seen what other hidden sophistications in the RL system await discovery.

Abstract

Principles in foraging and standard associative learning theories motivate a model for Pavlovian conditioning. The model tracks distal and proximal scales of expected reward probabilities plus the strength of signal-reward association. A combined reward probability is developed by combining the distal and proximal estimates through their uncertainties. Possible neural structure equivalents to the model variables are discussed. Model flexibility is demonstrated with data on the partial reinforcement extinction effect, a phenomenon difficult to explain with learning models.

Keywords: Mathematical model; Pavlovian conditioning; associative learning; foraging theory; partial reinforcement extinction effect, neural structures.

Foraging and Associative Learning

Pavlovian conditioning (PC), or associative learning, is one of the most well studied psychological processes and has an array of associated phenomena. The two main processes, acquisition of a behavior by pairing a signal and reward in trials and extinction of the behavior by removing the reward during the trials, can be explained by a number of models, the most common being the delta model where learning is guided by the error, i.e. delta, between the expected and received reward per trial (Rescorla & Wagner, 1972). However, the basic delta model cannot explain other widely known phenomena, including spontaneous recovery of behavior when signaling trials are conducted after extinguishing the behavior and the partial reinforcement extinction effect (PREE) where intermittent rewards during acquisition trials increase the resistance to extinguishing behavior and strengthen the response during spontaneous recovery trials. In particular, the PREE challenges associative models of PC, since lower reward expectations for partial compared to continuous reinforcement would appear in principle to produce faster extinction. One theory for PREE involve the rate of reinforcement, such the ratio of the current cumulative signal duration since the last reward to the average signal duration between rewards (Gallistel & Gibbon, 2000). However, this result is not supported experimentally (Haselgrove et al., 2004). An alternative verbal model proposed by Pearce et al. (1997) assumed that

unrewarded trials during partial reinforcement schedules create a different context where the unrewarded trials signal rewarded trials. We develop a model that readily explains PC phenomenon in what we believe is a robust manner. Our model builds on PC and foraging theories and the neuroscience of memory and decision-making.

Animals in natural and laboratory environments meld their past and current experiences in making decisions; it is often assumed that the laws and processes in both environments are similar if not identical. In foraging, animals choose between staying in the current patch and moving to another. Deciding when to give up on a patch depends on the expected reward rate of the current patch relative to the expected reward rate on another patch discounted for the interpatch travel time (Charnov, 1976). In PC the response rate reflects expectations within the single environment as dependent on learning and unlearning of signal-reward associations (Bouton, 1993). Notably, in both frameworks, responses are based on comparisons of distal and proximal information. Distal information in PC is the memory of the previous signal-reward patterns, while in foraging distal information is the memory of the average habitat reward rate. Proximal information in PC reflects the most recent reward outcomes, while in foraging it reflects the expected foraging rate in the current patch. In both frameworks, expected reward for the next trial is computed by a delta rule, which is an exponentially weighted moving average (EWMA) that adds a percentage of the most recent outcome to a percentage of the previous expectation.

The two frameworks diverge in how non-reward events and extinction are treated. PC models commonly consider acquisition-extinction patterns in terms of distinct learning streams. A stream developed during the acquisition phase of the experiment characterizes signal-reward expectations, and a second stream developed during the extinction phase characterizes a signal-no reward expectation. Extinction learning inhibits the original acquisition learning (Bouton, 1993). However, when animals are retested after some interval of time the extinction learning is forgotten and spontaneous recovery of the original learning appears (Sissons & Miller, 2009). In foraging models, the learning streams do not inhibit each other nor are they forgotten.

Expected probabilities of rewards are tracked for both the current patch, i.e. the proximate patch, and the habitat, i.e. the distal patch. With parallel information streams, the animal does not need to distinguish whether information belongs in the acquisition or the extinction learning stream, an issue in PREE experiments where signals without rewards occur during the acquisition phase. Rather, the animal is constantly adapting to an always changing environment.

Patch foraging models naturally involve multiple temporal scales because information on the proximal patch is always more recent than information on distal patches. To capture these temporal differences, models have expressed distal and proximal learning with slow and fast learning rates respectively (Anderson, 2002; Moorter et al., 2009). Mixed learning rates are also used in the primary value learned value (PVLV) model (O'Reilly et al., 2007), that seeks a mapping to dopaminergic neuron dynamics during reinforcement learning.

Retaining reward probabilities across different temporal and spatial scales requires memory systems, and here neuroscience provides information on their nature. McClelland et al. (1995) postulated memories are created and stored in a two-stage process involving short- and long-term processes. First, events are stored via synaptic changes in the hippocampal system, a short-term memory (STM) which then supports reinstatement of recent memories into long-term memories (LTM) in the neocortex. The neocortical synapses change by a small amount on each reinstatement, which assures that learning, as a stochastic process, converges to the mean value of the statistical association of ensembles of experiences. The hippocampal system permits rapid learning of new items without disrupting the neocortex structure, and interleaves and integrates them into the neocortical system. In essence, the LTM is built-up incrementally from activation of STM. Furthermore, since extinction involves new learning, evidence suggests multiple memory systems may be applicable to the neural basis of extinction (Gabriele & Packard, 2006). We suggest the distal and proximal information streams which are contained in both PC and foraging models represent the STM and LTM system identified by neurological studies.

Forgetting is the other side of remembering and is important in PC models to explain spontaneous recovery. The idea being that the information stream acquired in the extinction phase is forgotten over time, which then removes the inhibition of the information streams acquired in the acquisition phase. This process is offered as an explanation for the stronger spontaneous recovery response that is observed with greater time between extinction and recovery tests and thus supports the view that learning in the extinction phase dissipates more rapidly than learning in the acquisition phase (Brooks & Bouton, 1993; Rescorla, 2004; Sissons & Miller, 2009).

Studies on forgetting provide valuable insight into its significance in associative learning. Recent memories are

vulnerable to interference from other mental activity and Wixted (2005) suggested that forgetting is largely a function of nonspecific *retroactive interference* acting on memory traces that have not yet consolidated in the neocortex. Wang & Morris (2010) hypothesized that extinction trials involve reactivation of the acquisition-trial memories in the absence of further reinforcement. However, such interactions can be complex and two memories may mutually exclude each other or coexist depending on the timing of the signal during extinction (Perez-Cuesta & Maldonado, 2009).

Decision making is treated differently in PC and foraging models. In foraging models, the decision to leave a patch is depends on which patch has the higher reward probability (maximizing) or is selected probabilistically (matching) (Kacelnik, Krebs, & Ens, 1987). PC models do not have choice-based decision rules and express the response rate as a monotonic function of the reward expectation. However, if PC and foraging have the same basis, then PC models contain a hidden decision rule in which the animal chooses between proximal and distal information. However, decision rules in both PC and foraging models are incomplete because psychology, ecology, neuroscience, and machine learning research show that uncertainty in the reward assessment is an important factor in decision-making (Daw et al., 2005; Platt & Huettel, 2008).

The Model

We now develop a model for PC that has application to foraging models, draws on concepts from both modeling frameworks, and has some analogy to the neurology of decision-making. We model reward probability estimates for distal and proximal information streams, which correspond to the immediate patch and the surrounding habit in foraging models and to the short- and long-term estimates of rewards in PC models. We then combine the estimates with weightings based on their respective uncertainties. We also account separately for the process of learning that a signal can indicate a reward. Finally, we use the weighted expectation to model the animal's response rate in a trial.

Distal and Proximal Reward Estimates

For each trial we define the distal and proximal expected reward estimate with a modified delta model,

$$\hat{x}_{j,i} = m_j y_i \delta_{j,i-1} + \hat{x}_{j,i-1} \quad (1)$$

where $j = 1, 2$ indicates distal and proximal information streams, i designates a PC trial, m_j is the learning rate for stream j . For each stream the error between the expected reward probability and realized reward is

$$\delta_{j,i} = x_i - \hat{x}_{j,i} \quad (2)$$

where x_i is a reward/no-reward outcome (0,1) for trial i . The term, y_i , is a measure of the strength of the association of the signal-reward and is independent of reward probabilities. For convenience, we consider the distal and proximal information streams *unconscious* reward estimators because individually they are sub-process that must be combined to

affect the animal's response. We designate the combined estimator the *conscious* reward estimate.

Combined Estimate

The distal and proximal estimates of reward probability are combined into a single conscious reward estimate that the animal uses in making decisions:

$$\tilde{x}_i = w_{1,i}\hat{x}_{1,i} + w_{2,i}\hat{x}_{2,i} \quad (3)$$

where the estimates are combined according to their respective weighting factors that depend on their associated uncertainties $\tilde{\delta}_{j,i}^2$. As we develop next, the uncertainties are in fact EWMA's of the variance in the distal and proximal estimators and so the estimates can be combined using a standard statistical weighting formula in which the weight for estimate j on trial i is

$$w_{j,i} = \left(1/\tilde{\delta}_{j,i}^2\right) / \left(1/\tilde{\delta}_{1,i}^2 + 1/\tilde{\delta}_{2,i}^2\right). \quad (4)$$

It is noteworthy that this weighting scheme is not found in either PC or foraging models.

Temporal Discounting Uncertainty

The uncertainties used in weighting, $\tilde{\delta}_{j,i}^2$, are developed from the mean-squared errors of the distal and proximal reward estimates. Of relevance, the uncertainties depend on the time between trials as follows. First, compute unadjusted uncertainty estimates as EWMA's from errors defined by eq. (2):

$$\hat{\delta}_{j,i}^2 = n(\delta_{j,i-1}^2 - \tilde{\delta}_{j,i-1}^2) + \tilde{\delta}_{j,i-1}^2, \quad (5)$$

where n is the uncertainty learning rate. Next, adjust the uncertainties for the time interval $\Delta t = t_i - t_{i-1}$ between trials:

$$\tilde{\delta}_{j,i}^2 = \hat{\delta}_{j,i}^2 h_j^{\Delta t} \quad (6)$$

where h_j is a decay parameter that controls the rate at which the uncertainty in information stream j decays as time between trials increases. In this model, as the inter-trial time increases, we want to put more confidence on the distal (long-term) estimate and less on the proximal (short-term) estimate. The idea being that in a sequence of trials with uncertain outcomes, as time passes since the last trial we should trust the long-term estimate of reward probability more than the short-term estimate based only on the last few rewards. To insure this shift in confidence to the distal estimate, we decay the distal uncertainty but not the proximal uncertainty as time passes between trials: Mathematically this is achieved with $0 < h_1 < 1$ and $h_2 = 1$.

Signal-Reward Association

The term y_i in eq. (1) tracks the strength of the signal-reward association, which we assume is distinct from probability learning but also depends on the error of predictions. Learning requires repetition and reduction of errors in prediction, and we model these properties with a three step process. First, we track conscious error based on the difference between the trial outcome and the conscious expectation from eq. (3) giving

$$\delta'_i = x_i - \tilde{x}_i. \quad (7)$$

Second, because errors are by nature random and one correct prediction, $\delta'_i = 0$, is insufficient to develop an association, we compute an average error with a EWMA:

$$\tilde{\delta}_i^2 = n(\delta_{i-1}^2 - \tilde{\delta}_{i-1}^2) + \tilde{\delta}_{i-1}^2. \quad (8)$$

where n is again the uncertainty learning rate. Third, to capture the repetitive and asymptotic nature of appetitive learning, we incrementally accumulate the uncertainties with a standard saturation function

$$y_i = \sum_{k=1}^{i-1} 1/\tilde{\delta}_k^2 / \left(g + \sum_{k=1}^{i-1} 1/\tilde{\delta}_k^2 \right) \quad (9)$$

where g is the halfway point in the learning process.

Response Rate

We relate the conscious reward expectation to the response rate with a matching function that asymptotically increases a response from a background level to a maximum and is defined with scale and shape parameters r_{max} and r as

$$R = r_{max} \tilde{x}_i / (\tilde{x}_i + r(1 - \tilde{x}_i)). \quad (10)$$

Parameter Summary

The complete model combines elements of classical associative learning and patch foraging. While several models contain multiple memory streams that track information over different time scales, the model presented here tracks the uncertainties in the estimates as information streams as well. The model contains 7 parameters (Table 1).

Table 1: Model parameters and values fitted to data.

Parameter	Fitted value	Meaning
m_1	0.055	Distal learning rate
m_2	0.248	Proximal learning rate
n	0.075	Uncertainty learning rate
h_1	0.126	Distal uncertainty decay rate
g	971	Association half-way constant
r_{max}	6.88	Response function scale parameter
r	0.13	Response function shape parameter

Comparison to Experiment

To demonstrate the flexibility and perspective the model provides, we fit it to a study of partial reinforcement extinction conducted by Haselgrove, et al. (2004). We selected this experiment because PREE is difficult for PC models to explain. In addition, the study covers an acquisition phase and two extinction phases, which demonstrate spontaneous recovery. Several models produce these basic patterns but not when one of the groups is trained with partial rewards.

In the experiment, rats divided into partial and continuous reinforcement groups received the same signal and number of rewards during an acquisition phase in which the reinforcement schedules differed. In the partial group, half of the trials were reinforced with two rewards, while in the continuous group one reward was given on every trial. Following the acquisition sessions, the rats received two sessions with unreinforced signals. In Figures 1-3, each point designates an entire session in the acquisition phase, while each point represents a block of two trials in the two extinction sessions following.

We fit the model to the data from both groups with a single set of parameters (Table 1) using the “mco” package in the R statistical programming language. This is a multi-criteria optimization algorithm based on a genetic algorithm (cran.r-project.org/web/packages/mco/mco.pdf).

The model fit the response patterns for the continuous and partial groups reasonably well. The mean responses in the acquisition phase developed in a similar manner for both groups, while in the extinction phase the continuous group response decayed more rapidly than the response in the partial group. Both groups exhibited spontaneous recovery in the final extinction session with the continuous group response again decaying faster than the partial group response (Figure 1).

Figure 1: Haselgrove et al. (2004) data and model fit for partial and continuous reinforcement groups using parameter values in Table 1.

Discussion

The patterns of the underlying streams producing the fit to the Haselgrove et al. (2004) data for the continuous reinforcement group (Figure 2) and the partial reinforcement group (Figure 3) illustrate how a framework of multiple-scale estimators and uncertainties can account for seemingly complex patterns in PC studies. As in Figure 1, the first section consists of session averages for the acquisition sessions, and the next two sections each represent an extinction session in blocks of two trials.

Continuous Reinforcement Group In Fig. 2a the signal-reward association strength, y , rises over the acquisition phase to its full value and remains constant thereafter, implying that the animal has fully learned the association. The conscious reward probability also reaches its full value in the acquisition phase and then exponentially declines in the extinction phases. At the beginning of the second extinction phase, the expectation is higher than at the end of the first extinction phase, then the expectation again decays since the animal receives no rewards. This somewhat complex pattern of responses is generated by a unique weighting of relatively simple patterns in the distal and proximal estimators. The proximal estimator (Figure 2b), which is generated by a faster learning coefficient, rises quickly in the acquisition phase and then decays quickly in the first extinction phase and remains at zero throughout the second extinction phase. The distal estimator, being the slow learner, rises slowly in the acquisition phase and then decays slowly over the next two phases. The pattern in the weights (Figure 2c) that mix the two estimators produces the spontaneous recovery. Beginning in the acquisition phase, the weightings are equal. Because rewards are consistently received, the proximal estimator quickly adjusts and has less uncertainty than the distal estimator, giving the distal estimator the greatest weight in forming the conscious estimator in eq. (4). In the period between the acquisition and extinction phases, eq. (6) decays the distal uncertainty (trust the long-term estimate when information is old), so the two weights are nearly equal beginning the extinction phase. However, as signals are consistently unrewarded, the proximal estimator better represents the environment and its weight rises over the trials. The distal uncertainty decays again after the first extinction phase, and the pattern is repeated in the second extinction phase. At the beginning of the second extinction the proximal estimator, which predicts a reward, has a higher weight than the distal estimator, which predicts no reward, so the animal exhibits spontaneous recovery.

Partial Reinforcement Group In the acquisition phase, the patterns of conscious expectation and the signal-reward association (Figure 3a) are similar to the patterns in the continuous reinforcement group (Figure 2a), although the strengths are half the continuous reinforcement values. The patterns in the distal and proximal estimators are similar also (Figure 3b), and again the strengths are about half showing the accurate estimation of the 50% reward probability during acquisition. However, the experiments differ significantly in the weighing function patterns. These are reversed in the partial reinforcement group (Figure 3c) compared to that in the continuous reinforcement group (Figure 2c). This difference drives the differences in the response patterns (Figure 1). Again, at the beginning of the experiment, the distal and proximal uncertainties are equal, making for equal weights. However, both estimators

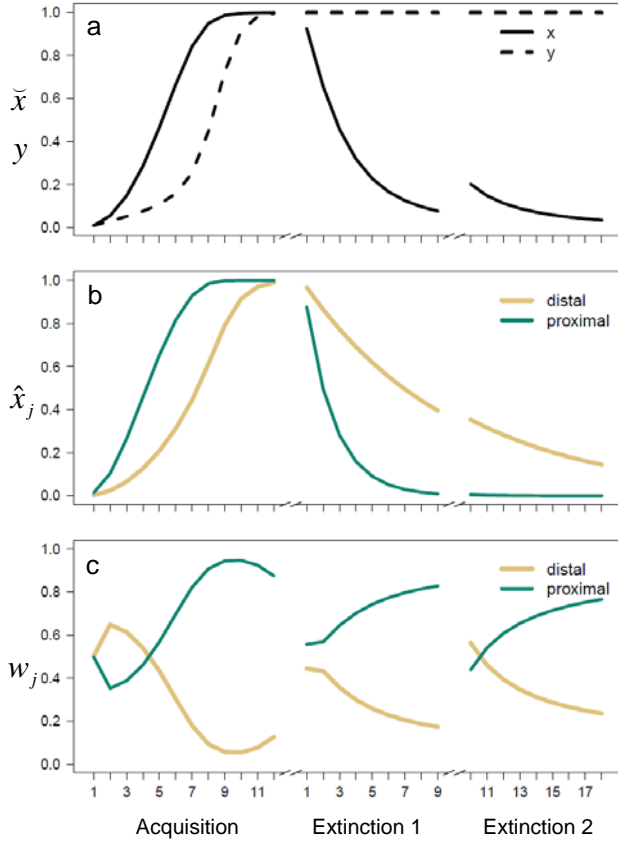

Figure 2: Changes in model variables for the continuous reinforcement group.

have higher uncertainty with partial reinforcement, but the proximal estimator, which is strongly influenced by the previous trial, has higher uncertainty than the distal estimator, which integrates the reward expectation over multiple trials. The result is lower uncertainty for the distal estimator and thus greater weight in forming the conscious estimator. Between the acquisition and extinction phases, the distal uncertainty declines while the proximal uncertainty is fixed, so the distal estimator is dominant at the beginning of the first extinction phase. Over the phase the distal uncertainty increases while the proximal uncertainty decreases until they are equal at the end of the extinction. Therefore, at the end of the extinction phase, the animal has a higher response rate than in the continuous case, which is dominated by the proximal estimator. Between the first and second extinction phases, the distal estimator uncertainty again decays giving it more weight in the second extinction phase, resulting in a higher response and slower decline in response for the partial acquisition group.

Neurological Analogies

As our ultimate goal is to model the brain, not just observed behavior, we seek to identify possible equivalences between the model's elements and neural structures as has been encouraged by Rangel et al. (2008) and others. In a broad

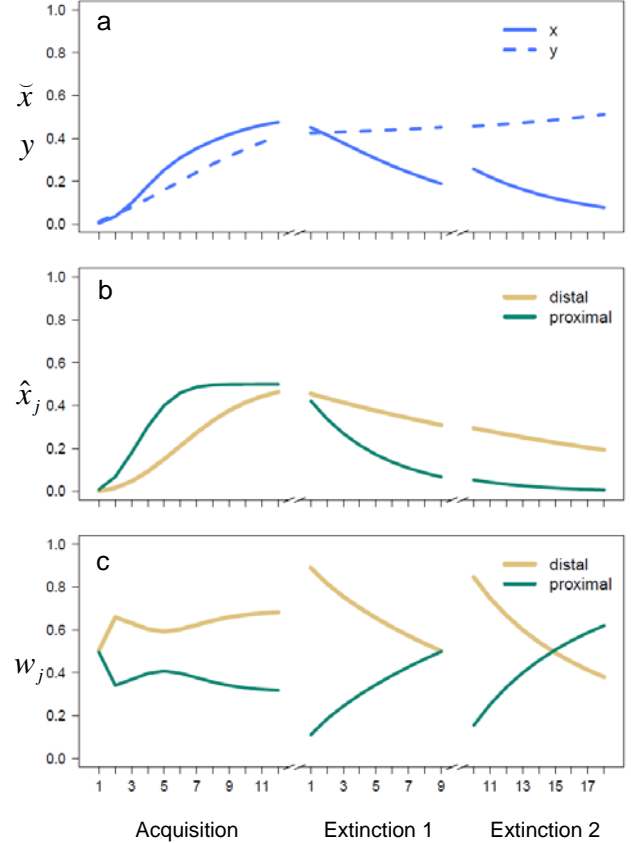

Figure 3: Changes in model variables for the partial reinforcement group.

sense, we suggest that the distal and proximal information streams $\hat{x}_{1,i}, \hat{x}_{2,i}$ represent parallel memory systems that characterize reward probabilities estimated on different temporal scales. These terms might be candidates for STM-LTM systems involving the hippocampus and neocortex. However, the two streams are competitive and so they might be representative of competitive memory systems such as the hippocampus and basal ganglia (White & McDonald, 2002; Poldrack & Packard, 2003). In our model the signal-reward association y_i represents a separate memory stream that builds in a cumulative manner by summing the inverse of trial-by-trial uncertainties. This incremental building of memories is also a feature of the STM-LTM interaction of the hippocampus and neocortex (McClelland, McNaughton, & O'Reilly, 1995).

Uncertainty is specifically formulated in our model, and neural structures are clearly involved with uncertainty in decision-making. For example, Doya (2008) noted uncertainty has two flavors: one resulting from the environmental stochasticity (risk) and one from the limited knowledge of the decision-maker (ambiguity). Studies suggest that risk is represented in the striatum and precuneus while ambiguity is represented in the lateral orbitofrontal cortex and amygdala (Platt & Huettel, 2008). Our model also has two flavors of uncertainty. The

uncertainty in the distal and proximal reward estimators $\hat{\delta}_{j,i}^2$ tracks variability in the environment that we suggest is akin to risk uncertainty. The uncertainty in signal-reward association $\hat{\delta}_i^2$ is a candidate for the decision-maker's ambiguity.

Final Thoughts

Under the assumption that animals in laboratory studies use behavioral strategies and neurological processes that evolved through natural selection, we reconsider Pavlovian conditioning in the context of animal foraging. From this perspective, animal behavior in a constrained environment has a hidden spatial component that leads us to consider the behavior in terms of distal (habitat) and proximal (local patch) information streams. In this framework the animal does not track distinct memory streams for acquisition and extinction phases, which we suggest is the experimenter's perspective. Instead of having to know when the experimenter ends one phase and starts another, the animal can view the environment as continuous yet random and simply track information measuring over two different time scales and weighting the estimates according to the trial-by-trial changes in their uncertainties.

Abstract

People use sanctioning behaviours differently according to what they believe and want to achieve, according to the context and to the situation. We need to understand the motivations for different forms of punishment in order to explain why sanctions and incentives have different effects on human behaviour. Aim of this work is to propose a cognitive model of three distinct kinds of punishing behaviours, differentiated in terms of the defining cognitive patterns.

Keywords: Cognitive modeling; Punishment; Cooperation.

Introduction

Punishment is a core mechanism to enforce and support social order, to promote cooperation and to prompt group beneficial behaviours. Social scientists have long debated on the nature and the effects of this mechanism, but there are many questions still open, as for instance the relationship between counter-punishment and cooperation. There is a growing body of evidence that altruistic punishment plays a crucial role in enforcing cooperation and in promoting group welfare (Fehr & Gächter, 2000, 2002), but some recent experimental results raised the problem of antisocial punishment, that is sanctioning people who behave socially. Herrmann, Thoni, and Gächter (2008) compared results on punishment and cooperation collected in sixteen different participant pools around the world. They showed the emergence of antisocial punishment in repeated public goods experiments, and proposed that differences can be explained in terms of different societal background. Nikiforakis and Engelmann (2008) used a public good game with multiple punishment stages aiming at investigating whether retaliatory behaviours would escalate into a feud. Interestingly, cooperation rates declined but feuds were avoided by participants.

Although a number of accounts (for some representative work see (Bowles & Gintis, 2004; Henrich & Boyd, 2001; Henrich et al., 2006) have stressed the relevance of punishment in human societies, they suffer the flaw that they consider punishment as a unique behaviour. In our view, punishing actually consists in a complex behavioral

repertoire in which it is useful to disentangle at least revenge (social-status punishment), retaliation (strategic punishment) and sanction (normative punishment).

Treating punishment as a single behaviour without caring for its cognitive foundations could be misleading especially if one is interested in explaining cooperation and its maintenance in evolutionary terms. There is neither a single form of punishment nor a single motive to punish other people, and the question is: How can we distinguish between punishment aimed at making the individual internalize the norm and pure revenge? How do people choose between punishment and revenge?

Cognitive modelling allows us to disentangle apparently indistinguishable acts and to understand the motives and objectives that pave the way to distinct ways of punishing. Taking revenge is not the same as punishing a wrongdoer or sanctioning a deviant behaviour, and explaining these differences and the related motivations could effectively advance research on cooperation and prosocial behaviours under several respects.

The rest of this article is organized as follows. Firstly, we will introduce a general theory of cognitive social action, in order to provide some basic concepts. Secondly, revenge will be analyzed, focusing on the explicit mental representations behind it. Therefore we will turn our attention to punishment, showing what is inside the punisher's mind. Finally, sanction will be described. Future work and conclusions will follow.

The cognitive roots of social behaviour

In general, this work aims at unveiling the proximate mechanisms of enforcement behaviours, in order to understand the mental mechanisms underlying revenge, punishment and sanction.

Before these arguments are developed, some terminological issues need clarification. As stated elsewhere (Conte & Castelfranchi, 1995), an agent is a goal-governed system.

By this, we mean an entity, not necessarily autonomous, that has the capacity to act upon the external world in order to reduce the discrepancy

between the world itself and some regulatory state that is somehow represented within the entity (p.1).

A cognitive agent is endowed with cognitive representations of the external world and of its internal states as well. Agents have *beliefs* about themselves and the world and they act on the basis of their *goals* to reduce the discrepancy between the world and what they want.

There are several ways to influence agents, but here we refer to *cognitive influencing* (Cialdini & Goldstein, 2004; Conte & Castelfranchi, 1995), a process by which a given entity, say *Ii*, acts on another entity, *mj*, in such a way that a given goal of *mj*'s be strengthened or generated anew. Notice that, since *mj* is an autonomous intelligent system, *Ii* must act on her beliefs in order to strengthen or generate new goals and modify her behaviours. We will address here the *goal-generation process*, as strengthening an existent goal is only a weaker case of cognitive influencing. To strengthen or generate a new goal, *mj* must acquire a new belief, say *Bjp* (*Ii* will harm *mj*, if she does not apply his will). This belief will activate a previous goal of *mj*'s, *Gjp* (avoid harm), and the interaction between *Bjp* and *Gjp* generates a new instrumental goal in *mj*'s, *Gjq* (adopt *Ii*'s will)¹.

This is a social plan of action, which is based on a complex variant of the *theory of mind*. In the classic theory of mind (Leslie, 1991; Baron-Cohen, 1991; Dennett, 1987; Premack & Woodruff, 1978), others' mental states are harboured in one's mind, giving rise to *social beliefs*, namely beliefs about others' mental states (e.g. beliefs, intentions, desires, emotions, etc). In cognitive influencing, instead, the influencing entity has *social goals* as well, i.e. goals about others' mental states.

As we will see in the following sections, the presence and the type of cognitive influencing permits to discriminate between apparently similar enforcing mechanisms that are actually very different.

The three punishing strategies can be arranged on two axes: cognitive complexity and intentionality of deterrence. In this way, revenge easily appears to be the lowest in cognitive complexity and to pursue deterrence as an emergent and unintended self-reinforcing effect. The opposite is true for sanction (high cognitive complexity and intentional deterrence), whereas punishment occupies an intermediate position.

Revenge

Revenge appears to be a common human trait, widespread in human history and societies. According to the Merriam-Webster dictionary, vengeance is *punishment inflicted in retaliation for an injury or offense*.

¹By means of the so called adoption rule (Conte & Castelfranchi, 1995), according to which an autonomous agent (adopter) will have another agent's (adoptee) goal as her own, if she, the adopter, comes to believe that the adoptee's achievement of this goal will increase the chances that the adopter will in turn achieve one of her previous goals.

The retaliatory aspect is the main feature of revenge and is what makes this form of reaction differing from the two forms of punishment described below. Vengeance is also strongly characterized by the presence of emotional aspects that contribute to the common view of revenge as a not fully rational behaviour.

This "flavour of irrationality" could have contributed to the paucity of interest in revenge, compared to punishment, among scholars. While justifications for punishing and individual motives to punish have been widely investigated, research on retaliatory actions has considered them either as tribal and archaic forms of norm enforcement (Boehm, 1986) or as genetic predispositions evolutionary evolved to react to aggressions (Elster, 1990).

Amegashie and Runkel (2008) present a differential game model of revenge in conflicts. In their model, revenge has a positive value in economic terms; this means that, however destruction is costly, given what has been suffered in the past, the victim derives satisfaction and then utility from exacting revenge in the present. Similarly, deQuervain et al. (2004) used neuroscientific methodology to investigate how brain regions reacted to defection in an interaction game. According to Knutson (2004) their results show that punishing a defector activates brain regions related to the anticipation of a reward, even when punishment was costly, thus explaining human preference for punishing violators. Interestingly, Nikiforakis and Engelman (2008) reported data on revenge causing collaboration to decline in the lab but without boosting a chain of reciprocal vengeance.

Broadly speaking, the term 'revenge' refers to two diverse but connected phenomena. On one side, revenge is a social ritual that requires and prescribes specific behaviors to group members to repair an offense. The Kanun, a customary set of laws used mostly in northern Albania and Kosovo, disciplined people's reactions to murder (blood revenge or *gjakmarrje*) and other offenses (*hakmarrje*) according to the roles and degree of kinship of all the people involved. Shirking revenge or taking it without respecting what is stated in the Kanun lead to the same result: honour can not be restored and the whole family or clan is to blame. Shackleford (2005) considers "cultures of honor", in which revenge is the primary form of reaction to aggressions, likely to emerge and be maintained where the state is weak and can not prevent or punish theft.

It is worth noticing that in general retributive concepts of law and the creation of institutions are considered as advancements to replace vengeance and avoid blood feuds², but the Kanun itself was a social institutions aimed at preserving social order (KLD, 1989).

On the other side, revenge is an individual behaviour

²In this work we are not interested in analyzing the emergence and function of blood feud and we consider revenge in isolation

found both in human (Zaibert, 2006) and non-human primates (Jensen, Call, & Tomasello, 2007), reacting to personally harmful actions.

As Elster observes, revenge is "the attempt at some cost or risk to oneself, to impose suffering upon those who made one suffer, *because they have made one suffer* (emphasis added)".

In our view, revenge serves a terminal goal, that of making the aggressor suffer, and this excludes any other concerns. Usually, vengeance occurs in groups of equals, in which the offense is perceived also as an attempt to reduce an individual's prestige, to declass him or her family. Repaying the offense becomes a way to reaffirm one's status in front of both the aggressor and the social group and this behaviour is far from being extincted in present societies.

It is worth noticing that revenge may act as a deterrent from further aggressions, but this is an emergent function that can not be even represented in the avenger's mind. Revenge is not pursued to affect the likelihood that the wrongdoer will repeat the aggression in the future, inducing her to cooperate next time or deterring her from further aggressions. The avenger wants to repay the damage she suffered with an equal or greater offense, no matter how much risky or dangerous this retaliation is. In a sense, we can say that the avenger is a "backward looker" that revolves around the past and acts in the present to rebalance what happened, without any concerns for his future.

Into the avenger's mind

We claim that vengeance entails a specific configuration of goals and beliefs and that this configuration differs from those implied by terminal and instrumental punishment. This means that, although the punisher and the avenger could perform the same action, their aims and intentions were deeply different as well as the resulting state of the world.

In order to describe revenge, we need first to introduce its actors. There are at least three roles agents play in revenge. There is the avenger (A), the Target (T), and the Onlookers (O). The avenger's beliefs and goals involve both the target (T) and the onlookers (O), whose presence, as we shall see, is crucial.

Looking into the avenger's mind, we find a set of beliefs that are necessary to trigger the desire to take revenge³. The offended agent should, at least, believe that (1) the offense he received was intentional, (2) T was the main or the unique responsible and then liable for punishment, (3) there is a material and/or symbolic dimension to be restored in front of T and O.

The above set of belief should be paired with a set of goals, also necessary to trigger the retaliatory response.

³Here we are not concerned with the actual punishing behaviour chosen by the actor, but we are interested in investigating which behaviours he considers the most appropriate

We identify at least three distinct goals: one referred to the material action, and the other two related to the influence the avenger wants to exert on the victim's and audience's representations. In fact, revenge is not motivated only by the desire of making the target suffering, but achieving this goal is pivotal to the objective of changing the target's and audience's beliefs about the avenger. What matters is what the others believe about the avenger and not what they are expected to do next time they are required to cooperate, as it is in punishment. In this case, cognitive influencing is aimed at modifying only the beliefs of the target and the onlookers, as depicted in Figure 2.

$$(Gx) \longrightarrow (By)$$

Figure 1: Cognitive Influencing in Revenge

The avenger's action is driven by the following goals: first, the goal of imposing a suffering on the target; second, the goal of changing the target's beliefs, making her aware that the avenger does not passively accept the aggression and is able and willing to strike back at the aggressor (influencing the target). Finally, there is the goal of changing the beliefs of the onlookers (influencing the onlookers). In revenge the audience plays a crucial role because the damage suffered is not only material, but it usually has a strong symbolic component. Honour, for instance, is an intangible asset that can be threatened by the aggressor and that can be restored only if there is an audience in front of which the retaliatory action is performed and that recognizes that action as an attempt of restoring the initial situation.

This picture needs to be enriched by some additional considerations. First, the avenger can strike back at the aggressor's family or closer relatives, because they share some common traits. Posner (1980) views this issue the other way around: family obligation to retaliate is needed to make the threat of revenge work as a deterrent.

Another relevant issue is the cost-benefit analysis the avenger could carry out in order to choose the best conduct. According to Elster (1990), the retaliator does not calculate pros and cons of her action, but simply react to the offense. In our view, the avenger considers benefits and costs, but in her utility function there is an element that overrule any other consideration, that is the symbolic gain in terms of respect, honour, power, etc. the revenge allows to take.

Kant, I. (1952). The science of right (W. Hastie, Trans.). In R. Hutchins (Ed.), Great books of the Western world: Vol. 42. Kant (pp. 397 446).

Punishment

Punishment is a more controversial phenomenon, as shown by the two following definitions explaining the competing views on it:

Punishment is the practice of imposing something unpleasant or aversive on a person or animal, usually in response to disobedient or morally wrong behavior (Stanford Encyclopedia of Philosophy, Punishment).

[...] individuals (or groups) commonly respond to action likely to lower their fitness with behaviour that reduces the fitness of the instigator and discourages or prevents him or her from repeating the same action (Clutton-Brock & Parker, 1995).

According to the first view, punishment is meant to *righting* a wrong, while the second one stresses the influencing aim of punishment, that of discouraging or *preventing* an agent from repeating the same action.

The first one is a *retributive approach* to punishment: a person deserves a punishment that is *proportionate* to the moral wrong committed. Unlike revenge, punishment is proportionate to the offence. Immanuel Kant (Kant, 1952) argued that punishment can never be administered merely as a means for promoting another good and should be pronounced over all criminals proportionate to their internal wickedness (p. 397). Its justification lies in righting a wrong, not in achieving some future benefits. The punisher wants the victim to perceive punishment as a *natural consequence* of offence: the greater the offence, the greater the punishment. We can find such a view either in the *lex talionis* of early Roman law and in Old Testament and Koran.

In the second view, punishment is assigned a *deterrent effect*: it reduces the frequency and likelihood of future offences. This approach is referred to as utilitarian and is most often attributed to Jeremy Bentham (Bentham, 1962). Based on the rational choice model, deterrence theory works by modifying the *costs* and *benefits* allowed within the circumstances so that the criminal activity becomes an *unattractive* option⁴.

According to these two views on punishment, we can say that the punisher is either a *backward-looker* and a *forward-looker*. The punisher aims to *repay* the damage she or someone else suffered with an offence *proportionate* to the one suffered, and to minimize the chance that the attacker will repeat the aggression in the future, thus *detering* him from further hostility.

This enforcing mechanism, controlling modern societies, is not at all easy to distinguish from revenge, but we suggest that the punisher and the avenger are aimed

at modifying the target and the audience's minds in different ways: unlike the latter, the punisher has the *explicit* goal to interrupt the chain of aggressions, with the further effect of preventing blood feuds and giving more stability to the social order.

Into the punisher' mind

Here follows a description of the punisher mental configuration - in terms of beliefs and goals. In order to trigger the punishing response, the offended agent should display the following beliefs (it is not necessary that he has all of them): (1) the damage/offense had a locus of responsibility then liable for punishment, (2) there is a material and/or symbolic damage to be refund and finally (3) the offense/damage will be repeated in the future, so that punishment might be useful to avoid such a re-iteration.

The above set of beliefs should be paired with a set of goals in order to trigger the punishing response. We identify the following set of distinct goals. More precisely, P aims at imposing an offence proportionate to the one suffered (*retributive goal*), and/or at establishing or maintaining a dominance hierarchy, and at deterring T (and possibly O) from further hostility (*deterrence goal*).

In order for the latter goal to be satisfied, P can employ different means, here we will focus on cognitive influencing. In order to achieve it, P has to act in such a way that the following belief is generated in T's and O's minds "P will harm me/will impose a cost to me, if I do not apply his will that the aggression will not be repeated in the future". This belief, *By*, will possibly activate a *previous* goal of T and O, *Gz* (avoid harm/avoid the costs of punishment), and the interaction between *By* and *Gz* will generate a new *instrumental* goal in T and O's minds, *Gy* (abstaining from repeating the aggression in the future). Social emotions - such as feeling of guilt - play a crucial role in achieving deterrence.

$$\boxed{Gx ((By) \longrightarrow (Gy))}$$

Figure 2: Cognitive Influencing in Punishment

Sanction

A particular case of punishment is that intended to deter future offences in observance not more of the punisher's will, but of a specific (social) *norm*. We refer to this case as (informal) *sanction*. In our view, a sanction is a particular case of cognitive influencing in which the sanctioner wants to modify the future action of T, making him form *two* beliefs at once: (i) a *normative belief* about the existence of a certain norm, and (ii) and the belief that T did violate that norm. Such a plan, which is incorporated to the act of sanctioning, is aimed at inducing the target to abstain from further offences not only

⁴It has to be said that deterrence can also be achieved through reinforcement learning, as suggested by behaviorism.

in order to avoid the sanction, but in order to *respect* the norm.

In our view, a norm - be it social, legal or moral - is a two-sided, internal (mental) and external (social), object, coming into existence only when it emerges, not only through the minds of the agents involved, but also *within* their minds (see (Conte & Castelfranchi, 2006; “On the Immergence of Norms: a Normative Agent Architecture”, 2007). In other words, norms work as such only when agents recognize them and take decisions upon them as norms. Only when the normative, i.e. prescriptive, character of an input is recognized by the agent, that input gives rise to a normative behaviour of that agent. In order for the norm to be satisfied, it is not sufficient that the prescribed action is performed, but it is necessary to comply with the norm because of the *normative goal*, that is, the goal deriving from the recognition and subsequent adoption of the norm. Thus, for a norm-based behaviour to take place, a normative belief has to be generated into the minds of the norm addressees, and the corresponding normative goal has to be formed and pursued.

Unlike the punisher, the sanctioner aims at drawing the target’s and the audience’s attention on the existence and violation of the norm and on the fact that there is an high rate of surveillance. Our hypothesis is that sanctioning is characterized by a *signalling* function that has the aim of making explicit the casual link between violation and sanction: “you are being sanctioned because you violated that specific norm”. Focusing T attention on the fact that the sanction is a consequence of a norm violation, possibly has the effect of encouraging the sanctionee to accept it as an *entitled* act, thus avoiding reiterated aggression (like in revenge) (see also (Bandura, 1991; Xiao & Hauser, 2009).

We also claim that sanction has the further effect, possibly aimed at by the sanctioner, to encourage the target to ground future decisions on *internal* evaluative criteria, established by the norm. This argument needs further elaboration, of course, and in order to test our hypothesis, we plan to conduct a series of laboratory experiments adopting a game-theoretical framework.

While imposing sanctions to them, we often request our children, pupils, etc. to observe the norm for its own sake. Isn’t this behaviour irremediably paradoxical? However, it is far from an exception: it appears to be a *pedagogic* strategy rather frequent at least in Westernized societies. In sanction, the penalty is inflicted with the aim to favour a full autonomous compliance with the norm. How is this possible? A plausible explanation calls into question mechanisms of *norm internalization* (Durkheim, 1951; Scott, 1971; Gintis, 2004; Bicchieri, 2006; Bowles & Gintis, 2003). In particular, under conditions and by mechanisms that require specification (see also, (“On norm internalization”, 2009), agents

internalize external enforcement, converting it into self-enforcement, based on self-esteem and moral emotions, like the feeling of guilt.

Into the sanctioner’s mind

In order to trigger the sanctioning response, the agent (S) should believe that (1) a norm has been violated. Regarding the motivations, there are at least two distinct goals that S aims to achieve. The first one is that of generating or reinforcing into the T’s and O’s minds a normative belief (NB) about the *existence* of a certain norm, and the belief that T did *violate* that norm. We will call this goal, a *pedagogic goal*. The second goal of S is that of making the norm be respected thus avoiding that the violation would happen again (*deterrence goal*) (Gx). In order for the latter goal to be satisfied, S has to act in such a way that the normative goal (I want to comply with the norm) will be activated. Once the normative goal has been activated, the agent will decide whether to adopt it or not. He can decide to obey a norm for instrumenental and terminal reasons. In the former case, the agent comply with the norm only to avoid punishment. In terminal norm adoption, agents decide to comply with the norm because “noms must be obeyed”.

Such a plan, which is incorporated to the act of sanctioning, is aimed at inducing the target to abstain from further offences *not* only in order to avoid the sanction, *but* ideally in order to respect the norm. This kind of cognitive influence is the most complex, since it entails not only goals and beliefs but also the Normative Goal.

$$\boxed{Gx ((NB)y \longrightarrow (NG)y)}$$

Figure 3: Cognitive Influencing in Sanctioning

To some extent the advantages of sanctions are easily identifiable: norm compliance is expected to be more robust than is the case when conducts are ruled only by external punishment: under ideal conditions agents abstain from violating because they want to respect the norm and not only in order to avoid punishment. Hence, sanctioned agents are expected to be more consistent and compliant than punished and endogenously motivated agents. A further consequence is that agents come to be much better at *defending* the norms: a consequence of the latter prediction is that sanction is decisive, if not indispensable, for *distributed* social control. A positive desired effect of sanction is an overall lowering of the costs associated to the social enforcement.

Conclusions and Future work

In this work we applied cognitive modelling to investigate the mental underpinnings of three different systems of norm enforcement: revenge, punishment and sanction. We argue that these are distinct behaviours people

choose in accordance with what they believe and want, thus entailing specific mental configurations. We also argue that without unraveling these cognitive bases, we can not fully explain complex phenomena like cooperation and altruistic punishment. Moreover, we claim that the transition from one to the other has been allowed by specific cognitive patterns, and suggesting that these mental mechanisms selected among given social structures, at the same time reinforcing and being reinforced by them. This preliminary model will be enriched by a simulation-based study of the different forms of enforcement.

Abstract

We provide a new approach to how, why and with what results people think about opposing or paradoxical categories. Using a two-part laboratory study, we found differences in whether people in China and the US categorized “attempts to outperform others” as an instance of both competition and cooperation. We call membership in both categories in a paradox *integrative categorization*. We found that Chinese were more likely than in the US to engage in integrative categorization, and that the cultural difference was mediated by differences in lay dialecticism. Finally, we showed behavioral effects: integrative categorization predicted peoples’ cooperative behavior after they experienced others’ attempt to outperform them.

Keywords: Categories; paradox; competition; cooperation; competition; culture; dialecticism; China.

Introduction

Opposing categories, such as *past* and *future*, *nature* and *nurture*, or *habit* and *originality*, can be powerful organizers of cognition and action if they demarcate endpoints of important causal dimensions. Alternatively, they can distort cognition and action if they impose too simple a distinction on a complex space of possibilities. When faced with opposing categories, people could try to determine what the right answer is: what are the properties of the two opposing categories, are they endpoints of a single dimension and hence mutually exclusive, and does that dimension capture important causal forces in a domain of knowledge and activity. Alternatively, people might rely on general reasoning tendencies about how categories relate to one another and on the guidance of their cultural norms. Because most categories that people think about are complex and ambiguous in practice, a logical examination of the properties of an instance and whether those properties do or do not warrant category membership may not be possible. People may instead take predictable shortcuts in their reasoning about categories, with predictable consequences.

The specific case of opposing categories that we examine is the case of cooperation and competition. We study how people in China and the US understand these categories and

the consequences for their behavior. Cooperation and competition are important categories. They are central to what it means to interact with others, be it in groups, organizations, industries or societies (e.g., Deutsch, 1949; Johnson & Johnson, 1989; Tyler & Blader, 2000).

Most research defines and operationalizes cooperation and competition as opposites (e.g., Bettenhausen & Murnighan, 1991). According to these views, individuals are either in a competitive situation or in a cooperative situation (Deutsch, 1949), either wanting to compete or wanting to cooperate (McClintock & Allison, 1989), or either acting competitively or acting cooperatively (Komorita & Parks, 1996). All of these views predict that the absence of cooperation indicates the presence of competition (and vice-versa) and treat the co-occurrence of both cooperation and competition as a contradiction.

Recently, an alternative theoretical perspective has emerged that conceptualizes cooperation and competition not as opposites, but distinct dimensions, which allows cooperation and competition to co-occur (“coopetition,” Brandenburger & Nalebuff, 1996; Tsai, 2002). For example, an individual might have a general disposition towards wanting to help others (a cooperative personality). At the same time, the individual might also like to be the most highly rewarded (a competitive personality; Xie, Chen, Yu, & Chang, 2006). All of these views predict that knowing about the presence or absence of cooperation will be uninformative regarding the presence or absence of competition.

There is a third logical possibility that no theory has yet defended but that is possible and empirically observable (Keller & Loewenstein, 2010). This is that cooperation and competition can at least partially overlap. At least in some cases, the presence of cooperation implies the presence of competition.

We provide a general framework for understanding how opposing or paradoxical categories can be related. We treat cooperation and competition as cultural categories (Atran, Medin, & Ross, 2005; Keller & Loewenstein, 2010; Sperber & Hirschfeld, 2004). Cultural categories are social conventions (Millikan, 2005) generated by cultural groups

for labeling and grouping sets of objects, practices, actors and other socially experienced examples (Douglas, 1986; Hannan, Pólos, & Carroll, 2007). Social conventions can also guide how people think about the relationship between categories. The words that are used to label cultural categories have semantic relationships (Lyons, 1977). If two words have antonymic semantic relationships (Jones, 2002; Murphy, 2003), this would imply a social convention that the named categories are in opposition.

The presence of these two kinds of social conventions—conventions about category membership and conventions about antonymy provides leeway for culture to shape which kind of convention has priority. If antonymy conventions dominate, then category membership conventions should conform, maintaining the distinction between categories by making category membership mutually exclusive. If category membership conventions dominate, then this allows paradoxes to be integrated. This is because an example that has features representative of two categories can be a member of both categories (Rosch, 1978; Smith & Medin, 1981). If those two categories happen to be antonyms, this example's dual categorization, which we call *integrative categorization*, represents a general account of how to integrate paradoxes. This is novel; discussions of paradoxes and paradoxical cognition (e.g., Miron-Spektor & Argote, 2008; Smith & Tushman, 2005) have claimed paradoxes can be integrated but not analyzed how in general this can be done.

For example, the words “work” and “play” are perceived as antonyms (Glynn, 1994). This is so regardless of the specific activities that constitute work or play, which might even have overlapping features (Jones, 2002). If an “engaging task” has features of both work and play, and work and play are antonyms, then engaging tasks establish a categorization paradox. Forcing engaging tasks to be categorized as either work or play would maintain the work-play distinction. Allowing engaging tasks to be categorized as both work and play (i.e., the integrative categorization of engaging tasks) would integrate the distinction.

We test whether people believe that cooperation and competition are antonymic cultural categories. Previous literature has found that antonymic patterns are often consistent across national cultures (Raybeck & Herrmann, 1996). Thus, our focus is on whether people engage in integrative categorization for cooperation and competition.

Testing whether people integrate the categories of cooperation and competition through overlapping category membership requires identifying an act with features of both categories. According to Tyler and Blader (2000), the key feature of a cooperative act is that it is an attempt to benefit the group. According to Johnson and Johnson (1989), the key feature of a competitive act is that it is an attempt to attain a higher relative position than others. Assuming these are accurate descriptions of conventional lay beliefs as well, then an individual's attempt to outperform others within a team or organization has features of both cooperation and competition. This act represents an attempt to gain a higher

status and an increase in effort on group tasks. Therefore, it is possible to categorize an attempt to outperform others as an instance of both competition and cooperation. This act provides an opportunity for integrative categorization.

To be clear, integrative categorization does not require that all members of one category also be categorized as members of the other category. For example, attempts to undermine others are attempts to gain higher status (and hence representative of competition) by harming others, which is detrimental to group outcomes (and hence representative of non-cooperation). There is no need for integrative categorization to include attempts to undermine others as instances of both cooperation and competition.

Our account suggests that whether people categorize attempts to outperform others as an instance of both cooperation and competition is at least in part a function of social conventions. Social conventions can be generated at different social levels, yet for fundamental social categories like cooperation and competition, the social conventions are likely to be generated at the level of the society because the categories are used in many social contexts (Keller & Loewenstein, 2010).

Societies appear to differ in their approaches to paradoxical categories. Theories of paradoxes have pointed to East Asian philosophy, with its emphasis on holism, dynamism and a “middle-way,” as fostering a societal level tendency towards integrating paradoxes (Chen, 2008; Eisenhardt, 1988). Integrating paradoxes is exemplified in the 阴阳(Yin-Yang) symbol found in the classic text 易经(Yi Jing, Book of Changes; Wilhelm & Baynes, 1968) demonstrating that black and white are part of one whole. Integrating paradoxes is a prominent feature in Laozi's 道德经(Dao de jing; Lao, 1997). In China, Japan, Korea and Vietnam, these texts have long been canonized (Schwartz, 1985), and the integration of paradoxes has long permeated stories, proverbs and other commonplace cultural artifacts within East Asian societies (Peng & Nisbett, 1999). As supporting evidence, cultural psychology research has found tendencies toward integration of paradoxes among lay people in East Asia, establishing societal-level lay theories on contradiction and change, or lay dialecticism (Norenzayan, Smith, Kim, & Nisbett, 2002; Spencer-Rodgers, Boucher, Mori, Wang, & Peng, 2009). Although dialecticism is present in Western philosophy (Walton 1990), its influence on lay people is less pervasive (Samson 2004), suggesting that societal-level cultural conventions that emphasize the integration of paradoxes are weaker in Western societies.

A heightened exposure to lay dialecticism encourages a tolerance of contradictions in people's general views of their self and their social relations (Spencer-Rodgers et al., 2009). Therefore, a tendency towards lay dialecticism could foster integrative categorization generally, and more specifically, could foster integrating the cultural categories of cooperation and competition (such as by categorizing attempts to outperform others as instances of both

cooperation and competition). So, people exhibiting a greater degree of lay dialecticism should be more likely to believe that even if cooperation and competition are generally opposites, it is possible that an act can be both cooperative and competitive because there are situations where contradictions can occur.

Taken together, the preceding discussion leads us to predict that national culture should influence people's predilection for lay dialecticism. Lay dialecticism, in turn, should influence people's tendency for integrative categorization—specifically, categorizing attempts to outperform as an instance of both cooperation and competition.

Integrative categorization should influence behavior. Categories serve as cognitive mediators between settings and actions (Keller & Loewenstein, 2010; Markman & Ross, 2003). Individuals use categories to interpret the type of setting they are in and the actions of others, and then use their interpretations to select appropriate responses (March, 1994; Smith, 1989). The interpretation and reaction to settings and prior actions is particularly important for cooperation, because cooperation requires reciprocity (Koster & Sanders, 2006). Reciprocity implies responding with an action of the same kind (Gouldner, 1960), that is, with a response drawn from the same category. Therefore, individuals' propensity to act cooperatively is contingent on whether they categorize the setting and others' actions as cooperative. If individuals categorize others' actions as non-cooperative, they are unlikely to respond with a cooperative act (Andersson & Pearson, 1999), even when the behavior does not have a material impact on the individual (Stanne et al., 1999). As a result, integrative categorization of attempts to outperform should increase people's likelihood of responding to attempts to outperform by cooperating.

Methods

Participants

Participants were 94 US undergraduates (62% female, mean age 20.3 years) and 100 Chinese undergraduates (65%, 21.2 years).

Part 1 procedure and materials

The study consisted of two parts, separated by 1-2 weeks. During the first part, participants completed computer-based questionnaire measures for lay dialecticism (from Spencer-Rodgers et al, 2009), integrative categorization (based on Keller & Loewenstein, 2010), antonymy (based on Herrmann & Conti, 1979), self-construal measures (as control variables) and demographics. All original materials were developed in English, translated into Chinese and back translated into English; tests of the back-translated versions showed comparable results.

The key new measure is the integrative categorization measure. Participants rated 25 behaviors three times; whether they indicated a strong or weak indicator of (1) cooperation, (2) commitment (as a foil), and (3)

competition. Four of these 25 behaviors were key, because they represented attempts to outperform others. They were: 1) "A team member attempts to outperform other team members", 2) "A team member gauges others' performance and makes sure that he or she is doing better than the others", 3) "A team member tries to get the quality of the his or her work to be better than the quality of others' work", and 4) "A team member tries to make sure that he or she isn't outdoing others in the team" (reverse-coded). These behaviors were consistently categorized by people in China and the US as indicating competition ($\alpha=.81$, $M=4.06$, $SD=.55$). There was considerable variance as to whether these items indicated cooperation ($\alpha=.73$), and hence we used their cooperation ratings as our measure of integrative categorization.

The remaining behaviors were mostly banal instances taken from prior research on lay beliefs about cooperation (Keller & Loewenstein, 2010) used as filler items so there would not be undue attention on attempts to outperform others. The exception was that we also included behaviors representing attempts to undermine others as a foil for attempts to outperform others. We found that people in both China and the US consistently rated attempts to undermine others as competitive ($M=4.06$) and non-cooperative ($M=1.52$). Thus, finding that some people's ratings indicate integrative categorization of attempts to outperform others should indicate their specific beliefs about attempts to outperform others rather than a general response bias.

Part 2 procedure and materials

Participants engaged in a group brainstorming task to facilitate the development of group entitativity (Campbell, 1958; Kramer, Kuo & Dailey, 1997). We assessed participants' ratings of how strongly they felt they were a group and part of a group as manipulation checks, and found that these ratings were generally high, and also that they did not account for the core findings we present later.

Participants next moved to a computer for a simulated group sales task. During the simulation, each participant managed a cart selling tea. Two simulated team members managed two other carts. During the simulation, participants had eight opportunities to share information with their teammates. The number of times they did so was our measure of cooperation.

Lastly, participants completed a post-task questionnaire. This included a manipulation check that showed that participants believed their teammates in the simulation were the people with whom they had completed the brainstorming task. The four participants who did not believe so were dropped from the analysis.

The participants in China and the US engaged in one of two versions of the tea sales simulation. In the outperform condition, participants received messages from their teammates stating that they wanted the team to do well and that they wanted to perform the best. During the simulation, the teammates constantly checked on the others' performance (this act was made visible in the interface). In a

baseline condition, bland messages were sent and little signs of checking on the others' performance occurred. A post-task manipulation check showed that those in the outperform condition stated they experienced their teammates attempting to outperform them more so than those in the baseline condition, ($M_{\text{outperform}} = 5.45$, $SD = 1.15$, $M_{\text{baseline}} = 2.83$, $SD = 1.35$, $t(199) = 13.26$, $p < .001$). Finally, we note that we used an unbalanced design, placing more participants in the outperform condition because at issue is whether there would be a difference in cooperation rates in the outperform condition. We expected (and found) no difference in the baseline condition.

Results

As shown in Table 1, we found China-US differences in lay dialecticism ($t(143) = 8.75$, $p < .001$); integrative categorization ($t(143) = 10.50$, $p < .001$); and cooperative behavior in the outperform condition ($t(143) = 4.41$, $p < .001$), but not the baseline condition. We also found China and US consistency in believing cooperation and competition to be antonyms.

Table 1: Descriptive Statistics.

	China (n=100)	US (n=94)
	Mean (SD)	Mean (SD)
Lay Dialecticism	4.33 (0.49)	3.57 (0.58)
Integrative Categorization	3.70 (0.47)	2.68 (0.67)
Cooperative Behavior in Outperform Condition	5.12 (2.28)	3.54 (2.03)
Cooperative Behavior in Baseline Condition	4.95 (1.85)	4.95 (1.68)
Antonymy of "Cooperation" and "Competition"	1.84 (1.12)	1.88 (0.90)
Independent Self- Construal	4.49 (0.63)	5.31 (0.74)
Group-Collective Self- Construal	5.23 (0.82)	4.63 (0.99)
Perceived Task Difficulty	4.45 (1.56)	4.65 (1.61)

We used stepwise linear regression models to examine relations among variables just for those in the outperform condition. First, we found that lay dialecticism predicted integrative categorization ($B = .48$; $SE = .11$; $p < .05$). National culture also predicted integrative categorization ($B = 1.09$; $SE = .12$; $p < .05$). To examine lay dialecticism as a mediator of the national culture effect, we ran a bootstrapped test of an indirect effect of national culture on integrative categorization through lay dialecticism (Preacher, Rucker, & Hayes, 2007). The mean indirect effect was 0.12 (95% CI: 0.01-0.22), $p < .05$, providing evidence of mediation. Therefore, the impact of national culture on integrative categorization can be at least partially attributed to differences in lay dialecticism.

Second, we found that lay dialecticism predicted cooperative behavior ($B = 1.09$; $SE = .31$; $p < .05$). Integrative categorization also predicted cooperative behavior ($B = .95$; $SE = .31$; $p < .05$). A bootstrapped test of the indirect effect of lay dialecticism on cooperative behavior through integrative categorization found that the mean indirect effect was 0.13 (95% CI: 0.02-0.35), $p < .05$, providing evidence of mediation. Therefore, the impact of lay dialecticism on cooperative behavior can be at least partially attributed to differences in integrative categorization.

Analysis of control variables showed that the nationality to dialecticism to integrative categorization to cooperative behavior pathway was not explained away by alternative factors. For example, we found national differences in independent self-construal and group-collective self-construal, but the mediation analyses included these variables—as well as age, gender, and subjective ratings of task difficulty—as controls and still found the predicted patterns.

Discussion

We found US and Chinese consensus that cooperation and competition are antonyms, providing evidence of a cooperation paradox. We introduced the concept of integrative categorization as a specific means of integrating a paradox. We found cultural and individual differences in the integrative categorization of attempts to outperform as instances of competition and cooperation. We further found predictable consequences of integrative categorization on people's cooperative behaviors in a group simulation task. Therefore, we advance research on categories and on cooperation and competition.

We found societal-level differences between the US and China, suggesting that integrative categorization is culturally conditioned. The cultural differences were attributable to lay dialecticism differences. This implies that the national culture difference in integrative categorization was due to broad cultural belief systems about how to think about contradictions and change. The broad cultural tendencies towards lay dialecticism, by influencing integrative categorization, influenced people's reactions to others' behaviors. Therefore, the results suggest that culturally-influenced lay beliefs about paradoxes establish broad conditions that make particular behaviors more or less likely to occur. Specifically, lay dialecticism makes integrative categorization more likely, which in the case of cooperative and competitive behaviors, makes cooperation and the sustaining of cooperation within a group more likely to occur.

We note here that the data pattern described here has turned out to be robust. Subsequent research manipulating participants' social motivations (whether they are trying to maximize their own outcomes, group outcomes, or both) has shown that motivation effects are distinct from the dialecticism and integrative categorization effects that are our focus. The results are also robust when controlling for participants' performance on the simulation task.

Our results have implications for research on categories. There is growing interest in how categories are used (Markman & Ross, 2003), in complex categories (Gentner & Kurtz, 2005), and in how categories relate to each other (Goldstone, 1996; Loewenstein & Gentner, 2005). We contribute to these streams of category research by showing that people's decisions about category membership are not entirely a function of the features of the instance. Membership in one category can suppress the possibility of acknowledging membership in another category. Further, this suppression is a function of general beliefs about contradiction and change that are acquired through cultural experience exogenous to the immediate social context and the particular categories at hand. Thus, our study demonstrates that research on how people think about and use multiple categories is not only a matter of the features of exemplars, but also subject to broad and predictable cultural influence.

Our results also have implications for research on cooperation and competition. It is well established that cooperation can facilitate effective social outcomes (Campion, Medsker, & Higgs, 1993; Kogut & Zander, 1992). It is less well established but also supported that competition can increase individual effort towards collective goals, and thereby also generate effective social outcomes (Luo et al., 2006). Finally, it is also established that many social situations involve mixed motives (Komorita & Parks, 1996). The results from this study suggest that integrative categorization is important to making effective use of the positives of both cooperation and competition to advance social outcomes. People who engaged in integrative categorization were more likely to maintain cooperation and less likely to treat cooperation and competition as "trade-offs." Accordingly, people with beliefs that facilitate the integration of paradoxes may be more suitable for jobs with paradoxical situations, such as working in teams with mixed motive incentive structures. In teams with mixed motives, members with higher overall propensities for lay dialecticism and integrative categorization may perform better than teams whose members have low propensities or a mixture of propensities for lay dialecticism and integrative categorization. They might better take advantage of the positives aspects of both cooperation and competition. More broadly, the implication is that by examining categories central to social interaction, we can improve our ability to predict and provide prescriptions for obtaining positive social outcomes.

To conclude, how people think about and use specific categories can be influenced by broader cultural tendencies as to how to address oppositions and paradoxes. This is consequential; we showed that cultural tendencies to maintain separation between categories, rather than to seek out ways to integrate them, can lead to failures to support social opportunities for mutual gain.

Theories of God: Explanatory Coherence in a Non-Scientific Domain

Andrew Shtulman (shtulman@oxy.edu)

Department of Psychology, Occidental College
1600 Campus Rd., Los Angeles, CA 91106

Abstract

Public representations of God range from the highly anthropomorphic to the highly abstract, and the present study explored whether differences in the interpretation of those representations are correlated with differences in one's religious beliefs and religious practices more generally. American adults of varying ages and religious backgrounds completed a questionnaire that probed their beliefs about a wide range of religious matters, including prayer, ritual, worship, sin, cosmogenesis, anthropogenesis, angels, Satan, Heaven, and Hell. Participants were divided into two groups based on their propensity to anthropomorphize God in a property-attribution task, and their responses were analyzed for internal consistency. Overall, the two groups exhibited explanatorily coherent, yet qualitatively different, patterns of beliefs and practices – patterns interpreted contrastively as a “humanistic theology” and an “existential theology.” These findings suggest that individuals' religious beliefs are organized in a theory-like manner despite their lack of direct perceptual support.

Keywords: Intuitive theories; religious cognition; conceptual representation; cultural transmission; explanation

Introduction

Belief in the existence of a divine being is prevalent both within and across cultures (Brown, 1991). This belief is particularly prevalent in the US, where the percent of individuals who report holding such a belief has hovered around 95% for the last six decades (Gallup, 2003). Theistic beliefs are of potential interest to cognitive developmentalists, as they present a challenge to standard, constructivist models of knowledge acquisition (e.g., Piaget, 1954; Gopnik & Meltzoff, 1997). Such models construe knowledge as a product of direct observation and exploration of the physical world, yet “knowledge” of God is rarely (if ever) acquired in this manner. Rather, individuals must learn about God from the art, literature, and discourse of their culture. How individuals make sense of such public representations is the topic of investigation in the present study.

The task of interpreting public representations of God is by no means trivial, for these representations range from the highly anthropomorphic (e.g., “heavenly father,” “divine ruler,” “intelligent designer”) to the highly abstract (e.g., “first cause,” “unmoved mover,” “universal spirit”). As a group, they paint a picture of God that is neither consistent nor coherent. For instance, God is commonly said to listen to prayers, yet an omniscient being would already know the content of those prayers. Likewise, God is commonly said to have created man in his image, yet an omnipresent being presumably has no “image.”

One way to resolve the tension between anthropomorphic and nonanthropomorphic representations of God is to treat the anthropomorphic representations as metaphors and the nonanthropomorphic representations as literal descriptions. Barrett & Keil (1996) investigated this possibility by comparing participants' self-professed beliefs about God to the kinds of beliefs revealed in a story-recall task. Although all participants claimed that God is omniscient and omnipresent when asked directly, many participants drew anthropomorphic inferences on the story-recall task that contradicted such claims. For instance, participants frequently mistook the statement “God was pleased by seeing the girl put the bird in its nest” for the statement “God was aware of the girl's deed and was pleased by it” in even though the former, but not the latter, implies that God must perceive an event in order to be aware of its occurrence. Likewise, participants frequently mistook the statement “When the woman awoke, God had already left” for the statement “When she woke, she saw no one” even though the former, but not the latter, implies that God occupies a discrete location in space.

These findings suggest that anthropomorphic descriptions of God do, in fact, influence the way individuals reason about God's actions and abilities, particularly in a narrative context. Still, not all the participants in Barrett and Keil's study anthropomorphized God to the same extent. Indeed, participants' accuracy in differentiating anthropomorphic descriptions of God from nonanthropomorphic descriptions ranged from 27% to 91%. Consistent with this finding, several other studies have documented significant differences in the anthropomorphization of God (e.g., Bassett & Williams, 2003; Shtulman, 2008; Trimeche, Vinsonneau, & Mullet, 2006), yet it is unclear how to interpret those differences in light of the commonly held view that what people say they believe about God is not necessarily true of what they actually believe (Boyer, 2003; Slone, 2004). One interpretation is that they are artifactual, reflecting nothing more than variation in participants' understanding of, or engagement with, the task at hand. Another (more interesting) interpretation is that they are symptomatic of variation in how to make sense of God's public representations as a whole, with anthropomorphic responses reflecting a fundamentally different interpretation of religious claims than nonanthropomorphic responses.

One reason to suspect the latter – i.e., that different God concepts are correlated with different patterns of religious belief – is that correlations of this nature have been documented in many other domains of knowledge. For instance, different concepts of matter are correlated with different beliefs about mass, weight, and density (Smith, Snir, &

Grosslight, 1992); different concepts of force are correlated with different beliefs about acceleration, momentum, and inertia (McCloskey, 1983); and different concepts of evolution are correlated with different beliefs about adaptation, speciation, and extinction (Shtulman, 2006). These correlations have been interpreted as evidence that our knowledge of natural kinds is organized in self-consistent, causal-explanatory networks (Carey, 1985; Keil, 1989; Murphy & Medin, 1985). Whether or not our knowledge of “supernatural kinds” is organized in a similar manner is an open question.

Previous research on religious cognition has not specifically looked for correspondences between God concepts and overall theologies. Instead, this research has focused either on explicating the content of God concepts apart from their associated beliefs (Bassett & Williams, 2003; Trimeche, Vinsonneau, & Mullet, 2006) or on comparing children’s God concepts to those of adults (Barrett, Richert, & Driesenga, 2001; Gimenez-Dasi, Guerrero, & Harris, 2005). In contrast, the present study sought to determine whether variation in adults’ God concepts tracks variation in their religious beliefs and religious practices more generally. Such a finding would imply not only that resolving the ambiguity inherent in God’s public representations has different consequences for different individuals but also that religious beliefs, like scientific beliefs, are organized in a theory-like manner.

Method

Participants

Thirty-two American adults, ranging in age from 18 to 46, were recruited from the study pool of a large, urban university and were compensated for their participation either monetarily or with course credit in an introductory psychology class. Participation was restricted to individuals who believed in the existence of God, though participants varied widely in their particular religious affiliations: 34% self-identified as Protestant, 16% Catholic, 9% Unitarian, 6% Jewish, 6% Buddhist, 3% Muslim, and 25% claimed not to be affiliated with any particular religion.

Procedure

Each participant completed a six-part questionnaire that probed their beliefs about (1) God’s appearance and occupation, (2) God’s relationship to nature, (3) God’s relationship to humankind, (4) supernatural beings associated with God (angels and Satan), (5) supernatural locations associated with God (Heaven and Hell), and (6) prayer, ritual, and worship. The particular questions on each topic are presented in combination with participants’ responses in the Results section. Questions for which participants’ responses exhibited little to no variation were omitted from these analyses for the sake of brevity.

Participants’ religious beliefs were analyzed in relation to their God concepts as measured by a property-attribution task. In this task, participants were asked to decide whether

God could or could not be attributed twelve human properties: “dreams,” “sees,” “talks,” “thinks,” “eats,” “grows,” “sleeps,” “sneezes,” “gets cold,” “gets wet,” “sits,” and “stretches.” The first four properties were intended to exemplify human psychological properties, the middle four human biological properties, and the last four human physical properties. The properties were arranged in alphabetical order, and the task itself was sandwiched between questions about God’s occupation and questions about God’s existence in the first part of the questionnaire.

Participants’ responses to the open-ended questions were coded using the schema presented in Table 1. All responses were coded by two independent judges. Overall agreement between judges was 90%, and all disagreements were resolved through discussion.

Results

Beliefs about God

The first part of the questionnaire probed participants’ beliefs about God’s appearance and occupation. It also probed participants’ beliefs about God’s anthropomorphic properties, as assessed by the aforementioned property-attribution task. Replicating previous research (Shtulman, 2008), participants attributed more psychological properties to God ($M = 2.8$, $SD = 1.1$) than biological properties ($M = 0.7$, $SD = 1.3$) or physical properties ($M = 0.7$, $SD = 1.1$), and they varied widely in the total number of properties attributed (range = 0 to 12).

For the purposes of data analysis, participants were split into two groups: those who attributed zero to three human properties to God ($n = 16$) and those who attributed four to twelve human properties to God ($n = 16$). The first group were labeled “weak anthropomorphizers” and the second “strong anthropomorphizers.” Note that the labels “strong” and “weak” denote relative, not absolute, amounts of anthropomorphism, for even the strong anthropomorphizers typically attributed fewer than half of the 12 properties to God. Still, 96% of the strong anthropomorphizers attributed at least one biological or physical property to God, whereas only 6% of the weak anthropomorphizers did. Thus, strong anthropomorphizers differed from weak anthropomorphizers not only in the *number* of properties attributed to God but also in the *type* of properties attributed.

Participants answered an additional five questions about God’s nature and existence. In response to the question “What does God look like?,” 56% of participants claimed that God has a definite physical appearance (e.g., “looks like a human being”), and 44% claimed that God’s appearance is either unknown or unknowable (e.g., “in our limitation as humans we cannot conceive of what God looks like”). In response to the question “What does God do?,” 69% claimed that God intervenes in human affairs (e.g., “he guides, chastises, advises, sacrifices, reminds and loves”), and 31% claimed that God’s occupation is either unknown or unknowable (e.g., “God is omnipresent, so he does not ‘do’ anything in the conventional sense”). In response to the

Table 1: The percentage of weak anthropomorphizers (WA) and strong anthropomorphizers (SA) who professed each of the following beliefs and practices, and the strength of association (ϕ) between being a strong anthropomorphizier and professing each belief/practice ($df = 1$ for all statistical comparisons).

Topic	Professed belief/practice	WA	SA	ϕ

question "Does God answer prayers?," 56% claimed that he does, and 44% claimed that he does not. In response to the question "How do you know that God exists?," 44% provided an "experiential" justification (e.g., "I can feel him in my soul"), 41% provided an "intellectual" justification (e.g., "acknowledging a higher power feels like a good way to order the universe"), and 16% simply appealed to faith. Finally, in response to the question "How confident are you, on a scale from 1 (not confident) to 7 (100% confident), that God exists?," participants provided an average confidence

rating of 5.2 ($SD = 2.0$), and a modal confidence rating of 7.

Displayed in Table 1 are the percentage of weak and strong anthropomorphizers who provided the five most common responses summarized above. Accompanying these percentages are a measure of the association between being a strong anthropomorphizier and providing each of response. As can be seen from this table, strong anthropomorphizers were significantly more likely than weak anthropomorphizers to claim that God (a) has a physical appearance, (b) intervenes in human affairs, and (c) answers

prayers. Moreover, strong anthropomorphizers were significantly more likely than weak anthropomorphizers to claim that they have experienced God's presence in their lives and are 100% certain that God exists. Participants' propensity to anthropomorphize God was thus correlated with their propensity to view God as a palpable (and pertinent) influence on everyday human affairs.

Beliefs about God's Relationship to Nature

The second part of the questionnaire probed participants' beliefs about God's role in the origin of the universe (cosmogogenesis) and the origin of human beings (anthropogenesis). Participants' beliefs about cosmogogenesis were elicited with the questions (1) "Do you believe that God created the universe?," (2) "Do you believe that the universe was created in the Big Bang?," and (3) "If you answered 'yes' to both questions, how do you resolve the apparent inconsistency between these two ideas?" Participants' beliefs about anthropogenesis were elicited with the questions (1) "Do you believe that God created human beings?," (2) "Do you believe that human beings evolved from other organisms?," and (3) "If you answered 'yes' to both questions, how do you resolve the apparent inconsistency between these two ideas?"

On the topic of cosmogogenesis, 44% of participants claimed that the universe was created by God alone, 25% by the Big Bang alone, and 31% by both God and the Big Bang. Those who claimed that the universe was created by both God and the Big Bang justified their claim by appealing to some kind of dual process (e.g., "God set in motion the forces that created the Big Bang"). On the topic of anthropogenesis, 31% of participants claimed that human beings were created by God alone, 38% by evolution alone, and 31% by both God and evolution via some kind of dual process (e.g., "God created the organisms that ultimately evolved into humans").

The percentages of weak and strong anthropomorphizers who provided each of the above responses are displayed in Table 1. Strong anthropomorphizers were significantly more likely than weak anthropomorphizers to endorse a creationist explanation for both phenomena. Weak anthropomorphizers, on the other hand, were significantly more likely than strong anthropomorphizers to adopt a naturalistic explanation for cosmogogenesis and a quasi-naturalistic explanation for anthropogenesis. Collapsing across "God only" explanations and "dual-process" explanations, strong anthropomorphizers were no more likely than weak anthropomorphizers to claim that God played at least *some* role in each process, indicating that the aforementioned differences are more nuanced than the difference between wholly accepting or wholly rejecting divine causation.

Beliefs about God's Relationship to Humankind

The third part of the questionnaire probed participants' beliefs about God's role in human suffering and human sin. These beliefs were elicited by asking participants to reason

about two theological problems, traditionally known as the "problem of evil" and the "problem of sin" (see Plantinga, 1977). Reasoning about the first problem was elicited with the questions (1) "Do you believe that God is all powerful?," (2) "Do you believe that God is all good?," and (3) "If you answered 'yes' to both, why do you think God allows (or fails to prevent) human suffering?" Reasoning about the second problem was elicited with the questions (1) "Do you believe that God is all knowing?," (2) "Do you believe that God holds human beings responsible for their actions?," and (3) "If you answered 'yes' to both, why do you think God holds human beings responsible for actions he knows they will make?"

With regard to the problem of evil, 38% of participants denied that God is either omnipotent or omnibenevolent, 44% claimed that God is both omnipotent and omnibenevolent but that God uses suffering to teach or to punish (e.g., "God gave man free will and man chose to sin and suffering is a result of this sin"), 16% claimed that God is both omnipotent and omnibenevolent but that suffering is simply part of the human condition (e.g., "suffering, in various degrees, is part of the natural course of life"), and 3% plead ignorance. With regard to the problem of sin, 47% of participants denied that God is omniscient, judgmental, or both, 47% claimed that God is both omniscient and judgmental but that he also gave human beings the freedom to disobey him (e.g., "God gave man free will and hopes they will make the right choice, but sometimes they don't"), and 6% plead ignorance.

The percentages of weak and strong anthropomorphizers who provided each of the above responses are displayed in Table 1. Strong anthropomorphizers were significantly more likely than weak anthropomorphizers to claim that God uses suffering to teach or punish, and weak anthropomorphizers were significantly more likely than strong anthropomorphizers to claim that suffering is part of the human condition. Moreover, strong anthropomorphizers were significantly more likely than weak anthropomorphizers to claim that God gave humans the freedom to disobey him, and weak anthropomorphizers were significantly more likely than strong anthropomorphizers to deny that God is omniscient, judgmental, or both. In short, weak anthropomorphizers tended to treat suffering and sin as secular phenomena, not particularly linked to God, and strong anthropomorphizers tended to interpret sin as the defiance of divine law and suffering as the consequence of divine justice – beliefs reminiscent of those previously characterized as "belief in a just world" (Lerner, 1980).

Beliefs about Angels and Satan

The fourth part of the questionnaire probed participants' beliefs about two supernatural beings commonly associated with God: angels and Satan. Participants were first asked a series of property-attribution questions identical to those described earlier for God, and their responses were analyzed for the presence of biological and physical attributions. They were then asked whether they believed in the existence

of each being, and, if so, what they thought those beings looked like and how they thought those beings were related to God. Responses to the first question were coded for evidence that angels and Satan were believed to possess a physical appearance (e.g., “most angels have wings and are bright,” “Satan looks like a ball of fire”), and responses to the second were coded for evidence that angels and Satan were believed to maintain a social relationship with God (e.g., “angels are God’s servants,” “Satan is God’s enemy”) rather than some type of existential relationship (e.g., “God is angels and angels are God,” “Satan is a part of God because God is everything”).

These responses are summarized in Table 1 as a function of participant group. Overall, strong anthropomorphizers were not significantly more likely than weak anthropomorphizers to believe in the existence of either angels or Satan, but they were significantly more likely to claim that these beings (a) possess the biological and physical properties of a human, (b) have a physical appearance, and (c) maintain a social relationship with God. In short, participants’ propensity to anthropomorphize God was correlated with their propensity to anthropomorphize other members of their religious cosmology.

Beliefs about Heaven and Hell

The fifth part of the questionnaire probed participants’ beliefs about two supernatural places associated with God: Heaven and Hell. Participants were asked whether they believed in the existence of each place, and, if so, where they thought those places were located, what they thought those places looked like, and what they thought the occupants of those places did. Responses to the first question were coded for evidence that Heaven and Hell were believed to occupy a discrete location in space (e.g., “Heaven is in the sky,” “Hell is below the earth’s crust”); responses to the second were coded for evidence that Heaven and Hell were believed to possess a physical appearance (e.g., “Heaven looks like a garden,” “Hell looks like a prison”); and responses to the third were coded for evidence that the occupants of Heaven and Hell continue to engage in human activities (e.g., “singing, talking, dancing,” “weeping and gnashing of teeth”).

These responses are summarized in Table 1. Consistent with the belief that God possesses discrete physical properties, strong anthropomorphizers were significantly more likely than weak anthropomorphizers to claim that Heaven and Hell occupy discrete locations in space and that the occupants of Heaven and Hell engage in human activities. Strong anthropomorphizers were also more likely than weak anthropomorphizers to believe in the very existence of Heaven and Hell. In short, participants’ propensity to anthropomorphize God was correlated with their propensity to accept, and to “spatialize,” both places.

Religious Practices

The last part of the questionnaire contained questions about participants’ religious practices and religious upbringing.

Most participants (66%) claimed to engage in prayer at least occasionally, with 28% claiming to engage in prayer weekly. Likewise, most participants (72%) claimed to attend religious services at least occasionally, with 31% claiming to attend religious services weekly. In terms of affiliation, 50% claimed to belong to a Christian religion, 25% claimed to belong to a non-Christian religion, and 25% claimed to belong to no religious whatsoever. Finally, in response to the question “From whom did you acquire your current religious beliefs?”, 44% claimed to have acquired their beliefs from a religious authority (e.g., a priest, a rabbi, “the church”), 34% claimed to have acquired their beliefs from their family, and 22% claimed to have acquired their beliefs from independent scholarship or personal reflection.

The percentage of weak and strong anthropomorphizers who claimed to engage in each of the aforementioned practices is displayed at the bottom of Table 1. Overall, strong anthropomorphizers were significantly more likely than weak anthropomorphizers to pray once or more per week, to attend religious services (at all), and to have acquired their beliefs from a religious authority. Weak anthropomorphizers, on the other hand, were significantly more likely to have acquired their beliefs from independent scholarship or personal reflection. The finding that participants’ propensity to anthropomorphize God was correlated with their propensity to subscribe to the teachings of a religious authority is particularly interesting in light of the popular assumption that an anthropomorphic concept of God is not a “theologically correct” concept of God (e.g., Barrett & Keil, 1996; Boyer, 2003). Apparently, many strong anthropomorphizers would disagree.

Discussion

The present study explored the relationship between individuals’ endorsement of an anthropomorphic God concept and their various beliefs and practices related to God. Overall, it was found that participants’ propensity to anthropomorphize God was correlated with their propensity to (a) view God as a palpable and pertinent influence on human affairs, (b) adopt a creationist stance toward the origin of the universe and the origin of human beings, (c) adopt a “just world” view of human suffering and human sin, (d) anthropomorphize angels and Satan; (e) spatialize Heaven and Hell, and (f) engage in traditional religious activities, like prayer and worship.

Underlying these correlations were two qualitatively different, yet internally consistent, patterns of belief. One pattern, exhibited by strong anthropomorphizers, appeared to be structured around participants’ understanding of human existence and human affairs. On this pattern, God is conceptualized as a divine ruler, angels are conceptualized as God’s political allies, Satan is conceptualized as God’s political opponent, Heaven and Hell are conceptualized as God’s political territory, cosmogenesis and anthropogenesis are conceptualized as God’s greatest achievements, and sin and suffering are conceptualized as God’s primary spheres of influence. The other pattern of belief, exhibited by weak

anthropomorphizers, appeared to be structured around more abstract, and more limited, metaphysical commitments. On this pattern, God is conceptualized as an immaterial entity (rather than a physical object), angels and Satan are conceptualized as aspects of God (rather than independent agents), Heaven and Hell are conceptualized as states of being (rather than spatial locations), cosmogenesis and anthropogenesis are conceptualized as acts of nature (rather than acts of God), and sin and suffering are conceptualized as part of human nature (rather than part of a divine plan). Whereas the first pattern might best be described as a “humanistic theology,” the second might best be described as an “existential theology.”

The fact that these patterns of belief were associated with different religious practices suggests that different God concepts have different behavioral implications in addition to different cognitive implications. Presumably, the reason strong anthropomorphizers are more likely than weak anthropomorphizers to engage in prayer and worship is that only an anthropomorphic God would attend to, or care about, such activities. Of course, these correlations may be interpreted in the opposite manner – i.e., that individuals who engage in religious activities are more likely to hold a concept of God that is consistent with those activities. Tied to this concern is the broader concern that individual differences in God concepts may be due more to differences in religious education than to differences in the inferential relationship between one’s God concept and one’s God-related beliefs and practices.

There are at least three reasons to doubt that individuals inherent, rather than create, their personal theologies in the course of religious education. First, complete theologies are likely difficult to communicate given that God concepts are only one of many religious concepts open to multiple interpretations, as evidenced by participants’ divergent interpretations of angels, Satan, Heaven, Hell, prayer, sin, and suffering. Second, the theologies documented in the present study were not specific to any one religion (see the section on religious affiliation in Table 1), implying that they are not the byproduct of a particular religious education (e.g., a Protestant education). Third, participants were unlikely to have pondered each and every issue broached by the questionnaire prior to participation, yet their responses to these questions were internally consistent nonetheless.

That said, future research could explore the development of personal theologies more directly. For instance, one could investigate the theologies of young children and chart how these theologies change over time, particularly their explanatory coherence and inferential scope. Alternatively, one could compare the theologies of different members of the same cultural unit, like the same church or the same family, to assess the dimensions along which personal theologies are most likely (and least likely) to differ. Such research would not only increase our understanding of religious cognition but would also increase our understanding of the interaction between culture and cognition more generally.

The Cultural Transmission of Explanations: Evidence that Teleological Explanations are Preferentially Remembered

Nicholas Z. Gwynne (nzg@berkeley.edu)

Tania Lombrozo (lombrozo@berkeley.edu)

Department of Psychology, 3101 Tolman Hall
Berkeley, CA 94703 USA

Abstract

Teleological explanations – explanations in terms of functions, purposes, or goals – are pervasive in religion and feature prominently in intuitive theories about the world, such as theory of mind and folk biology. Previous findings suggest that such explanations reflect a deep, explanatory preference. Here we explore the mechanisms underlying the prevalence and persistence of such explanations, following a method developed by Boyer and Ramble (2001) to examine which religious concepts are likely to survive processes of cultural transmission. Specifically, we test the prediction that novel teleological explanations are remembered better than mechanistic explanations, even when effects of an explanation's quality are taken into account. Two experiments support this prediction for artifact and biological trait explanations, but find the opposite pattern for explanations of non-living natural entities.

Keywords: explanation; teleological explanation; functional explanation; religion; memory; cultural transmission

Introduction

Why-questions are ubiquitous, ranging from those a child might ask to those of existential importance. While different questions solicit different answers, there seem to be systematic patterns in the properties of folk explanations (Lombrozo, 2006). Consider the difference between *mechanistic explanations*, which appeal to causal mechanisms, and *teleological explanations*, which appeal to functions and goals. The origin of human life can be explained mechanistically by appeal to evolution, but is often explained teleologically by appeal to some greater purpose.

In this paper we consider why folk explanations are so often teleological, and suggest that part of the answer lies in their mnemonic properties: teleological explanations are more likely to be remembered than mechanistic alternatives, and hence to survive processes of cultural transmission.

Teleology in folk explanations

Teleological explanations pervade intuitive theories. Folk psychological explanations, for example, often appeal to an agent's goals (e.g. Gopnik & Wellman, 1992; Wellman, 1992), while those in folk biology prominently feature biological functions (e.g. Atran, 1994). Teleological explanations even figure in early physics, as in Aristotle's appeals to teleological causation (Aristotle, *Physics II*).

Teleological explanations are particularly prominent in religion. Consider, for example, explanations for the origin of the universe. In the familiar Judeo-Christian creation story, the Old Testament God forms trees and animals for man to use (KJV, Genesis, 2:9, 2:18). Appeals to functions and goals likewise infuse the explanations for more mundane goods: we have wine because it "makes glad the heart of man," and bread because it "strengthens man's heart" (KJV, Psalm 104:14, 15).

What accounts for the prevalence of teleology in folk explanations? One possibility is that teleological explanations are common because they correspond to the structure of the world. This possibility is at best incomplete given that so many teleological folk explanations extend beyond those sanctioned by contemporary science (e.g. Kelemen & Rosset, 2009).

A second possibility is that teleological explanations are common because they are psychologically privileged, meaning that they are found more satisfying and generally preferred over alternatives. Evidence for this possibility comes from a growing literature on 'promiscuous teleology' demonstrating that young children prefer teleological explanations (e.g. "clouds are for raining"), and that this preference may persist into adulthood (Lombrozo, Kelemen, & Zaitchik, 2007; Kelemen and Rosset, 2009). Moreover, teleological and mechanistic explanations have unique consequences for categorization (Lombrozo, 2009). While some have suggested that teleological explanations are privileged in only some domains, such as folk biology (Atran, 1994, Keil, 1994), others suggest the preference is more widespread (Kelemen, 1999).

A third possibility is that teleological explanations are common because they are likely to survive processes of cultural transmission. Specifically, if teleological explanations are more likely to be reliably recalled, one should expect culturally transmitted beliefs such as religion to over-represent such explanations.

The possibility that mnemonic properties play a role in explaining the properties of religious explanations is particularly attractive in light of past research on cultural transmission. Within the domain of religion, Boyer and colleagues have successfully explored the role of memory and transmission in explaining the properties of religious concepts, such as demons and deities (e.g. Boyer, 2003). In these studies, participants read about

religious entities and were later asked to recall as many as possible. Boyer argued that if religious concepts have the properties they do because of cultural transmission, the concepts surviving this process should reflect the characteristics of concepts in the world's religions. Although the details have been disputed (e.g. Gonce et al. 2006; Norenzayan, Atran, Faulkner & Schaller, 2006; Tweney et al. 2006), Boyer's findings are broadly consistent with this proposal.

Beyond the domain of religion, research on iterated learning suggests that small biases in transmission can have large consequences over time (Kirby, 2001; Kalish, Griffiths, & Lewandowsky 2007). In the case of teleological explanations, a small bias in memory could have large consequences for the nature of folk explanations after several generations of transmission.

Our aim in this paper is to explore this third possibility: that teleology pervades folk explanations in part because teleological explanations are more likely to be remembered than mechanistic alternatives. We also explore the relationship between this hypothesis and the idea that teleological explanations are psychologically privileged – and hence deemed more satisfying – in all domains or in some domains.

How might memorability and satisfaction interact? It could be that teleological explanations are better remembered than mechanistic alternatives, and that this is *because* teleological explanations are judged more satisfying. Alternatively, memorability may influence satisfaction. Specifically, explanations that are more reliably encoded or recalled may lead to a greater sense of understanding, and hence be found more satisfying. A final possibility, and the one we favor, is that memorability and satisfaction have a common cause. If teleological and mechanistic explanations are supported by different kinds of representations or have a unique relationship to prior knowledge, both greater satisfaction and enhanced memory could result. By examining whether satisfaction mediates effects of explanation type on memorability we can begin to distinguish these alternatives.

In two experiments, participants read novel explanations that were either teleological or mechanistic and about biological traits, artifact properties, or (in Experiment 2) nonliving natural entities. Memory was then tested with recall and recognition tasks to examine the relationships between explanation type, explanation satisfaction, and memory.

Experiment 1

Experiment 1 examines whether teleological or mechanistic explanations are more reliably recalled and recognized. Additionally, it examines the relationship between explanations' memorability and their rated satisfaction, plausibility, detail, and unfamiliarity.

Explanation satisfaction and plausibility ratings were included to examine whether these factors mediate memorability. Ratings for detail and unfamiliarity were added because previous research suggests that explanations of moderate detail (Frazier et al, under review) and moderate unfamiliarity (Boyer & Ramble, 2001) are better remembered. By soliciting detail and unfamiliarity ratings we can examine whether memory differences, if found, result from differences in the detail or familiarity of the novel teleological and mechanistic explanations generated for the experiment. Having participants rate explanations along these four dimensions additionally provided a task to ensure that explanations were encoded prior to the memory tests.

Participants

One-hundred University of California students and community members (68% female, mean age = 22) participated in exchange for course credit or monetary compensation.

Materials and Procedure

The experiment involved twenty why-questions: ten regarding artifact properties and ten regarding biological traits. Each why-question had four possible answers of approximately equal length, two teleological and two mechanistic, for a total of 40 explanations of each type. Tables 1 and 2 provide sample why-questions and answers for each domain.

Table 1: Sample artifact trait explanations.

An istup is a kind of shovel with a compressible handle. Why do istups have compressible handles?
Teleological A: Because that way they can be used by aliens of various heights.
Teleological B: Because that way they can fit inside a regular toolbox.
Mechanistic A: Because the handle is made of distinct, interlocking segments.
Mechanistic B: Because the handle has hinges that allow it to fold.

These explanations were divided into four stimulus sets. In each set, half the questions were mechanistic and half teleological, with equal numbers across domains.

Data were collected via a computerized survey in a laboratory setting. Participants were instructed that they would “learn about the properties of plants, animals, and objects from alien planets and civilizations” and “receive explanations for those properties.” Each participant was presented with explanations from a single stimulus set, and was asked to rate each explanation along four dimensions: satisfaction, plausibility, detail, and unfamiliarity. These scales

ranged from 1 (not at all satisfying, plausible, detailed, or unfamiliar) to 7 (very satisfying, very plausible, etc.).

Table 2: Sample biological trait explanations.

Bligs are a kind of animal with fur that is blue. Why do bligs have blue fur?
Teleological A: Because that way they can hide from predators in their environment, which contains blue rocks.
Teleological B: Because that way they can attract others of their species, who are drawn to blue.
Mechanistic A: Because of their mineral-rich diet, which contains compounds that are blue.
Mechanistic B: Because the surface of their planet contains fine, blue dust that sticks to their fur.

Following this encoding task, participants completed 24 distractor questions involving “Alien Math” which took 3 minutes to complete. Participants then completed a cued recall task and a recognition task. The cued recall task involved prompts such as the following:

You previously saw the following: “Bligs are a kind of animal with fur that is blue. Why do bligs have blue fur?” What was the answer provided for this question? Please reproduce the answer you received as accurately as you can.

This prompt was repeated for each why question.

In the recognition task, the 20 why-questions were again repeated along with four candidate answers. The four answers included the one previously seen by that participant, as well as three additional answers for that why-question drawn from the three unrepresented stimulus sets.

Participants were randomly assigned to a stimulus set. The question orders for encoding, recall, and recognition were randomized, as were the multiple-choice answers in the recognition task.

Results and Discussion

To analyze recall data, two independent coders categorized participant responses to cued recall questions as correct or incorrect/absent based on whether the explanation captured the gist of the mechanism or function. Coder agreement was 93%.

Recall accuracy was analyzed as a dependent measure in an ANOVA with explanation type and domain as within-subjects factors. This analysis revealed significant main effects of explanation type, $F(1,99)=25.5$, $p<.01$, and domain, $F(1,99)=7.90$, $p<.01$, with teleological explanation recalled more reliably than mechanistic explanations, and explanations for artifacts recalled more reliably than explanations for biological traits (see Fig. 1).

Recognition errors were analyzed as the dependent measure in an equivalent ANOVA, revealing a main effect of explanation type, $F(1,99)=5.05$, $p<.05$. Participants made an average of .83 errors (of 10) for teleological explanations, and 1.06 errors for mechanistic explanations.

These results suggest differential memory for teleological and mechanistic explanations, with teleological explanations remembered more reliably. To examine whether these effects stem from differences in the rated satisfaction, plausibility, detail, or unfamiliarity of teleological versus mechanistic explanations, the two analyses above were repeated as Linear Mixed Model analyses with satisfaction, plausibility, detail, and unfamiliarity as covariates. The main effect of explanation type on recall remained statistically significant, $F(1,396)=10.05$, $p<.01$; the effects of domain on recall and of explanation type on recognition did not. Notably, however, the explanations did differ in satisfaction, with higher ratings for the teleological explanations, $t(99)=5.71$, $p<.01$ (see Table 3).

Table 3: Mean satisfaction ratings in Experiment 1.

Biological Mechanistic	Biological Teleological	Artifact Mechanistic	Artifact Teleological
4.32	4.86	3.90	4.16

While these findings are consistent with several hypotheses, they suggest that differential recall is not a product of differential satisfaction. Instead, memorability and satisfaction may have a common cause, potentially stemming from the way teleological explanations relate to prior knowledge.

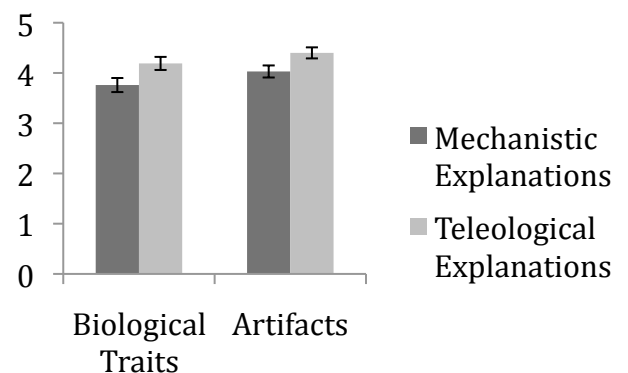

Figure 1: Recall accuracy in Experiment 1.

Experiment 2

Experiment 1 finds that teleological explanations are better remembered in two domains for which teleology is warranted. Are the mnemonic benefits of teleological explanation restricted to these domains, or do they extend more broadly? One aim of Experiment 2 is to

examine this question by extending the task to include nonliving natural entities (NNEs), such as lakes and mountains, which do not typically support teleological explanations.

Experiment 2 additionally aims to examine the nature of memory errors. To increase errors, Experiment 2 involves a larger number of explanations: 10 why-questions for each domain (artifacts, biological traits, NNEs), with one teleological and one mechanistic explanation for each why-question. Of particular interest are errors in explanation type, such as a mechanistic explanation that is “misremembered” as a teleological explanation, as systematic trends in error type could have implications for the cultural transmission of explanations. We target this issue in the recognition task by including two between-subjects conditions: one examining within-explanation type errors (e.g. teleological to teleological), and the other between-explanation-type errors (e.g. mechanistic to teleological).

Participants

Sixty University of California students and community members (72% female, mean age = 19 have participated for course credit or monetary compensation.

Materials and Procedure

The stimuli from Experiment 1 were augmented with 10 new why-questions involving the properties of Nonliving Natural Entities (NNEs), such as lightning and lakes. Four explanations for each question were generated as in Experiment 1 (see Table 4).

Table 4: Sample nonliving natural entity explanations.

A wernuct is a type of geyser that shoots very high into the air. Why do wernucts shoot high into the air?
Teleological A: Because that way giant reptiles can bathe under them.
Teleological B: Because that way the surrounding foliage can remain lush.
Mechanistic A: Because pressure builds up under ground and shoots water through cracks in the planet surface.
Mechanistic B: Because hot temperatures underground cause steam in the water, increasing its reach.

Explanations were subdivided into two stimulus sets, with each set containing a single teleological and mechanistic explanation for each why question.

The procedure mirrored Experiment 1, with the following modifications. In the explanation encoding task, participants saw each why-question twice: once presented with a teleological explanation, and once with a mechanistic explanation.

The distraction and recall tasks were identical to Experiment 1. Note that the recall prompt asked participants to report the answer to the question that they had previously seen; they were not explicitly prompted to provide two explanations.

There were two versions of the recognition task. In each version, participants received all 30 why-questions with two candidate responses: either one teleological and one mechanistic (between-type condition) or two of the same type (within-type condition), with the unseen explanations drawn from the unseen stimulus set.

Participants were randomly assigned to stimulus set and to recognition condition (between-type or within-type). Questions were presented randomly, but separated into two blocks, with order counterbalanced across participants, such that participants would see one answer for each why-question before seeing a second answer to any question. Answers for the recognition test were presented in random order.

Results and Discussion

Coding for the recall portion of the experiment was completed as in Experiment 1, with 88% agreement.

Figure 2: Recall accuracy in Experiment 2.

Recall accuracy was analyzed as a dependent measure in an ANOVA with explanation type and domain as within-subjects factors (see Fig. 2). This analysis revealed a significant effect of domain, $F(2,58)=13.4$, $p<.01$, as well as an interaction between explanation type and domain, $F(2,58)=70.5$, $p<.01$. Paired samples t-tests comparing recall for teleological and mechanistic explanations within each domain revealed significant differences, but in different directions. Teleological explanations were recalled more reliably than mechanistic explanations for biological traits, $t(59)=-3.91$, $p<.01$, and for artifacts, $t(59)=-4.39$, $p<.01$, replicating Experiment 1. In contrast, mechanistic explanations were recalled more reliably than teleological explanations for NNEs, $t(59)=8.94$, $p<.01$.

To determine whether these differences were driven by the satisfaction, plausibility, detail, or unfamiliarity of stimulus items, recall accuracy was analyzed separately for each domain in a Linear Mixed Model with explanation ratings as covariates. This analysis confirmed that teleological explanations were more reliably recalled than mechanistic explanations for biological traits, $F(1,118)=12.1$, $p<.01$, and artifacts, $F(1,118)=13.6$, $p<.01$, with the reverse pattern for NNEs, $F(1,118)=82.9$, $p<.01$. We did not replicate the satisfaction difference between mechanistic and teleological explanations found in Experiment 1.

Recognition errors were analyzed as the dependent measure in an ANOVA with explanation type and domain as within-subjects factors. This revealed a main effect of explanation type, $F(1,59)=63.9$, $p<.01$, with better recognition for teleological than mechanistic explanations (26.4 versus 22.4 of 30). There was also a main effect of domain, $F(2,58)=78.9$, $p<.01$, with better recognition for NNE (17.8/20) and artifact (17.7) explanations than for biological trait (13.3) explanations. Finally, there was an interaction between explanation type and domain, $F(2,58)=37.7$, $p<.01$, with teleological explanations recognized more reliably than mechanistic explanations for biological traits and for artifacts, but a non-significant trend in the reverse direction for NNEs (9.1 versus 8.8). These patterns of significance remained identical in a Linear Mixed Model with explanation ratings (satisfaction, etc) as covariates.

To examine the nature of memory errors, recognition accuracy was analyzed as the dependent measure in an ANOVA with recognition test (within-type versus between-type) as a between-subjects factor and explanation type as a within-subjects factor. This analysis confirmed the main effect of explanation type on recognition accuracy, $F(1,58)=75.3$, $p<.01$, with teleological explanations recognized more reliably than mechanistic explanations, and also revealed an interaction between explanation type and recognition test, $F(1,58)=11.5$, $p<.01$. Teleological explanations were correctly distinguished from teleological lures about as often as they were correctly distinguished from mechanistic lures (26.9 versus 25.8). In contrast, mechanistic explanations were more likely to be correctly distinguished from teleological lures than from mechanistic lures (23.4 versus 21.4). This suggests that mechanistic explanations were more “interchangeable” than teleological explanations.

It is worth noting that despite the sizeable advantage for mechanistic explanations of NNEs in recall, recognition performance was comparable for both teleological and mechanistic explanations. This suggests that recall performance may have reflected a preference to report warranted explanations in addition to or instead of differential effects of memory.

General Discussion

Experiments 1 and 2 suggest that when it comes to explaining the properties of biological traits or artifacts, teleological explanations are recalled more reliably than mechanistic alternatives. However, when it comes to explaining the properties of nonliving natural entities, mechanistic explanations are recalled more reliably than teleological alternatives. These effects persist when explanations’ satisfaction, plausibility, detail, and unfamiliarity are taken into account.

Data for recognition were more variable, but yielded two suggestive results. First, mechanistic explanations were more likely to be “misrecognized” as other mechanistic explanations, suggesting that mechanistic explanations generated less distinctive memories. Second, despite the overwhelming advantage for mechanistic explanations of non-living natural entities in recall, recognition performance was comparable for teleological and mechanistic explanations, suggesting that even unwarranted teleological explanations were remembered remarkably well.

The current findings suggest that memory for teleological explanations is privileged in domains for which such explanations are typically warranted – namely biological traits and artifacts – but do not rule out the possibility that memory benefits extend more broadly. In follow-up work, we plan to explicitly prompt participants to report all provided explanations in recall, thereby helping to identify whether the benefit for mechanistic explanations of NNEs resulted from a genuine difference in memory or a preference to report explanations that are believed to be warranted.

While the memory differences we find are small – especially for recognition – models of cultural transmission suggest that small biases can quickly magnify over time (Kirby, 2001; Kalish, Griffiths, & Lewandowsky 2007). Thus a modest tendency to recall or report teleological explanations could result in a disproportionate representation of such explanations after only a few generations. When it comes to religious explanations, which are arguably less responsive to data than explanations in scientific or folk theories, biases in transmission may be responsible for systematic trends across the world’s religions (see also Boyer, 2003).

We conclude by considering three important questions for future research. First, to what extent are differential effects of teleological and mechanistic explanations driven by the close relationship between teleology and intentional agency? Could it be that it is intentional explanations, not teleological explanations, that are preferentially remembered? While our effects extended to biological traits, it could be that participants construed the biological organism or natural selection as an intentional agent. Research suggests a close correspondence between teleology and intentional agency (e.g. Kelemen & DiYanni, 2005), but there is also

evidence that teleological explanations are reliably distinguished from intentional explanations (Lombrozo & Carey, 2006).

Second, to what extent are there individual differences in memory and transmission biases when it comes to explanations? In particular, what is the relationship between an individual's religious commitments and differential memory for explanation types? There is already some evidence that scientific training decreases teleological tendencies (Casler & Kelemen, 2008), while science training is inversely related with belief in god (Larson & Witham, 1997), particularly for top scientists (Larson & Witham, 1998).

Finally, and most critically, future research will need to explore the basis for differential memory for teleological and mechanistic explanations. Examining the contributions of explanation satisfaction, plausibility, detail, and unfamiliarity is a first step, as is considering a range of domains. But what is it about some explanations that make them more memorable, and hence more likely to survive processes of cultural transmission? We speculate that teleological explanations may be encoded differently from beliefs about causal mechanisms, and may have a more integrated relationship to prior knowledge. Of course, these speculations require further elaboration and empirical examination.

Abstract

We investigated the influence of sentence context on initial integration of novel word meanings into semantic memory. Adults read strongly or weakly constrained sentences ending in known and unknown (novel) words as electrical brain activity was recorded. Word knowledge was assessed via a lexical decision task where recently seen known and unknown word sentence endings served as primes for related, unrelated, and synonym/identical target words. N400 amplitudes to target words preceded by known word primes were reduced by prime relatedness. Critically, N400 amplitudes to targets preceded by novel words also varied with prime relatedness, but only if they initially appeared in highly constraining sentences. These results demonstrate that electrical brain activity accompanying one-shot contextual word learning is modulated by contextual constraint and reveals a rapid neural process that can integrate information about word meanings into the mental lexicon.

Keywords: word learning; N400; event-related brain potentials; language learning

Word learning is a lifelong process. However, research on adult first language word learning has largely been eclipsed by word learning in children and in adult bilinguals. Though these areas of study have yielded important insights into word learning, the mode by which adults learn words in their native language is likely to differ from that of children. For example, while children typically map words to novel or unnamed concepts (Markman & Wachtel, 1988), adults more often learn nuanced meanings for name-known concepts (e.g. *jocund/happy*). Furthermore, younger children often learn words in oral and ostensive contexts, whereas older children and adults acquire words largely via incidental learning in various language contexts, especially during reading (Jenkins, Stein, & Wysocki, 1984; Sternberg, 1987).

Word learning can be remarkably fast under the right conditions. A single exposure to a novel word can be sufficient for a learner to infer its probable meaning (Carey & Bartlett, 1978; Dollaghan, 1985). However, little is known about contextual influences on the representation of novel word meanings learned from a single exposure, how quickly this new information is integrated with the existing semantic system, or what the neural correlates of this rapid learning may be. The main goal of our research is to explore these issues by measuring modulation of event-related brain potentials (ERPs) during single trial word learning in sentence contexts of varying strength.

Background

Studies of adult first and second language learners provide evidence for rapid neural changes in young adults in association with word learning in both first (L1) and second (L2) languages (Borovsky, Elman, & Kutas, 2007; McLaughlin, Osterhout, & Kim, 2004; Mestres-Misse, Rodriguez-Fornells, & Münte, 2006; Perfetti, Wlotko, & Hart, 2005; Stein et al., 2006). For example, McLaughlin and colleagues (2004) compared brain responses in native French speakers to undergraduates learning French as a second language. They found that college language learner's brain responses during a semantic priming task using French words were indistinguishable from native speakers after only a few months of instruction. Their findings demonstrate not only that the brain may process word meanings acquired in childhood and adulthood similarly, but that lexical acquisition over extended training can be measured by modulations in neural activation.

L1 word learning studies have suggested that even faster neural changes due to word learning are possible (Perfetti, Wlotko & Hart, 2005; Mestres-Missé, Rodriguez-Fornells & Münte, 2007; Borovsky, Elman & Kutas, 2007). For example, Mestres-Missé and colleagues (2007) found that three presentations of a novel word in progressively constraining sentence contexts can significantly modulate the associated neural responses. We (Borovsky, Elman & Kutas, 2007) further examined the influence of contextual constraint on novel word usage after only a single presentation. Novel words were presented in a single highly or weakly constraining sentence context. Subsequently, participants were asked to differentiate between appropriate and inappropriate usages of these novel words as objects of particular verbs. Participants were able to incorporate significant information about the proper usage of novel words after a single exposure, but only when the novel words initially appeared in highly (and not in weakly) constraint contexts.

While comprehending a word's usage is an important aspect of vocabulary acquisition, knowledge of a word's relationship to other words is also vital. For example, part of our understanding of the words CAT, DOG and CHAIR, is that CAT and DOG have many overlapping similarities and features that neither shares with CHAIR. Research has indicated that adults can gain significant knowledge of these

relationships with a few exposures in sentences (Mestres-Misse et. al, 2006). In the present study, we ask whether even one exposure suffices to enable learners to incorporate the novel word into the semantic network that functionally connects words with related meanings, and how sentence contexts might influence this acquisition, if at all. More specifically, we use an event-related brain potential (ERP) component - the N400 - to index knowledge of word meaning via semantic priming when unknown words are initially presented in sentences that either strongly or weakly constrain their meaning.

The N400 is an ERP component that is a sensitive measure of semantic processing. It is a negative going wave with a centroparietal maximum that peaks approximately 400ms after the onset of any potentially meaningful stimulus. The N400 amplitude of word is reduced when it is (contextually) expected or when features associated with its meaning are easily integrated within the surrounding context (Kutas & Federmeier, 2000; Kutas & Hillyard, 1980). Additionally, the N400 to orthographically legal and pronounceable nonwords (pseudowords) is large (Ziegler, Besson, Jacobs, Nazir, & Carr, 1997); it is not present for true nonwords that do not have orthographically legal spellings, or are unpronounceable (Bentin, 1987). The N400 is modulated by lexical frequency and is larger for lower frequency words in lists (Smith & Halgren, 1987). N400 amplitude, thus, is associated with a word's meaningfulness in a given context, ranging from small in amplitude when a word is very easily integrated or understood, to large when a word's meaning is unknown. These findings suggest that N400 amplitude is likely to vary with the degree to which the meaning of a newly encountered word is appreciated – a prediction that has been borne out by recent research in L2 and L1 word learning (e.g., McLaughlin, Osterhout & Kim, 2004; Mestres-Misse et. al. 2007).

Target words preceded, or primed, by an identical or related word (for example doctor- NURSE, or doctor-DOCTOR) are associated not only with faster response times (e.g., Neely, 1991), but with reduced N400 amplitudes (Bentin, McCarthy, & Wood, 1985; Nobre & McCarthy, 1994), compared to target words preceded by words that are unrelated in meaning, or by nonwords (i.e. doctor-CHAIR, or doctor-FOOP). Such semantic priming effects have been interpreted as reflecting the functional organization of words in the brain (Collins & Loftus, 1975; Lucas, 2000).

In this study, we examine the impact of context on novel words' initial integration in semantic memory via semantic priming. Following an initial exposure in a strongly or weakly constraining sentence, we gauge successful word meaning acquisition by means of semantic priming in a lexical decision task. In this case, N400 amplitude modulation to a target word by a recently experienced prime word is taken as an index of semantic integration of the novel word's meaning into semantic memory. We use N400 amplitudes to gauge how contextual constraint influences acquisition of word meaning by contrasting how these novel words prime target words that are identical, related, or

unrelated in (implied) meaning. We can also explore how context impacts the integration of novel word meaning into the mental lexicon by assessing the interaction between the priming effect and contextual constraint.

Methods

Participants:

24 college students (13 F) were given credit or paid \$7/hr for their participation. Ages ranged between 18-30 (mean: 19.50). All participants were right-handed, native English speakers and had no significant exposure to another language at least before the age of 12. Participants reported no history of mental illness, learning disability, language impairment, drug abuse, or neurological trauma. All participants had normal hearing and normal (or corrected to normal) vision. An additional 11 participated but were not analyzed: 5 had excessive blinking or motion artifact, 1 due to equipment failure, and 5 reported a characteristic which disqualified them from analysis (4 had significant childhood second language exposure, 1 had non-normal vision.)

Materials:

Stimuli consisted of 132 sentence pairs selected from Federmeier and Kutas (1999), and 528 word pairs selected to correspond with 132 sentence final words. Both are described in detail below:

Sentences: 64 high constraint and 64 low constraint sentence pairs were selected from Federmeier and Kutas (1999). These pairs had previously been extensively normed to ensure adequate levels of cloze probability for high and low constraint sentences. Sentence pairs consisted of an initial sentence that set up an expectation of a meaning and item category, and a second sentence that was matched with sentence final words that were either plausible and expected known word sentence completions (Federmeier & Kutas, 1999), or unknown pseudowords, yielding 32 sentences in each of four main conditions: 1) High constraint / Known word ending, 2) High Constraint / Unknown word ending 3) Low constraint / Known word ending and 4) Low constraint / Unknown word ending (see Table 1a for examples). Sentences pairs were counterbalanced such that each appeared with a Known and Unknown ending equally across all versions, but not repeated within a subject. Known word target items consisted of words in 64 categories, and these categories were used as the basis for selecting semantically related and unrelated prime-target pairs, described below.

Word-Pairs: 528 word pairs were constructed that consisted of a prime followed by a target word presented one stimulus at a time. Since repetition is known to diminish N400 effects (Van Petten, Kutas, Kluender, Mitchiner, & McIsaac, 1991), and it is unclear if repetition and constraint might interact, we designed the priming task such that the N400 of interest was to the presentation of a target word that followed a prime that was either a Known or Unknown words from the sentence endings described above. The N400 effect of interest would thus be elicited to previously unseen real

word targets in three conditions: 1) Synonym/Identical (Syn/ID: rabbit-RABBIT), 2) Related (Rel: rabbit-MOUSE), and 3) Unrelated (Unrel: rabbit-RIBBON). Unrel and Rel word pairs were selected to be closely matched to other target conditions in word frequency ($F(2, 353)=1.09$, $p=0.34$) length ($F<1$), syllables ($F<1$), and phonemes ($F<1$), as reported by the MRC psycholinguistic database (Wilson, 1988). Efforts were also made to match targets as closely as possible on Concreteness, Familiarity and Imageability ratings when they were available. Additionally, targets in each condition did not differ as a function of constraint in frequency [Syn/ID: $|t| < 1$, Rel: $|t| < 1$, Unrel: $t(130)=1.06$, $p=0.29$] length [Syn/ID: $t(130)=-1.45$, $p=0.15$, Rel: $|t| < 1$, Unrel: $t(130)=-1.27$, $p=0.21$], # syllables [Syn/ID: $|t| < 1$, Rel: $|t| < 1$, Unrel: $|t| < 1$], and #phonemes [Syn/ID: $t(130)=-1.36$, $p=0.18$, Rel: $|t| < 1$, Unrel: $t(130)=-1.32$, $p=0.19$]. Highly associated word pairs were not included (like mouse-CHEESE), as confirmed via the Edinburgh Associative Thesaurus (Kiss, Armstrong, Milroy, & Piper, 1973). In cases involving Unknown word primes, Syn/ID, Rel and Unrel, was determined by its implied meaning from sentence context in which it had previously appeared.

An equal number of Nonword targets were also constructed so that the proportion of “Yes” and “No” lexical decision responses were equivalent. Nonwords were constructed using the ARC Nonword database (Rastle, Harrington, & Coltheart, 2002), and were selected to be pronounceable, and to contain between 4-7 letters.

In each version, each Known and Unknown prime was paired with two of three possible real word targets, and two nonword targets. The proportion of targets in each condition was: Nonwords=1/2, Syn/ID=1/6, Rel=1/6, Unrel=1/6. Known and Unknown prime was matched with the targets with equal frequency across versions. Table 1b includes examples of word pairs in the study.

Procedure:

Participants were tested in a soundproof, electrically-shielded chamber and were seated in a comfortable chair in front of a monitor. The experiment consisted of two interleaved tasks: sentence comprehension and priming.

In the sentence comprehension task, participants were instructed to read the sentence pairs for comprehension and to try to understand the sentences even when nonsense words appeared. The first sentence in each pair was presented in its entirety, and participants pressed a button to indicate that they were ready for the second. The second sentence was preceded by a series of crosses (500 ms duration with a stimulus-onset-asynchrony (SOA) varying randomly between 300-800 ms) to orient the participant toward the center of the screen. Sentences were presented one word at a time, each for 200 ms with a SOA of 500 ms. Participants were asked to minimize blinking and movement during sentences. The final target word appeared for 1400 ms.

In the priming task, participants were instructed to read every word that appeared on the screen and indicate with a button press if the target item (which always appeared in

capital letters) was or was not a real word. Participants viewed two sets of prime/target pairs, and were given a 2500ms offset period to blink between pairs. Prime pair onsets were preceded by a set of fixation crosses that were randomly presented for 200-500ms. Immediately following the fixation cross, a prime word appeared for 200 ms, followed by an offset of 300ms, followed by the target word presentation for 200ms, and offset of 800ms. Participants provided a lexical decision response as soon as possible after each target word appeared in capital letters.

Table 1. Examples of sentences and word pairs

A) Context Sentence Pairs (Context Constraint / Word Type)	
High/ Known	Peter sat gaping at the centerfold. He asked his friend if he could borrow the MAGAZINE.
High/ Unknown	Peter sat gaping at the centerfold. He asked his friend if he could borrow the YERGE.
Low/ Known	The package was rectangular and heavy and suspiciously academic. Bianca was disappointed that her uncle was giving her a BOOK.
Low/ Unknown	The package was rectangular and heavy and suspiciously academic. Bianca was disappointed that her uncle was giving her a SHUS.

B) Word Pairs (prime – TARGET)			
	Syn/ID	Rel	Unrel
High/ Known	magazine- MAGAZINE	magazine - NOVEL	magazine- ACCIDENT
High/ Unknown	yerge – MAGAZINE	yerge – NOVEL	yerge- ACCIDENT
Low/ Known	book – BOOK	book – LETTER	book – ROAD
Low/ Unknown	shus – BOOK	shus – LETTER	shus – ROAD

Note: all word pairs were also paired with an equal number of pseudoword targets, not depicted in this table

The experiment consisted of 11 blocks of sentence/prime sets that were interleaved as follows. Participants read 12 sentence pairs, before completing the priming task consisting of 48 pairs, with primes being selected from the 12 immediately preceding sentence endings. Participants were given a break after each sentence/priming set.

In order to ensure that participants attended to the study sentences, participants were given a surprise old/new memory post-test containing 50 sentences that had appeared in the study, and 50 sentences that had not.

Electrophysiological recording:

Scalp potentials were continuously recorded from 26 geodesically arranged sites using an ElectroCap with tin electrodes and a left mastoid reference. Potentials were digitized at a sampling rate of 250 Hz and hardware bandpass filter of 0.1-100Hz with Grass Amplifiers. Impedances were kept below 5 kΩ.

Data analysis: Data were re-referenced offline to an average left and right mastoid. Trials contaminated by eye movements, blinks, excessive muscle activity, or amplifier blocking were rejected offline before averaging. ERPs were computed for epochs extending from 100 ms pre-stimulus onset to 920 ms post-stimulus onset. Averages of artifact-free ERP trials were computed for the target words in the four learning conditions (High/Known, High/Unknown, Low/Known, Low/Unknown) as well as to targets in all priming conditions (Syn/ID, Rel, and Unrel targets for each of the four main conditions High/Known, High/Unknown, Low/Known, Low/Unknown) after subtraction of the 100 ms pre-stimulus baseline

Table 2. Mean reaction times (ms) and mean percentage of correct responses for priming task.

	Real Word Primes		Novel Word Primes	
	Constraint		Constraint	
	High	Low	High	Low
% correct				
Syn/ID	99 (0.6)	99 (1.9)	97(6)	98(2.1)
Rel	97 (2.4)	93 (4.1)	94(4.3)	95(3.5)
Unrel	93 (6.8)	96 (3.2)	95(3.4)	94(3.8)
RT				
Syn/ID	512 (80)	488 (82)	543 (77)	553 (76)
Rel	568 (87)	561 (72)	567 (79)	570 (83)
Unrel	586 (79)	578 (75)	571 (75)	567 (79)

Note: Standard deviations are reported in parenthesis.

Results

Behavioral performance:

Participants made lexical decisions for words that were identical, related, or unrelated in meaning to a prime word. Mean accuracy and RTs are shown in Table 2. We did not statistically analyze accuracy since accuracy was near ceiling, with the lowest accuracy in any condition being 93%. For RT, A three factor repeated measures ANOVA on RT was carried out with factors of Word type (Unknown and Known) x Constraint (High and Low) x Prime relationship (Identical, Related and Unrelated). A main effect of Prime was found [$F(2, 46)=85.49, p<0.0001$], with Tukey tests revealing that this effect was driven by faster responses to Identical targets than every other condition. No overall difference was found between Rel and Unrel conditions. There was also a main effect of Word Type [$F(1, 23)=11.94, p=0.002$] driven by faster responses to targets preceded by Known vs. Unknown words. An interaction of Prime x Type was also found [$F(2, 46)=29.2, p<0.0001$]. Follow-up Tukey tests revealed that this interaction was driven by targets that were preceded by Syn/ID Known words eliciting the fastest responses compared to other conditions. There were no other significant interactions. Although no significant three-way interaction was found, pairwise comparisons were conducted to examine the relationships between Syn/ID, Rel and Unrel meanings in each of the four prime conditions: Known/High, Unknown/High,

Known/Low, and Unknown/Low. These analyses revealed that targets preceded by Known/High and Known/Low primes elicited faster RTs when preceded by a word identical in meaning, compared to a related or unrelated word. On the other hand, targets preceded by Unknown words did not elicit priming effects in any condition (all $p>0.05$).

ERP data: N400 amplitude

Context sentence endings: We analyzed ERP responses to sentence endings in four conditions: Known/High, Known/Low, Unknown/High and Unknown/Low. ERPs to sentence endings are shown in Figure 1. N400 mean amplitude was measured between 250-500ms post final word onset at four centro-parietal electrode sites (RMCe, LMCE, MiCe, MiPa) where N400 effects are typically largest. A two-factor repeated measures ANOVA with factors of Word Type (Known and Unknown) and Constraint (High and Low) revealed an effect of Word Type [$F(1,23)=28.85, p<.0001$] with Unknown word endings eliciting larger N400s than Known word endings. No other main or interaction effects were observed.

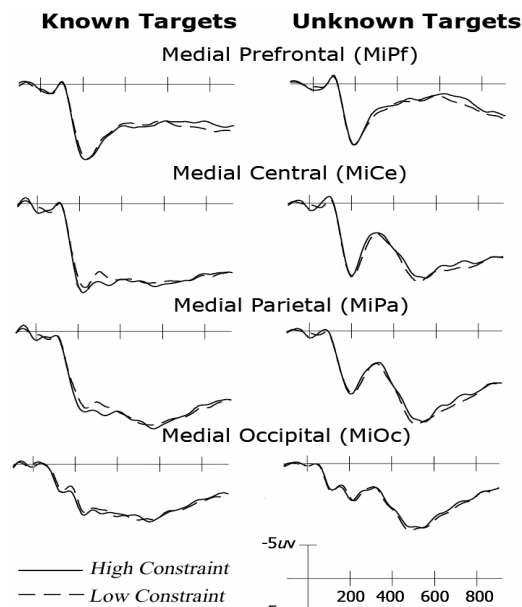

Figure 1. Grand average ERPs to known and unknown target words in context sentences at medial electrode sites.

Priming task: a shows ERPs to target words in the four main prime word conditions (Known/High, Known/ Low, Unknown/High, Unknown/Low). As can be seen from this figure, an effect of Target type is seen via modulation of the negative going peak from 250-500ms (N400) in all Prime conditions, except for Unknown/Low words. N400 mean amplitude was measured between 250-500ms post target word onset at four centro-parietal electrode sites (RMCE, LMCE, MiCe, MiPa) where N400 effects are typically largest (Figure 2b). A three-factor repeated measures ANOVA was conducted with factors of Prime-Type (Known or Unknown), Prime-Constraint (High or Low) and Target relationship (Sy/ID, Rel, Unrel), using Greenhouse-Geisser. univariate epsilon values

Table 3. F-values from pairwise ANOVAs comparing mean amplitude N400 to related, unrelated, and synonym/ID targets

		Syn/ID	Rel	Unrel
Known/High	Syn/ID	--	14.92**	30.22***
	Rel	14.92**	--	11.17**
	Unrel	30.22***	11.17**	--
Known/Low	Syn/ID	--	27.80***	23.69***
	Rel	27.80***	--	Ns
	Unrel	23.69***	ns	--
Unknown/High	Syn/ID	--	6.22*	32.24***
	Rel	6.22*	--	4.61*
	Unrel	32.24***	4.61*	--
Unknown/Low	Syn/ID	--	ns	Ns
	Rel	Ns	--	Ns
	Unrel	Ns	ns	--

* - $p < 0.05$, ** - $p < 0.01$, *** - $p < 0.0001$

This analysis revealed a significant effect of Word Type [$F(1,23)=5.4990$, $p=0.02$], with Unknown words eliciting larger N400 amplitudes than known words, and Target [$F(1.8922, 43.522)=32.439$, $p<0.0001$], with Syn/ID targets eliciting the smallest N400 amplitudes, but no main effect of Constraint [$F(1,23)<1$]. There was also an interaction of Constraint x Prime [$F(1,23)=6.29$, $p=0.02$]. No other interactions were significant. Preplanned pairwise repeated measures ANOVA comparisons were conducted to compare mean N400 amplitude between Rel, Unrel and Syn/ID targets in each of the four main Prime word conditions. The results of these comparisons are shown in Table 3. As seen from this table, significant priming effects were observed in all conditions, except for Unknown prime words that initially appeared in Low constraint contexts.

Discussion

This study explored the neural correlates of the rapid acquisition of recently experienced novel word meanings in adults' native language. Our goal was to understand the influence of sentential constraint on the integration of novel word meanings into the "mental lexicon" after only a single exposure. We measured behavioral and ERP responses in priming task to ask if the information that is rapidly integrated about novel word meanings includes information about a word's lexico-semantic relationships with other (known) words.

The behavioral (lexical decision) results did not reveal evidence of priming between novel words and related or synonymous targets. This result alone would suggest that no learning occurred regardless of sentential constraint. The electrophysiological results, however, support a different conclusion.

Known word primes produced N400 priming effects replicating a well-established result: smaller N400 amplitudes to target words preceded by identical or related words, relative to unrelated words. This was also the pattern for Unknown words (or perhaps more accurately, recently seen words) but only if it had initially appeared in a strongly

constraining context. Semantic relatedness between an Unknown (novel word) prime and a real word target could only have been inferred from the sentence context in which that novel word previously appeared and apparently only strongly constraining contexts supported this inference.

A) Known Word Primes Unknown Word Primes

Figure 2. A) Grand average ERPs to target words in priming task at the vertex electrode (MiCE). B) N400 Mean amplitudes 250-500ms. Since the N400 is a negative going wave, larger N400 amplitudes are represented by smaller values on this figure.

Previous work has suggested that adults can integrate and organize information about word meanings after a few of weeks of second language instruction (McLaughlin et al., 2004; Stein et al., 2006), and even more rapidly in adult's first language, such as after only an hour of study of word definitions (Perfetti et al., 2005) or after three presentations in sentential context (Mestres-Misse et al., 2006). Our results extend these findings to show that in some cases a single exposure of a novel word in a strongly constraining sentence context is sufficient to convey significant information about its meaning to support semantic priming, and that there is a very fast neural process which enables the integration and retention of this information over at least a several minute delay. We add to a growing body of evidence that the rapidly acquired information about novel words includes

information not only about its usage in sentences but also about its meaning.

More generally, this paradigm suggests a novel method to examine the impact of sentential context and constraint on word processing. Further research will be necessary to extend these findings to other aspects of word meaning and knowledge, and to determine how long such information about a word's usage and meaning is retained and is effective.

Abstract

In reading, it is often assumed that words are recognized sufficiently quickly, accurately, and unambiguously that downstream processes may proceed with perfect information about word identity. For example, word predictability is believed to affect early reading time measures, yet a word's predictability cannot be calculated without knowledge of the word's identity. We argue that such information is not, in general, available to the language processing system, and that it proceeds with only probabilistic information about word identity. We predict therefore that what have been analyzed previously as predictability effects must instead be based on noisy estimates of word predictability that are influenced by the predictability of visually similar words (neighbors). We test this prediction by building a Bayesian model of visual word recognition, using it to compute the 'average neighborhood surprisal' of words in a corpus, and testing the ability of this novel measure to explain human reading time data.

Keywords: Psychology, Cognitive Science, Perception, Language Understanding, Bayesian Modeling, Neighborhood Effects, Visual Uncertainty, Reading

Performance in isolated word recognition tasks is often affected by the existence or properties of words that are not presented, but that are visually similar to the words which are presented. For instance, a word with many neighbors — especially high frequency neighbors — tends to produce a faster response in the lexical decision task, and a slower response in naming or reading tasks (Perea & Rosa, 2000). Norris (2006) has argued that these divergent results can be best explained by uncertainty in the processing system. That is, noise is an inevitable component of all biological computation, and if the processor receives only noisy information about a word's shape, then it must consider all similar looking words as candidates for identification. When there are many such candidates, identifying the single correct candidate (as in the naming task) becomes more difficult, because there are many incorrect distractors and only one correct target; resolving this difficulty requires the acquisition of more sensory information, which requires more time. In the lexical decision task, however, it is not necessary to determine *which* word is seen, only *whether* a word is seen, and therefore increasing the number of candidates only makes it easier to give a correct response (even if for the 'wrong' reason).

However, in reading — that is, processing connected language, rather than isolated words — another consideration arises. In a naming task, no response can be given until the

word is identified, but when reading, the ultimate outcome is not the name of a single word, but an understanding of the text as a whole. Here, we ask: can the linguistic processing associated with a word proceed before that word is uniquely identified? And if so, what are the consequences for processing? It's possible that neighborhood effects are limited to some early, serial, word identification process, in which any uncertainty is resolved before higher-level linguistic processes begin. Alternatively, this uncertainty may be propagated through the linguistic processing system itself.

Most current models of high-level language processing fall into the former category; for instance, they take as input words, rather than probability distributions over words. However, there is some reason to suspect that the latter possibility is more plausible. Spoken language, in particular, is a very noisy signal, in which word identification is generally impossible without reference to high-level linguistic constraints. Furthermore, listeners are willing to revise their identification of perceptually ambiguous phonetic material in light of disambiguating material that follows within a short period (Connine, Blasko, & Hall, 1991). In reading, the availability of a stable visual record makes it possible in principle to acquire substantially more detailed perceptual information — but in practice the average fixation length in reading is 200 ms, comparable to the time required to plan a motor saccade. This suggests that the next saccade must be initiated almost as soon as the fixation begins, and that decisions about its timing — and thus the fixation time for the current word — must be made before the current word is fully processed. In addition, Levy, Bicknell, Slattery, and Rayner (2009) have recently used evidence from a reading task to argue that certain syntactic constructions associated with garden-path-like processing difficulty may arise from uncertainty about the identity of critical words earlier in the sentence. Therefore it seems plausible that the language processing system not only has the capacity to handle uncertain input, but that this ability is used in natural reading.

Here, we examine this question via the well-known effect of word predictability on reading time (predictable words are read more quickly, Ehrlich & Rayner, 1981). This is a useful tool, because (i) the effect is very early; it affects the duration of initial fixations on a word, in the 200–300 ms range, when we would most expect some uncertainty to remain, and (ii)

as word predictability depends on the fit between the present word and its context, it implicates higher-level linguistic processing in a way that word frequency, for instance, might not, and yet (iii) it cannot affect processing until the word is fully identified, because different words are differently predictable. All theories which invoke word predictability to explain early reading time measures therefore implicitly assume that word identification occurs early and fully.

We hypothesize that this effect does not arise from predictability *per se*, but from the processing system's 'best guess' at the word's predictability, given the uncertain information available to it. To test this hypothesis, we build a simple Bayesian model of visual word recognition, use it to estimate 'best guess' predictabilities on a corpus, and test whether this improves our ability to predict human reading-time measures.

Word recognition model

We begin with a standard Bayesian model of word recognition in sentence context, in which beliefs about the identity of the word on which the eyes are currently fixated are formed by integrating top-down prior expectations from language knowledge and context with bottom-up perceptual input:

$$P(\text{word}|\text{context}, \text{input}) = \frac{P(\text{word}|\text{context})P(\text{input}|\text{word}, \text{context})}{P(\text{input})} \quad (1)$$

The first term in the numerator, $P(\text{word}|\text{context})$, corresponds to top-down prior expectations and can be estimated from any of a variety of language-modeling techniques standard in computational linguistics (Manning & Schütze, 1999). The second term in the numerator, $P(\text{input}|\text{word}, \text{context})$, corresponds to bottom-up perceptual evidence and is the present focus: we are investigating the possibility that this evidence is imperfect and that this imperfection may be reflected in rapid eye-movement decisions in reading.

We introduce three simplifying assumptions to make our model of perceptual evidence more tractable. First, we assume conditional independence between input and context given word identity, which is natural since it is the word being identified rather than the preceding context that generates the relevant perceptual input. Second, we assume that readers are aware of how many letters exist in the word that they are looking at, and only their identity is in doubt. (A more detailed model would certainly relax this assumption, but we believe that the high visual salience of inter-word spaces makes it a reasonable initial approximation.) Third, we assume that the subjective evidence for a given letter depends only on the noisy input we receive describing that letter (and this noisy input, of course, depends in turn on the letter that is actually present in the world). In particular, we assume that our bottom-up perceptual evidence for each letter in a word is probabilistically independent of that for the other letters. Therefore, we can write the perceptual evidence for

a word as simply the product of the evidence for each of the n letters which comprise it. If E is the complete perceptual input derived from a word and E_i is the component of that perceptual input arising from the i -th letter, then normative Bayesian inference for the word's identity looks as follows:

$$\begin{aligned} P(\text{letters}|\text{input}) &= \frac{P(E|\text{letters})P(\text{letters})}{P(E)} \\ &\propto P(E_1, \dots, E_n|\text{letters})P(\text{letters}) \\ &= P(\text{letters}) \prod_{i=1}^n P(E_i|\text{letter}_i) \end{aligned}$$

The term $P(\text{letters})$ is simply the prior probability of the word in question; the perceptual evidence for the word is represented by the term $\prod_{i=1}^n P(E_i|\text{letter}_i)$.

To estimate the perceptual evidence $P(E_i|\text{letter}_i)$ obtained from each position in the word, we made use of letter-confusion matrices derived from previous norming experiments with the lowercase English alphabet (Engel, Dougherty, & Jones, 1973; Geyer, 1977). In each of these experiments, participants were presented with isolated letters for durations brief enough to induce considerable identification error, and the frequency with some presented letter α was identified as some letter β was tabulated as $f_{\alpha\beta}$. Here $\alpha = \beta$ implies correct identification and $\alpha \neq \beta$ implies misidentification. Finally we used these frequency tables to obtain a matrix M , in which each entry $M_{\alpha\beta}$ denotes the estimated probability of identifying letter α as β . For example, M_{ii} is relatively high, presumably reflecting the visual similarity of the letters t and i , whereas M_{tn} is relatively low.

Since these norming studies used viewing conditions rather unlike those that occur in natural reading, we assume that the matrix entries $M_{\alpha\beta}$ specify only the *relative* perceptual evidence provided by each letter of the word, rather than the *absolute* evidence. We therefore introduce a single free parameter q which scales the matrix as a whole, so that for the i -th letter of a word in a sentence,

$$P(E_i = \alpha|\text{letter}_i = \beta) \propto (M_{\alpha\beta})^q. \quad (2)$$

This allows us to estimate the overall level of noise in the model when analyzing human reading-time data.¹ The parameter q can be interpreted as the overall quantity of information acquired by the reader and used to inform downstream decisions; each entry in the confusability matrix is raised to the power q , and then rows are renormalized. Thus, $q = 0$ creates a uniform posterior distribution over letters, or perfect ignorance, while in the limit as q goes to infinity, the matrix becomes diagonal — representing perfect in-

¹Note that we are making a simplifying assumption by equating the perceptual evidence from the i -th letter with the letter actually in the word, rather than with noisy perceptual input generated from the actual letter, as is done in models such as (Norris, 2006). This simplifying assumption can be interpreted roughly as marginalizing over the perceptual input itself; see (Smith, Chan, & Levy, 2010) for discussion of the justification for and implications of this simplifying assumption.

formation about letter identity. Varying q between these extremes smoothly varies the overall accuracy of letter information available, while preserving relative differences in letter similarity and recognizability. Figure 1 depicts the resulting letter-confusion matrices for $q = 1$ and $q = 2$.

This idea of rescaling was also used in producing our perceptual confusion matrix M from the raw norming data. We assumed that the two experiments had different overall levels of perceptual noise, and we used maximum likelihood to find the single matrix M that — when rescaled for each experiment — best explained the data from both. However, simply averaging the two norming matrices would produce similar results.

In aggregate, these assumptions give us the following final estimate of the subjective probability that we are observing a particular word given both context and visual input:

$$P(\text{word}|\text{context}, \text{visual input}) \propto P(\text{word}|\text{context}) \prod_i P(\text{letter}_i|\text{visual input}). \quad (3)$$

Average neighborhood surprisal

Now that we have a model of the uncertainty affecting the language processing system, we can model its consequences for the predictability effect. Word predictability itself is well-described computationally by surprisal — the negative log-probability of a word in context (Hale, 2001; Levy, 2008). For clarity, in this paper we will refer to this as the *raw surprisal* (RS). We now define the *average neighborhood surprisal* (ANS) of a word in some context to be the average of the surprisal of every word that might occur in that context, weighted by that word’s similarity to the visible word, $P(\text{word}|\text{context}, \text{visual input})$. More formally,

$$ANS(\text{word}_k|\text{context}) = \sum_i P(\text{word}_i|\text{context}, \text{word}_k) RS(\text{word}_i|\text{context}). \quad (4)$$

Our fundamental prediction is that ANS will better predict reading times than RS.

The intuition here is that the processing system would prefer to spend an amount of time on a word proportional to its RS, but since visual noise makes the RS unavailable, the ANS is the best available approximation. The visual system is accurate enough that in most cases $P(\text{word}_k|\text{context}, \text{word}_k)$, the subjective probability that one is looking at word k given that one is, in fact, looking at word k , will be close to one; therefore ANS will generally be close to the RS for any given word. However, if a word has visually similar neighbors with higher surprisals, then this will pull up the ANS, and the reader will spend more time on that word ‘just in case’ it turns out to be one of those high-surprisal neighbors that require more time to process. Contrariwise, if a word has visually similar neighbors with lower surprisals, then this will pull down the average, and our reader will hurry onward faster than they otherwise might. Note especially that in this model,

a word with a dense neighborhood may be read either faster *or* slower than a word with a sparse neighborhood. It’s not the size of your neighborhood that matters, it’s who your neighbors are.

It should also be noted that other models of neighborhood effects generally predict that the presence of higher-frequency neighbors will produce an inhibitory effect on word identification, as these neighbors interfere with recognition of the true word (e.g., Perea & Rosa, 2000). Our prediction is nearly the opposite — that in reading, the presence of high probability neighbors should lead to shorter initial fixations (though it is possible that later, as more information about the word’s true identity becomes available, the eyes may slow or regress in compensation).

Methods

We compared average neighborhood surprisal to raw surprisal as predictors of human reading times in the Dundee eye-movement corpus (Kennedy, Hill, & Pynte, 2003), which consists of all eye-movements made by 10 subjects while reading a collection of newspaper articles totaling approximately 50,000 words. Several previous studies have already demonstrated surprisal effects on reading times in the Dundee corpus (Demberg & Keller, 2008; Frank, 2009; Smith & Levy, 2008). We analyzed both first fixation times — defined as the duration of the first fixation to land on each fixated word in a text — and second fixation times, defined as the duration of the second fixation to land on each word that was fixated a second time. We eliminated all fixations on words that occurred at the beginning or end of a line, which preceded or followed punctuation, that did not occur in the BNC (i.e., unknown words), or that occurred in the BNC but in segmented form (e.g., the BNC codes *don’t* as two words, *do* followed by *n’t*). Finally, we eliminated any remaining words containing uppercase letters, since our confusion norms only cover the lowercase alphabet. This left 182,169 first fixations and 42,024 second fixations for further analysis.

To obtain conditional word probabilities for both raw surprisal estimates and noisy conditional word-probability estimates (Equation 3) we used a trigram language model trained on the 100 million word British National Corpus (BNC), using the SRI Language Modeling Toolkit (Stolcke, 2002); the trigram model was smoothed using modified Kneser-Ney (Kneser & Ney, 1995), a standard technique for broad-coverage language modeling. Average neighborhood surprisal was estimated for each fixated word by plugging in raw surprisal estimates to Equation (4), and repeating this process at each value of q required by the fitting process.

As Smith and Levy (2008) have previously demonstrated that the relationship between surprisal and first fixation times in this corpus is linear, we simply regressed fixation time on RS and ANS simultaneously, with frequency (estimated from the BNC) and word length as controls. The noise parameter q was fit simultaneously with the regression coefficients by maximum likelihood. Gamma distributed error was assumed,

Figure 1: The letter confusability matrix, for different values of the scaling parameter q . For instance, presentation of the letter a to the noisy input system eventually gives rise to a particular posterior distribution over letters that is represented by the top row in each matrix. The diagonal represents the probability of veridical perception; we can see that the letter d is the least confusable in the lowercase English alphabet. As q increases (right), more information becomes available, causing the posterior distribution to cluster around the diagonal.

in order to properly account for the long right-ward tail in fixation durations.

Results

First fixations

The best fitting model had a moderate level of noise ($q = 1.306$), corresponding to a mean naming accuracy for individual letters of 66%. While this may seem low, most words contain enough letters that, combined with the constraint of linguistic context, this allows for substantial information about word identity. As a result, ANS and RS are highly correlated ($R^2 = 0.96$) — suggesting that while the models differ greatly in terms of the cognitive processes they postulate, they may be difficult to disentangle experimentally.

Even so, our data set turned out to be large enough for the regression model to give an unambiguous result: ANS better predicts human behavior than RS. That is, ANS is highly significant after controlling for RS ($t(182155) = 4.164, p \ll 0.001$), while RS has no significant effect after controlling for ANS ($t(182155) = 0.489, n.s.$). This result also remains after controlling for neighborhood size (N).

Second fixations

The same analysis on second fixations produces analogous results; ANS is highly significant ($t(42010) = 4.209, p \ll 0.001$), while RS is marginally significant in the wrong direction ($t(42010) = -1.847, p = 0.06$). More interesting, how-

ever, is examination of the q value; we predicted that a second fixation would provide more visual information about word identity, and thus result in a higher q . In fact, for second fixations, we found $q = 2.939$, suggesting that by the end of the second fixation, the eye movement control system has access to somewhat more than twice the information it has at the end of the first fixation.

Frequency prior

Equation (4) suggests that to compute the estimated, average neighborhood surprisal, the processing system must be able to, in some sense, compute the probability of *all possible* words in the current context, and sum over all of them, in time to affect the first fixation. This is a strong claim, and so to test it we calculated a simplified version of ANS in which we modified Equation 3 to replace the context-sensitive prior over words, $P(\text{word}|\text{context})$, with a simple, context-insensitive word frequency prior, $P(\text{word})$. This modified ANS was then added to our regression as an additional control. Our original context-sensitive ANS remained highly significant ($t(182154) = 4.413, p \ll 0.001$), suggesting that in the neighborhood effects we describe, the definition of ‘neighborhood’ is indeed sensitive to linguistic context.

Other determiners of reading time

While in this preliminary work we have focused on surprisal as a model reading time predictor, the essential argument applies to any word property which is believed to affect reading time, and one could define *average neighborhood X* for any interesting property *X* that was believed to affect reading time (or language processing behavior more generally). Generally, we would predict that to the extent the brain processes sensitive to property *X* must work from noisy representations of linguistic input, *average neighborhood X* would also be a better predictor of human behavior than *X* alone.

We have begun to examine this more general prediction, and in the process discovered a mystery. Using the above model to define average neighborhood word frequency, we find our regression against reading times gives just as unambiguous results as for surprisal — but the other way. That is, raw frequency is significant, and average neighborhood frequency is not. This suggests that whatever process produces word frequency effects in reading times appears to have exact information about the frequency (and therefore identity) of the word being processed, while the process which produces predictability effects has only noisy and imperfect information. Furthermore, this is true even on first fixations, so it cannot be a simple matter of the frequency effect arising later in the processing stream, when more information is available. (Evidence for frequency as a later effect than predictability would also, it seems safe to say, surprise most experts in the field.)

Discussion

Our fundamental prediction — that early predictability effects in reading are modulated by the predictability of visually similar (but unseen) words — was confirmed. Furthermore, the reduction of this effect on second fixations gives insight into the time course for resolution of uncertainty about word identity, and the failure of the word frequency prior to adequately explain the data argues for the ability of high-level linguistic constraint to quickly and robustly modulate the resolution of visual uncertainty. All our results — with the possible exception of the mysterious frequency non-effect — are compatible with a model of reading in which uncertainty about the input is propagated forward into the linguistic processing system itself.

Going forward, a major question is whether the noise we observe is truly visual noise, or whether it has another source. After all, biological computation necessarily involves noise and uncertainty at every level. When reading, for example, visual information must be gathered at the retina, transmitted and analyzed by the visual system, and converted to some higher level representation of word identity; then, this representation must be maintained in memory for semantic processing and integration. None of these processes can be perfectly veridical or reliable; all must introduce some amount of noise and uncertainty. Here, we built a specifically visual noise model, relying on a visual confusability matrix and a

letter-based word representation, but presumably all models of word similarity/confusability are similar to the first order, and we did not compare against any other noise model; therefore, while our results suggest that average neighborhood surprisal drives reading time, it may be premature to conclude that the visual system is the source of uncertainty being averaged over.

In future work, we hope to make a sharper test of this part of the model in two ways. First, we can fit a different noise parameter *q* for letters at different degrees of eccentricity from visual fixation; if this reproduces the classic curve of acuity falling off with increasing eccentricity, then that would be stronger evidence that our noise arises from visual processing limitations. Second, looking the other direction, we plan to build a simple phonological/auditory noise model, and use it to estimate ANS for written words. If this model outperforms the visual noise model, then that would be strong evidence that the noise is in fact noise in some post-recoding internal representation. Finding auditory noise in a visual paradigm would be quite curious, but there is some precedent; for instance, it has been argued that the true determiner of neighborhood size for purposes of word naming effects is the number of words which are simultaneous visual and phonological neighbors (Adelman & Brown, 2007).

Finally, we hope that further investigation may shed light on the lack of a neighborhood effect on word frequency. One possibility is that further study of the noise, as described above, will provide a clue — perhaps visual information is highly accurate, the frequency effect is a relatively early and low-level effect acting on this low-level, accurate visual representation, and the predictability-sensitive process is working with a later representation more subject to internal noise. However, this remains mere speculation, and we welcome any suggestions on this matter. In another way, though, this dissociation of frequency and predictability is quite exciting, as it suggests a possible avenue for understanding the relationship between these highly similar linguistic properties. (Indeed, as they are inherently confounded in any study using isolated words stripped of context, and quite difficult to accurately measure and deconfound in more naturalistic stimuli, it has long been unclear whether they represented distinct effects at all.) This is, to our knowledge, the first study to find qualitatively different effects of each, and we hold high hopes that our current confusion may lead to a deeper future understanding.

Acknowledgments

We are grateful to Michael Tanenhaus for the initial suggestion of averaging surprisal over the visual neighborhood, and to Shane T. Mueller for maintaining the invaluable Letter Similarity Data Set Archive (<http://obereed.net/lettersim/>). This research was partially supported by NIH Training Grant T32-DC000041 to the Center for Research in Language at UC San Diego to NJS, and by NSF grant 0953870 to RL.

Abstract

While there have been neuroimaging studies of text comprehension, little is known about the brain mechanisms underlying strategic learning from text. It was hypothesized that reading strategies would involve areas of the brain that are normally involved in reading comprehension along with areas that are involved in strategic control processes because the readers are intentionally using a complex learning strategy. The present study was designed to answer the question of what brain areas are active during performance of complex reading strategies. Activation was found in both executive control and comprehension areas, and furthermore, learning gains were found to be associated with activation in the anterior prefrontal cortex (aPFC).

Keywords: Reading Strategies; fMRI; Cognitive Control

Introduction

The importance and difficulty of comprehending expository text is obvious to anyone who has tried to learn about a new field of science by reading a textbook. The complexity of text comprehension and learning processes results in large individual differences in the strategies that students engage in to understand texts and what students extract from texts (e.g., Chi, Bassok, Lewis, Reimann, & Glaser, 1989; McNamara, 2004). While there have been neuroimaging studies of text comprehension, these studies have not examined the differences in brain activity associated with different reading strategies. Thus, understanding the neural correlates of different types of strategic reading comprehension should help us to better understand both the brain mechanisms underlying comprehension as well as the way in which these strategies affect comprehension.

There have been a number of neuroimaging studies that have investigated the brain areas involved in text comprehension (e.g., Xu, Kemeny, Park, Frattali, & Braun, 2005; Yarkoni, Speer, & Zacks, 2008). These studies show that a network of neural regions are used in text

comprehension including inferior frontal and temporal areas associated with language comprehension and production as well as areas distributed throughout the temporal, parietal, and frontal cortices that appear to be associated with building coherent representations of texts.

When contrasting sentence-level processing with narrative-level processing, Xu et al. (2005) identified a network of areas including the hippocampus, caudate, thalamus, prefrontal cortex, precuneus, posterior cingulate, and angular gyrus. Hippocampal areas are likely associated with memory formation and retrieval. They hypothesized that the caudate, thalamus, and prefrontal cortex were involved in the sequencing of higher-level processes associated with reading comprehension. Medial prefrontal cortex, precuneus, and posterior cingulate were hypothesized to be involved with linking text content with global themes and other information in memory, and the angular gyrus was hypothesized to be involved in the mental scanning of spatial representations built from the text.

A number of the areas involved in discourse comprehension are also considered part of the brain's default network that is active when people are not engaged in an external task (Buckner, Andrews-Hanna, & Schacter, 2008). Some studies of discourse processing have noted this overlap between the default network and areas active during comprehension (e.g., Xu et al., 2005; Yarkoni, Speer, Balota, McAvoy, & Zacks, 2008). The default network has been associated with self-referential processing and the generation of coherent mental representations (Hassabis & Maguire, 2007). If the reader's goal is to form a coherent representation of the text, then these processes would be involved in all forms of comprehension including strategic reading comprehension.

Reading comprehension strategies improve readers' comprehension of text. Some readers use strategies naturally, and others benefit from being provided with strategy instruction. Self-explanation is one reading strategy

that has been shown to be effective at improving readers' comprehension when students are trained or prompted to use it (Chi et al., 1994; McNamara, 2004).

Because instructing readers to self-explain often benefits readers who are skilled self-explainers more than less skilled self-explainers (Chi et al., 1994), McNamara (2004) developed Self-Explanation Reading Training (SERT) in which students are provided with instruction and practice on using reading strategies while self-explaining texts. This approach combined the technique of self-explanation with reading strategies with demonstrated effectiveness. SERT includes five component reading strategies: comprehension monitoring, paraphrasing, elaboration, bridging, and prediction (McNamara, 2004). Comprehension monitoring is being aware of whether the text is being successfully understood while reading. Paraphrasing is putting the text into one's own words. The process of putting text into one's own words helps to activate relevant semantic knowledge in long-term memory and prepares the reader to make further inferences. Inferences are necessary in most text comprehension situations because most texts do not state all relevant pieces of information explicitly (Kintsch, 1998). Elaboration involves making inferences that aid in understanding the text by using knowledge from memory. Bridging involves making inferences across sentence boundaries to aid in understanding the text. Prediction is making predictions at the end of a sentence or paragraph about what information will be contained in the next section of the text. Collectively, these strategies help the reader to process challenging, unfamiliar material by scaffolding the comprehension process. The process of self-explaining externalizes the comprehension process and the reading strategies help the reader to understand the text (i.e., using paraphrasing and comprehension monitoring) and go beyond the text by generating inferences (i.e., using elaboration, bridging, and prediction).

Because self-explanation is a strategy that enhances existing comprehension processes, then it can be expected to involve areas of the brain that are normally involved in reading comprehension along with areas that are involved in strategic control processes. A network of brain areas have been shown to be active in a variety of tasks involving executive control (Chein & Schneider, 2005; Cole & Schneider, 2007). This control network includes dorso-lateral prefrontal cortex (DLPFC), anterior cingulate cortex (ACC), pre-supplementary motor area (pSMA), dPMC, anterior insular cortex (AIC), inferior frontal junction (IFJ), and posterior parietal cortex (PPC). These areas have been shown to be active in a variety of tasks involving executive control (Chein & Schneider, 2005; Cole & Schneider, 2007). Because learning strategies such as self-explanation are effortful and complex, we hypothesize that this executive control network will be active during self-explanation. We expect lower levels of activation for less complex learning strategies that do not involve as much effort and management of complex information, such as simple paraphrasing or rereading of information.

The present study contrasted these three learning strategies—rereading, paraphrasing, and self-explaining—differing in complexity and effectiveness. Rereading is commonly used as a reading strategy but has been found to be less effective than self-explanation and is often used as a control condition to evaluate the effectiveness of self-explanation training (Chi et al., 1994). Paraphrasing a text to put it into one's own words is another learning strategy that could be used to aid comprehension. It was predicted that more complex strategies would show more engagement of the executive control network as well as greater activation of areas that previous studies have associated with text comprehension. It is an open question whether strategy effectiveness is primarily a function of more engagement (as measured by activation of the executive control network) or primarily a function of specific text comprehension processes beyond the executive control components. In addition to examining activation associates with each learning strategy, this study will examine if there are areas that are associated with measurable learning gains.

Method

Participants

Twenty-two right-handed, native English speakers were recruited from the University of Pittsburgh and Carnegie Mellon University communities (14 female, M age = 20.7; SD = 2.4; range = 18-28). None of the participants were biology majors. One participant was excluded from analysis due to excessive head motion during the scanning session.

Materials and Design

Three biology texts that were matched on length were selected along with a set of 15 short-answer questions for each text. Text and question difficulty were equated using data from a pilot study in which students answered the questions before and after reading and self-explaining the texts. The texts were separated into 12 paragraphs, each containing 2-4 sentences. Each participant performed all three learning strategies: rereading, paraphrasing, and self-explaining. Each participant was instructed to use a given learning strategy to read all of a given text. The assignment of learning strategies to texts was counterbalanced across participants. The order in which participants performed the strategies was randomized. Each text was presented over three blocks consisting of four paragraphs each. Each block of paragraphs for each of the texts was presented before the next block of paragraphs for each text (e.g., Text1-Block1, Text2-Block1, Text3-Block1, Text1-Block2, ...).

Procedure

This study took place over two sessions, separated by 2-5 days, with fMRI data collected only in the second session.

Session 1 During the first session, participants were given up to 30 minutes to complete a pretest including all of the questions for each of the three texts. Participants then

completed an iSTART session which provided instruction on how to self-explain using reading strategies.

iSTART provides high school students with instruction and practice on how to self-explain texts using the five SERT strategies described in the introduction. iSTART is described in greater detail by McNamara and colleagues (2004). iSTART training took approximately 90 minutes.

After iSTART training, the participants were provided with task practice in an MRI simulator. The MRI simulator was designed to closely simulate the physical conditions of the MRI scanner and included a magnetic tracking system to track and present feedback to the participant regarding head movement. Participants were presented with paragraphs from a practice text that was of a similar expository nature but contained different content than the texts in the experiment. Before each block of paragraphs, participants read instructions on the screen indicating the learning strategy they were to use for that block.

The title of the text was centered on the top of the screen with the paragraph appearing on the center of the screen. Along the bottom of the screen was a prompt reminding the participant of the current strategy. Participants were instructed to read the paragraph aloud once, and then to press a button on a response glove. Once they did so, the color of the paragraph's text changed from black to blue which served as a cue that they were to perform the given learning strategy aloud. The participants then reread, paraphrased, or self-explained the text and pressed a button.

The paraphrasing and self-explanation strategies were introduced within iSTART, and thus, participants were provided only brief instructions on how to either paraphrase or self-explain out loud each sentence in the text. In the paraphrase condition, participants were told to put each sentence in the paragraph into their own words without using any of the self-explanation strategies. In the self-explanation condition, participants were instructed to self-explain each paragraph using the reading strategies covered in iSTART. For the rereading condition, they were told to read and then reread each paragraph out loud until the computer indicated it was time to move to the next paragraph of text. A prompt, which flashed at the bottom of the screen, instructed the participant to stop rereading and move on to the next paragraph. The rereading condition was designed this way in order to roughly equate the amount of time spent rereading with the amount of time spent paraphrasing and self-explaining. The amount of time allotted for rereading was 45 seconds, which was determined from a pilot study in which participants applied the three strategies to the same texts.

Session 2 The second session occurred 2-5 days after the first session in order to reduce the chance that participants would read the passages with the pretest questions in mind. This session began with an iSTART practice session, which gave the participants additional practice self-explaining. fMRI data was collected for the remainder of the session. All tasks were presented using E-Prime (Psychology Software Tools, Inc., Pittsburgh, PA) on a Windows PC for

task presentation and response collection. To verify strategy use within each condition, verbal responses were collected using an active noise canceling microphone system (Psychology Software Tools, Inc., Pittsburgh, PA), which almost entirely removed the scanner background noise.

A 30-second rest period was placed before and after each block of paragraphs. A fixation cross was presented in the middle of a white screen for the rest period. Participants were told to relax and to try not to think about anything during this time. The participants completed a total of 9 blocks with each block consisting of 4 paragraphs (3 blocks for each text/learning strategy pair). Following these 9 learning blocks, participants were presented with a posttest for each text. Although the posttest was collected in the scanner, we do not examine this fMRI data in this paper.

After the posttest, participants were presented with a line search task that served as a functional localizer to localize activity in control areas. The task involved detecting a target line orientation by monitoring lines of differing orientation in four locations on the screen. The lines in these four locations changed over time, and the participants were asked to press a button when one of the locations matched the target orientation. This task has been used in prior research on executive control (Cole & Schneider, 2007).

In order to increase statistical power in the learning comparison across learning strategy conditions while constraining the number of fMRI participants, a second group of 14 behavioral participants participated using the same learning strategy paradigm outside of the scanner.

Data Acquisition and Analyses

Structural and functional images were collected on a whole body Siemens Trio 3-T scanner at the University of Pittsburgh during a 2-hour scanning session. The functional runs were acquired as 39 oblique-axial slices parallel to the AC-PC plane using a T2*-weighted echo-planar imaging pulse sequence (TE = 25 ms, TR = 2000 ms, FOV = 21, thickness = 3.5 mm, flip angle = 76, in-plane = 3.28 mm²).

The raw neuroimaging data were preprocessed and analyzed using the AFNI software package (Cox, 1996). All functional images were realigned to the first image of each run, which were aligned to the first run of each participant. The images were then transformed into Talairach space (Talairach & Tournoux, 1988). For visualization, statistical maps were mapped onto the cortical surface using Caret (Van Essen et al., 2001).

Analyses of the fMRI data used voxel-based statistical techniques. Unless otherwise specified, all results were corrected for multiple comparisons using family-wise error (FWE) cluster size thresholding. At the individual participant level, general linear models were fit to the data using a set of boxcar functions for the conditions of interest convolved with a standard hemodynamic response function. Each group-level analysis used a mixed effects model with participants treated as a random factor.

The line search task was used to define participant-specific regions of interest (ROIs) for the six bilateral areas

of the control network. Local peaks of activation corresponding to the anatomical location of the control net areas were used to identify each ROI. All statistically significant voxels within a sphere of radius 15 mm from the peak were included in the ROI.

Results

Behavioral Results

The proportion correct on the pretest and posttest were used to calculate a learning gain score, where $\text{gain} = (\text{posttest} - \text{pretest}) / (1 - \text{pretest})$. This gain score adjusts for the fact that questions already answered correctly on the pretest cannot be improved upon on the posttest (Cohen, Cohen, Aiken, & West, 1999). Due to technical difficulties, the recordings from a portion of two participants' posttests were not available to be scored. These missing scores corresponded to the paraphrase strategy for one participant and the self-explanation strategy for another.

The gain scores for the behavioral and imaging participants did not differ on any of the three conditions (for all comparisons, $p > .3$), so the data for these two groups were combined for the analyses of the effect of strategy on learning. Planned comparisons showed that rereading gain ($M = .41$, $SD = .26$) did not differ from paraphrasing ($M = .42$, $SD = .22$), $t < 1$. As expected, self-explanation led to greater learning ($M = .51$, $SD = .19$) than paraphrasing, $t(32) = 2.41$, $p = .02$, Cohen's $d = 0.4$, and rereading, $t(33) = 2.03$, $p = .05$, Cohen's $d = 0.4$. With a relatively short learning period for complex science materials and a short delay between learning and test, these moderately-sized condition differences in learning were as expected.

The verbal protocols were transcribed, and the self-explanation for each paragraph was coded for whether it contained each of the five techniques comprising self-explanation. Agreement between two independent coders was reliable, 89% agreement (Cohen's kappa = .66). The self-explanation coding was used to determine whether participants were performing the strategy that they had been instructed to perform. All participants in the imaging portion of the study performed the line search task well; d' was greater than 2 for all participants.

Imaging Results

In order to directly examine differences in activation between the different strategies, a voxel-wise ANOVA with strategy (reread, paraphrase, self-explain) as a within-participant factor was conducted followed by three planned contrasts (paraphrase – reread, self-explain – reread, and self-explain – paraphrase). Contrasts were done using the strategy participants had been instructed to perform as well as using the self-explanation coding process described above to determine the condition. If a participant did not use any self-explanation strategy other than paraphrasing during a self-explanation, then it was classified as being a paraphrase. This reclassification resulted in an average of 1.7 out of 12 self-explanations per participant being

reclassified as paraphrases. The fMRI results were similar for both versions of this analysis so only the reclassified analysis is reported.

The areas more active for self-explanation compared to rereading are shown in Figure 1. The areas in the contrast between paraphrasing and rereading were a subset of these areas. Self-explanation and paraphrase both involve greater activation of the control network. These areas include DLPFC, IFJ, AIC, ACC/pSMA, PPC, and dPMC. The results are consistent with the notion that control activity increases with more complex learning strategies.

Figure 1. Areas more active while self-explaining than while rereading.

However, the contrast between the self-explanation and paraphrase conditions shows a different pattern of results as seen in Figure 2. These areas included posterior cingulate, precuneus, angular gyrus, middle temporal gyrus, and aPFC. Many of these areas are known to be part of the default network (Buckner et al., 2008). These results indicate that control areas do not account for the differential learning when using self-explanation and paraphrasing.

Analysis of areas that were active in the line search task indicated that all six areas of the control network were active, as expected. The amount of activation in control areas during performance of the learning strategies was examined by using the active voxels in a participant's line search task to identify ROIs for that participant. Average percent signal change was examined in these areas for each of the three learning strategies relative to the rest condition. For the average activation averaged across all ROIs, self-explanation and paraphrase both activated control areas more than reread, $F(1,20) = 8.94$, $p = .007$, $F(1,20) = 18.40$, $p < .001$, respectively. However, self-explanation and paraphrase did not differ in control area activation, $F(1,20) = 2.45$, $p = .13$. This analysis of control areas is consistent with the findings shown in Figures 1 and 2. Self-explanation and paraphrase do not differ in control activation.

The previous analysis examined areas that were active when participants were self-explaining. However, an alternative approach is to examine those times when it led to measurable learning. Thus, a separate analysis was conducted to examine whether there were brain regions with

Figure 2. Areas more active while self-explaining than while paraphrasing.

activity associated during successful learning with self-explanation over and above that seen for self-explanation in general. This was achieved by creating an amplitude-modulated regressor in addition to the strategy regressor for the self-explanation runs. The amplitude of this regressor was based on the gain score for a particular slide. The gain score for each slide was calculated by first determining for each question on which slide the information to answer the question was presented. Some slides may have mapped to multiple questions. In this case, the average gain across all questions mapping to that slide was calculated. The regressor for the analysis was formed by convolving a boxcar function whose value was determined by the gain score with a hemodynamic reference function. This process was used to identify brain areas exhibiting a linear relation to gain scores (Buchel, Holmes, Rees, & Friston, 1998).

This learning analysis identified a set of bilateral pre-frontal areas that were positively associated with learning gain. These areas are shown in Figure 3. There were no areas negatively associated with learning gains. In addition to the areas which were active during self-explanation, these pre-frontal areas were more active during self-explanation trials during which material was learned well enough to be answered correctly on the posttest.

Discussion

The results presented here provide evidence that complex learning strategies engage executive control regions, semantic/comprehension regions, and bilateral aPFC. The behavioral learning results confirmed that the three learning strategies differed in effectiveness as hypothesized. Comparing the least complex strategy, rereading, with the next most complex strategy, paraphrasing, showed that predominantly areas known to be involved in executive control were more active for the more complex strategy. This is consistent with our initial hypothesis that more complex strategies would require more cognitive control.

However, the control network was not more active for self-explanation than it was for paraphrasing. The effectiveness of self-explanation was never expected to be

Figure 3. Areas linearly related to measurable learning gain during self-explanation.

solely due to the controlled effort involved, but it is interesting that the more effective learning strategy requires a similar amount of control activity as a less effective one.

The areas that were more active for self-explanation than the less effective strategies include areas associated with text comprehension, memory, and the default network. Areas previously shown to be associated with text comprehension that were more active during paraphrasing and self-explaining include L IFG, caudate, thalamus, PFC, bilateral precuneus, posterior cingulate, bilateral PPC, L parahippocampal gyrus, and L angular gyrus. Given that both paraphrasing and self-explanation usually lead to better comprehension than does rereading, it seems likely this network of areas are performing similar comprehension-related processing during performance of these reading strategies. In particular, the bilateral angular gyrus, right PPC, bilateral precuneus, bilateral posterior cingulate, left fusiform gyrus, and left parahippocampal gyrus were most active only in the self-explanation condition. Of these areas, PPC, left fusiform, and right precuneus have been previously been implicated in the construction and updating of situation models (Yarkoni et al., 2008). The angular gyrus, posterior cingulate, and precuneus have been associated with relating text to prior knowledge and the use and manipulation of mental models (Xu et al., 2005). The areas active in the MTG active in self-explanation are similar to areas that have been found when people draw inferences during text comprehension (Virtue, Haberman, Clancy, Parrish, & Jung Beeman, 2006). These are exactly the kinds of cognitive processes that a strategy such as self-explanation is supposed to engage to support deep comprehension of the text.

A number of the areas more active in the self-explanation condition than in the paraphrase condition are considered to be part of the default network that is active in the absence of goal-directed activity (e.g., Buckner et al., 2008). The areas of the default network typically include mid-orbital cortex, angular gyrus/inferior parietal, lateral temporal cortex, and the hippocampus. These areas were highly active during self-explanation. One hypothesis about the default network is that it is associated with an internal stimulus-independent mode of thought (Buckner et al., 2008). These stimulus-independent thoughts have been associated with lapses in attention and mind wandering (Christoff, Gordon, Smallwood, Smith, & Schooler, 2009), but this mode of

thought is also thought to have adaptive purposes including retrieval of episodic and semantic memory along with the generation of coherent and use of coherent mental representations (e.g., Hassabis & Maguire, 2007). The retrieval of prior knowledge and the generation of coherent representations during the use of reading strategies likely make use of these same brain areas.

The analysis of the areas active during self-explanation that were correlated with the amount learned mainly included bilateral aPFC. That is, in addition to the activity in executive control and default network areas associated with self-explanation, the aPFC was more active during self-explanation of paragraphs where measurable learning took place. The aPFC is active during performance of a number of higher-order tasks, but a recent theory of aPFC function refers to it as a router or gateway between modes of thought (Burgess, Dumontheil, & Gilbert, 2007). One mode of thought is one in which external representations drive thought, and the other mode is one in which internal representations drive thought. This gateway hypothesis might help to explain the correlation of the aPFC with learning in this study. The aPFC might be helping to coordinate the reading and processing of the text presented on the screen with the internal retrieval of memories and construction of situation models. It may also reflect the coordination of an explicit strategy with the internal thought processes associated with the default network. Self-explanation may be most effective when there is strategic processing of internal representations.

This initial exploration of the neural correlates of strategic reading comprehension has shown that a network of areas associated with executive control and the manipulation of internal representations and memories underlie the effectiveness of these strategies. Future work should explore the role of aPFC in reading strategies as well as whether these results will generalize to other texts.

Abstract

During conversation, speakers and listeners act on certain basic assumptions, which enable them to communicate swiftly and seemingly effortlessly (Grice, 1975). The speaker, for instance, is supposed to say no more, but also no less than is necessary in a given conversational context (Maxim of Quantity). The present study looks at how language users react when this pragmatic assumption is violated. Participants were presented with written mini-dialogues while their ERPs (Event-Related brain Potentials) were measured. Dialogues in the violation condition, where the answer did not meet the quantity requirements, differed from control dialogues in three different time-windows, time-locked to the presentation of a critical word. Violating the Maxim of Quantity was signalled immediately and gave rise to effortful processing at different levels of representation.

Keywords: Psycholinguistics; Gricean Maxims, Implicature, Coordination, Pragmatics, Topic Structure, ERP.

Introduction

When taking part in a conversation, speaker and listener act upon specific assumptions about shared and private knowledge, and about the informativeness of the utterances that are exchanged. Grice (1975) formulated a framework in which these conversational assumptions are realized as four maxims:

- 1 a. Quality: Be truthful
- b. Quantity: Be as informative as required
- c. Relation: Be relevant
- d. Manner: Be clear

It is sometimes thought that the maxims are a kind of overly detailed puritan recipe for successful conversation. Indeed, Horn (2004) quotes a contemporary linguist exclaiming: "Would we want to have dinner with such a person, such an impeccably polite maxim observer?". A more fruitful approach, however, is to view these maxims as identifying a

default set of assumptions - specifically the listeners' assumptions about the speaker - of which all participants in a communicative situation are aware (Horn, 2004). Grice's Maxim of Quantity, for example, describes how a listener expects the speaker to say no more, but also no less than necessary in a given conversational context. In the present experiment we will investigate what happens when the speaker does not comply to this conversational rule. Consider, for instance, the mini-dialogue in (2). There, the actions of two persons, John and Peter, are under discussion, and the answer provides all the information that is needed about these two protagonists, unlike dialogue (3).

2. Question: What did John and Peter do?

Answer: John kissed Annet and Peter kissed Hank.

3. Question: What did John and Peter do?

Answer: John kissed Annet and Peter on the cheek.

It is obvious that crucial information is missing, namely an answer to the partial question "What did Peter do?" By withholding this information, the speaker is violating the Maxim of Quantity.

There are different ways in which one can violate the Maxim of Quantity. For instance, someone can answer the question about how many children she has, with "two", when in fact she has three, or incorrectly say that the water is "not cold", while it is piping hot. These are called scalar implicatures, as they involve the computation of the intended meaning (i.e., what is implicated) from a *semantic hierarchy* or *scale* (e.g., cold - warm - hot). In another situation, a speaker wanting to *refer* to a specific object should refrain from giving too much or too little information describing it. For instance, Engelhardt, Bailey, & Ferreira (2006) present eye-tracking evidence suggesting that listeners are acutely sensitive to overdescription, even though they are not consciously aware of any processing problems.

The example that we are looking at in (3), however, takes place at a different level, and is closely related to the

pragmatic concept of ‘topic-structure’ (Hoeks, Vonk, & Schriefers, 2002). A *topic* can be loosely described as the entity about which the sentence imparts information (Lambrecht, 1994). The question in (3) introduces two entities in a way that makes them very likely topics of the answer, either as a unit (“They did X”), or in a construction with contrastive topics, in which each of the entities performs a separate action (“John did X, and Peter did Y”). Their results expectation of additional information due to the Maxim of Quantity clearly played a role in the resolution of the syntactic ambiguity seen in these sentences.

Until now there have only been very few investigations of how conversational assumptions impact on-line language processing. Most of these studies focus on scalar implicatures, which are instances of the class of generalized implicatures, that is, they can be computed without reference to the preceding context. In contrast, our study looks at the on-line processing of *particularized* implicatures, where the pragmatic interpretation of an utterance is crucially dependent on the preceding context.

Experiment

In this experiment, participants read short dialogues that appeared word-by-word in the middle of a computer screen. The sentences that are used in this experiment are all grammatically correct and semantically intact; they only differ in the extent to which the answer part of the dialogues is *pragmatically felicitous* with respect to the preceding question. During the reading of the mini-dialogues, brain activity of the participants was monitored by the continuous recording of ERPs (Event Related brain Potentials). Dialogues were structured such that at the final word of the answer sentence it became clear that the answer was pragmatically anomalous, as it violated the Maxim of Quantity (equals: give exactly as much information as required, no more and no less!).

Method

Participants The participants were 18 undergraduate students from the University of Groningen (6 male, 12 female, age-range 18-29, mean 20), who received payment or course credits for taking part in the experiment. All were right-handed native speakers of Dutch with normal, uncorrected vision.

Materials In this experiment we used sentences containing NP-coordinations that were based on materials taken from Hoeks (1999). For example, see sentence (4):

4. The mayor praised the councilor and the alderman exuberantly.

In the absence of a context, language users show a clear preference for structures where the conjunct *and* conjoins NPs, instead of sentences (as in e.g., “{the mayor praised the councilor} and {the alderman laughed}”) (For English: Frazier, 1987; Frazier & Clifton, 1997; for Dutch: Hoeks, 1999; Hoeks et al., 2006). Using NP-coordinations in our experiment will thus avoid so-called ‘garden-path’ effects that occur when ambiguous utterances are ultimately

resolved towards the non-preferred reading. These sentences were embedded in two kinds of dialogue: - in the neutral condition, the sentences were preceded by a ‘neutral’ question: “What happened?”, which does not give rise to any specific expectation of the form or content of the answer (see, e.g., (5)); in the violation condition (see e.g., (6)) sentences were preceded by a question like “What did the mayor and the alderman do?”, which requires a more specific answer pertaining to what both people actually did.

The adverb (“exuberantly”) unambiguously indicates (at least in Dutch, the language used in this experiment) that the answer is a sentence with only one topic (i.e., “the mayor”), and not two, as would be expected from the question in the violation condition. Thus, the NP “the alderman” turns out not to be the expected topic, which constitutes a clear violation of the Maxim of Quantity.

5. Neutral:

Q: What happened?

A: The mayor praised the councilor and the alderman exuberantly.

6. Violation:

Q: What did the mayor and the alderman do?

A: The mayor praised the councilor and the alderman exuberantly.

Besides these two kinds of experimental dialogues - 40 in total, 20 per condition - where the answer sentence contained an NP-coordination, there were also 40 filler dialogues (half with a neutral and half with a two-topic question) in which the answer consisted of an S-coordinated sentence, so as to minimize the chance of participants developing processing strategies. In addition, there were 100 filler items from an unrelated experiment on relative clause processing; these will not be discussed further.

Design Experimental lists were created using a Latin Square, with equal numbers of items occurring in each condition on each list, and no list containing more than one version of a given item. The order in which experimental and filler items appeared was determined semi-randomly (i.e., allowing maximally three experimental items in consecutive order, but never two consecutive items in the same condition) and was the same for all lists. Each list was presented to an equal number of participants and each participant only saw one list.

Procedure Participants were tested in a dimly lit, sound-proof booth. They sat facing a computer screen at approximately 60 cm distance; a chin-rest was used to minimize movement artifacts. Participants were instructed to read each sentence for comprehension, and to respond to the occasional content question (35 in total, quasi-randomly distributed over the experiment) in order to answer “yes” or “no” by lifting the right or left index finger, respectively. Content questions were always followed by filler items, so that possible problems in answering the questions would not influence the processing of experimental items.

At the beginning of each trial, a fixation mark (an asterisk) appeared for 1 second. After that, the dialogue sentences were presented word-by-word in the centre of the screen. Each word remained on screen for 243 mSec (durations have to be a multiple of the screen refresh time), and was followed by a blank screen with a duration of 243 mSec. Between the question-part of the dialogue and the answer there was an interval of 729 mSec. At the end of an experimental item, the word “Knipper” (= “Blink”) was shown for 3 seconds, giving participants the opportunity to blink; they were instructed to try and avoid blinking during the presentation of the sentence to avoid eye-movement and blink-related artifacts. After every 50 trials, the participant could take a short break. The experiment took about 105 min, including preparation.

EEG recording parameters The EEG activity was recorded by means of 20 tin electrodes mounted in an elastic cap (see Figure 1): FP1, FP2, FZA, F7, F3, FZ, F4, F8, T7, C3, CZ, C4, T8, P7, P3, PZ, P4, P8, O1, and O2. Bipolar horizontal EOG was recorded between electrodes at the outer left and right canthus. Bipolar vertical EOG was recorded for both eyes. Electrode impedances were kept below 5 k Ω . EEG and EOG signals were sampled at 1000 Hz, amplified (EEG: 0.2 mV/V; EOG: 0.5 mV/V; time constant: 10 sec.), and digitally low-pass filtered with a cut-off frequency of 30 Hz; effective sample frequency was 100 Hz.

Figure 1: Electrode placement (triangle indicates nose of participant)

Results

Data Analysis Participants read attentively, answering on average 85% (SD = 5.6) of the content questions correctly. Visual inspection of the ERP waveforms following the presentation of the critical adverb (‘exuberantly’) suggested three effects of the violation condition as compared to the neutral condition (see Figure 2): an early bipolar component in the ELAN time-window (180-320 mSec post-onset), which was followed by a positivity in the N400 time-window (350-550 mSec post-onset), and a late positivity in the early P600 time-window (550-750 mSec post-onset).

For each of those intervals, average ERPs were computed for each electrode site, each participant, and each condition

separately. Prior to averaging, trials with ocular or amplifier-related artifacts were excluded from analysis.

The ambiguous NP in the answer sentence (e.g., “the alderman”) was mentioned in the question of the Violation condition (“What did the mayor and the alderman do?”) but not in the question of the Neutral condition (“What happened?”), which might have given rise to a reduction of the N400 due to repetition priming (Kutas et al., 2007) or other effects. To rule out the possibility that effects on the preceding word influenced the pattern of results at the critical adverb, a 100 mSec post-stimulus onset baseline was used instead of a pre-stimulus baseline, time-locked to the onset of the critical word (for a similar procedure, see Philips, Kazanina, & Abada, 2005; Mueller, 2008).

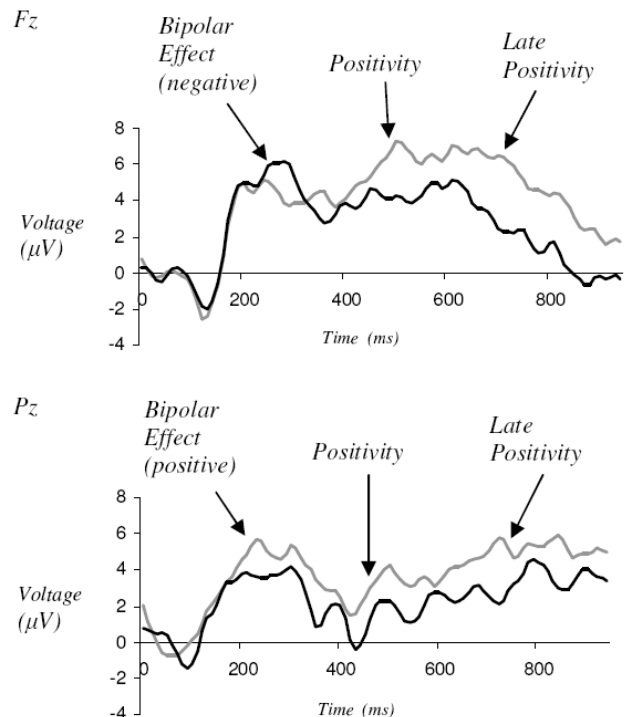

Figure 2. ERP-waveforms starting at the presentation of the *disambiguating adverb* for dialogues containing violations (grey) and neutral dialogues (black) on a frontal (Fz) and a posterior electrode (Pz).

For analysis purposes, three sets of electrodes were used: the prefrontal electrodes FP1, FZA, and FP2; the occipital electrodes O1 and O2; and the main set of electrodes. For each of these sets (and for each of the three relevant time-windows) average ERPs were statistically analyzed using Repeated-Measures ANOVA (Analysis of Variance) with Violation (violation vs. neutral) as a within-participant factor. In each of these ANOVAs topographical factors were also included: 1) for the prefrontal set this was the factor Laterality with 3 levels (i.e., left, midline, and right side of the scalp); 2) for the occipital set Laterality only had 2 levels (i.e., left and right); 3) for the main set of 15 electrodes, Laterality had 5 levels (far left, left, middle, right, far right),

and a second factor, Anteriority, had 3 levels (anterior, central, and posterior). Where appropriate, the Huynh-Feldt correction was applied to correct for violations of the statistical assumption of sphericity. We will report the corrected p-values with the original degrees of freedom. Because only effects involving the factor Violation tell us something about our pragmatic manipulation, other effects will not be reported.

Early Bipolar Effect (180-320 mSec post-onset: *ELAN time-window*)

In the analysis of the main set of electrodes, the interaction of Violation x Anteriority was significant ($F(2,30) = 5.34$; $p < .05$), but qualified by a significant three-way interaction of Violation x Anteriority x Laterality ($F(8,120) = 2.22$; $p < .05$).

Follow-up analyses showed significant and near to significant interactions between Violation x Anteriority for every level of Laterality, except for the electrodes on the far right (far left: $F(2,30) = 3.20$; $p = .07$; left: $F(2,30) = 7.36$; $p < .01$; middle: $F(2,30) = 8.72$; $p < .01$; right: $F(2,30) = 3.18$; $p = .07$; far right: $F < 1$). Each of these interactions was characterized by a frontal negativity (violation more negative than neutral), coupled with a posterior positivity (violation more positive than neutral), with central electrodes falling in between. Table 1 displays the size of the violation-effect as a function of Anteriority and Laterality. Analysis regarding the occipital electrodes produced a significant main effect of Violation ($F(1,15) = 5.35$; $p < .01$), where the violation condition was more positive than the neutral condition (a difference of $0.8 \mu V$); there were no significant effects in the analysis of the prefrontal electrodes.

Table 1: Effect Sizes (*violation minus neutral*, in μV) for frontal, central, and posterior electrodes on every level of Laterality in the first time-window (180-320 mSec post-onset)

	Far Left	Left	Middle	Right	Far Right
Frontal	-0.8	-0.7	-0.9	-0.5	-0.4
Central	0.0	0.4	0.5	0.2	0.2
Posterior	0.9	1.1	1.2	0.6	0.1

Positivity (350-550 mSec post-onset: *N400 Time-Window*)

For the main set of electrodes we found a significant effect of Violation ($F(1,15) = 5.95$; $p < .05$), with a larger positivity for the violation condition as compared to the neutral condition (a difference of $1.3 \mu V$). There was no interaction with topographical factors Anteriority and Laterality (all F-values < 1). In the analysis on the prefrontal electrodes there was also only a main effect of Violation (a difference of $1.8 \mu V$; $F(1,15) = 7.61$; $p < .05$). There were no significant effects in the analysis of the occipital electrodes (all p-values $> .19$).

Late Positivity (550-750 mSec post-onset: *P600 Time-Window*)

The analysis on the main set of electrodes produced a significant main effect of Violation ($F(1,15) = 7.99$; $p < .05$), with a larger positivity for the violation condition versus the neutral condition (a difference of $1.9 \mu V$). There was no interaction with Anteriority ($F < 1$); the interaction with Laterality was marginally significant ($F(4,60) = 2.22$; $p = .10$).

These effects were qualified by a significant three-way interaction of Violation x Anteriority x Laterality ($F(8,120) = 7.61$; $p < .05$). This interaction ensued from the effect of Violation (violation more positive than neutral) being quite pronounced on the left side of the scalp, and significantly less strong on the right (and even absent on far right electrodes). See Table 2 for the effect sizes on all electrodes contained in the main set. Analysis of the prefrontal electrodes showed a main effect of Violation where the violation condition was much more positive than the neutral (a difference of $2.8 \mu V$; $F(1,15) = 11.65$; $p < .005$). At the occipital electrodes, the violation condition gave rise to a positivity on the left (O1: $0.5 \mu V$), but to a slight negativity on the right (O2: $-0.2 \mu V$); this interaction was marginally significant ($F(1,15) = 3.64$; $p = .08$).

Table 2: Effect Sizes (*violation minus neutral*, in μV) for frontal, central, and posterior electrodes on every level of Laterality in the P600 time-window (550-750 mSec post-onset)

	Far Left	Left	Middle	Right	Far Right
Frontal	2.1	3.2	2.6	2.3	1.1
Central	2.3	2.1	1.2	1.4	1.3
Posterior	2.3	2.7	1.9	1.3	0.5

Discussion

Violating the Maxim of Quantity in these mini-dialogues had a very clear effect on ERPs, in three different time-windows.

The early frontal negativity seems to be related to the Early Left Anterior Negativity (ELAN) that has been found in response to word category violations (Friederici, 1995). The strong topic-structure expectation created by the question presumably translates into a strong syntactic expectation for an inflected verb to occur after the name of the second protagonist. If participants read an adverb instead of a verb, this may be detected very quickly. The positivity accompanying the anterior negativity may reflect the detection of the additional pragmatic violation.

After this early effect we found a broadly distributed positivity in the interval between 350 and 550 mSec after presentation of the critical word. This effect is highly reminiscent of a positivity reported by Bornkessel, Schleuisky, and Friederici (2002). According to Bornkessel et al., this positivity reflected a form of thematic reanalysis that occurs when the thematic role that is initially assigned to a discourse entity turns out to be wrong. In the present experiment the ambiguous NP (e.g., ‘the alderman’) is expected to be an AGENT (the entity that performs an action) on the basis of the question, but turns out to be a PATIENT (the entity that undergoes an action), requiring thematic reanalysis.

Finally, there was a large positive effect for the Violation condition in the P600 time-window. A P600 is generally found as a response to syntactic violations (Hagoort, Brown, & Groothusen, 1993), syntactic dependencies (Kaan et al., 2000), but also to some kinds of semantic violations (e.g., Hoeks, Stowe, & Doedens, 2004). It is generally thought to reflect the effortful processing involved in syntactic integration, or syntactic reanalysis following an error somewhere in the utterance. This effortful processing is most likely motivated by the wish to create a coherent representation of the language input. The scalp distribution of the late positivity in the present experiment, however, is not centro-parietal, as in the typical case, but is shifted to the left, and especially large at frontal electrodes. Following Friederici et al. (2002) and Hagoort et al. (1999) we might assume that the more anteriorly oriented P600 reflects the difficulty of the revision process, whereas a posterior P600 effect might result from a general failure to compute. On a more speculative note, the late positivity that we find here may in part also reflect the computation of whether the speaker wants to impart something by not giving an adequate answer to a question. In Grice's terms there is an implicature: Answering a question about X and Y solely by relating what person X did, without reference to person Y, may be an indirect way of asserting for instance that what person Y did was in fact very insignificant. Ongoing research in our lab is in fact aimed at investigating under what circumstances people will compute implicatures of this kind.

Conclusion

If Grice is right, then all language users work from the default assumptions that their conversational partners are rational beings, who produce utterances that are true, clear, and relevant, and do not contain more, but certainly not less information than is required in the specific conversational setting in which they occur. And indeed, whenever a given utterance for instance violates the Maxim of Quantity, this will be detected within 200 mSec, leading to thematic and syntactic reanalysis - and possibly also the computation of an implicature - all of which are motivated by the desire to create a coherent representation of what the other person is saying.

Acknowledgements

We would like to thank Charlotte Wunderink and Ingeborg Prinsen for their help in running the experiment.

Abstract

The wording of political messages is known to affect voting behavior, including judgments about the electability of candidates. Yet the question remains whether voting behavior also depends on fine-grained grammatical details of political messages. Results from two studies suggest that the grammatical forms used in describing political candidates' past actions can affect attitudes about electability under certain conditions. The findings provide novel insights on how language can shape thought in the political realm.

Introduction

Millions of dollars are spent on campaign ads each year. Yet little is known about how linguistic details in these messages influence people's attitudes about political candidates and ultimately whether they are elected. Here we offer new results to show that altering grammatical information can lead to different opinions about electability.

We know that the linguistic content of political messages can influence attitudes about candidates running for office (e.g., Lau & Redlawsk, 2006). People base their voting decisions on criteria emphasized by news coverage (e.g., Druckman, 2004), and their votes can be biased by the editorial slant of the newspaper they read (e.g., Druckman & Parkin, 2005). People reject incumbent candidates if times are portrayed as bad (e.g., Quattrone & Tversky, 1988). They turn away from candidates or vote for no one at all if presented with an excess of negative language (e.g., Ansolabehere & Iyengar, 1995; Garramone, 1984). Their candidate preferences are more entrenched when opposition is emphasized (e.g., Bizer & Petty, 2005). They reject candidates who contradict their metaphorical conceptions of politics and government (e.g., Lakoff, 1996). What we do *not* know is how fine-grained linguistic details in political messages influence voters. Can grammatical information affect attitudes about candidates and whether they are electable, and if so, how?

In English and many other languages, information about the temporal organization of events is provided by aspectual markers that accompany verbs. For past events, imperfective aspectual markers (*was* VERB+*ing*) emphasize the ongoing nature of actions, and perfective aspectual markers (VERB+*ed*) emphasize the completion of actions (e.g., Comrie, 1976; Frawley, 1992; Madden & Zwaan, 2003; Magliano & Schleich, 2000). These grammatical markers can influence how people think about past events. In

interpreting imperfective descriptions of past events, people take an internal perspective (e.g., Ferretti & Katz, 2010). In interpreting descriptions of motion events, for example, people tend to situate a moving character in the middle range of a trajectory toward a destination with imperfective information (Morrow, 1985; 1990). Also, details such as the individuals, objects and locations of the events are more accessible after imperfective event descriptions (e.g., Carreiras, Carriedo, Alonso, & Fernández, 1997; Ferretti, Kutas, & McRae, 2007; Madden & Theriault, 2009; Truitt & Zwaan, 1997).

In addition, when processing event descriptions people infer that more action occurs with imperfective descriptions than with perfective descriptions. For instance, people estimate that more houses were painted after reading "*John was painting houses last summer*" than after reading "*John painted houses last summer*" (Matlock, in press). People also remember past actions more easily, and are more likely to continue them in future behavior, after imperfective descriptions than perfective descriptions (e.g., Hart & Albarracín, 2009; Magliano & Schleich, 2000).

In the current work, we investigated the role of grammatical information in the interpretation of political messages, precisely, whether and how imperfective "*was* VERB + *ing*" and perfective "*VERB + ed*" would influence attitudes about the electability of political candidates. Would the imperfective form, which draws attention to details and the ongoing process of actions, lead to different attitudes about electability than would the perfective form? And might this effect be more pronounced for political messages that are negative versus positive, especially because negative information arouses emotions (e.g., Westen, 2007), captures attention (e.g., Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001; Rozin & Royzman, 2001), and affects perceptions of political candidates (e.g., Basil, Schooler, & Reeves, 1991; Lau, 1982; see Lau, Sigelman, & Brown Rovner, 2007, for a broad perspective)? Finally, can grammatical information ever influence inferences about actions themselves? Would, for instance, a phrase such as *was taking hush money* lead people to believe that more dollars were taken than a phrase such as *took hush money*? These questions are important because voters rely on information about the past to infer what politicians will do in future elected positions (e.g., Fiorina, 1981).

Two studies were designed to investigate these issues. In each, participants read about the past actions of a senator who was seeking re-election. Then they decided whether he would be re-elected. Next they provided a confidence rating for the decision. Last, participants provided a numeric estimate about the actions (e.g., amount of hush money in Study 1).

Study 1

Participants read a short passage about a fictitious politician who did (perfective) or was doing (imperfective) past actions that were either negative or positive. Based on previous research showing that an increment toward a negative pole may carry more weight in decision-making than “the same” increment toward a positive pole (e.g., Kahneman & Tversky, 1979), we hypothesized that grammatical form may more strongly influence people’s judgments about negative past actions than about positive past actions. Further, people may pay closer attention to negative events than to positive events (e.g., Baumeister et al., 2001; Rozin & Royzman, 2001), perhaps heightening the effect of any particular linguistic construal of the past event. Thus, our main prediction was that the politician would be evaluated more negatively when negative past actions were described with imperfective rather than perfective grammatical markers.

Method

Participants. A total of 369 undergraduate students at the University of California, Merced, received partial course credit in an introductory cognitive science course or an introductory psychology course. Fifteen of the individuals provided illegible responses or did not finish the task, leaving 354 participants.

Materials, Design and Procedure. Participants completed a questionnaire that appeared on a single page in a booklet that contained a set of unrelated tasks. Participants had five days to complete and return the booklet, and were told not to discuss the task with others.

Participants first read a short description of a fictitious senator who was up for re-election. The senator did or was doing negative or positive actions (see Table 1 for the four description versions). For example, he *was taking hush money* or *took hush money*, and for positive actions, he *was collecting donations* or *collected donations*.

Then these participants answered two questions, “*Will this candidate be re-elected?*” (circled Yes or No) and “*How confident are you about your decision regarding re-election?*” (used a seven point scale, ranging from “*Not at all confident*” (1) to “*Very confident*” (7)).

Next participants answered a question about the financial dealings of the senator, either “*Please estimate the total amount of hush money (in dollars)*” (in the negative valence condition) or “*Please estimate the total amount of donation money (in dollars)*” (in the positive valence condition). The senator was fictitious to avoid bias about actual political candidates.

Table 1: Stimuli for Study 1

Grammatical form		
Action	Perfective	Imperfective
valence	(verb+ed)	(was verb+ing)
Negative	Mark Johnson is a Senator in the United States Senate. He is up for re-election. He graduated from the University of Texas, Austin with a degree in political science. Mark’s first term as a United States Senator is almost complete. Last year, Mark <u>had an affair</u> with his assistant and <u>took hush money</u> from a prominent constituent. (N=92)	Mark Johnson is a Senator in the United States Senate. He is up for re-election. He graduated from the University of Texas, Austin with a degree in political science. Mark’s first term as a United States Senator is almost complete. Last year, Mark <u>was having an affair</u> with his assistant and <u>was taking hush money</u> from a prominent constituent. (N=96)
Positive	Mark Johnson is a Senator in the United States Senate. He is up for re-election. He graduated from the University of Texas, Austin with a degree in political science. Mark’s first term as a United States Senator is almost complete. Last year, Mark <u>rekindled his relationship</u> with his wife and <u>collected donation money</u> for the American Cancer Society. (N=85)	Mark Johnson is a Senator in the United States Senate. He is up for re-election. He graduated from the University of Texas, Austin with a degree in political science. Mark’s first term as a United States Senator is almost complete. Last year, Mark <u>was rekindling his relationship</u> with his wife and <u>was collecting donation money</u> for the American Cancer Society. (N=81)

Results

First, we examined the valence of past actions and electability. Not surprisingly, participants viewed the senator as more electable when his past actions were positive (80%) versus negative (22%), $\chi^2(1, N=354) = 119.94, p < .001$. Twenty-one percent of the participants did not conform to this pattern, and indicated that the candidate would be re-elected if he had done negative actions ($N = 41$), or not be re-elected if he had done positive actions ($N = 33$).

Second, we analyzed people’s confidence about their electability decision. Electability decisions were weighted by confidence, resulting in a scale ranging from -7 (Strongly Confident “No” vote) to +7 (Strongly Confident “Yes” vote). Histograms of this weighted decision are shown in Figure 1a (negative actions) and Figure 1b (positive actions).

Figure 2: Grammatical aspect changes how people view a politician's negative actions. Voter confidence in deciding not to re-elect a politician. Proportion of sample is plotted on the y-axis.

Figure 3: Grammatical aspect changes how people view a politician's negative actions. Median split judgments of hush money taken. Proportion of sample is plotted on the y-axis.

The subgroups that are evident in these data correspond to participants whose decision did, and did not, align with the action valence. This distinction may be analogous to the common distinction of correct versus incorrect responses in reaction time analyses. Only those responses that are clearly interpretable are submitted to further analyses. In this study, subsequent analyses were therefore restricted to those participants whose decision aligned with the action valence.

Figure 1: Confidence weighted electability decisions: (a) Negative Events, (b) Positive Events.

Data bearing on whether grammatical aspect influences electability were the confidence weighted scores for decisions that were consistent with the action valence. Because some of these data were skewed, and also showed some heteroskedasticity across conditions, we took a conservative approach and did a non-parametric analysis. Conclusions remain the same using parametric analyses.

Confidence ratings were divided into “Weak confidence” (rating of 3 or less extreme), “Middle confidence” (rating of 4), and “Strong confidence” (rating of 5 or more extreme) groups. As shown in Figure 2, participants’ confidence about electability varied depending on the grammatical markers used to describe the senator’s past actions. Participants were more strongly confident about their “no” decisions when the senator *was doing* negative actions (77%) than when he *did* negative actions (47%), $\chi^2(2, N = 147) = 18.27, p < .001$. They were about equally confident for their “yes” decisions when the senator *was doing* (45%) and when he *did* (39%) positive actions, $\chi^2(2, N = 133) = .65, n.s.$

Third, we analyzed estimates for money taken (hush money) or collected (donations) by the senator. Unsurprisingly, these distributions were highly skewed. We again took a conservative analysis approach, and conclusions remain the same using parametric analyses.

We divided responses into “Low” and “High” money groups based on the median estimate value of the respective decisions. The median estimate for hush money (\$100,000) structured the two groups for negative financial actions, and the median estimate for donations (\$50,000) structured the two groups for positive financial actions.

Grammatical form influenced the inferences that people made about money. Dollar estimates were higher when the senator *was taking* hush money (58% were above overall median) versus *took* hush money (37% were above overall median), $\chi^2(1, N = 147) = 6.74, p = .009$ (Figure 3). For positive actions, there was no difference (47% versus 53%, $\chi^2(1, N = 133) = .36, n.s.$).

Finally, using independent participants in a separate manipulation check, we confirmed that our “negative” and “positive” stories differed in valence. Forty-six participants who were among the English speakers who use Amazon’s Mechanical Turk Service (mturk.amazon.com) read one story selected randomly from the four versions used in the main study (Negative perfective, Negative imperfective, Positive perfective, Positive imperfective). After reading the story, participants answered the question “Please use the scale below to indicate what you think of the senator’s actions” using a 15-point scale ranging from “Very Negative” (1) to “Very Positive” (15).

As expected, participants judged the negative stories ($M = 3.48$, $SE = .64$) to be more negative than the positive stories ($M = 11.91$, $SE = .52$), $t(44) = 10.21$, $p < .001$. Further, grammatical aspect itself (perfective versus imperfective) did not influence participants’ judgments of negativity, overall or within each kind of story (all p ’s $> .18$).

In sum, people were more confident in voting not to re-elect a senator who *was doing* negative actions than a senator who *did* negative actions. They also inferred that more negative action was involved when the past event was described using imperfective aspect compared to perfective aspect.

Study 2

In everyday life, politicians do good and bad things. Here we were interested in cases involving both a positive and negative outcome. In this study, the senator was responsible for an eminent domain policy with a negative *and* a positive outcome. All participants read about both outcomes, but some read about an imperfective negative outcome and a perfective positive outcome (*was removing homes and extended roads*) and others, about a perfective negative outcome and an imperfective positive outcome (*removed homes and was extending roads*) (see Table 2). We hypothesized that the overall eminent domain policy would be interpreted more negatively when the negative action was in the imperfective than when the negative action was in the perfective.

Method

Participants. A total of 127 members of the Stanford University community were paid to participate. Most were students. Data from participants whose age was greater than 3 SDs above the mean age ($N = 5$) and from individuals who returned incomplete surveys ($N = 2$) were excluded, leaving 120 participants.

Materials and Procedure. Participants read a passage about a fictitious senator who was seeking re-election and who had implemented an eminent domain policy with a negative and a positive outcome (home removal and road extension, respectively), and then answered the same questions as in Study 1. The task appeared on a single page in a booklet of unrelated materials. Participants had a week to complete the task.

Table 2: Stimuli for Study 2

Negative Imperfective	Mark Johnson is a Senator in the United States Senate. He is up for re-election. Last year, his district faced rush hour traffic problems. Under eminent domain Mark <u>was removing homes</u> and <u>extended roads</u> in his district. Traffic conditions improved. (N = 58)
Negative Perfective	Mark Johnson is a Senator in the United States Senate. He is up for re-election. Last year, his district faced rush hour traffic problems. Under eminent domain Mark <u>removed homes</u> and <u>was extending roads</u> in his district. Traffic conditions improved. (N = 62)

Results

As shown in Figure 4, participants who read about “*removing homes*” were more likely to respond that the candidate would *not* be re-elected (60%) than participants who read about “*removed homes*” (44%). The pattern was reliable, $p = .049$ (Fisher’s exact test, one-tailed, was used given our directed prediction). Participants were about equally confident in their decisions in the two conditions. There were no reliable differences in estimates about the number of roads extended or homes removed. Thus, again, grammatical information influenced attitudes about electability. In this case, despite having read about both components of an eminent domain policy, participants were biased by the use of the imperfective: They judged a politician to be less electable when the negative outcome of his policy was highlighted using imperfective aspect compared to when it was described using perfective aspect.

Figure 4: Grammatical aspect influences electability. Proportion of sample is plotted on the y-axis.

As in Study 1, we again queried independent participants ($N = 22$) about the valence of the senator's actions, using the same procedure and valence scale as Study 1. In this case, participants judged each version of the story to be about equally negative ("*removed*" $M = 6.18$, $SE = .50$; "*was removing*" $M = 8.00$, $SE = 1.21$, $t(13.32)$ (assuming unequal variances)) = 1.39, *n.s.*). It appears that the effect of grammatical aspect on electability may be somewhat insidious when reasoning is based on scenarios with mixed outcomes. When making explicit valence judgments, people see both the good and the bad, but grammatical aspect may implicitly color judgments about the political candidate himself.

General Discussion

Our studies suggest that grammar can influence electability. In Study 1, a change in the grammatical form of negative action descriptions resulted in a change in reasoning about a political candidate. People were more confident in their "no" vote, and provided higher dollar estimates for hush money when negative actions were described using imperfective than perfective. They were not sensitive to grammar when reasoning about a candidate's past positive actions. In Study 2, grammar again influenced electability, such that people reasoned about electability in line with whatever action was highlighted by imperfective aspect. Over 50% of people judged a candidate who "removed homes and *was* extending roads" to be electable while under 50% did so when the verb markers *-ed* and *-ing* were reversed.

Why did the imperfective form result in higher confidence ratings and larger money estimates than did the perfective form, for negative actions in particular? Several explanations are worth considering. First, people may pay more attention to negative events than to positive events (e.g., Baumeister et al., 2001; Rozin & Royzman, 2001), making any mental representation driven by a linguistic construal relatively more robust for negative events. Further, the contrast between two negative alternatives is often perceived to be larger than the contrast between two "equally spaced" positive alternatives (e.g., Kahneman & Tversky, 1979), and so any contrast due to grammatical form may have been amplified for negative events.

The effects of negative information and imperfective information on decision-making may be additive. The combination of negative information and imperfective information could have made for strong attitudes, including pronounced confidence about "no" votes. This is plausible given that negative information arouses emotions and captures attention (e.g., Baumeister et al., 2001; Rozin & Royzman, 2001; Westen, 2007) and the imperfective form widens scope (Frawley, 1992) and draws attention to details of actions (e.g., Carreiras et al., 1997; Ferretti, Kutas, & McRae, 2007; Madden & Theriault, 2009; Truitt & Zwaan, 1997). With heightened attention to negative details, it may be especially easy for voters to confidently reject a candidate.

Another possible explanation may simply be that people generally prefer to avoid losses when there are unknown outcomes (Kahneman & Tversky, 1979). More negative actions could be construed as risky, and lead to stronger confidence that a "no" vote was the right choice. In the same vein, the imperfective form may have prompted a sense of "ongoingness" of the politician's negative actions while the perfective form may have provided closure on negative actions. If a political candidate *did* negative events in the past, those actions could have been perceived as over and done with, and less likely to influence the future. With positive information, there are no risks or adverse consequences and thus no reason to have a strong opinion about a "yes" vote.

These mechanisms – heightened attention to negative details and risk aversion – may also operate when voters reason about mixed outcome scenarios as in Study 2. Here, the combination of imperfective and negative information ("*removing*") appeared to shift attention away from beneficial policy outcomes and lead to more decisions that the candidate would not be elected.

Further research on the fine-grained linguistic details of political messages must be conducted for a full understanding of how language influences everyday thought in the political realm. Our novel results are an initial attempt to detail these important effects of language, and suggest that under certain conditions grammatical information affects whether a political candidate is electable. Future research should examine a wider range of actions, including future actions and policy proposals, as well as other fine-grained grammatical features of political messages. Investigations of grammar using linguistic data from real political campaigns will also be informative.

Voters appear to be sensitive to fine-grained linguistic details when judging political candidates. When the past actions of a candidate were negative, descriptions using imperfective aspect damaged the candidate's electability more than descriptions using perfective aspect. Because 'scandals' involving political candidates are a hot topic in media coverage and campaign ads, insight into the power of the grammar used to communicate negative information will likely improve our understanding about how linguistic media shapes voting patterns. The current findings are consistent with previous psycholinguistic results and extend our understanding of the role of grammar in political decision-making.

How much for a transitive?

Subtle linguistic cues influence blame and punishment

Caitlin M. Fausey (cmfausey@stanford.edu)

Abstract

When bad things happen, how do we decide who is to blame and how much they should be punished? In this paper we examined whether subtly different linguistic descriptions of accidents influence how much people blame and punish those involved. In three studies, participants judged how much people involved in particular accidents should be blamed and how much they should have to pay for resulting damage. The language used to describe the accidents differed subtly between conditions: either agentive (transitive) or non-agentive (intransitive) verb forms were used. Agentive descriptions led participants to attribute more blame and request higher financial penalties than non-agentive descriptions. Further, linguistic framing influenced judgments even when participants reasoned about a well-known event like the ‘wardrobe malfunction’ of Super Bowl 2004. Importantly, this effect of language held even when people were able to see the event for themselves on video. These results demonstrate that even when people have rich established knowledge and visual information about events, linguistic framing can shape event construal, with important real-world consequences. Subtle differences in linguistic descriptions can change the way people construe what happened and how they attribute blame and dole out punishment.

Introduction

When bad things happen, how do we decide who is to blame and how much they should be punished? Linguistic and contextual framing has been shown to affect people’s reasoning in a variety of domains (e.g., Lee, Frederick, & Ariely, 2006; Levin, 1987; Levin & Gaeth, 1988; Loftus, Miller, & Burns, 1978; Loftus & Palmer, 1974; Shiv, Carmon, & Ariely 2005; Tversky & Kahneman, 1973; Tversky & Kahneman, 1981), including causal attribution (see Pickering & Majid, 2007, for a recent review). In this paper we build on this work by exploring the effects of linguistic framing in a domain of paramount real-world importance: blame and punishment.

Linguistic descriptions are of course ubiquitous in legal disputes. People linguistically frame incidents right from the very moment they occur and later in police reports, legal statements, court testimony and public discourse. Could the linguistic descriptions of an event influence how much we blame the people involved? Could language also influence how financially liable we think a person is for any resulting damage? Could linguistic framing shape construal even for well-known events (ones for which we already have rich knowledge and established mental representations) and even when we can witness the event with our own eyes?

The particular linguistic contrast of interest in this paper is between transitive agentive descriptions and intransitive non-agentive descriptions. A canonical agentive description

(e.g., *Timberlake ripped the costume*) includes a person as the subject in a transitive expression describing a change of state (in this case, ripping). A canonical non-agentive description (e.g., *The costume ripped*) is intransitive and does not place the person as the subject for the change of state event.¹ Previous work has shown that people are sensitive to this distinction between agentive and non-agentive frames. For example, people are more likely to remember the agent of an event when primed with agentive language than with non-agentive language (e.g., Fausey & Boroditsky, 2010). The attributional consequences of these linguistic frames, however, are not well understood.

The linguistic contrast between agentive and non-agentive frames has the potential to have serious real-world consequences, especially in legal contexts. For example, in the 197,745 trials held between 1674 and 1913 at London’s central criminal court (*Old Bailey Proceedings Online*, 2009), cases with the agentive phrase “*broke it*” in the court records resulted in a guilty verdict more often than cases with the non-agentive phrase “*it broke*” (76% and 70% guilty, respectively), with similar patterns for other consequential actions such as “*burned it*” versus “*it burned*” (77% and 57% guilty, respectively), $\chi^2(1, N = 2748) = 11.04, p < .05$. In the most serious of cases (when the charge was “killing”), the transitive/intransitive contrast as marked by different verbs also predicted verdicts. Saying “*killed*” resulted in more guilty verdicts than saying “*died*” (65% and 56% guilty, respectively), $\chi^2(1, N = 3814) = 21.34, p < .05$. These examples suggest that agentivity may be part of a suite of linguistic cues that are influential in legal reasoning.

In a correlational analysis like this, however, it is impossible to determine whether different linguistic forms actually caused a difference in verdicts. It could be that agentive descriptions indeed led the court more often to guilty verdicts. But it is also possible that people were simply more likely to use agentive language in cases where the defendant was actually more guilty. While the attributional consequences of transitivity have not been directly explored in the empirical literature, the question has been debated (and adjudicated!) in court. For example, in a case petitioning to change the title of a ballot measure (California’s high-profile Proposition 8 in the 2008 election

¹ The distinction we draw here is different from active versus passive voice (e.g., Garvey, Caramazza, & Yates, 1976; Kassin & Lowe, 1979; White, 2003). Here we focus on transitivity and investigate not just the attributional consequences of transitivity (blame) but also the concrete real-world outcomes of these attributions (punishment).

titled “Eliminates right of same-sex couples to marry”), the judge rejected the petitioners’ claim, ruling that “*There is nothing inherently argumentative or prejudicial about transitive verbs*” (*Jansson v. Bowen*, 2008). Few other questions in psycholinguistics have risen to a sufficient level of civic importance to be ruled on in high court.

With the high stakes of guilt, innocence and the legality of constitutional amendments on the line, it is important to empirically establish whether agentive and non-agentive frames indeed have any attributional consequences. In this paper we examine the effects of agentive and non-agentive linguistic frames on important real-world decisions about blame and punishment.

Study 1

In this study, participants read about an accidental restaurant fire that resulted in property damage. They then made judgments about the person involved in the accident. The survey was one of many unrelated surveys in a packet presented to participants.

Method

Participants. 236 students at Stanford University (96 male; mean age = 19.22 years) completed one survey in partial fulfillment of a course requirement. 116 read the agentive version of the story and 120 read the non-agentive version of the story.

Materials. Participants read either the agentive or the non-agentive account about an individual – Mrs. Smith – involved in a restaurant fire, and then answered two questions (Table 1). The two accounts contain all of the same content words (all of the same nouns, verbs and adjectives are used), involve the same individual and describe the same outcomes. The accounts differ only in the frames used to describe the accidental events (underlined in Table 1): transitive frames are used in the agentive account and intransitive frames in the non-agentive account.

Results and Discussion

Linguistic framing influenced both people’s judgments of blame and financial liability. Participants who read the agentive account ($M = 4.83$, $SE = .14$) blamed Mrs. Smith more than did participants who read the non-agentive account ($M = 4.01$, $SE = .15$), $t(234) = 4.04$, $p < .001$, $d = .53$. Impressively, a subtle difference in language caused a big difference in dollars: people who got the agentive report ruled that Mrs. Smith should pay \$247, or 36%, more in fines ($M = \$935.17$, $SE = \$43.48$) than participants who got the non-agentive report ($M = \$688.75$, $SE = \$43.64$), $t(234) = 3.99$, $p < .001$, $d = .52$.

In Study 1, linguistic framing influenced people’s judgments of financial liability. One explanation for this result could be that Mrs. Smith was punished more harshly because she was also blamed more harshly. That is, the effect of language on financial liability might be indirect, such that language influences blame, which then determines punishment. Could language *directly* impact judgments of financial liability? This question is important because of the

somewhat flexible sentencing process that occurs after guilt judgments in legal decision-making. A direct impact of language on sentencing would be an important applied result. Study 2 was designed to address this question.

Study 2

In Study 2, participants got an agentive or non-agentive accident description and also learned of a blame attribution generated by an independent review panel. This panel attributed either low, middle, or high blame to the person involved in the accident. After learning how blameworthy other people judged the person to be, participants determined the person’s financial liability for the property damage. This paradigm allows us to target the independent role of language on financial liability sentences. People’s decisions about financial liability may be guided by blameworthiness, language, or both.

Table 1: Studies 1 and 2 Reports and Questions

Agentive Report	
Mrs. Smith and her friends were finishing a lovely dinner at their favorite restaurant. After they settled the bill, they decided to head to a nearby café for coffee and dessert. Mrs. Smith followed her friends and as she stood up, <u>she flopped</u> her napkin on the centerpiece candle. <u>She had ignited</u> the napkin! As Mrs. Smith reached to grab the napkin, <u>she toppled</u> the candle and <u>ignited</u> the whole tablecloth too! As she jumped back, <u>she overturned</u> the table and <u>ignited</u> the carpet, as well. Hearing her desperate cries, the restaurant staff hurried over and heroically managed to put the fire out before anyone got hurt.	
Non-agentive Report	
Mrs. Smith and her friends were finishing a lovely dinner at their favorite restaurant. After they settled the bill, they decided to head to a nearby café for coffee and dessert. Mrs. Smith followed her friends and as she stood up, her <u>napkin flopped</u> on the centerpiece candle. The <u>napkin had ignited</u> ! As Mrs. Smith reached to grab the napkin, the <u>candle toppled</u> and the whole <u>tablecloth ignited</u> too! As she jumped back, the <u>table overturned</u> and the <u>carpet ignited</u> , as well. Hearing her desperate cries, the restaurant staff hurried over and heroically managed to put the fire out before anyone got hurt.	
Questions for Study 1	
Blame	Mrs. Smith is discussing the damage with the restaurant. How much should she be blamed for the fire? (Likert scale from 1 to 7, anchored by “Not at all to blame” and “Completely to blame”).
Financial Liability	The restaurant’s insurance policy does not cover minor fires. The restaurant has sought legal action to require Mrs. Smith to pay for the damage. Total costs to the restaurant were \$1500. How much should Mrs. Smith be required to pay?
Question for Study 2	
Financial Liability	The restaurant’s insurance policy does not cover minor fires and so the restaurant has sought legal action to require Mrs. Smith to pay for the damage. An independent review panel used their standard blame assessment scale in reviewing this case. On this scale, 0 means “not at all to blame” and 8 means “completely to blame”. The panel gave Mrs. Smith a {1,4,7}. The total costs to the restaurant were \$1500. How much should Mrs. Smith be required to pay?

Method

Participants. 179 students at Stanford University (59 male; mean age = 19.01 years) completed one survey in partial fulfillment of a course requirement. 91 read the agentive account of the restaurant fire accident (33 low-blame, 30 mid-blame, 28 high-blame) and 88 read the non-agentive account (33 low-blame, 28 mid-blame, 27 high-blame).

Materials. As in Study 1, participants read either the agentive or the non-agentive narrative and then answered the financial liability question shown in Table 1. Thus, participants in this study answered only the financial liability question, after learning that an independent panel judged the person to be either a “one” (low), a “four” (mid) or a “seven” (high) in terms of blame.

Results and Discussion

The level of blame assigned by the independent panel influenced participants’ judgments of financial liability (Figure 1). Overall, people judged that Mrs. Smith should pay more in damages when the independent panel ruled her to be highly to blame ($M = \$974.19$, $SE = \$61.97$) than when the panel assigned her a middle level of blame ($M = \$615.00$, $SE = \$56.27$) than when she was ruled to be of low blame ($M = \$425.63$, $SE = \$50.89$).

Interestingly, language also influenced financial liability judgments. As in Study 1, a subtle change in language led to a substantial change in financial liability: Mrs. Smith was held responsible for \$153, or 26%, more in damages by people who got the agentive report ($M = \$730.75$, $SE = \$49.57$) than by those who got the non-agentive report ($M = \$577.77$, $SE = \$52.35$).

A 3 (Blame: Low, Mid, High) by 2 (Language: Agentive, Non-agentive) factorial ANOVA revealed reliable main effects of assigned blame level ($F(2, 173) = 25.23$, $p < .001$) and of language ($F(1, 173) = 5.53$, $p = .02$). Assigned blame level and language did not interact, $F(2, 173) = 1.40$, $n.s.$

Guilt and linguistic framing independently influenced how much someone was required to pay for accidental property damage. Increasing assigned blame led to greater financial liability and agentive framing led to greater financial liability than non-agentive framing. This finding replicates the result from Study 1. Further, sentencing itself appears to be susceptible to linguistic framing effects.

Results from the first two studies suggest that agentive and non-agentive language can shape how people attribute blame and financial liability to individuals involved in accidents. Of course, in these two studies the only information that reasoners had about the accident was linguistic. Were people inevitably swayed by language because it was the only thing that guided what they imagined about the event? Perhaps people who received differently phrased reports imagined substantially different scenarios of what happened? In many real-life situations, the information we have about an event is purely linguistic – in court arguments, insurance claims, news accounts. But in other situations we may also have visual evidence, either as

eye-witnesses or on videotape. Would linguistic framing still have an effect even if people were able to see the event with their own eyes? Further, the restaurant fire described in Studies 1 and 2 was a novel event, one for which participants had no other previous information. Would people be so easily influenced by linguistic framing if they were reasoning about an event that they already knew something about, for which they already had a rich set of mental representations?

To address these questions, we capitalized on a widely known, much discussed, well-publicized and video-recorded event: the “wardrobe malfunction” of Super Bowl 2004 when a performance by Justin Timberlake and Janet Jackson ended with Janet Jackson’s breast being exposed on national television. Post-experiment questioning confirmed that this is indeed a well-known event; nearly all of our participants (96.9%) had heard about it and many had also seen the video (67.9%) before the experiment. With prior knowledge, and current visual evidence, could linguistic framing still influence blame and punishment?

Figure 1: Independent contributions of guilt and linguistic framing to financial liability sentences (Study 2). Mean values are plotted on the y-axis, with whiskers representing ± 1 SEM.

Study 3

In Study 3, participants reasoned about the wardrobe malfunction incident under one of three conditions: (a) they read about the incident, (b) they first read about the incident and then watched the video, or (c) they first watched the video and then read about it. In each condition, people read either an agentive or non-agentive account of the incident.

Method

Participants. 589 participants (188 male; mean age = 31.17 years) were paid for completing one survey online. Participants were recruited from the pool of English speakers who use Amazon’s Mechanical Turk (<https://www.mturk.com/mturk/welcome>). 306 read the agentive account of the event (116 read-only; 88 read-then-watch; 102 watch-then-read) and 283 read the non-agentive account of the event (93 read-only; 106 read-then-watch; 84 watch-then-read).

Materials and Design. Participants read either the agentive or non-agentive account of the “wardrobe malfunction” incident (Table 2). In two conditions participants viewed a video of the final six seconds of the performance, which included the infamous malfunction.

After reading about the incident (and in two of the conditions also watching it on video), participants answered the questions shown in Table 2. The order of the three response options was randomized and the particular order presented to each participant was the same for the blame and financial liability judgments. Because Timberlake initiated movement right before the “wardrobe malfunction” and also because of his prominent apology to Super Bowl viewers (in which he coined the very phrase “wardrobe malfunction”, Timberlake, 2004), our narratives focused on the actions of Timberlake. As a result, we expected that any effects of linguistic framing should be strongest for judging the guilt and financial liability of Timberlake. Also, because the FCC tried to fine CBS for broadcasting the incident, CBS was included among the possible targets for financial liability.

Results and Discussion

In brief, linguistic framing affected people’s judgments of blame and financial liability in all conditions: language mattered whether it was presented before, after, or without video evidence. The main results of interest are shown in Figure 2.

Conclusions from these data are the same whether all three framing contexts are considered (as reported below) or whether only the two multimodal contexts are considered. Conclusions are also supported by nonparametric analyses.

Blame and financial liability attributions were analyzed using a 2 (Language: Agentive, Non-agentive) by 3 (Task context: Read-only, Read-then-watch, Watch-then-read) factorial ANOVA for each dependent measure. For clarity of presentation, we focus on effects of language here. Language and task context never interacted.

Blame. Linguistic framing influenced people’s blame attributions (Figure 2a). Overall, people blamed Timberlake more after reading agentive language ($M = 38.76\%$, $SE = 1.59\%$) than after reading non-agentive language ($M = 30.49\%$, $SE = 1.43\%$), $F(1, 583) = 17.94$, $p < .001$. The effect of language was seen across the three conditions, with no interaction of the effect of language by condition, $F(2, 583) = .15$, $n.s.$

Language also affected attributions to chance. Overall, people attributed the outcome to chance more after reading non-agentive language ($M = 42.87\%$, $SE = 2.40\%$) than after reading agentive language ($M = 33.92\%$, $SE = 2.26\%$), $F(1, 583) = 8.99$, $p = .003$. Again this effect of language was seen across the three conditions, with no interaction of the effect of language by condition, $F(2, 583) = .20$, $n.s.$

Financial liability. The modal response for financial liability was \$0 (57.2% of all data). This is likely because the sentence “*Eventually the fine was dismissed in court*” appeared in the liability question. Nevertheless, the linguistic framing of the event influenced people’s judgments about financial liability. Overall, the proportion

of people who gave any non-zero amount of financial liability to Timberlake depended on linguistic framing. 46.7% assigned a non-zero fine after reading agentive language, while only 38.5% did so after reading non-agentive language, $\chi^2(1, N = 589) = 4.05$, $p = .044$.

The amount of money for which Timberlake was held liable likewise depended on linguistic framing (Figure 2b). Participants who got the agentive report asked that Timberlake pay an extra \$30,828.69, or 53%, more in fines than those who got the non-agentive report (*Agentive* $M = \$88,818.12$, $SE = \$8,115.75$; *Non-agentive* $M = \$57,989.43$, $SE = \$6,465.34$), $F(1, 575) = 10.31$, $p = .001$.^{2,3,4} Again there was no interaction of the effect of language by condition, $F(2, 575) = 1.22$, $n.s.$

Agentive and non-agentive linguistic framing did not affect people’s attributions of blame or financial liability to Janet Jackson or CBS.

Table 2: Study 3 Reports and Questions

Agentive Report
Justin Timberlake and Janet Jackson performed during the 2004 Superbowl Half-time Show. Toward the end of the song, Timberlake followed Jackson across the stage and stood beside her. As they sang the last line, Timberlake reached across the front of Jackson’s body. In this final dance move, <u>he unfastened</u> a snap and <u>tore</u> part of the bodice! <u>He slid</u> the cover right off Jackson’s chest! This incident made for a lot of controversy.
Non-agentive Report
Justin Timberlake and Janet Jackson performed during the 2004 Superbowl Half-time Show. Toward the end of the song, Timberlake followed Jackson across the stage and stood beside her. As they sang the last line, Timberlake reached across the front of Jackson’s body. In this final dance move, a <u>snap unfastened</u> and part of the <u>bodice tore</u> ! The <u>cover slid</u> right off Jackson’s chest! This incident made for a lot of controversy.
Questions
Blame. In your opinion, was someone to blame or was it just chance? Please allocate the percentage of blame. Be sure your numbers add up to 100%! (Response options: Justin Timberlake, Janet Jackson, Chance)
Financial Liability. The FCC (Federal Communications Commission) tried to fine CBS \$550,000 for this incident. Eventually the fine was dismissed in court. How much do you think each of the parties below should have been fined for this incident? (Response options: Justin Timberlake, Janet Jackson, CBS)

² Eight participants whose financial liability responses exceeded \$550,000 were excluded from this analysis.

³ These conclusions are the same when analyses consider just those participants who assigned Timberlake a non-zero fine ($N = 244$). Among these participants, those who got the agentive report assigned more fines ($M = \$193,726.47$, $SE = \$12,893.53$) than those who got the non-agentive report ($M = \$153,179.61$, $SE = \$12,430.78$), $t(242) = 2.22$, $p = .028$.

⁴ These data show some heteroscedasticity, but our main conclusions remain the same after appropriate corrections. A t-test which does not assume equal variances confirms a reliable difference between the financial liability assigned by participants who got agentive versus non-agentive reports, $t(559.36) = 2.97$, $p = .003$.

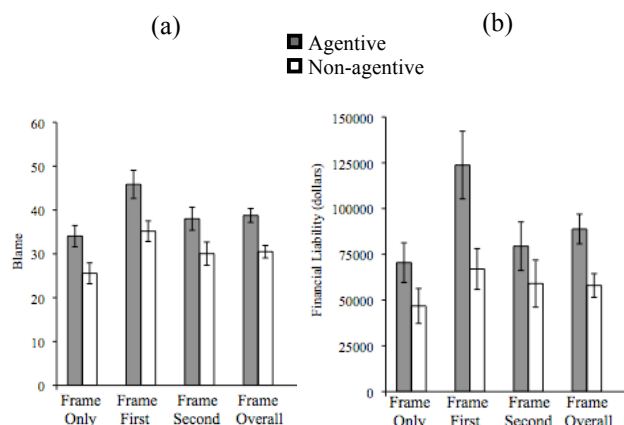

Figure 2: Language changes punishment of an observed individual (Study 3). (a) Blame attribution to Timberlake, (b) Financial liability to Timberlake. Mean values are plotted on the y-axis, with whiskers representing ± 1 SEM.

In an additional set of analyses, all of the reported contrasts were conducted with an additional factor: whether or not the participant reported having seen the video of this incident prior to the experiment. This factor was not a reliable main effect nor did it interact with effects of linguistic framing in any of the analyses.

Linguistic framing influenced how much people punished an individual involved in an event, even when they witnessed the event with their own eyes, and even though the event was one our participants already knew about. Agentive language led to harsher punishment than non-agentive language. Replicating results from the first two studies, linguistic framing not only influenced attributions of blame but also financial liability. In the case of the wardrobe malfunction incident, an agentive report led people to think that Justin Timberlake owed more than \$30,000 more (an extra 53%) in fines compared to a non-agentive report. In real-world contexts, visual evidence of accidents is rarely presented in the absence of linguistic framing. These results suggest that the form of this framing guides punishment.

General Discussion

In three studies, linguistic framing influenced participants' judgments about blame and punishment. Financial liability judgments in particular were strongly affected by linguistic framing: agentive descriptions led to 30-50% more in requested financial damages than non-agentive descriptions. Judgments of financial liability were affected by linguistic frame even when blame was held constant. This finding suggests that linguistic framing can have an influence not only on verdicts of guilt and innocence, but also on the sentencing process. Impressively, linguistic framing influenced reasoning even about an event that people knew a lot about, had seen before, and witnessed (again) right before judging the individual involved.

Previous inquiries into effects of language on attribution have examined the role of verbs, voice, and word order in guiding how people determine the cause of an event (e.g., Brown & Fish, 1983; Garvey, Caramazza, & Yates, 1976; Kasof & Lee, 1993; Kassin & Lowe, 1979; Pryor & Kriss, 1977; Schmid & Fiedler, 1988; Semin, Rubini, & Fiedler, 1995). Here, we provide the first report on the impact of transitivity on both people's attributions of blame and also on the real-world outcomes of these attributions (punishment). These studies extend previous research in several important ways. First, we probed people's decisions about a concrete form of punishment – financial liability, freely estimated in dollars – in addition to more abstract ratings of blame. Second, we examined effects of linguistic framing in the presence of previous knowledge as well as with current visual evidence – a condition that is absent from many previous attribution framing studies but present in many real-world reasoning contexts. Finally, we considered the transitive/intransitive alternation, a property of event description that both has important real-world consequences and differs interestingly across languages.

Previous work has shown that languages differ from one another in their preference for agentive versus non-agentive frames (e.g., Fausey & Boroditsky, 2010; Fausey, Long, & Boroditsky, 2009). The present findings raise the possibility that speakers of different languages may prescribe more or less severe punishment as a function of the frequency of particular grammatical frames in their language. While there have been many demonstrations showing the power of linguistic frames in shaping people's decisions, there has not been much contact between such findings and the literature investigating cross-linguistic differences in cognition. Establishing that linguistic framing has psychological consequences in a domain where languages naturally differ from one another opens the possibility for connecting these two rich bodies of knowledge.

In particular, as Sher and McKenzie (2006) have pointed out, the linguistic frames typically provided in framing studies often are not informationally equivalent. Each linguistic description is situated in a set of pragmatic norms within a language, and participants may be responding to the pragmatic cues implied by the choice of frame. The possibility of cross-linguistic comparisons offers an exciting extension to the framing literature: rather than having frames provided by an experimenter, in the cross-linguistic case, speakers of different languages may self-generate different frames for the same events because of the prevalent patterns in their respective languages (e.g., Maass, Karasawa, Politi, & Suga, 2006). In this way, cross-linguistic comparisons may allow us to investigate conceptual framing not just as a phenomenon in the communicative context (where participants may use pragmatic information to infer what the experimenter must mean by their choice of frame), but also in contexts where the participant naturally frames the event for themselves.

The linguistic (and cross-linguistic) framing of agentivity is of particular importance in court proceedings. Filipovic (2007) highlights a case from Northern California, in which a Spanish-speaking defendant's non-agentive (and

appropriate in Spanish) description of events (“*se me cayó*”, roughly “*to me it happened that she fell*”) was translated into English for the broader court into the agentive (and appropriate in English) “*I dropped her*.” Do these two descriptions mean the same thing? Or does this change in framing have serious attributional consequences? Our results raise the possibility that speakers of different languages may arrive at rather different conclusions regarding blame and punishment for the same events.

In three studies we find that agentive descriptions of events invite more blame and more severe punishment than do non-agentive descriptions. These results demonstrate that even when people have knowledge and visual information about events, linguistic framing can significantly shape how they construe and reason about what happened. In the case of agentive and non-agentive language, subtle differences in linguistic framing can have important real-world consequences. Deciding how much to blame an individual, and how much to hold them financially liable, appears to be broadly susceptible to linguistic framing.

Can mirror-reading reverse the flow of time?

Abstract

Across cultures, people conceptualize time as if it flows along a horizontal timeline, but the direction of this implicit timeline is culture-specific: in cultures with left-to-right orthography (e.g., English-speaking cultures) time appears to flow rightward, but in cultures with right-to-left orthography (e.g., Arabic-speaking cultures) time flows leftward. Can orthography influence implicit time representations independent of other cultural and linguistic factors? Native Dutch speakers performed a space-time congruity task with the instructions and stimuli written in either standard Dutch or mirror-reversed Dutch. Participants in the Standard Dutch condition were fastest to judge past-oriented phrases by pressing the left button and future-oriented phrases by pressing the right button. Participants in the Mirror-Reversed Dutch condition showed the opposite pattern of reaction times, consistent with results found previously in native Arabic and Hebrew speakers. These results demonstrate a causal role for writing direction in shaping implicit mental representations of time.

Keywords: Culture, Metaphor, Orthography, Space, Time

Introduction

Space and time are intertwined in the human mind, as they are in the physical world. The theory that people use spatial representations to think about time, first inspired by patterns in metaphorical language (Clark, 1973; Lakoff & Johnson, 1980), is now supported by numerous behavioral and neuroscientific experiments (e.g., Basso, et al., 1996; Boroditsky, 2000; Casasanto & Boroditsky, 2008; Torralbo et al., 2007; Weger & Pratt, 2008).

Yet, the way people use space to *talk* about time is not necessarily the same way they use space to *think* about it. In English and many other languages, metaphors suggest that time flows along the sagittal (front-back) axis: deadlines lie *ahead of us* or *behind us*; we can *look forward* to our golden years or *look back* on our salad days. Other languages also make use of the vertical axis to talk about time. In Mandarin Chinese, ‘the up month’ means a month earlier and ‘the down month’ a month later (Boroditsky, 2001). Yet, no known spoken language uses the lateral (left-right) axis to talk about time conventionally, and invented left-right metaphors for time sound nonsensical: Monday comes *before* Tuesday, not *to the left of Tuesday* (Cienki, 1998).

Despite the total absence of left-right metaphors in spoken language, there is strong evidence that people implicitly associate time with left-right space. Furthermore, the direction in which time flows along people’s imaginary timeline varies systematically across cultures. In one study,

Tversky, Kugelmass, & Winter (1991) asked children and adults to place stickers on a page to indicate where *breakfast* and *dinner* should appear relative to the *lunch* sticker, in the middle of the page. Whereas English speakers placed breakfast on the left and dinner on the right of lunch, Arabic speakers preferred the opposite arrangement. Fuhrman and Boroditsky (2007) showed a similar pattern in a reaction time (RT) task. English- and Hebrew-speaking participants judged whether the second of two pictures showed an earlier or later stage of an unfolding event. English speakers’ judgments were fastest when *earlier* was mapped to the left button and *later* to the right, but Hebrew speakers showed the opposite pattern. Ouellet, et al. (in press) asked Spanish and Hebrew speakers to judge auditorily presented words referring to the past or future with either their left or right hand, and found a similar reversal of the lateral space-time mapping across groups.

These experimental data reflect patterns that can be found in spontaneous behavior, as well. When English speakers produce co-speech gestures they tend to use the lateral axis for time, much more often than the sagittal axis (Casasanto, 2009a; see also Boroditsky, 2008; Cienki, 1998; Cooperrider & Nunez, 2009). Earlier times are on the left and later times on the right of body-centered space. Preliminary data from our lab suggests that Spanish speakers’ gestures follow a similar pattern, but Arabic speakers’ spontaneous gestures show the reverse mapping (Romàn, Casasanto, Jasmin, & Santiago, in prep).

Across cultures, the direction in which time flows along the mental timeline varies predictably with the orthography of the dominant language: time flows rightward in cultures whose literate members use a left-to-right orthography and leftward in cultures that use a right-to-left orthography. Yet, despite this clear correlation, it is not known to what extent reading and writing direction is a *cause* or an *effect* of cross-cultural variation in implicit space-time mappings.

In principle, a culture’s writing system could emerge with one directionality or another as a consequence of culture-specific conceptions of time -- not the other way around. This seems especially plausible for cultures where literacy (or mass-literacy) is a recent development. Alternatively, directionality in *both* orthography and in thought could arise due to cultural bootstrapping from material artifacts like calendars (whether a grid on a piece of paper, knots on a string, notches on a branch, etc.) or other devices for keeping track of time (e.g., a solar clock) or number (e.g., a horizontal abacus; Dehaene, 1999). Cultural practices tend to covary: groups who write from left to right

often spatialize time on calendars and numbers on graphs from left to right, as well. Based on the correlational data reviewed above, it is not possible to determine whether experience reading or writing plays any causal role in fixing the direction of implicit space-time mappings.

Here we performed an experimental intervention to determine whether experience with reading a left-to-right or right-to-left orthography is sufficient to determine the direction of people's implicit associations from space to time. Native Dutch speakers were assigned to perform one of two space-time congruity tasks. In one task (Experiment 1), participants saw past-oriented phrases (e.g. *a year earlier*) and future-oriented phrases (e.g. *a decade later*) appear on the screen one at a time, in standard Dutch orthography. As soon as each phrase appeared, they pressed a button (located on the left or right of a keyboard) to indicate the temporal reference of the phrase (past or future). Each participant performed two blocks: in one block the left-right key mapping required responses that were congruent with a left-to-right flow of time, and in the other responses were congruent with a right-to-left mapping. The order of blocks was counterbalanced across participants. We predicted that, on average, participants would show an RT advantage for responses consistent with standard Dutch orthography (left-to-right).

The other task (Experiment 2) was identical to the first, with one exception: all instructions and stimuli were presented in mirror-reversed text. Reading requires scanning the page in a particular direction: normally for Dutch speakers reading each line of a text requires moving the eyes gradually from the left to the right side of the page or the computer screen. As such, moving rightward in space is tightly coupled with 'moving' later in time. We reasoned that if the habit of reading from left-to-right contributes to an implicit left-to-right mapping of time in readers' minds, then practice reading in the opposite direction should weaken and eventually reverse this mapping.

Experiment 1: Standard Orthography

In Experiment 1, all instructions and stimuli were presented in standard Dutch orthography. We conducted Experiment 1 to validate the use of this space-time congruity paradigm in native Dutch speakers, and to provide a comparison group for the mirror-reading group.

Methods

Participants Native Dutch speakers (N=32) performed Experiment 1 in exchange for payment.

Stimuli Temporal phrases were constructed in Dutch, each with 3 words. The first word was an indefinite article, the second word a temporal interval, (tr., *second, moment, minute, hour, day, week, month, season, year, decade, century, millennium*), and the third word a temporal modifier (tr., *before, after, earlier, later*). The twelve temporal intervals were fully crossed with the four temporal modifiers to produce 48 temporal phrases (e.g., *a day*

before; a century after; a year earlier; a week later). Half of the phrases referred to an earlier (past-oriented) interval of time (i.e., if the modifier was *earlier* or *before*), and the other half referred to a later (future-oriented) interval (i.e., if the modifier was *later* or *after*). Two of the modifiers were spatial terms used metaphorically (*before, after*), and the other two were purely temporal terms with similar meanings (*earlier, later*). Phrases were presented in the center of a Macintosh laptop screen (resolution=1024x768), in black 48-point Arial font, on a white background.

Apparatus Participants were seated at a desk. Two A4 Xerox paper boxes were stacked on the desk, and a laptop computer was secured on top of them, to raise the screen to approximately the participants' eye-level. A standard USB keyboard was mounted horizontally on the side of the upper box, with the keys facing the participant, at about shoulder level. The keyboard was covered with a sheet of black plastic with holes that exposed only the three keys needed for responses: the "A" key on the left, the "apostrophe" key on the right, and the "H" key in the middle. The middle key was aligned with the center of the laptop screen, and the left and right keys were equidistant from it. The left key was covered with a blue sticker and the right key a red sticker, or vice versa, with the key colors counterbalanced across subjects.

Procedure The experiment consisted of two blocks. In each block, each of the 48 temporal phrases was presented once, for a total of 96 trials. Written instructions appeared on the screen before each block. In one of the blocks, participants were instructed that as soon as each phrase appeared, they should press the blue button if the phrase referred to an interval of time in the past (e.g., a week *earlier*) and the red button if it referred to an interval of time in the future (e.g., a week *later*). In the other block, the mapping between the red/blue keys and pastward/futureward phrases was reversed. To ensure that participants remembered the correct color-time mapping, after reading the instructions they were required to rehearse the correct color-time mapping aloud 5 times, before each block (e.g., "past=blue, past=blue, past=blue, etc.; future=red, future=red, future=red, etc.")

At the beginning of each trial the word 'ready' appeared in the center of the screen and remained there until the participant pressed the middle white button. 'Ready' was then replaced by a fixation cross. Participants were instructed to hold down the white button for as long as the fixation was shown. Its duration was varied randomly from 300-450 ms, in 50 ms increments, to make its duration unpredictable and discourage anticipatory movements. The fixation was then replaced by one of the 48 temporal phrases. Participants were instructed to press the colored button corresponding to the temporal reference of the phrase as quickly and accurately as possible. The phrase remained on the screen until the participant responded, at which time it was replaced by the 'ready' message to begin the next trial.

Participants pressed buttons with the index finger of the dominant (writing) hand. To ensure they would use the same hand for both rightward and leftward responses, participants were required to sit on their non-dominant hand.

The spatial direction of responses was never mentioned, but one colored button was on the right and the other on the left of the middle white button. Therefore, in one block pressing the correctly colored button called for a movement that was congruent with the space-time mapping encoded in standard Dutch orthography (e.g., pressing the blue button for a pastward phrase when the blue button was on the left); in the other block pressing the correctly colored button called for an incongruent movement (e.g., pressing the blue button for a futureward phrase when the blue button was on the left). The order of congruent-movement and incongruent-movement blocks was counterbalanced across participants. The space-time congruity effect was computed for each subject by comparing response times during Congruent and Incongruent responses (between-blocks, within-items). Testing lasted about 10 minutes.

Results and Discussion

Participants pressed the correct button on 96% of trials. Only accurate responses were analyzed. This resulted in the removal of 4% of the data. Responses greater than 5000 ms were also excluded, which resulted in the removal of 0.2% of the accurate trials.

A 2 X 2 ANOVA was conducted with Congruity of Movement Direction (Congruent with Time flowing leftward, Congruent with time flowing rightward) and Block (Block 1, Block 2) as within-subject and within-item factors. There was a highly significant main effect of Congruity ($F_1(1,15)=30.56$, $p=.0001$; $F_2(1,47)=119.38$, $p=.0001$). There was no main effect of Block ($F_1(1,15)=0.75$, ns ; $F_2(1,47)=2.99$, ns). The Congruity X Block interaction was significant by items but not by subjects ($F_1(1,15)=1.41$, ns ; $F_2(1,47)=6.27$, $p=.02$).

Congruity of Movement was then compared within each block (Block 1: $F_1(1,30)=9.62$, $p=.004$; $F_2(1,47)=116.31$, $p=.0001$; Block 2: $F_1(1,30)=3.64$, $p=.07$; $F_2(1,47)=32.55$, $p=.0001$). Mean RTs are shown in figure 1.

Overall, there was a strong effect of Congruity. Participants responded faster when the mapping between the color of the buttons and the temporal reference of the phrases required leftward movements for past-oriented phrases and rightward movements future-oriented phrases. This space-time congruity effect is similar to effects found previously in English and Spanish speakers (e.g., Torralbo, et al., 2006; Weger & Pratt, 2008). We are not aware of previous studies showing this effect in Dutch speakers, but given the correlation between writing direction and the direction of the space-time mappings across cultures, we had no reason to expect that Dutch speakers should perform differently from speakers of other languages that use a Roman alphabet.

For our present purposes, it is important that this paradigm produced a congruity effect in the same direction

for both blocks. Having shown that this task provides clear evidence for the implicit space-time mapping typically found in left-to-right reading cultures, we can proceed to test effects of exposure to an orthography in which 'progress' along a spatio-temporal continuum proceeds in the opposite direction.

Figure 1. Results of Experiment 1. Error bars indicate s.e.m.

Experiment 2: Mirror-Reversed Orthography

To test for a causal role of orthography in the mental representation of temporal order, we replicated Experiment 1 in a new group of participants using stimuli and instructions presented in mirror-reversed font.

Methods

Participants A new sample of native Dutch speakers ($N=32$) performed Experiment 2 in exchange for payment.

Materials and Procedure

Materials and procedures were identical to Experiment 1, with one exception. All instructions and stimuli were presented mirror-reversed. Testing lasted about 15 minutes.

Results and Discussion

Accuracy

Participants pressed the correct button on 97% of trials. Only accurate responses were analyzed. This resulted in the removal of 3% of the data. Responses greater than 5000 ms were also excluded, which resulted in the removal of 4% of the accurate trials.

A 2 X 2 ANOVA was conducted with Congruity of Movement Direction (Congruent with Time flowing leftward, Congruent with time flowing rightward) and Block (Block 1, Block 2) as within-subject and within-item factors. There was no main effect of Congruity ($F_1(1,15)=.79$, ns ; $F_2(1,47)= 2.29$, ns). There was a highly significant effect of Block ($F_1(1,15)= 66.37$, $p=.0001$; $F_2(1,47)= 321.81$, $p=.0001$), and crucially, a highly significant Congruity X Block interaction ($F_1(1,15)= 31.89$, $p=.0001$; $F_2(1,47)= 206.56$, $p=.0001$).

Congruity of Movement was then compared within each block (Block 1: $F_1(1,30)=5.00$, $p=.03$; $F_2(1,47)=98.36$, $p=.0001$; Block 2: $F_1(1,30)=3.02$, $p=.09$; $F_2(1,47)=125.21$, $p=.0001$). Mean RTs are shown in figure 2.

Figure 2. Results of Experiment 2. Error bars show s.e.m.

Finally, we compared the congruity effects found in Experiment 1 and Experiment 2 using a 2 X 2 X 2 ANOVA with Congruity and Block as within-subject/within-item factors and Orthography (Standard orthography, Mirror-reversed orthography) as a within-subject/within-item factor. Consistent with the prediction that orthography can influence mental representations of time, we find a highly significant 3-way interaction ($F_1(1,30)=22.71$, $p=.0001$; $F_2(1,94)=125.38$, $p=.0001$). By subtracting the RTs during trials where movements were congruent with the leftward flow of time from RTs during trials where movements were congruent with the rightward flow of time (RT_{rightward} - RT_{leftward}), this 3-way interaction can be simplified, and conceptualized as a 2-way interaction of Block X Orthography (see figure 3).

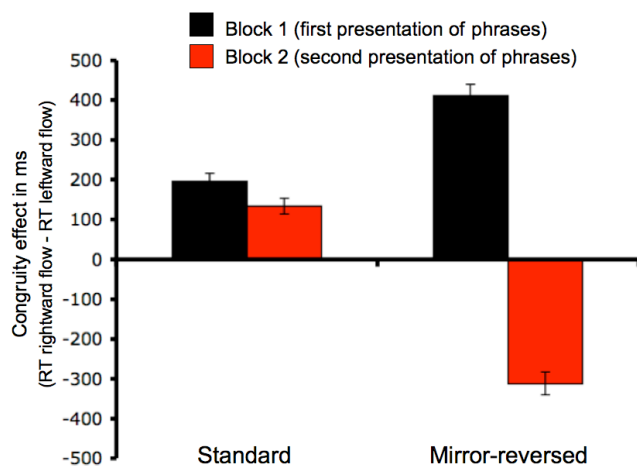

Figure 3. Congruity effects across blocks for Experiment 1 (left) and Experiment 2 (right). Error bars indicate s.e.m.

As is evident from figure 3, the absolute values (ABS) of the congruity effects in both blocks of Experiment 2 are greater than the ABS of the effects in Experiment 1. This was not expected, and although it is not relevant to our experimental hypothesis, it bears further investigation. On one possible explanation, congruity effects result from a failure of cognitive control; that is, they may result from participants' inability to ignore the irrelevant spatial dimension of their responses when judging the temporal reference of the stimuli. The cross-dimensional effect of space on time judgments may have been greater in Experiment 2 because cognitive control resources were taxed by reading backwards, contrary to habit.

Although the dominant space-time mapping in Dutch culture continued to influence RTs during the first block of Experiment 2, by the second block exposure to mirror-reversed writing was sufficient to reverse the congruity effect. Since this is the first experiment to test for a causal influence of writing direction on time representation, we did not have any *a priori* prediction about how much experience with reversed orthography would be needed to produce a significant change in the congruity effect, nor could we predict whether the congruity effect would be reversed or merely diminished. To support our hypothesis, it would have been sufficient to show a reduction in the left-to-right congruity effect from Block 1 to Block 2 that was greater in Experiment 2 than in Experiment 1. However, the fact that the congruity effect completely reversed here provides a particularly clear demonstration that even brief experience with one orthography or another can influence people's implicit spatial representations of time. (For compatible evidence of the flexibility of space-time metaphors in language and thought, see Boroditsky, 2000; 2001; Casasanto, 2008; Clark, 1973; Evans, 2004; Torralbo, et al., 2006).

General Discussion

It is now well established that people activate implicit associations between space and time when processing temporal language, and that the specifics of these associations vary systematically across cultures (Fuhrman & Boroditsky, 2007; Ouellet, et al. in press; Tverksy, Kugelmass, & Winter, 1991). Since time is not associated with left-right space in any known linguistic metaphors, it is unlikely that these culture-specific mappings are learned through experience with spoken language.¹ Here we tested whether orthography can play a causal role in fixing the direction in which time flows along the imaginary mental timeline. Experiment 1 showed that, when exposed to temporal phrases presented in standard left-to right orthography, Dutch speakers implicitly associated earlier time intervals with leftward movements and later time intervals with rightward movements, consistent with previous findings in members of other cultures that use the Roman writing system.

¹ Although spoken languages do not use the lateral axis for time, some signed languages do (see Emmorey, 2001).

However, when exposed to several minutes of mirror-reversed writing, Dutch participants began to show space-time congruity effects that revealed a reversal of their normally dominant implicit space-time mapping. By the second time they were judging each of the 48 temporal phrases (Block 2 of Experiment 2), participants were faster to make responses when key presses associated earlier events with *rightward* movements and later events with *leftward* movements -- a pattern observed previously in speakers of Hebrew, which is written from right to left. It appears that experience reading a right-to-left orthography (which requires the reader to 'progress' leftward across the screen with his/her eyes) is sufficient to reverse the flow of time in the reader's mind, at least transiently.

Although this rapid retraining of a space-time association stored in long-term memory may seem surprising, it is not unprecedented. In one study, Boroditsky (2001) found that horizontal spatial primes facilitated English speakers' judgments of temporal sentences (e.g., *April comes earlier than May*) more than vertical primes did, but found the opposite pattern in Mandarin speakers, consistent with the difference between these languages in the prevalence of horizontal and vertical metaphors for time. To test whether linguistic experience could affect these mappings, she trained a new group of English speakers to use Mandarin-like vertical spatial metaphors for time. After brief training, English speakers showed a pattern of priming similar to native Mandarin speakers.

In a test of a different set of space-time metaphors Casasanto (2008) and colleagues showed that when English and Greek speakers perform non-linguistic duration reproduction tasks, they show language-specific patterns of cross-dimensional interference from space. Whereas English speakers have a harder time screening out interference from (1-dimensional) spatial distance, Greek speakers have more difficulty screening out interference of (3-dimensional) volume. This pattern was predicted based on the relative prevalence and productivity of distance and volume metaphors for duration across languages (e.g., a *long* time (like a *long* rope); a *large amount* of time (like a *large amount* of water)). To find out whether using volume metaphors could cause the volume-interference found in Greeks, US English speakers were trained to use Greek-like volume metaphors for time. Results showed that after one brief (but concentrated) training session, English participants showed a pattern of cross-dimensional interference from volume in a low-level psychophysical task that was statistically indistinguishable from the pattern seen in native Greek speakers.

Time is not the only domain that appears to be mentally represented, in part, through spatial metaphors (which may or may not correspond to linguistic metaphors). Emotional valence is also spatialized on a left-right axis: whereas right-handers tend to associate the right hand and the right side of space with positive things and the left with bad, left-handers show the opposite set of implicit associations (Casasanto, 2009b). It was proposed that this mapping arises due to

asymmetries in motor fluency: people like things on their dominant side better because they can interact with things on that side more easily. To test this proposal, Casasanto (2009c) asked right-handers to perform a 2-part training task. In the first part, they arranged dominoes according to a symmetrical pattern on a tabletop, standing them on end, moving both hands in synchrony. The challenge was that they were randomly assigned to wear a bulky ski glove one hand or the other while performing the task, which either enhanced their natural right-handedness or made them temporarily more skillful with their left hand.

After 12 minutes of this asymmetric motor experience, participants were taken to a different room by a different experimenter for some ostensibly unrelated questionnaire studies, one of which tested implicit associations between space and valence. This questionnaire was shown previously to produce distinctive patterns of judgments in right- and left-handers (Casasanto, 2009b). Participants whose training experience preserved their natural dominance showed the typical right-handers' pattern. But participants who had worn the skiglove on their right hand during training, becoming transiently left-handed, produced a pattern of responses that was indistinguishable from natural lefties'.

We are aware of one training study that manipulated writing direction in order to test a role for orthography in the spatial representation of gender and agency. Several studies suggest that males (seen as more agentive) tend to be represented to the left of females in the minds of people who speak left-to-right languages like English, but not for speakers of right-to-left languages like Arabic (Suitner, 2009). Yet, Suitner (2009) showed that this spatial bias can be nullified in speakers of Italian who are trained to perform a leftward writing exercise, reversing not only their habitual writing direction but also their habitual associations of gender, agency, and space.

How enduring are these training effects? Presumably, without further reinforcement of the new habits, participants who show rapid training effects will also revert to their long-term habits rapidly. Exactly how soon remains a question for further research. Depending on the goal of the training exercise, the durability of the behavioral change may matter more or less. In the present study the goal was to test the sufficiency of a proposed cause of cross-cultural differences. The total reversal of the congruity effect as a function of reading experience demonstrates that orthography can, indeed, influence the implicit spatial representation of time. This simple demonstration would serve its theoretical goal even if the effect were quickly reversed when participants resumed normal reading habits.

How best to characterize the learning mechanisms that afford this representational plasticity remains another open question. It may be fruitful to consider the changes participants undergo in Experiment 2 in terms of a hierarchical Bayesian model (Kemp et al., 2007). To sketch this suggestion briefly, people's associations between space and time could be characterized as intuitive hypotheses. Based on ordinary reading experience, Dutch speakers form

the hypothesis that by default events unfold from left to right. Yet after training, they appear to entertain the hypothesis that events unfold from right to left.

To explain how participants can switch from one hypothesis to a contradictory hypothesis (and presumably switch back) so quickly, it may help to posit that they also entertain a more enduring overhypothesis, of which both the ‘Dutch-like’ and ‘Arabic-like’ space-time associations are specific instances. The overhypothesis could be that time is associated with motion along a linear path. Such a belief would be well supported by observable correlations in the physical world: spatial succession is a reliable index of temporal succession.

Consistent with this proposal, we suggest that if orthography is responsible for determining the direction in which time flows along people’s left-right mental timelines, this directional mapping likely builds upon a prior less-specific space-time association, which arises (either in developmental or evolutionary time) from space-time correlations that have no particular directionality: on any trajectory, it is the case that as a moving object travels farther, more time passes. The hierarchical model can help to explain how ‘mental metaphors’ linking space-time can be universal at one level of level of description but culture-specific at another.

Abstract

How are space and time represented in the human mind? Here we evaluate two theoretical proposals, one suggesting a symmetric relationship between space and time (ATOM theory) and the other an asymmetric relationship (metaphor theory). In Experiment 1, Dutch-speaking participants saw 7-letter nouns that named concrete objects of various spatial lengths (*tr.* pencil, bench, footpath) and estimated how much time they remained on the screen. In Experiment 2, participants saw nouns naming temporal events of various durations (*tr.* blink, party, season) and estimated the words' spatial length. The implicit length encoded in object nouns modulated time estimates, but the implicit duration encoded in event nouns did not affect estimates of spatial length. Nouns that named short objects were judged to remain on the screen for a shorter time, and nouns that named longer objects to remain for a longer time. By contrast, variations in the duration of the event nouns' referents had no effect on judgments of the words' spatial length on the screen. This asymmetric pattern of cross-dimensional interference cannot be attributed to differences in the discriminability or perceptual salience of space and time in the stimuli. Results support metaphor theory and challenge ATOM.

Keywords: ATOM, Metaphor, Psychophysics, Space, Time

Introduction

Space and time are intimately related in the human mind, as they are in the physical world. But exactly *how* are these dimensions related? Here we evaluate two theoretical proposals, one suggesting a symmetric and the other an asymmetric relationship between space and time.

According to the first proposal, space and time are represented in the brain and mind by a common analog magnitude system, which also generates representations of number and quantity. This view, summarized in Walsh's ATOM (A Theory of Magnitude; 2003), is consistent with neurological data showing shared brain areas for processing space, time, and quantity (e.g., Basso, et al., 1996), and with many behavioral studies in animals and humans (e.g., Church & Meck, 1984; Fischer, 2003; Gallistel & Gellman, 2000; Cappelletti, et al, 2009).

Implicit in ATOM is an assumption that these 'ATOMic' dimensions are symmetrically interrelated: not hierarchically related in the brain/mind. Accordingly, Walsh (2003) frames predictions in symmetrical terms, positing "overlapping brain regions" and "cross-domain, within-magnitude priming" between dimensions, without specifying any *directionality* to the priming (or interference) effects. Indeed, if space and time are both manifestations of

the same general-purpose analog magnitude system, there may be no *a priori* reason to posit that one dimension should depend asymmetrically on another.

On an alternative proposal, space, time, and quantity are importantly related, but in a different way. According to theories of metaphorical mental representation (e.g., Lakoff & Johnson, 1999), representations of time, number, and quantity depend asymmetrically on representations of space. The claim that some domains are asymmetrically dependent on others, which is at the core of metaphor theory, was originally supported by patterns in metaphorical language. In English, it is nearly impossible to talk about domains like time without using words whose primary meaning is spatial (denotatively, developmentally, or historically (Clark, 1973)). Vacations can be *long* or *short*, meetings can be *moved forward* or *pushed back*, deadlines can loom *ahead* or lie *behind* us. Yet, it is far less common to use temporal words to talk about space (Lakoff & Johnson, 1999). This asymmetry in language has been echoed by behavioral findings in psycholinguistics (Boroditsky, 2000), cognitive development, (Casasanto, Fotakopoulou, & Boroditsky, in press), and psychophysics (Casasanto & Boroditsky, 2008).

In one set of studies, participants viewed lines of various spatial lengths that appeared on a screen for varying durations (Casasanto & Boroditsky, 2008). They were asked to estimate either the duration or the spatial length of each line, using mouse clicks. Participants were unable to ignore irrelevant spatial information when making judgments about duration, but not the converse. For stimuli of the same average duration, lines that extended shorter in space were judged to take a shorter time, and lines that extended longer in space were judged to take a longer time. By contrast, for stimuli of the same average spatial length, spatial estimation was not affected by the line's duration. This cross-dimensional asymmetry, predicted based on patterns in language, was shown here in non-linguistic psychophysical judgments. Five follow-up experiments varied the attentional, mnemonic, and perceptual demands of the stimuli, and all six experiments supported the same conclusion: mental representations of time depend on representations of space, more than vice versa.

This robust space-time asymmetry supports metaphor theory, but presents a challenge to ATOM. If space and time are both derived from (or are both manifestations of) a general-purpose magnitude metric, then why should representations of time depend on representations of space more than the other way around -- in adults and children, and in language and thought?

It might be possible to reconcile these results with ATOM by positing that in previous studies, space influenced time asymmetrically because space was either (a) the more discriminable dimension, or (b) the more perceptually salient dimension in the stimulus. Discriminability, in this context, refers to the resolution at which a dimension is sampled. Salience means the extent to which one dimension attracts attention relative to the other. Differences in discriminability and perceptual salience have been shown to modulate the strength or direction of cross-dimensional interference and priming effects across numerous studies (see Santiago, Román, & Ouellet, submitted, for review). In general, the dimension that is more discriminable or salient interferes with the dimension that is less discriminable or less salient. Can task-related differences in the relative discriminability or salience of stimulus dimensions account for the space-time asymmetries observed previously?

One set of studies reviewed above addressed these questions. Tests of cross-dimensional relationships often manipulate more levels of one dimension than of the other, creating an imbalance in discriminability (see Pansky & Algom, 1999). In the space-time experiments by Casasanto & Boroditsky (2008), however, there were 9 levels of each dimension fully crossed, to equate discriminability.

Differences in discriminability may correspond to differences in the accuracy, precision, or variability of judgments across domains. This complicates the interpretation of cross-dimensional interference effects. In the limit, if performance in one domain is perfect, there is no opportunity for variation in the other domain to influence it: the ‘clean’ domain can influence performance the ‘messy’ domain, but not vice versa. In Casasanto & Boroditsky’s studies, however, within-domain performance was equivalent across space and time (see also Casasanto, Fotakopoulou, & Boroditsky, in press).

But is it possible that space was more salient than time in these studies? Following Garner (1976), Casasanto & Boroditsky (2008) asked participants to judge different dimensions of the same stimuli (e.g., the spatial or temporal extent of a line). Thus, people had the exact same perceptual input during space and time judgments. But this does not guarantee that the dimensions were equally perceptually salient: it is possible to *see* the spatial extent of a line, but not its duration. To address the concern that space may have been more salient than time, in one experiment each line was accompanied by a tone, which sounded for the duration that the line remained on the screen. Tones have temporal extent but no spatial extent. Thus, temporal information was available to the participant through two sensory channels, but spatial information through only one. Yet, increasing the salience of temporal information did not diminish the space-time asymmetry.

Still, on a skeptical interpretation, these previous studies did not definitively rule out cross-dimensional differences in perceptual salience. It is possible that space will *always* be more perceptually salient than time whenever perceptible spatial stimuli are used, since it is possible to perceive

space, but arguably it is not possible to perceive time directly through the senses (Ornstein, 1969). The question remains, then, whether the space-time asymmetry would persist in psychophysical judgments if differences in the perceptual salience of space and time in the stimulus were eliminated.

In the present study, we eliminated differences in perceptual salience by eliminating perceptible variation in the critical dimension (space or time), altogether. We tested whether the implicit spatial information encoded in object nouns can influence estimates of time (in Experiment 1), and whether the temporal information encoded in event nouns can influence estimates of spatial length (in Experiment 2). Participants saw words presented one at a time and reproduced either the duration for which they remained on the screen or their spatial length, using mouse clicks as in Casasanto & Boroditsky (2008). In the duration estimation task (Experiment 1), the target words named objects of various spatial lengths (e.g., *pencil*, *clothesline*, *footpath*). All target words had the same number of letters in Dutch, and therefore the same physical length on the screen. In the spatial length estimation task (Experiment 2) the target words named events of various durations (e.g., *blink*, *party*, *season*). Again, all target words had the same number of letters, but they were presented with a varying number of spaces between letters (1-9 spaces), stretching them out to different spatial lengths on the screen.

Word meanings were irrelevant to the length and duration estimations. We expected, however, that participants would read the words while viewing them, and activate their meanings (voluntarily or involuntarily). Presumably, the meaning of an object noun typically includes a representation of the object’s spatial form, and the meaning of an event noun a representation of the event’s duration. If internally generated spatial and temporal representations cued by words are sufficient to modulate estimates of experienced duration and spatial length, then we should observe cross-dimensional interference. Following metaphor theory, we predicted that the cross-dimensional interference should be asymmetric, even in the absence of cross-dimensional differences in perceptual salience: spatial representations cued by object nouns should modulate estimates of their duration more than temporal representations cued by event nouns modulate estimates of their spatial extent on the screen.

Experiment 1: Does implicit spatial length modulate time estimates?

Experiment 1 tested whether the spatial length of a word’s referent can modulate estimates of how much time the word remained on the screen.

Methods

Participants Native Dutch speakers (N=39) performed Experiment 1 in exchange for payment.

Materials Dutch nouns naming 9 concrete objects (Targets) and 9 abstract entities (Fillers) were presented on a computer monitor (resolution = 1024 x 768 pixels) for varying durations. The concrete nouns referred to objects whose characteristic spatial lengths ranged from short (normally measured in centimetres) to long (normally measured in kilometres). English equivalents of these nouns are listed here in order of increasing length: *cigarette, pencil, ruler, meter stick, bench, clothesline, footpath, lane, highway*. In Dutch, all 9 target nouns had 7 letters, and were presented on the screen in a fixed-width font (62-point Courier New). Therefore, the targets did not differ in their physical spatial lengths on the screen; rather, they differed in their implicit lengths (i.e., the typical spatial lengths of their referents).

The filler nouns referred to abstract entities that have no physical spatial length: *guess, idea, pride, opinion, envy, thought, philosophy, suspicion, dignity*. However, they varied in their number of letters in Dutch (from 3-11 letters) and therefore in their physical length on the screen (nine different lengths, varying from 50-450 pixels as measured from the left edge of the first letter to the right edge of the last letter). By contrast with the targets, the fillers did not differ in the implicit lengths of their referents; rather, they differed in their physical lengths on the screen.

Each target and filler word was presented 9 times throughout the experiment, for 9 different durations. Durations ranged from 1000 to 5000 ms in 500 ms increments. Fully crossing these 9 durations with the target words (which had 9 different implicit spatial lengths) produced 81 target trials. Likewise, fully crossing the 9 durations with the filler words (which had 9 different physical lengths on the screen) produced 81 filler trials. The 162 different trials were presented in random order, with fillers and targets intermixed. Words were presented in white letters on a black background in the center of the screen. Participants were tested individually and testing lasted about 30 minutes.

Procedure Participants viewed the 162 words, one word at a time, from a viewing distance of approximately 50 cm. Immediately after each word disappeared an “hourglass” icon appeared in the upper left corner of the monitor indicating that the subject should reproduce the amount of time the word remained on the screen. To estimate duration, subjects clicked the mouse once on the center of the hourglass, waited the appropriate amount of time, and clicked again in the same spot, thus indicating the beginning and end of the temporal interval. All responses were self-paced.

After the experiment there was a two-part debriefing. In the first part, the experimenter asked the participant “What do you think this experiment is about?” and “What do you think we were looking for?” to determine whether the participant was aware of any relationship between the implicit lengths of the target words and their durations. In the second part, participants saw each target word again, in random order, and verbally estimated the typical spatial

length of the target words’ referents (using an appropriate unit of measurement). These subjective length estimates were used in later analyses as predictors of subjective duration.

Results and Discussion

Four participants were removed from the analyses below: one for giving nonsensical answers in the debriefing, one for excessively poor time estimation performance according to the criterion used by Casasanto & Boroditsky (2008)¹, and two for guessing that there was a connection between the meanings of the target words and time estimation.

For the remaining 35 participants, we first analyzed participants’ duration estimates as a function of the actual duration of the stimuli. Overall, duration estimates for target words were highly accurate (mean effect of actual duration on estimated duration: $y=0.83x + 154.11$, $r^2=.99$, $df=7$, $p<.001$; fig 1a).

We then tested for effects of implicit length on duration estimation. Target words were rank-ordered according to the typical lengths of their referents (this *a priori* ranking was confirmed by participants’ post-test length estimates). Non-parametric correlation showed that implicit spatial length affected estimates of duration ($y=3.77x + 2605.70$, $r_s(\text{Spearman's rho})=0.75$, $df=7$, $p<.001$; fig.1b).

Finally, we conducted a parametric analysis of the effect of implicit length on duration estimation. Participants’ post-test ratings of the typical spatial length of each target word’s referent were used as a predictor of their duration estimates. Ratings for each target item were averaged, and the average length estimates in meters were transformed by a base 10 logarithm. This analysis corroborated the non-parametric analysis, showing a highly significant effect of implicit spatial length on duration estimation ($y=5.60x + 2619.20$, $r^2=.57$, $df=7$, $p<.001$).

Participants incorporated irrelevant spatial information into their temporal estimates. For stimuli of the same average duration, words with (spatially) shorter referents were judged to remain on the screen for a shorter time, and words with longer referents for a longer time. This was true even though the task did not require participants to process the words’ meanings.

This result shows that perceptible spatial input is not necessary to modulate time estimates; rather, internally-generated spatial representations cued by words are sufficient. This outcome, *per se*, is equally consistent with metaphor theory and with ATOM. To distinguish between the theories, it is necessary to conduct a complementary experiment to determine whether implicit duration can affect estimates of spatial length, and whether cross-

¹ Participants were excluded if the slope of their within-domain duration or length estimates was less than 0.5 (see Casasanto & Boroditsky, 2008). This criterion, which resulted in the exclusion of only one participant overall, is unbiased with respect to the predicted cross-dimensional interference because length and duration are orthogonal in the designs of both experiments.

dimensional interference effects are as symmetric, as expected on ATOM (Effect of Space on Time \approx Effect of Time on Space) or asymmetric, as predicted by metaphor theory (Effect of Space on Time $>$ Effect of Time on Space).

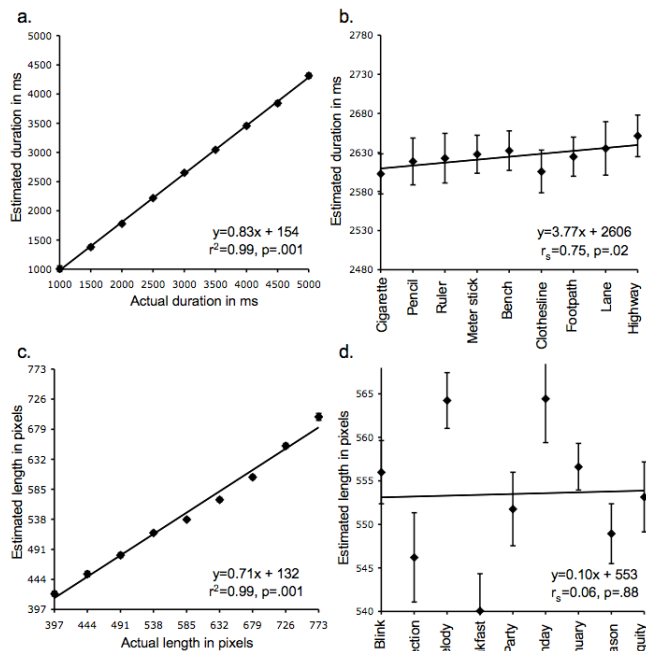

Figure 1. Results of Experiment 1 (top) and Experiment 2 (bottom). 1a. Within-domain effect of actual word duration on estimated duration. 1b. Cross-domain effect of words' implicit spatial length on estimated duration. 1c. Within-domain effect of actual word length on estimated spatial length. 1d. Cross-domain effect of words' implicit duration on estimated spatial length. The axes of the top and bottom plots (a-c, b-d) are proportional with respect to the total range of target values. Error bars show s.e.m.

Experiment 2: Does implicit duration modulate estimates of spatial length?

Experiment 2 tested whether the duration of a word's referent can modulate estimates of the word's spatial length as presented on the screen.

Methods

Participants Native Dutch speakers (N=35) performed Experiment 2 in exchange for payment.

Materials Dutch nouns naming 9 events (Targets) and nine concrete objects (Fillers) were presented on a computer monitor (resolution = 1024 x 768 pixels). The target nouns referred to events whose characteristic durations ranged from short (normally measured in seconds) to long (normally measured in years). English equivalents of these nouns are listed here in order of increasing duration: *blink*, *injection*, *melody*, *breakfast*, *party*, *Monday*, *January*, *Season*, *Antiquity*. All targets were presented for 3000ms.

Therefore, the targets did not differ in the physical durations for which they remained on the screen; rather, they differed in their implicit durations (i.e., the typical durations of their referents).

The filler nouns referred to concrete objects that have no inherent duration: *doormat*, *ballast*, *portrait*, *detritus*, *crystal*, *device*, *case*, *sawdust*, *handle*. Each filler noun appeared for 9 different durations from 1000-5000ms, increasing in 500ms increments. By contrast with the targets, the fillers did not differ in the implicit durations of their referents; rather, they differed in the physical durations for which they remained on the screen.

In Dutch, all target and filler nouns had seven letters, and were presented on the screen in a fixed-width font (62-point Courier New). Each word was presented 9 times throughout the experiment, with a varying number of spaces in between the letters (1-9), to stretch the words out to 9 different spatial lengths on the screen. Due to the font selected, word lengths ranged from 397 to 773 pixels, in 47 pixels increments. Presenting each word at each of these 9 spatial lengths produced 81 filler trials and 81 target trials. For the fillers, spatial length was fully crossed with the physical duration for which they were presented. For the targets, spatial length was fully crossed with the implicit duration of their referents. The 162 different trials were presented in random order, with fillers and targets intermixed. Words were presented in white letters on a black background in the center of the screen. Participants were tested individually and testing lasted about 30 minutes.

Procedure Participants viewed the 162 words, one word at a time, from a viewing distance of approximately 50 cm. Immediately after each word disappeared an "X" appeared in the upper left corner of the monitor indicating that the subject should reproduce the spatial length that the word had occupied on the screen. To estimate length, subjects clicked the mouse once on the center of the X, moved the mouse to the right the appropriate distance, and clicked again, thus indicating the beginning and end of a spatial interval. All responses were self-paced.

After the experiment there was a two-part debriefing, as in Experiment 1. The first part was to determine whether the participant was aware of any relationship between the implicit durations of the target words and their spatial lengths. In the second part, participants saw each target word again, in random order, and verbally estimated the typical duration of the target words' referents (using an appropriate unit of measurement). These subjective duration estimates were used in later analyses as predictors of subjective spatial length.

Results and Discussion

One participant was removed from the analyses below for guessing that there was a connection between the meanings of the target words and spatial length estimation.

For the remaining 34 participants, we first analyzed participants' spatial length estimates as a function of the actual spatial length of the stimuli. Overall, length estimates

for target words were highly accurate (mean effect of actual length on estimated length: $y=0.71x + 132.44$, $r^2=.99$, $df=7$, $p=.001$; fig 1c).

We then tested for effects of implicit duration on spatial length estimation. Target words were rank-ordered according to the typical durations of their referents (this *a priori* ranking was confirmed by participants' post-test duration estimates). Non-parametric correlation showed that implicit duration did not affect estimates of spatial length ($y=0.10x + 553.00$, $r_s(\text{Spearman's rho})=0.06$, $df=7$, ns ; fig.1d).

Next, we conducted a parametric analysis using participants' post-test ratings of the typical duration of each target word's referent were used as a predictor of their length estimates. Ratings for each target item were averaged, and the average duration estimates in minutes were transformed by a base 10 logarithm. Again, there was no effect of implicit duration on spatial length estimation ($y=0.04x + 553.39$, $r^2=.0003$, $df=7$, ns).

Finally, we compared the strength of the cross-dimensional interference effects across Experiments 1 and 2. The difference of correlations showed the predicted cross-dimensional asymmetry ($r_{\text{effect of spatial length on duration}} - r_{\text{effect of duration on spatial length}} = 0.74$, $z=1.66$, $p=0.05$, one-tailed; see fig. 1b, 1d). This difference cannot be attributed to differences in within-domain performance ($r_{\text{effect of actual duration on estimated duration}} - r_{\text{effect of actual spatial length on estimated spatial length}} = 0.00$, $z=0.00$, ns ; see fig. 1a, 1c).

General Discussion

This study tested whether implicit spatial information encoded in concrete object nouns can influence estimates of time (in Experiment 1), and whether implicit temporal information encoded in event nouns can influence estimates of spatial length (in Experiment 2). When participants reproduced the duration for which an object noun remained on the screen, their estimates were influenced by the implicit length of the word's referent. Words that named shorter objects (e.g., *cigarette*, *pencil*) were judged to last a shorter time, and words that named longer objects (e.g., *bench*, *highway*) to last a longer time. By contrast, when participants reproduced the spatial length of an event noun, the duration of the word's referent did not influence judgments of spatial length.

This asymmetric pattern of cross-dimensional interference was predicted based on patterns in language: people talk about time in terms of space more than they talk about space in terms of time (Lakoff & Johnson, 1999). These data show that people incorporate spatial information into their temporal judgments even when they're not using any metaphorical language, and support the hypothesis that mental representations of time are asymmetrically dependent on representations of space: people use spatial length to think about duration, more than vice versa.

This space-time asymmetry cannot be attributed to differences in how well participants reproduced the actual durations and lengths of the stimuli, per se, since there was no significant difference between the effect of actual

duration on estimated duration (fig. 1a) and the effect of actual length on estimated length (fig. 1c). Thus, differences in cross-dimensional interference were not due to differences in within-domain performance.

Furthermore, the space-time asymmetry cannot be attributed to differences in the perceptual salience of the interfering dimensions (i.e., space in Expt. 1, time in Expt. 2). In previous experiments, space could have influenced time asymmetrically because space is inherently more perceptually salient than time (which some scholars have argued can never be perceived directly (Ornstein, 1969)). But here there was no perceptible variation in the spatial component of duration-reproduction stimuli, and no perceptible variation in the temporal component of length-reproduction stimuli. Internally generated representations of spatial length, cued by words, were sufficient to modulate estimates of the words' physical duration. This was true even though the words' meanings were task-irrelevant.

Before discussing theoretical implications of these data further, it is important to consider whether the observed pattern could be due to unintended features of the stimulus words. For example, is it possible that duration estimates in Experiment 1 were influenced by implicit *speed* encoded in the concrete nouns, rather than implicit length? The three longest objects (*footpath*, *lane*, and *highway*) are all spatial paths. The speed of motion associated with these paths increases with their lengths (i.e., *footpath-walking*, *lane-slow driving*, *highway-fast driving*). The conflation of length and speed in these items was a consequence of restrictions on the stimuli: items had to increase in ordinal length unambiguously, and had to have 7 letters in Dutch.

If the effect of object length on duration estimates had been driven by these three items, this would be problematic. However, even a causal inspection of fig. 1b shows this was not the case. For the majority of the items there were no clear speed associations, and yet the effect of implicit length was found. For the first 5 items (*cigarette*, *pencil*, *ruler*, *meter stick*, *bench*), ordinal increases in implicit length corresponded to a monotonic increase in estimated duration. The predicted effect of length on duration was significant in these 5 items, alone ($y=6.84x + 2600$, $r_s(\text{Spearman's rho})=1.00$, $p=.001$). Thus, implicit speed was not responsible for the effect of implicit spatial length we report here (see Casasanto & Boroditsky, 2008, Expt. 6 for further evidence that spatial length affects duration estimates independent of speed).

On another skeptical possibility, could implicit *duration* encoded in object nouns have produced the observed effect on duration estimation? Looking at the longest and shortest items alone, this seems plausible. *Cigarette* could be associated with the time it takes to smoke a cigarette (a short time), and *highway* with the amount of time one typically drives on a highway (a longer time). Yet, looking at the full range of stimuli, this alternative explanation seems implausible. What durations are prepotently associated with *clothesline*, *pencil*, *ruler*, *bench*, or *meter stick*? Ordinal increases in spatial length predicted ordinal increases in

duration estimates for 7 out of the 8 ordinal pairs of stimuli (i.e., *cigarette* < *pencil*; *pencil* < *ruler*; *ruler* < *meter stick*; etc.) Pairwise differences in the typical spatial lengths of the words' referents are self-evident (and were confirmed by participants' post-test ratings), but for most of these word pairs, it seems unlikely that there are corresponding pairwise differences in durations associated with the words' referents.

Finally, although the space-time asymmetry cannot be due to differences in the *perceptual salience* of the interfering dimensions, could they be due to differences in *conceptual salience*? Could the spatial component of the object words' meanings be more salient than the temporal component of the event words' meanings? We cannot rule out this possibility definitively, but this seems unlikely to be the case. It is difficult to evaluate how salient spatial length is in the meaning of *bench* or *cigarette*, and to compare this with the salience of temporal duration in the meaning of *melody* or *party*. But a few of the stimuli are very strongly associated with a unit of space (*ruler*, *meter stick*) or a period of time (*Monday*, *January*, *season*, *Antiquity*). For these items, it is reasonable to assume that a spatial or temporal representation is the most salient aspect of the word's meaning. This was the case for only two of the object words (22% of targets) but for four of the event words (44% of targets). Therefore, overall, it seems likely that any asymmetry in conceptual salience favored the temporal meanings of the event words, thus working against the hypothesized space-time asymmetry.

These results suggest that the asymmetric dependence of time on space in psychophysical judgments is not an artifact of perceptual or conceptual asymmetries built into the stimuli. Rather, this performance asymmetry reflects a fundamental difference in the way people mentally represent space and time. Yet, this asymmetric relationship between space and time in the mind may, indeed, result from an asymmetry in how perceptible space and time are more broadly -- not in any particular experimental stimuli, but rather in the observable world, in general. Space and time are correlated in our everyday experiences (e.g., as objects travel farther more time passes), and tracking these correlations may be useful for anticipating changes in the physical environment. Correlation is a symmetrical relationship, but people may rely more heavily on the more perceptually available dimension (space), using it heuristically as an index of changes in the less perceptible dimension (time).

It appears that time and space are, in Garner's (1976) terminology, *asymmetrically separable* dimensions: it is possible to ignore irrelevant variation in time while judging space but not possible (or more difficult) to ignore irrelevant variation in space when judging time. At present, there is nothing in Walsh's (2003) ATOM proposal that can predict or explain the asymmetric separability of space and time. Yet, this cross-dimensional relationship is readily predicted by metaphor theory.

Importantly, space and time are predicted to be related *asymmetrically* but not *unidirectionally*. There is evidence that time can influence space in some paradigms (e.g., Miles, Nind, & Macrae, 2010), just as people can sometimes use temporal words to talk about space (e.g., "*I live two minutes from the station*" is a temporal metaphor for spatial distance). Simply showing that time can influence spatial judgments in some cases does not challenge the asymmetry we report here: to address the question of asymmetry, the cross-dimensional influences of time and space must be appropriately compared, controlling for salience and discriminability across dimensions, and for within-dimension performance.

We propose that Garner-like tests of dimensional separability will be critical for either modifying ATOM or deciding to abandon it in favor of a metaphorical theory of spatial, temporal, and numerical magnitude representation. In order to understand how space, time, and other prothetic dimensions are represented in the brain and mind, it is necessary to go beyond investigating *whether* these dimensions interact and determine *how* they interact.

Introduction

Attempts to develop an accurate measure of eye movements are over a century old (e.g., Delabarre, 1898; Huey, 1898; as cited in Karatekin, 2007), and predate the earliest studies of categorization (Hull, 1920). Given the long history of both categorization and eye-tracking, it is surprising that eye-tracking has only recently been added to the categorization researcher's toolbox (Rehder & Hoffman, 2005a).

Selective attention is an important component of theories of categorization and eye-tracking provides a measure of what features of a stimulus participants have selected to attend. There are alternatives to eye-tracking, such as inferring attention allocation based on model fits or carefully designed transfer tasks. However, these methods lack the directness of eye-tracking and provide only a coarse measure of how attention shifts over the course of learning. Moreover, they provide no account of how attention is allocated early in learning and within a single categorization trial (including after feedback is presented). This more fine-grained data can not only clarify our understanding of key phenomena, it broadens the range of experimental questions that can be asked to understand how humans learn categories (Blair, Watson & Meier, 2009; Blair, Watson, Walshe & Maj, 2009; Hoffman & Rehder, 2009; Kim & Rehder, 2009; Rehder, Colner & Hoffman, 2009; Rehder & Hoffman, 2005a; Rehder & Hoffman, 2005b; Watson & Blair, 2008).

This symposium brings together four talks on eye-tracking and categorization. Each talk focuses on a different aspect of categorization and demonstrates how using eye-tracking can extend our knowledge. One recent trend in category learning is the use of alternative training

procedures. The inference learning task is the most popular of these procedures and in the first talk Aaron Hoffman presents eye-tracking data illuminating the differences between inference learning and categorization. Bob Rehder then presents his recent work on understanding the learning difficulties associated with Parkinson's disease. Marcus Watson discusses work using eye-tracking to inform our understanding of the basic issue in category learning: error. Finally, Mark Blair discusses the relationship between working memory, attention and performance in a category learning tasks.

Inference versus classification learning

It has been proposed that whereas feature inference learning promotes learning a category's internal structure (e.g., typical features and feature correlations), classification promotes the learning of diagnostic information (Markman & Ross, 2003). We tracked learners' eye movements and found that inference learners fixated features that were unnecessary for inferring a missing feature—consistent with their acquiring the categories' internal structure. However, those fixations were limited to features that needed to be predicted on future trials. Inference learning appeared to induce both supervised and unsupervised learning of category-to-feature associations, rather than any general motivation to learn the internal structure of categories.

In a second study, we compared how inference and classification learning support learners' ability to draw *novel contrasts*—category distinctions that were not part of training. We found that classification learners were at a disadvantage at making novel contrasts. Eye movement data indicated that this *conceptual inflexibility* was due to (a) a narrow attention profile that fails to encode many category features and (b) learned inattention that inhibits the reallocation of attention to newly relevant information. Implications of these costs of supervised classification learning for views of conceptual structure will be discussed.

Using eye-movements to understand Parkinson's patients learning difficulties

Those with Parkinson's disease (PD) exhibit not only motor difficulties such as tremors, rigidity, and postural instability but also a variety of cognitive deficits, including deficits in procedural learning and in switching to new tasks ("set shifting"). Our central hypothesis is that deficits in selective attention are central to many of PD patients' learning difficulties. Moreover, assessing how attentional deficits in PD affect learning is critical to understanding how other learning mechanisms are affected by the disease. A probabilistic category learning paradigm known as the weather prediction task (WPT) has played a central role in theorizing about learning in PD patients. We report eye movement data from both PD patients and controls while performing the WPT and discuss implications our results have for current theories of category learning.

Over and under-estimating the importance of error-processing in categorization

The category label (i.e., the correct answer) has a central role in most models of the categorization. It supplies the information necessary to improve both categorization and attentional performance. But despite its theoretical importance, there has been little direct investigation of how errors are processed.

In this presentation we first evaluate the necessity and sufficiency of errors for optimizing attention. Error-driven models predict large shifts of attention when errors are most common and the absence of shifts when learners are not making mistakes. We review data that shows the opposite result. We next use eye-tracking to assess how participants process stimuli and category labels while receiving feedback on their errors. Results show that temporal aspects of this process that are not captured in extant models are consequential for learning.

Working memory, attention and category learning

Categorization is a core cognitive task that involves accessing information, remembering relationships, focusing on relevant aspects of the stimuli, etc. While long-term memory and selective attention have long been employed by theories of categorization, working memory has had nothing much to do. This is especially surprising given that working memory is described by some researchers as executive attention, and its influence has been demonstrated to be very broad. Intuitively, working memory capacity might influence categorization performance in a variety of ways. High working memory span might be associated with faster learning or improved accuracy. It also might influence how participants attend to stimulus features.

This presentation will describe work aimed at demystifying the effects of working memory capacity on categorization performance, including on attentional optimization. Studies reveal that, depending on the task,

working memory span is related to both attentional optimization and learning speed. Working memory span (measured by the symmetry span task) is compared to measures of attentional network efficiency (measured by the Attention Network Test), and to several other aspects of attentional learning and categorization data.

Abstract

Young children often find it difficult to learn two labels for a single object. However, there is a great deal of variability across studies in children's bias to reject second labels. In this study, we investigated three possible factors affecting this variability including age, task, and parental input in a cross-sectional sample of children from 12- to 28-months-old. We show that children reject second labels differently depending on their age, task demands, and the amount and type of parental input. Importantly, there is also a correlation between the ways in which parent's use second labels and children's acceptance of first and second labels for objects. These results suggest that both previous experience and the task at hand determine children's learning of second labels.

Keywords: Word learning, language acquisition, vocabulary, parental input

Introduction

Sometime after their first birthday, children begin to add words to their vocabulary at an increasingly greater rate. These words almost exclusively share a one-to-one relationship with object categories. Learning more than one label for the same object, like "banana" and "fruit", can be difficult, especially for younger children (Liittschwager & Markman, 1994; Markman & Wachtel, 1988). The propensity to reject second labels can be useful when it comes to learning a new novel name. For example, when shown two objects, one familiar and one unfamiliar, and asked to hand the experimenter a "dax", children can correctly choose the unfamiliar object. But, this tendency can sometimes make it hard to learn certain kinds of words like adjectives (Hall, Waxman, & Hurwitz, 1993), part labels (Hansen & Markman, 2009; Saylor, Sabbagh, & Baldwin, 2002), proper names, (Gelman & Taylor, 1984) and labels at different levels of specificity (Au & Glusman, 1990).

Converging evidence from a variety of tasks supports the idea that children prefer a single label per object. There is also a great deal of variability from study to study in the degree to which children reject second labels. Context factors shown to influence this bias include: bilingual input (Au & Glusman, 1990; Davidson & Tell, 2005; Merriman & Kutlesic, 1993), pragmatic information (Bloom, 2000; Clark & Grossman, 1998; Diesendruck & Markson, 2001), and parts of speech and relationship between words (e.g. part

versus a whole object or level of specificity) (Hall, Waxman, & Hurwitz, 1993; Saylor, Sabbagh, & Baldwin, 2002; Waxman & Senghas, 1992). All of these influences have in common that they depend on parental input. In this study we investigate the impact that the relationships between these different parental factors and how children learn second labels. Though attempts have been made to construct a unified explanation that includes all of these factors (Hollich et al., 2000), few studies have directly investigated the interaction between these input factors and the resulting impact on the learning of second labels.

In this study, we investigate the relationship parent input and the *process* of word learning. Specifically, we investigated the link between second label learning and the context in which second labels are learned. Both task differences and object properties may influence second label learning. We investigate both context variables in relation to parent's use of second labels in a naturalistic task.

Second Label Learning Tasks

In general, tasks used to measure second label learning can be separated into two groups (see Figure 1). They either 1) directly measure the child's ability to learn two labels for one object or they 2) require the child to infer by exclusion to which object a second label applies. This difference in task is often confounded with age such that older children do better than younger children when learning by exclusion (Markman, Wasow, & Hansen, 2003).

In direct learning, children are presented with a familiar object (e.g. a ball) and told that it is a "dax". They are then asked to identify the "dax" among one or more distractors. In this way, children are required to directly map the word

Task Type	Training	Testing
Direct Learning		
Learning By Exclusion		

Figure 1. Examples of tasks used to test label learning.

“dax” to an object (Liittschwager & Markman, 1994; Mervis, Golinkoff, & Bertrand, 1994). Tasks requiring learning by exclusion, on the other hand, require that children infer the referent of a second label. For example, children may be shown two objects – one that they already have a name for and one that is unfamiliar. They are then simply asked to choose the “dax”. Experimenters never directly label the unfamiliar object as “dax”. Thus, children must infer that the novel word should refer to the unfamiliar object (Hollich et al., 2000; Markman, Wasow, & Hansen, 2003).

Parental Input

Several papers have also suggested that parental input influences second label learning. This is based on studies showing that parents differ in the amount and type of second labels they use for different age groups. This difference is related to vocabulary size (Callanan & Sabbagh, 2004; Masur, 1997). This conjecture is reasonable given that parental input effects language development in several ways (Girolametto, Weitzman, Wiigs, & Pearce, 1999; Hoff & Naigles, 2002; Huttenlocher, Vasilyeva, Cymerman, & Levine, 2002). The drawback to studies showing a difference in parent input is that they do not investigate the subsequent impact on children’s biases. Furthermore, these studies have not investigated the interaction between amount and type of parental input and the type of task used to test children’s second label learning. Different types of input may affect first and second label learning differently and may interact with task.

In this study, we investigate the amount and type of second labels that parents use and any to second label learning across age. Five age groups, from 12- to 28-months, were tested on their ability to learn first and second labels directly and by exclusion. These same children were also videotaped playing with one of their parents. This allowed us to not only determine the amount and type of second label use by parents but look at the interaction between parental input and task type.

Method

Participants

One-hundred and twenty child-parent dyads were recruited for the study, including 24 dyads per each of five age groups, included 12-, 16-, 20-, 24, and 28-month-olds. Equal numbers of males and females were included and were distributed approximately equally across age groups.

Materials

Parents completed a vocabulary checklist of words their child says using the MacArthur Communicative Development Inventories (MCDI) (Fenson et al., 1994). Total vocabulary size was determined using the number of items that parents indicated their child knew. In addition, parents and children completed two tasks twice, once each

in two different sessions. The two tasks were always completed in the same order at each session. Tasks are described separately below.

Label Learning Task Children were taught four new labels (e.g. “lep”) for four new objects, counterbalanced across two sessions. At one session they were taught two new labels for two familiar objects (i.e. a ball and a spoon). At the second session they were taught two different new labels for two unfamiliar objects (i.e. a rubber pot holder and a honey dipper). At each session, during training children saw eight objects in the following order: three objects that weren’t labeled, one object that was labeled with a first new label, three more objects that weren’t labeled, and a final object that was labeled with a second new label.

Children were then tested on six types of trials. The first two trial types were control trials: 1) known label trials where they were asked to pick an object they knew (e.g. doll) from two familiar objects and 2) no label trials where they were asked to “pick one” of two objects – one target and one non-target object. The remaining four trials tested 3) first labels (unfamiliar objects) directly and 4) by exclusion and tested 5) second labels (familiar objects) directly and 6) by exclusion (see Figure 2). The direct learning questions tested children’s abilities to learn new words for objects where the new word was either a second label for a familiar object (i.e. ball) or a first label for an unfamiliar object (i.e. pot holder). Learning by exclusion trials were similar to the direct trials except that children were now asked to identify a “toma”, a fifth new word that they had not heard in training, such that the unlabeled distractors from training now became the target objects.

Input Task This task consisted of a simple play session in which children and one of their parents (the primary caregiver when possible) played with four separate sets of toys for four minutes each. They played with two sets during one session and the other two sets at a second session, counterbalanced within and across sessions. The four sets included a sea animals set, a construction vehicles set, a fruit and vegetables set, and a kitchen utensils set. Each set consisted of 14 objects including 12 objects from the relevant category (roughly half familiar and half unfamiliar to the 20-month-olds according to MCDI percentages), one thematically related object, and one taxonomically related object. For example, the fruits and

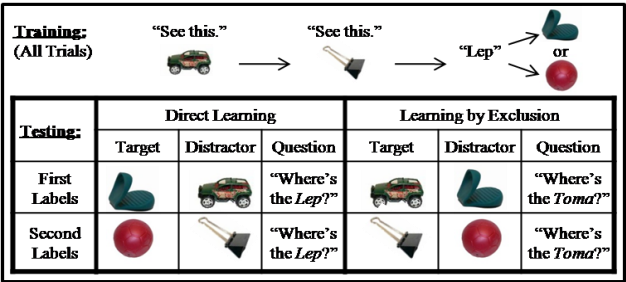

Figure 2. Testing trials design label learning task.

vegetables set included 12 related food toys (an orange, an apple, a banana, asparagus, a bean, an onion, a tomato, a slice of watermelon, a radish, an eggplant, a carrot, and a pepper), one thematic toy (a cutting board), and one taxonomic toy (an egg). Parents were told to sit on a large floor mat and play with their children as if they were at home. Audio and video was recorded.

Procedure

Parent/child dyads attended two sessions within two weeks of each other. Parents completed the MCDI vocabulary checklist on or close to the first session. At each session, the dyads completed the input task first and the label learning task second. Parents did not participate, but were present, for the label learning task.

Coding

Following data collection, all videos of child-parent dyads were reviewed. Coding of the videos consisted of two phases; one to identify instances of labeling and one to identify the types of relations used between first and second labels.

Label Identification First, all instances of the parent labeling an object were identified. Children's labeling instances were not considered. Specifically, the number of times that parents labeled the object was recorded separately for each different label used for each object. For example, a parent might label the orange object "orange" twice and "ball" three times. Four separate measures were calculated using this information including: 1) the proportion of objects that were labeled, 2) the proportion of labeled objects that were given two or more labels, 3) the number of times an object was labeled, and 4) the proportion of labeling instances that were applied to objects given two or more labels. Each measure was calculated separately for familiar and unfamiliar objects, giving us a total of eight input measures. Familiarity was determined separately for each child based on parent report.

Second Label Relations After all instances of second labeling had been identified, the videos were reviewed a second time and the relationship between each label pair was coded into one of eight categories: 1) no relation or labels separated in time (NR), 2) parent indicated that one label was "not" correct (NT), 3) parents stated that one label was not correct but that the object looked like another object (LK), 4) parent used one label as a proper name and one as a common name (PP), 5) parent used one label as a shortened version of the other (e.g. "crab" and "crabby") (SV), 6) parent stated that an object could be named using one label "or" another label (OR), 7) parent indicated that they didn't know which of two labels were correct (DK), and 8) parent stated that an object could be named using one label "and" another label (AND).

Results

Vocabulary

Both children's total vocabulary and their knowledge of the 56 items in the play sets was assessed using parental report. Overall, although children's total vocabulary scores did increase with age, $F(4,115)=92.94$, $p<.001$, their average vocabulary percentile rank did not, $F(4,115)=1.21$, $p=.31$. On average, children knew 23.65 ($SD=12.42$) of the 56 test objects. This average increased with age, $F(4,115)=25.24$, $p<.001$.

Label Learning Task

For each of the six trial types, the average number of times that each child chose the target object was recorded. The known and no label trials were analyzed separately from the four label learning trials.

Known and No Label Trials An analysis of the known label trials showed that overall children were able to correctly identify the known objects above chance, $t(113)=21.45$, $p<.001$, with older children doing better, $F(4,109)=11.94$, $p<.001$. In addition, all five age groups separately identified the target object greater than chance, all p 's $<.05$. A similar analysis of the no label trials showed that, overall, children continued to choose the target object greater than chance, $t(119)=3.44$, $p<.01$. This did not vary by age, $F(4,115)=.80$, $p=.53$.

Label Learning Trials An initial 2 (learning type: direct or by exclusion) x 2 (label type: first or second labels) x 5 (age group) was conducted (see Table 1 for means and comparisons to chance). Results showed a main effect of age, $F(4,115)=25.52$, $p<.001$, such that older age groups learned labels more easily. A main effect of label type, $F(4,115)=16.05$, $p<.001$, showed that children learned first labels better than second labels overall. This interacted with learning type, $F(4,115)=4.81$, $p<.01$, such that this difference was greater when children had to learn labels by exclusion rather than by direct means. Finally, a significant 3-way interaction suggested that the greater difference between first and second label learning for exclusion than by direct

Table 1. Average percent of children correctly identifying the target object label learning task compared to chance.

Age	Direct Learning		Learning by Exclusion	
	1 st Label	2 nd Label	1 st Label	2 nd Label

All	.61** (.28)	.59** (.26)	.69** (.23)	.50 (.24)

[†] $p<.1$, * $p<.05$, ** $p<.01$

means was more pronounced for older than younger kids and somewhat reversed for 20-month-olds. No other main effects or interactions were significant.

Correlations Correlation analyses showed a significant correlation between learning a first label directly and age, $r(120) = .22$, $p < .05$, and a marginal correlation between learning a second label directly and age, $r(120) = .16$, $p = .08$. No correlations for learning by exclusion were found.

Input Task

A series of one-way ANOVAs with age group as a between-subjects factor were conducted on each of the eight input measures. Results showed that all eight measures changed with age, all p 's $< .05$, with the exception of the proportion of unfamiliar objects labeled (See table 2 for means and SDs), $p > .05$. A series of correlations were also computed for each of the eight measures with age and vocabulary. Age was correlated with all eight measures, all p 's $< .05$, with the exception of the proportion of unfamiliar objects labeled, $p > .05$. Vocabulary was correlated with all measures except for the proportion of familiar and unfamiliar objects labeled, $p > .05$.

Generally speaking, the percent of familiar objects named, but not unfamiliar objects named, increased with age. The percent of both familiar and unfamiliar labeled objects that were given two or more labels also increased with age. The total number of labels used for familiar objects increased with age, whereas the total number of labels used for unfamiliar objects decreased. Finally, the percent of labeling instances that were second labels increased for both familiar and unfamiliar objects.

Factor Analysis on Relations between Labels A series of one-way ANOVAs with age were also conducted on the percentage of each of the eight label relations (NT, NR, etc...) used of the total relations used per participant. None of these types of relations changed with age, all $F < .01$, with the exception of the PP code, which decreased with age, $F(4,115) = 3.92$, $p < .01$. Only one relationship type, NT, was correlated with age and vocabulary, $r(120) = .19$, $p < .05$ and $r(120) = .18$, $p < .05$, respectively.

Because it was likely that the seven codes in which parents provided relations for two or more labels (all but the NR code) were heavily interrelated, a factor analysis was conducted using PCA (principal components analysis) to look for relation types that loaded onto similar factors or components. The factor analysis passed several common

criteria for use. First, with over 17 cases per factor, the factor analysis was reliable. Second, the Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy was .53, above the cutoff of .5. Third, Bartlett's test of sphericity was significant, $\chi^2(21) = 46.28$, $p < .01$. Finally, the diagonals of the anti-image matrix and the commonalities between the relations were all at or above .5.

The principal components analysis produced three components with Eigen values above 1.0 that were retained in the model. The first component explained 23.79% of the variance, the second 17.30%, and the third 14.77%, for a total variance explained of 55.85%. Four other components had Eigen values less than 1.0 and were excluded from the model. Rotation of the solution was utilized to facilitate interpretation of the three components. For this rotation, the varimax solution was used, though no difference in interpretation was obtained using an oblimin solution. None of the relation types were eliminated from the analysis as all seven had loadings or cross-loadings of .6 or higher on one of the three components (see Table 3).

Upon inspection, using values at or greater than .6, it was clear that the first component (henceforth called Contrast Relations) represented greater use of the NT and LK relations as opposed to the AND relation. A higher score on this component is consistent with input that rejects second labels while a lower score is consistent with acceptance of second labels. The DK and OR codes loaded onto the second component (called Ambivalent Relations) with a higher score indicating a greater use of relations that are ambivalent towards rejecting or accepting second labels. The PP and SV codes loaded onto the third component (called Elaborative Relations) with a higher score indicated a greater use of relations in which one label is an elaboration

Table 3. Factor loading for principal components analysis of multiple-labels relationships.

Code	Contrast	Ambivalent	Elaborative
NT	.72*	.06	-.01
LK	.60*	-.12	-.27
AND	-.83*	-.11	-.08
OR	.09	.77*	.08
DK	-.03	.75*	-.07
SV	-.11	-.06	.74*

Age	% of Objects Labeled		% of 2+ Object Labels		# of Labeling Instances		% of 2+ Total Labels	
	Familiar	Unfamiliar	Familiar	Unfamiliar	Familiar	Unfamiliar	Familiar	Unfamiliar
12	50.8 (28.1)	56.3 (15.9)	14.7 (14.5)	20.2 (11.7)	26.5 (28.6)	58.0 (33.4)	25.6 (27.6)	35.7 (18.8)
16	66.8 (20.9)	54.1 (23.7)	22.9 (21.6)	23.4 (16.2)	40.0 (24.6)	50.5 (31.1)	29.3 (22.7)	41.0 (21.2)
20	72.7 (14.8)	56.9 (13.2)	25.7 (13.2)	30.7 (13.0)	57.2 (28.7)	44.0 (20.4)	38.5 (13.4)	52.9 (18.9)
24	69.7 (19.3)	57.4 (22.3)	29.2 (13.8)	32.4 (19.6)	50.8 (22.6)	33.8 (16.2)	45.7 (18.3)	54.4 (19.1)
28	66.6 (14.0)	55.2 (19.6)	35.9 (15.2)	28.8 (17.8)	63.5 (22.1)	26.8 (16.9)	51.9 (14.2)	48.7 (24.7)

(e.g. longer version) of the other label. It should be noted that adding age and vocabulary to the model did not change the qualitative conclusions except that a fourth component reached an Eigen value above 1.0 on which age and vocabulary, but none of the relations, loaded. Further analyses showed that none of these three components were significantly different by age group, nor were they correlated with age or vocabulary, all p 's > .05.

Relationship between Tasks

In order to evaluate any relationship between the input task and language learning task, a series of correlations were computed between the four language learning measures, the eight measures of label use by parents in the input task, and the three components identified for the label type relations.

Label Use and Label Learning The number of times that parents labeled unfamiliar objects was negatively correlated with children's ability to learn first labels directly, $r(120) = -.22$, $p < .05$, whereas the ability to learn first labels by exclusion was positively correlated with the proportion of unfamiliar objects given two or more labels, $r(120) = .19$, $p < .05$. The ability to learn second labels directly was negatively correlated with the number of times that parents labeled unfamiliar objects, $r(120) = -.22$, $p < .05$. None of the input measures were related to second label learning by exclusion.

If the two second label learning measures are pooled together to get an overall measure of second label learning, there is a significant negative correlation with the number of labels used for unfamiliar objects, $r(120) = -.16$, $p < .05$, and a positive correlation with the proportion of *familiar* objects given two or more labels, $r(120) = .16$, $p < .05$.

Multiple-labels Relations and Label Learning Parents use of contrast relations, the first component, was positively correlated with the ability to learn second labels by exclusion, $r(120) = .19$, $p < .05$, such that the more likely parents were to state that one label was correct and one was not, the more likely children were to learn second labels by exclusion. The second component, ambivalent relations, was negatively correlated with direct learning of second labels, $r(120) = -.18$, $p = .05$, such that the more ambivalent relations that parents use, the less likely children were to learn second labels directly. Finally, the elaborative relations component was related to the learning of first labels. It was positively correlated with learning by exclusion, $r(120) = .15$, $p = .10$, and negatively correlated with direct learning, $r(120) = -.25$, $p < .01$.

Discussion

At the outset of this paper, we asked whether parent use of second labels was related to second label learning. Several interesting relationships between parents' use of second labels and children's learning of first and second labels were found. In particular, parents who labeled unfamiliar objects more had children who were *less* likely to learn first labels directly. This suggests that direct learning of first labels is hindered by parents labeling unfamiliar objects. On the

other hand, parents who gave unfamiliar objects two or more labels, had children that learned first labels by exclusion more easily. This suggests that while labeling unfamiliar objects in general disrupts first label learning, if those same unfamiliar objects are given more than one label, it helps children make inferences about first labels. In addition, the more likely parents were to give two or more labels to familiar objects, the easier it was for children to learn second labels (either directly or by exclusion), providing some evidence for a link between amount of second label use by parents and second label learning in children.

Further support for this relationship was found when looking at the types of relations that parents used to connect multiple labels. Parents who use less elaborative relations have children who learn first labels easier when learning is direct, possibly because input is less muddled. However, more elaborative relations are associated with *better* learning by *exclusion*, possibly because they support more complex language relations. Additionally, children learned second labels directly when input relations were less ambivalent. This relationship seems, intuitively, to suggest that using ambivalent relations such as stating that you don't know which label is correct hinders second label learning by direct means. On the other hand, parents who made clear contrasts between the two labels, stating that one of the two labels was correct and the other not, had children who found it easier to learn second labels by exclusion. Though this may seem unintuitive at first glance, it can be explained by thinking of learning labels by exclusion as needing to clearly understand which object should *not* have a new label. Parental input that rejects one label in favor of another helps children do the same when they reject a new label for an already familiar object in favor of an unfamiliar object.

Overall, these results suggest that learning both first and second labels is related to the contrasts that parents make between labels. First labels are easier to learn directly when the input is simple and less ambivalent, but easier to learn by inference with complex input. Second labels are easier to learn either directly or by exclusion when input is heavy on clear, less ambivalent, contrasts between labels.

In addition to the relationship between input and second label learning, we were also able to characterize both the input and the process of second label learning separately. First, in regards to second label learning, children easily learned first labels regardless of whether learning was direct or by exclusion. However, they had a much more difficult time when learning second labels by exclusion than by direct means, and this difference was greater as children got older. In other words, children rejected second labels more as they got older, which is consistent with previous literature (Merriman, Bowman, & MacWhinney, 1989).

Second, we asked whether the amount and type of parental input in regards to second labels varies and whether this was related to age. Parents gave both familiar and unfamiliar objects a higher percentage of second labels as

children got older. In addition, a higher percentage of labels were used as a second label as children got older. More interesting, however, is the finding that, although the percent of second labeling changed with age, the types of relations that parents made between the two labels did not.

Together these results suggest that the manner in which parents label objects, not merely the amount, is related to children's processing of words. In particular, the types of contrasts that parents make can support or hurt children's word learning. However, it is not the case that providing children with more label contrasts will boost their word learning skills. Rather, whether elaborative contrasts with similar words or concrete contrasts of different words are better depends on the status of the word as a first or second label and the task demands.

In sum, not only does input relate to overall language variables such as vocabulary size, but it is also related to the way that children *process* language when presented with a new word. Several contextual influences, including previous experience, task and label type work together to determine children's responses at a given moment. More generally, these results suggest that parental input influences language biases in highly complex ways, something that should be carefully controlled and accounted for in future studies on linguistic biases.

Abstract

This paper presents a model of sensorimotor learning grounded in the sensory streams of a real humanoid robot (the iCub robot). The robot participates in a replication of two developmental psychology experiments, in which it is shown how spatial cues are sufficient for associating linguistic labels with objects. The robot, using auto-associated self-organizing maps connecting is perceptual input and motor control, produces similar performance and results to human participants. This model confirms the validity of a body centric account of the linking of words to objects as sufficient to account for the spatial biases in learning that these experiments expose.

Keywords: Developmental Robotics; Neural Networks; Sensorimotor; Learning; Spatial Bias; Category Learning.

Introduction

At the heart of all sensorimotor theories of cognition is the claim that perception is to a large degree based upon the use of sensorimotor knowledge in predicting the future sensory consequences of an action, either overtly executed or covertly simulated (Gallese & Lakoff, 2005; Morse, Lowe, & Ziemke, 2008; Noë, 2004, 2009; O'Regan & Noë, 2001). As such our perception of continuous contact with a rich visual world laid out in front of us is somewhat misleading, as sensory input is highly impoverished by comparison to perception; for example visual acuity is focused on an area the size of a thumb nail at arm's length. From a sensorimotor perspective, our perception of things outside the fovea is largely constructed from predictions of what you would see were you to look in this or that direction (Noë, 2004). Clearly such perception is supported by processing of the sparse input from the periphery of our visual field, and mechanisms drawing attention to movement, flashes, and other such changes, yet there remains a large disparity between sensory input and perception.

In taking a sensorimotor perspective, the recognition and categorization of objects in our perceptual field can be achieved through the identification of profiles of interaction unique to each object category. As an example we can perceive a plate as round, not because it projects a round image onto our retina, but rather because we can predict how our sensory contact will change as we move a little this

way or a little that way. This rather sparse account supposes that such profiles can be constructed and recognized, leading to the recognition of objects in the world in terms of their Gibsonian affordances (Gibson, 1979). This construction of profiles of interaction is crucial to the ability of sensorimotor theories to account for high-level cognitive and mental phenomena such as perception, but is also the least detailed and most challenging aspect of these theories. Few sensorimotor theories do more than just suppose an ability to do this. Nevertheless such embodiment centric accounts of perception are supported by a large number of psychology experiments and neuroscientific evidence exposing various bodily biases in categorization (Richardson & Kirkham, 2004; Smith, 2005; Smith & Samuelson, 2010). For example, for Gallese and Lakoff (2005) the biological sensorimotor system is not merely foundational to our mental conceptual abilities but constitutes action and perception which are inseparably interwoven in those sensorimotor systems. In addition, the re-activation of visual and motor areas during imagined actions (Jeannerod, 1994; Kosslyn & Press, 1994) "shows that typical human cognitive activities such as visual and motor imagery, far from being of a disembodied, modality-free, and symbolic nature, make use of the activation of sensory-motor brain regions." (Gallese & Lakoff, 2005, p. 465). Similarly while paralysis and neuromuscular blockades do not disrupt conscious thought processes (Topulos, Lansing, & Banzett, 1994), the current activity of the motor cortex is highly influential on both perception and thought. Barsalou et al. (2003) highlight some of the ways in which body posture and action affect perception and cognition; for example, subjects rated cartoons differently when holding a pen between their lips than when holding it between their teeth. The latter triggered the same musculature as smiling, which made the subjects rate the cartoons as funnier, whereas holding the pen between the lips activated the same muscles as frowning and consequently had the opposite effect (Strack, Martin, & Stepper, 1988). Moreover, bodily postures influence the subjects' affective state; e.g., subjects in an upright position experience more pride than subjects in a slumped position. Further compatibility between bodily and cognitive states enhances performance. For instance, several motor

performance compatibility effects have been reported in experiments in which subjects responded faster to ‘positive’ words (e.g. ‘love’) than ‘negative’ words (e.g. ‘hate’) when asked to pull a lever towards them (Chen & Bargh, 1999).

In the remainder of this paper we describe a developmental robotics (Cangelosi & Riga 2006; Weng et al. 2002) model of a simple sensorimotor system grounded in the sensors and actions of iCub, a child-like humanoid robot. The robot then participates in a psychology experiment highlighting the role of body posture and spatial locations in learning the names of objects. Finally we compare the results of the robot experiments to the data from human child psychology experiments conducted by Smith and Samuelson (Smith & Samuelson, 2010).

The ‘Modi’ Experiment

In a series of experiments related to Piaget’s famous A-not-B error (1963), and derived from experiments by Baldwin (1993), Linda Smith and Larissa Samuelson (Smith & Samuelson, 2010) repeatedly showed children between 18 and 24 months of age two different objects in turn, one consistently presented on the left, and the other consistently presented on the right. Following two presentations of each object, the child’s attention is drawn to one of the now empty presentation locations and the linguistic label “modi” is presented. Finally the children are presented with both objects in a new location and asked; “can you find me the modi”. Not surprisingly the majority (71%) of the children select the *spatially correlated* object despite the fact that the name was presented in the absence of either object. Varying the experiment to draw the child’s attention to the left or right rather than to the specific location that the object, when saying “modi”, resulted in a similar performance where 68% of the children selected the spatially linked object. The results of this experiment challenge the popular hypothesis that names are linked to the thing being attended to at the time the name is encountered.

In a follow up experiment, using the same basic procedure, one group of children were presented with only a single object labeled while in sight; a second group were repeatedly presented with a consistent spatial relationship until finally an object is labeled while in sight but in the spatial location where the other object was normally presented. In the control group, where a single object is presented and labeled, 80% correctly picked the labeled object over the previously unencountered object; in the second group (spatial competition) a majority of 60% selected the spatially linked object rather than the object that was actually being attended while labeled. In both experiments changes in posture from sitting to standing disrupted the children’s ability to link the absent object to the name through space, while other visual or auditory distracters did not. This is strong evidence challenging the simple hypothesis that names are associated to the thing being attended at the time the name is heard, and strong evidence for the role of the body’s momentary disposition in

space playing a role in binding objects to names through the expected location of that object.

While several other variations of this experiment have been conducted with children, it is these two versions of the experiment that we have replicated with our robot model.

The Robot Experiments

The ‘modi’ experiments, though not conclusive, strongly suggest that body posture is central to the linking of linguistic and visual information, especially as large changes in posture such as from sitting to standing disrupt the effect reducing performance in the first experiment to chance levels. In our model this suggestion is taken quite literally, using body posture information as a ‘hub’ connecting information from other sensory streams in ongoing experience. Connecting information via a ‘hub’ allows for the spreading of activation via this hub to prime information in one modality from information in another. Furthermore using the body posture as a ‘hub’ also makes a strong connection to the sensorimotor literature reviewed in the introduction; as actions, here interpreted as changes in body posture, also have the ability to directly prime all the information associated with that new position and hence indicate what the agent would expect to see were it to overtly move to that posture. Such predictive abilities are the foundation of sensorimotor theories.

In this experiment we use the humanoid robotic platform iCub, an open source platform which has been recently developed as a benchmark platform for cognitive robotics experiments (Metta et al., 2008). It has 53 degrees of freedom, allowing experiments on visual, tactile and proprioceptive perception, manipulation and crawling. Initial iCub experiments were carried out in simulation through the open source iCub simulator (Tikhonoff et al. 2008), and then adapted and tested on the physical robot platform.

Grounding information in sensory streams

The information linked via the body-posture hub is the result of processing visual input from the iCub robots cameras, taking the average RGB color of the foveal area and using this as an input to a 2D self-organizing map (SOM) (Kohonen, 1998) described in Equation 1, Equation 2, and Equation 3 below. The SOM provides pattern recognition over the input space preserving input topology while capturing the variance of the data. The body-posture ‘hub’ similarly used the joint angles of the robot as input to another SOM. Though the iCub robot has 53 degrees of freedom, for simplicity in the experiments detailed herein only 2 degrees from the head (up/down and left/right), and 2 degrees from the eyes (up/down and left/right) were actually used, thus the body map of the iCub robot has 4 inputs, each being the angle of a single joint. Further experiments are underway using a more complex body posture map involving all the degrees of freedom of the iCub robot. Finally, auditory input is abstracted as a collection of explicitly represented ‘words’, each active only while

hearing that word. In the experiments herein these ‘words’ are artificially activated, though in related work we are using the open source CMU Sphinx library (<http://cmusphinx.org/>) to provide voice processing, achieving the same result from genuine auditory input.

Both the color map and the body posture map are initialized using random values in the appropriate sensory ranges with an increased probability of values in the extremes of each range until the SOM’s have stabilized. Increasing the probability of extreme values ensures that the resulting stable map fully covers the range of possible input values, without this step mid range values would tend to pull in the extremities of the map resulting in poor coverage.

Equation 1: Initial activation of SOM units

$$A_j = \sqrt{\sum_{i=0}^{i=n} (v_i - w_{ij})^2}$$

Where A_j is the resulting activity of each node in the map following a forward pass, v_i is an input, and w_{ij} is the weight between that input and the current node. The winning node is the node with the smallest value for A_i

Equation 2: Final activation of SOM units

$$y_i = e^{\left(\frac{-\beta_i}{2\sqrt{n}}\right)}$$

Where y_i is the final activation of the i^{th} node in the map, β is the distance from node i to the winning unit, and n is the total number of nodes in the map. Note: units not within the neighborhood size are set to zero activation, the neighborhood size and learning rate are monotonically decreased and the map is taken to be stable when the neighborhood size is zero.

Equation 3: Weight changes

$$\Delta w_{ij} = \alpha (v_i - w_{ij}) y_i$$

Where w_{ij} is the weight between input j and unit i , and α is the learning rate.

The neural model forms the upper tier of a 2 layer subsumption architecture (Brooks, 1986) where the lower tier continuously scans whole images for connected regions of change between temporally contiguous images. The robot is directed to orient with fast eye saccades and slower head turns to position the largest region of change (above a threshold) in the centre of the image. This motion saliency mechanism operates independently from the neural model, generating a motion saliency image driving the motor system. This motion saliency image can be replaced with a color-filtered image to provoke orientation to regions of the image best matching the color primed by the neural model.

Using the model described we then replicated the experimental setup used by Smith and Samuelson (2010), linking the activity of the color map and the auditory words

to the body map in real time using positive Hebbian connectivity following Equation 4 below.

Equation 4 Positive Hebbian learning

$$\Delta w_{ij} = \alpha x_i x_j$$

Where w_{ij} is the weight between node j and node i , α is the learning rate (0.01), x_i is the activity of the winning node in one map, and x_j is the winning node in the posture map.

These Hebbian associative connections were then only modified from the current active body posture node. Inhibitory competition between any simultaneously active nodes in the same map provides arbitration between multiple associated nodes resulting in dynamics similar to those expressed in Interactive Activation and Competition (IAC) models which have a long history of use in modeling psychological phenomena (Burton, Bruce, & Hancock, 1999; McClelland & Rumelhart, 1981; Morse, 2003).

As the maps are linked together in real time based on the experiences of the robot (see Figure 1), strong connections between objects typically encountered in particular spatial locations, and hence in similar body postures build up. Similarly, when the word ‘modi’ is heard, it is also associated with the active body posture node at that time. The relative infrequency of activity in the word nodes

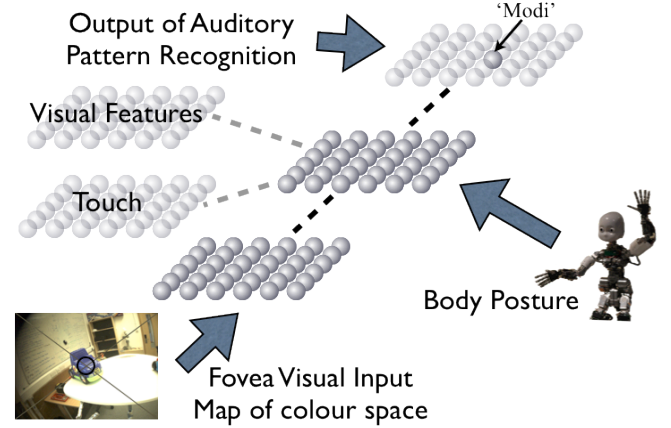

Figure 1: The general architecture of the model. SOMs are used to map the color space, the body posture, and the word space. These maps are then linked using Hebbian learning with the body posture map acting as a central ‘hub’. The model can easily be extended to include other features such as visual and touch information in additional SOMs.

compared with continuous activity in the color map is not a problem as competition is between nodes within each map and not between the maps themselves. Finally at the end of the experiment, when the robot is asked to ‘find the modi’, activity in the ‘modi’ word node spreads to the associated posture and on to the color map node(s) associated with that posture. The result is to prime particular nodes in the color map, the primed color is then used to filter the whole input

image and the robot adjusts its posture to center its vision on the region of the image most closely matching this color. This is achieved using the same mechanism that detects and moves to look at regions of change in the image, replacing the motion saliency image with a color-filtered image. Here the robot moves to look at the brightest region of the color-filtered image, circled in Figure 2 below.

Figure 2 left: Image from the iCub robot's left camera. Right: the same image color-filtered with the primed blue color of the toy truck. The brightest area (circled) indicates the closest match to the primed color.

Given that the number of associations constructed will grow over time in the absence of negative Hebbian learning and in a changing environment, large changes in body posture are used to trigger a removal of these associative connections consistent with the eradication of spatial biases in the psychology experiment following changes from sitting to standing. Additionally, external confirmation that the correct object has been selected leads to more permanent connections being constructed either directly between word and color maps or via a second pattern recognition based 'hub'. As these mechanisms are superfluous to the experiments modeled herein their details have been omitted.

The model as described is then used to replicate each condition of the two psychology experiments described in the previous section as detailed below.

Experiment 1 No Switch Condition

1. Object A is presented to the robot's left – the robot then looks at object A,
2. Object B is presented to the robot's right – the robot then looks at object B,
3. Steps 1 and 2 are repeated,
4. The robot's attention is drawn to its left in the absence of objects A and B and the word 'modi' is

spoken,

5. Steps 1 and 2 are repeated again,
6. Object A and object B are presented in a new location and the robot is asked 'where is the modi' – the robot then looks at one of the objects.

This experiment was repeated 18 times resetting the model between each run and starting with a different random seed thereby simulating 18 different individuals. The position of object A and object B (to the left and right) was swapped between each trial and the location that the robots attention was drawn to in step 4 was changed between the first 9 and the remaining trials thereby removing any bias favoring one object or one location over the other. The whole experiment was videoed and stills from steps 1, 2, 4 & 6 are shown in Figure 3. The results recorded which object was centered in the robots visual field following step 6.

Experiment 1 Switch Condition

In the switch condition the location of presentation of objects A and B was swapped for the first presentation only of each object (step 1). Subsequent presentations of each object in steps 2 and 5 remained consistent with the original locations in the no switch condition. Again the experiment was repeated, this time 20 times, with the same variations as used in the no switch condition and the results recoded which object if any is centered in the robots visual field following step 6.

Experiment 2 Labeling while in sight – Control Condition

Experiment 2 provides a variation on experiment 1 in which objects are labeled while in sight. In the control condition a single object is presented either to the left or to the right and labeled 'modi' while being attended, the object is then presented in a new location with a second object and the robot is asked to 'find the modi'.

Experiment 2 Labeling while in sight – Switch Condition

1. Object A is presented to the robots left – the robot then looks at object A
2. Object B is presented to the robots right – the robot then looks at object B
3. Steps 1 and 2 are repeated

Figure 3: The experiment sequence with the iCub robot.

4. Steps 1 and 2 are repeated again
5. Steps 1 and 2 are repeated yet again
6. Object A is presented to the robots right (i.e. in the wrong location) and the word 'modi' is spoken
7. Steps 1 and 2 are repeated again
8. Object A and object B are presented in a new location and the robot is asked 'where is the modi' – the robot then looks at one of the objects

Experiment 2 was repeated 20 times in each condition with differently seeded networks where the identity of object A and object B was swapped on each consecutive trial and the locations (left and right) were reversed following 10 trials to remove any object or location specific bias.

This model represents preliminary work investigating spatial biases in object categorization. Further work developing and extending this model as a model of sensorimotor learning is currently underway.

Results

In each condition of each experiment, the results recorded which object, if any, was centered in the robots view following the final step of each experiment where the robot was asked to 'find the modi'. In the no-switch condition of experiment 1, 83% (15/18) of the trials resulted in the robot selecting the spatially linked object, while the remaining trials resulted in the robot selecting the non-spatially linked object. This is comparable to the reported result that 71% of children selected the spatially linked object in the human experiment in the same condition (Smith & Samuelson, 2010).

Figure 4: The percentage of spatially linked objects selected in each experimental condition for both robot data and for the human child data.

Reducing the consistency of the object-location correlation in the switch condition resulted in a significant reduction in the spatial priming effect with a close to chance performance of 55% (11/20) of the trials finishing with the spatially correlated object being centered in the view of the robot. The remaining 9 trials resulted in the other object being selected. In experiment 2 objects were labeled while being attended, the control group resulted in 95% (19/20) of the trials selecting the labeled object while in the switch condition only 45% (9/20) of the trials resulted in the labeled object being selected. The remaining trials all

selected the other object. These results are compared to the reported human child data in Figure 4.

Discussion and Conclusion

The close match between the results from the robot experiments and the human child results reported by Smith and Samuelson (Smith & Samuelson, 2010) suggests that the hypothesis that body posture is central to early linking of names and object, and can account for the spatial biases exposed by these experiments. What is of relevance here is that the relations between the conditions of each experiment are consistent between the human and robot data, rather than the absolute values achieved. As can be seen from Figure 4 the robot data consistently produced a slightly stronger bias toward the spatially linked objects than the human data.

That the priming effect did not cause the robot to always select the spatially linked object in every variation of the experiments was due to a variety of factors including; noise in the input sensors, varying lighting and reflectance properties as objects are rotated slightly, inaccuracies in the orienting mechanism and so on. In combination these factors produced variations in which a node in the color map was activated as one particular object is being observed, this can lead to weak connections between several similar nodes rather than a single strong connection to one node. In the switch condition of experiment 1, this situation more frequently resulted in object B having a stronger connection to the body posture in which object A was more frequently observed, thus object B was more strongly primed and selected. In these cases increasing the consistency in which an object is seen in the labeled location promotes the strengthening of connections leading to that object being selected, as is seen in the no-switch condition of exp. 1.

It is anticipated that the inclusion of other visual features, though likely to be subject to similar variance, would increase the discrepancy between the data from this model and the human data. This would be due to activation spreading between maps, influencing the priming in much the same way a localist IAC model (Burton et al., 1999; McClelland & Rumelhart, 1981; Morse, 2003). Despite this the relative effects of the various conditions across each experiment should remain relatively consistent. We suggest that the close fit to human data could be misleading, as by comparison in the human case spatial priming would be in competition with far more complex factors influencing the saliency of the objects, factors we have not attempted to model here. Conversely such competition may in fact reduce the models tendency to over perform thereby more closely matching the human data.

As indicated in the introduction our model is consistent with the sensorimotor approach to understanding cognition as the model is able to predict the sensory input it would receive were it to move to different body-postures. This information is accessed simply by a spread of activation from primed body-posture nodes in the 'hub'. The model is also easily scaled up to include additional information presented in additional maps retaining the current IAC-like

architecture. Such models are also suitable for use in hierarchies providing a better fit to the underlying biology.

In conclusion our model accurately reproduces the human data from Smith and Samuelson's (2010) experiments, in an ongoing embodied human robot interaction. In fact, the close fit between our data and the reported human data is in part due to the difficulties and inaccuracies inherent in conducting experiments with complex real robots rather than simulations. In future work we are developing and demonstrating this architecture in a variety of related sensorimotor and psychological tasks involving object manipulations. The goal is close empirical studies of robots and children – in which robot models generate new predictions tested in children. Such joint studies should advance robotics, our understanding of human cognitive development, and the nature of embodied intelligence more generally.

Effects of simultaneously presented visual information on adults' and infants' auditory statistical learning

Erik D. Thiessen

5000 Forbes Ave, Pittsburgh PA 15213

Abstract

Infant and adult learners are able to identify word boundaries in fluent speech using statistical information. Similarly, learners are able to use statistical information to identify word-object associations. Successful language learning requires both feats. In this series of experiments, we presented adults and infants with audio-visual input from which it was possible to identify both word boundaries and word-object relations. Adult learners were able to identify both kinds of statistical relations from the same input. Moreover, their learning was actually facilitated by the presence of two simultaneously present relations. Eight-month-old infants, however, do not appear to benefit from the presence of regular relations between words and object. Adults, like 8-month-olds, did not benefit from regular audio-visual correspondences when they were tested with tones, rather than linguistic input. These differences in learning outcomes across age and input suggest that both developmental and stimulus-based constraints affect statistical learning.

Keywords: statistical learning, cross-modal stimuli, development of cross-modal integration

Introduction

Learners are able to identify many different kinds of statistical regularities from linguistic input, including phonological and syntactic patterns (e.g., Chambers, Onishi, & Fisher, 2003; Mintz, 2002; Thiessen & Saffran, 2003). Despite the power of statistical learning, though, there is little doubt that human learners are constrained. Learners do not identify all kinds of statistical patterns equally well (e.g., Newport & Aslin, 2004; Peperkamp, le Calvez, Nadal, & Dupoux, 2006; Redford, 2008; Saffran & Thiessen, 2003). However, most of the research into constraints on human learning has focused on how learners do when presented with a single learning task. This is insufficient for a complete understanding of statistical learning for two reasons. First, language frequently presents learners with multiple problems simultaneously. For example, when exposed to a novel word form in fluent speech, learners have the opportunity to both learn the word form, and to learn the referent of the word. Second, constraints on learning may be especially important when the input is complex enough to support multiple learning problems (e.g., Fiser & Aslin, 2002; Pinker, 1984).

Consider the interaction between the statistical information useful for segmenting words from fluent speech (e.g., Saffran, Aslin, & Newport, 1996), and

identifying referents for words (e.g., Smith & Yu, 2008). Taken in isolation, both word segmentation (e.g., Thiessen, Hill, & Saffran, 2005; Toro, Sinnett, & Soto-Faraco, 2005) and referential learning are constrained (Golinkoff, Shuff-Bailey, Olguin, & Ruan, 1995; Landau, Smith, & Jones, 1988; Markman, 1990; Markman & Wachtel, 1988). It is also clear that these learning processes interact. Learners who are previously familiar with a word form map it more easily to a novel referent (e.g., Graf Estes, Evans, Alibali, and Saffran, 2007; Storkel et al., 2001). Conversely, children map familiar objects to novel labels more easily than unfamiliar objects (e.g., Hall, 1991). Because these learning tasks interact, different constraints may operate when learners are presented with both problems simultaneously. If the interaction between the problems is unconstrained, the additional complexity when they are presented together may hinder learning (Fiser & Aslin, 2002; Pinker, 1984). Alternatively, learning may be constrained in such a way that the learning occurs sequentially, with one problem privileged and learned first. It is even possible that learning, if appropriately constrained, could be facilitated by the simultaneous presentation of multiple regularities. This could be the case if learning of one regularity reinforces the other.

To explore these possibilities, it is critical to present learners with the opportunity to identify simultaneous regularities. This set of experiments did so by building on prior research demonstrating that learners benefit from the embedding of audio input in a visual context (e.g., Hollich, Newman & Jusczyk, 2005). Appropriate visual information helps learners determine whether speakers are producing one language or multiple languages (Soto-Faraco et al., 2007). Similarly, the presence of a video improves adults' ability to identify word boundaries in fluent speech (Sell & Kaschak, under review). In all of these tasks, however, the auditory learning task is the only task, and vision facilitates that task. The current experiments differ by presenting learners with two problems simultaneously: word segmentation, and discovery of word-object relations. This better simulates the richness of language, where any single utterance may provide information about many different aspects of language (e.g., Saffran & Wilson, 2001).

Experiment 1

All learners in this experiment were presented with words embedded in fluent speech. As in previous statistical learning experiments (e.g., Saffran et al., 1996), these words could be segmented via use of transitional probabilities that were high within words, and low at word boundaries. A subset of the participants in this experiment (in the *no-video* condition) were presented solely with fluent speech. The only learning task this group faced was identifying word boundaries.

A second group of participants (in the *regular-video* condition) saw objects synchronized to the onset and offset of the words in the fluent speech. Each word in the fluent speech was consistently paired with a unique object. As such, this group of participants was presented with two potential statistical regularities to learn: word boundaries, and the relations between particular words and objects.

A third group of participants (in the *irregular-video* condition) also saw shapes synchronized to words in fluent speech, but these participants saw objects that were not consistently associated with the words. This condition serves as a control to make sure that performance in the regular-video condition is not affected by some aspect of the visual stimuli other than the regular relation between words and shapes.

Method

Participants

Participants were 60 undergraduates at Carnegie Mellon University. Twenty participants apiece were randomly assigned to one of three stimulus conditions: no-video, irregular-video, or regular-video.

Stimuli

Audio Stimuli

All participants were exposed to a stream of synthesized speech used in Saffran et al.'s (1996) experiments. This artificial language contained four words: *padoti*, *bidaku*, *tupiro*, and *golabu*. The transitional probabilities between syllables within a word were 1.0, and the transitional probabilities between syllables across word boundaries were .33. Two words (*bidaku* and *tupiro*) and two part-words (*tigola* and *bupado*) were used as test items. Unlike words, part-word test items contained a transition between syllables with low transitional probability.

Visual Stimuli

In the *no-video* condition, participants saw a static checkerboard image for the duration of their exposure to the synthesized speech.

Participants in the *regular-video* and *irregular-video* condition saw looming shapes synchronized with the word boundaries. Shapes appeared at the same instant the word began to play, and remained onscreen for the duration of the word. At the beginning of a word, each shape occupied roughly 1/16th of the screen. Over the course of the presentation of the word, the shape increased in size until it filled the screen.

In the regular-video condition, each word was paired with a particular object (*padoti*: white cross; *bidaku*: green diamond; *tupiro*: purple heart; *golabu*: yellow

hexagon). In the irregular-video condition, words and shapes co-occurred with no consistent pattern. *Procedure*

In all three conditions, participants sat in front of a portable DVD player with a 10" screen wearing airline-pilot style headphones. Participants were simply informed that after watching the video, they would answer a series of questions about what they saw and heard.

Segmentation Test

There were 16 two alternative forced choice questions in the segmentation test. For each question, participants heard a word and a part word (in counterbalanced order), separated by one second of silence. They were asked to circle the item that sounded more like the speech they heard (for discussion of this procedure, see Saffran et al., 1997).

Word-Shape Correspondence test

After completion of the 16 segmentation test items, participants in only the regular-video condition were informed that they would now answer an additional series of 16 questions. These questions assessed whether participants learned that particular words corresponded to shapes. For each question, participants heard one of the four words from the synthesized speech. They then saw a sequence of four shapes on the screen, looming with the same animation as during the initial exposure. They were asked to circle which of the four shapes went with the word.

Results

A one-way ANOVA was performed on participants' scores on the word-segmentation test as a function of condition. There was a significant effect of condition, $F(2,57) = 5.4, p < .01$. Participants performed best in the regular-video condition ($M = 12.0, SE = 0.5$), and less well in the irregular-video ($M = 9.9, SE = 0.5$) and no-video condition ($M = 8.9, SE = 0.5$). Scores in all three condition differed from chance (all condition: binomial $p < .05$). To follow up the effect of condition indicated by the ANOVA, planned t-tests were performed. Here and elsewhere, all t-tests reported are two-tailed. There was no significant difference between participants' performance in the no-video and in the irregular-video condition: $t(38) = 1.1, p = .30$. However, participants in the regular condition scored significantly better than participants in either of the other two conditions (regular- vs. no-video: $t(38) = 3.4, p < .01$; regular- vs. irregular-video: $t(38) = 2.2, p < .05$).

Participants in the regular-video condition also learned word-object relations. On average, participants scored 8.8 (out of 16; chance = 4) correct on the correspondence test ($SE = 0.8$), which was significantly above chance, binomial $p < .01$. Further, as illustrated by Figure 2, the correlation between the two tests was positive, $r = .64$, and significant, $p < .01$. Higher scores on one test were associated with higher scores on the other. Results from the segmentation and correspondence test converge to indicate that the presence of regular word-object relations facilitated learning

Experiment 2

Prior experiments have demonstrated that infants are able to segment words from fluent speech via transitional probabilities (e.g., Saffran et al., 1996), and identify relations between words and shapes (e.g., Thiessen, 2007), but no experiments have assessed both simultaneously. Because infants are the primary learners of language, their performance is both theoretically and pragmatically important. For example, given the capacity limitations of infants, it is plausible to hypothesize that they would fail to integrate audio and visual information as effectively as adults. If so, they may not benefit from the audio-visual corresponded in the regular-video condition.

Method

Participants

Participants in this experiment were 60 infants between the ages of 7.5 and 9 months ($M = 8.26$). Infants were randomly assigned to one of three groups: no-video, regular-video, and irregular-video. In order to obtain data from 60 infants, it was necessary to test 66. The additional six infants were excluded for the following reasons: fussing or crying (3), parental interference (2), and experimenter error (1). According to parental report, all infants were full term, and free of ear infections at the time of testing.

Procedure

This experiment used a slightly modified version of the HPP, presenting the visual stimuli on a central monitor rather than from the side of the room. Preferential looking experiments with a central monitor are commonly and successfully used with infants (e.g., Fernald, 1985). Infant participants were seated on their parents' lap in a sound-isolated room, approximately one foot away from a 30" monitor. There were two speakers adjacent to the monitor and a camera mounted above it. The parents wore noise-canceling headphones to eliminate bias. An experimenter outside the room watched the infant over a closed-circuit monitor to initiate test trials and code the direction of the infants' gaze.

There were two phases to this experiment: the segmentation phase, and the test phase. During the segmentation phase, infants heard the synthesized speech from speakers adjacent to the monitor, while the monitor displayed the visual stimuli appropriate to the infants' condition.

The test phase used the same two words and two part-words as the adult test. Each item was repeated 3 times, for a total of 12 trials. Before each trial, an attention-getter (a brightly colored Winnie the Pooh video, coupled with an excited exclamation) attracted infants' gaze to the monitor. Once the infant oriented to the monitor, the experimenter initiated the test trial. Each trial consisted of a repetition of a single word (or part-word), with a pause of 1 second between repetitions. For as long as infants' gazed at the monitor, the test item continued to repeat. When infants looked away from the monitor for two continuous seconds, the test trial ended.

Stimuli

The stimuli during the segmentation phase were presented for 50 seconds and were identical to the audio and video presentations used in Experiment 1. This exposure is half of the length in Experiment 1; pilot testing indicated that 100 seconds yielded an unacceptably high fuss-out rate. The test items were also identical to Experiment 1. During test phase, words and part-words were paired with an orange bar rotating like a propeller (it completed one revolution every three seconds). Pilot testing indicated that infants were far more likely to maintain their interest in the experiment if the monitor displayed a moving object rather than a static image. Both the color and the shape of the bar were novel with respect to the segmentation phase of the experiment, and the motion was unlike the looming animation infants saw during the segmentation phase.

Results

Infants in the no-video condition looked at word trials for 12.4 sec ($SE = 1.0$), and at part-word trials for 11.8 sec ($SE = 0.9$). This difference in looking trials between words and part-words was not significant, $t(19) = 1.1$, $p = .28$. Infants in the regular-video condition looked at word test trials for 9.7 sec ($SE = 0.7$), and to part-word test trials for 11.7 sec ($SE = 0.8$). This difference was significant, $t(19) = 3.7$, $p < .05$. Infants in the irregular-video condition showed the same pattern, looking at words ($M = 9.9$, $SE = 1.2$) less than part-words ($M = 11.6$, $SE = 1.1$). The difference in looking time to words and part-words was also significant for infants in this group: $t(19) = 2.5$, $p < .05$. Unlike infants in the no-video condition, infants in both the regular- and irregular-video condition listened longer to part-words than to words. This indicates that they had learned enough about the identity of words to distinguish them from part-words.

Infants appeared to perform better in the regular-video condition than in the no-video condition, as infants in the no-video condition failed to respond differentially to word and part-word trials. However, infants' performance in the regular- and irregular-video conditions was not significantly different, as indicated by a 2 (condition) \times 2 (test item) ANOVA. As expected, since infants in both groups showed a preference for part-words, there was a main effect of test item: $F(1, 38) = 12.6$, $p < .01$. There was no main effect of condition: $F(1, 38) < 1$. There was also no interaction between test item and condition: $F(1, 38) < 1$. That is, infants' preference for part-words in the irregular-video condition was statistically equivalent to infants' preference in the regular-video condition. These analyses indicate that while infants may benefit from the presence of looming shapes synchronized with word boundaries (present in both video conditions), they do not gain an added advantage from the regular relations between words and shapes present in the regular-video condition. These results present two compelling questions, discussed separately below.

Why do infants fail to distinguish between words and part-words in the no-video condition, when they can do so in the regular- and irregular-video condition?

One possible explanation is that infants in the regular- and irregular-video conditions received some benefit not present in the no-video condition. The looming shapes may have facilitated learning by maintaining infants' attention (e.g., Frick & Richards, 2001; Thiessen, et al., 2005). Another possible benefit that infants may have received in both the regular- and irregular-video condition is the synchronization between the appearance of the shapes and word boundaries. For young infants, synchronization is one of the most important factors that enable identifying links between audio and visual events (e.g., Bahrick, Flom, & Lickliter, 2002; Gogate & Bahrick, 1998; Lewkowicz, 1986; 2003). Infants may have relied upon synchronization as a cue to word boundaries, a cue that was equally available in both the regular- and irregular-video conditions.

Why do infants, unlike adults, fail to benefit from the regular relations between words and shapes available in the regular-video condition?

The fact that infants' performance in the irregular-video condition is equivalent to their performance in the regular-video condition suggests that infants failed to detect the relations between words and shapes present in the regular-video condition. This suggestion is consistent with a variety of converging evidence indicating that infants at this age are relatively insensitive to relations between words and objects in the visual world. Eight-month-old infants have a small vocabulary (e.g., Fenson et al., 2002). In controlled word-learning experiments, infants typically fail to acquire names for novel objects until around a year of age (Werker, Cohen, Lloyd, Casasola, & Stager, 1998). If infants cannot detect the relation between words and objects in the regular-video condition, they cannot benefit from any facilitation that identifying the relation provides to adult learners.

Experiment 3

There are at least two (not mutually exclusive) factors that can explain why infants in Experiment 2 failed to benefit from the regular audio-visual pairing, unlike adults in Experiment 1. One is that adults' ability to take advantage of the regular-video condition is due to the fact that they are faster, more efficient information processors than infants (e.g., Pelphrey & Reznick, 2003). To detect a relation between words and shapes, learners must process the identity of the shape (and the word) in a brief time. There are several experimental results suggesting that young infants are less successful in processing multiple sources of information than older infants and adults (e.g., Stager & Werker, 1997). A second potential factor is that the difference between 8-month-olds and older learners is due to differences in their prior linguistic experience. Adults are well aware that one of the primary functions of words is to refer to features of the visual world such as shape. Eight-month-olds may not yet expect to discover relations between words and shapes (cf. Werker et al., 1998). Infants may fail to detect the regular relations in the input because they do not expect them.

Both factors converge to suggest that older infants should be more successful in identifying and benefiting

from regular word-object associations. Thus, in Experiment 3, we presented 20-month-old infants with the same stimuli used in Experiment 2. These children have a year of additional word-learning experience, and more advanced cognitive processing abilities. Should infants of this age fail to benefit from the regular-video condition, it may suggest that the infant paradigm is simply insensitive to infants' abilities to benefit from word-object relations. However, should infants benefit from regular word-object relations in Experiment 3, it will indicate important developmental differences in infants' abilities to integrate audio and visual information in a statistical learning task.

Method

Participants

Participants were 45 infants between the ages of 19.5 and 20.5 months ($M = 20.12$). Infants were randomly assigned to one of three groups: no-video, regular-video, and irregular-video. To obtain data from 45 infants, it was necessary to test 63. The additional 18 infants were excluded for the following reasons: fussing or crying (16), test trial looking times averaging less than 3 seconds (1), or parental interference (1). According to parental report, all infants were full term, and free of ear infections at the time of testing.

Stimuli

The stimuli were identical to those in Experiment 2.

Procedure

The procedure was identical to that of Experiment 2.

Results

Infants in the no-video condition looked at word trials for 8.3 sec ($SE = 0.6$), and at part-word trials for 8.2 sec ($SE = 0.5$). This difference in looking trials between words and part-words was not significant, $t(14) < 1$. Like the younger infants in Experiment 2, 20-month-olds in the no-video condition failed to distinguish between words and part-words, showing no evidence of learning. At neither age should this be taken as evidence that infants are unable to learn from audio stimuli alone – prior experiments clearly demonstrate that infants are able to do so (e.g., Saffran et al., 1996). Infants' failure in the current experiments is due to the fact that the stimuli are presented much more briefly than in prior experiments. While infants can learn from stimuli presented for this duration, they may only do so for natural – as opposed to synthesized – speech (e.g., Thiessen et al., 2005).

Infants in the irregular-video condition also showed no significant preference, looking equivalently long at word trials ($M = 9.6$, $SE = 0.7$) and part-word trials ($M = 9.1$, $SE = 0.6$), $t(14) < 1$. Interestingly, unlike the 8-month-olds in Experiment 2, 20-month-olds did not appear to learn from the irregular-video condition. Note that 8-month-olds' looking times were much longer to both kinds of test trials ($M = 11.1$ sec) than that of the 20-month-olds. This may indicate that the testing situation was more interesting to 8-month-olds than 20-month-olds. Sustained attention to the input facilitates statistical learning (e.g., Toro et al., 2005). The 20-month-olds in the current experiment may simply have failed to attend to the stimuli long enough to learn.

Regardless of infants' performance in the other two conditions, the question that motivated this experiment was whether they are facilitated in learning from the regular-video stimuli. Infants in the regular-video condition looked at word test trials for 7.2 sec ($SE = 0.6$), and to part-word test trials for 8.5 sec ($SE = 0.7$). This difference was significant, $t(14) = 2.3, p < .05$. Only infants in the regular-video condition showed evidence of learning; no other group demonstrated the ability to distinguish between words and part-words. A series of planned 2 x 2 ANOVAs comparing looking times across conditions assessed this more rigorously. In none of the ANOVAs was there a significant main effect of condition, nor of test trial (all F s < 1). Similarly, there was no interaction between condition and test trial when comparing participants in the no-video condition to participants in the irregular-video condition ($F < 1$).

Most importantly, though, there were significant interactions between condition and looking time when comparing participants in the regular-video condition to participants in both the no-video condition [$F(1, 28) = 3.2, p < .05$] and the irregular-video condition [$F(1, 28) = 3.4, p < .05$]. These interactions indicate that infants' preference in the regular-video condition was significantly different from their lack of preference in either of the other two conditions. This confirms that 20-month-olds, like adults, performed significantly better in the regular-video condition than either of the other two conditions. For children at this age, complexity can facilitate learning by providing multiple learnable regularities in the input. This suggests an important developmental difference between 8- and 20-months of age, with only 20-month-olds showing the ability to benefit from regular audio-video relations in a manner comparable to adults.

General Discussion

One of the reasons that language is such an effective communicative tool is that it allows speakers to express multiple pieces of information simultaneously. For example, a simple observation about the state of the world, such as "the Pirates won," is coupled with affective information that indicates how the speaker feels about that state of affairs. This means that language is rich in possible relations for learners to discover, both between aspects of the speech signal (such as words and pitch), and between speech and meaning. Indeed, infants are able to detect many of these possible relations (e.g., Fisher, Klinger, & Song, 2006; Saffran et al., 1996; Smith & Yu, 2008; Thiessen & Saffran, 2007). However, the need for constraints is necessary for learners presented with rich input, especially input in which multiple relations are present simultaneously.

The current results indicate that at least one of those constraints is a developmental constraint. The ability to integrate simultaneous audio and visual information in a statistical learning task develops during the first two years of life. Whereas adults benefit from the presence of regular word-object associations, 8-month-old infants do not. Critically, 20-month-olds, like adults, benefit from

the regular relations between words and visual objects available in these stimuli. One possibility for this developmental difference relates to older children's vastly greater experience with word-object correspondences in language. Ongoing work with non-linguistic stimuli will assess this possibility. Though the current data do not differentiate between domain-specific maturational accounts (e.g., Waxman & Booth, 2000) and accounts that implicate more general processes, both kinds of accounts share an important commonality. On either account, young infants are not learning as much as adults are when presented with stimuli in which words and objects co-occur. This may actually be beneficial for young learners. By preferentially detecting only some of the available relations in the stimuli, infant learners may avoid a combinatorial explosion (e.g., Newport, 1990).

Abstract

In traditional linguistics, it has been assumed that the sounds of words are not related to their semantic contents, and that meanings of words are not directly linked to sensory systems. Nevertheless, many languages have a word class in which the sound and meaning of words are systematically related. In this study, by using functional magnetic resonance imaging (fMRI), we scanned brain activity in adult Japanese-speakers while they were seeing locomotion videos together with sound symbolic mimetic words, non-sound symbolic adverbs or verbs. Mimetic words were neurally processed differently from non-sound symbolic adverbs and verbs: We identified extensive bi-hemispheric activations in the regions typically associated with nonverbal cognitive processes for mimetic words but not for non-symbolic verbs or adverbs. The results suggest that mimetic words, by their direct sound-meaning link, have dual neural status both as linguistic symbols and non-linguistic iconic symbols that are directly linked to sensory experience.

Keywords: sound symbolism, brain imaging, symbol grounding in language

Introduction

In the tradition of formal linguistics, language is regarded as an encapsulated system which is functionally separated from other cognitive functions. In this tradition, word meanings are assumed to be represented as a set of universal atomic semantic features that are amodal and not connected to direct sensory experiences. Here, sound symbolism, in which the sound and meaning of words are systematically related, is considered to be a marginal phenomenon in language. However, such a statement seems to be too strong when one looks beyond Indo-European languages. Many languages of the world have a large grammatically-defined word class in which sound symbolism is apparent. For example, in Japanese, mimetic words include not only onomatopoeias for animal sounds but also words referring to motion, tactile sensation and emotional states in which sound

is not essential. Mimetic words constitute a large open class of words, and new words can be easily created.

These words are frequently used in everyday conversations and newspaper articles, as well as in various forms of verbal arts, from comic books to novels and poems. Japanese is by no means an exception among languages of the world. Many languages of the world have a similar grammatical class of words with clear sound symbolism (Hinton, Nichols, & Ohara, 1994; Nuckolls, 1999; Voeltz & Kilian-Hatz 2001), including most sub-Saharan African languages (Childs, 1994), and many of the South East Asian languages (called Diffloth, 1972; Watson, 2001; Enfield, 2005) and East Asian languages (Lee, 1992; Mok, 2001; Bodomo, 2006). Even in Indo-European languages that do not have a distinct grammatical class for sound symbolic words (e.g., English), linguists (e.g., Bloomfield, 1933/1984; Bolinger, 1950; Firth, 1935/1957) have pointed out that there is clear sound symbolism in some words (e.g., *squeeze*, *squirt*, *squint*, *bump*, *thump*, and *plump* in English).

Starting with Köhler (1929), there has been a body of empirical work, which demonstrates psychological reality of sound symbolism. Köhler found that, when presented with a curvy round shape and a spiky angular shape, one has the intuition that *baluma* is a better name for the former and *takete* is a better name for the latter (see also Ramachandran & Hubbard, 2001; Westbury, 2004). Sapir (1929) also demonstrated that English speakers associate novel words containing the vowel /i/ with smallness more frequently than words containing /a/.

More recently, empirical evidence for the role of sound symbolism in language processing and novel word learning has been accumulated. For example, sound-shape correlates facilitate category learning involving novel objects both in English-speaking children (Maurer, Pathman and Mondloch, 2006) and adults (Kovic, Plunkett, & Westermann, 2009; Nygaard, Cook & Namy, 2009). Imai and colleagues demonstrated that Japanese 25-month-olds and English

speaking adults who had no exposure to Japanese could detect the sound symbolism underlying novel mimetic words expressing human locomotion (Imai, Kita, Nagumo & Okada, 2008; Kita, Kantartzis & Imai, in press). They further demonstrated that Japanese- as well as English-reared children were greatly helped by sound symbolism in mimetic verbs when they needed to extend a novel verb.

These effects of sound symbolism are not harmonious with formal theories of linguistics. However, when considered from the neurological perspective (e.g., Maurer & Mondloch, 2005; Ramachandran & Hubbard, 2001), researchers may find sound symbolism much less problematic. However, the neural substrate of the phenomena of sound symbolism is still at a stage of speculation. For example, Ramachandran and Hubbard speculated that sound symbolism involves cross-domain mappings between sound contours and motor patterns in or close to Broca's area (possibly mediated by mirror neurons), and between hand gestures and articulatory gestures in the motor area. Also, if sound symbolism is considered as mimicry of the environment by sound, we might expect the activation in the area responsible for integration between sound and other sensory domains such as vision, motion, and touch (cf. Maurer & Mondloch, 2005).

There are a few existing studies in the literature that examined neural representation of mimetic words (Hashimoto et al., 2006; Osaka, 2004). For example, Osaka (2004) compared mimetic words expressing pain and nonsense words. He identified the activation of anterior cingulate cortex (ACC) -the region known to be active when people experience pain-- when the pain mimetic words were processed.

Hashimoto et al. (2006) examined the pattern of neural activations when Japanese speakers processed mimetic words for animal sounds (e.g. *wan-wan*, *bow-wow*) as well as actual animal sounds (dog barking). These researchers showed that Japanese mimetic words for animal sounds (e.g. dog barking) elicited the bilateral activation in the superior temporal sulcus (STS) areas.

Importantly, Thierry et al (2003) demonstrated that there is a functional dissociation between the left and right STS: The left STS is mainly responsible for linguistic sound, whereas the right STS is used when environmental sound is processed. The bilateral STS activation may thus suggest that mimetic words expressing animal sounds have dual nature, being processed both as a linguistic sound (word) and environmental sound. Importantly, in this study, both mimetic words and actual animal sounds were presented auditorily. Hashimoto et al reasoned that mimetic words were processed as environmental sounds because mimetic words sounded like actual animal sound, in connection to Thierry et al.'s results, and argued that the bilateral activation in the STS area reflected the prosodic property of the mimetic words.

These two studies suggest two important characteristics of mimetic words: (1) they are directly anchored to sensory experiences; (2) mimetic words have dual nature, being

processed both as a linguistic sound(word) and environmental sound. However, they leave some important questions concerning the nature of sound symbolism unanswered.

First, it is difficult to determine whether the result by Osaka reflect the sound symbolism in the mimetic words per se, as recent neuro-imaging studies have shown that a word could activate the corresponding sensory area in the brain. For example, several studies revealed that verbs encoding face actions (e.g., *lick*), arm/hand actions (e.g., *pick*), and leg/foot actions (e.g., *kick*) differentially engage their corresponding sensory area in the primary motor and premotor regions (e.g., Hauk et al., 2004; Hauk & Pulvermüller, 2004). Thus, all or most words may be anchored to the sensory experience in some degree, whether or not they carry sound symbolism (Barsalou et al., 2003; Kemeler & Tranel., 2008). Still, it is possible that sound symbolic words, especially mimetic words, are tied to sensory experience more strongly and extensively than non- sound symbolic words due to the iconicity they carry.

Concerning the possibility for the cross-domain mappings between auditory and other sensory modalities in sound symbolic words, it is interesting to see whether or not the bilateral STS activations are also seen for sound symbolic words other than animal sound onomatopoeia. If the sound is strongly tied to the meaning in mimetic words, we might expect to see the bilateral STS activations not only for mimetic words expressing actual sounds but for those representing other sensory domains (e.g. motion) which do not directly involve environmental sound. Furthermore, we might expect to see the same activation pattern even when a mimetic word is presented orthographically instead of auditorily.

To uncover these questions, in this research, we compared the neural representation of mimetic words to that of non-sound symbolic verbs and adverbs, all of which express aspects of human locomotion. We scanned brain activities in Japanese speakers while they were presented with locomotion videos together with sound symbolic mimetic words, non-sound symbolic adverbs or verbs. Here, the words were presented orthographically, and the participants were asked to judge how the word semantically matched the locomotion.

As discussed above, mimetic words are expected to be more strongly tied to perceptual experience than non-sound symbolic verbs and adverbs because of their iconicity in the meaning. In fact, it is possible that mimetic words are processed as "gesture in language" by their sound symbolic nature (Ramachandran & Hubbard, 2001). If so, at a broad level, we may expect activations in the right as well as left hemisphere for the mimetic words, as is the case with non-linguistic gesture (e.g., Kita & Lausberg, 2008). When considering specific regions involved with processing mimetic words for locomotions, if they are in fact tied to sensory experiences more strongly than verbs and adverbs, we might expect stronger activations in the middle temporal (MT), motor, and premotor areas for mimetic words than

for verbs and adverbs. Furthermore, if the sound-meaning link is a part of the meaning for mimetic words but not for adverbs or verbs, stronger activation is expected in the STS and superior temporal gyrus (STG) in both hemispheres, as if linguistic sound and environmental sound are both processed (Hashimoto et al., 2006; Thierry et al., 2003).

Method

Participants

Sixteen native Japanese speakers who were either undergraduates or graduates students (mean age = 23.7; age range = 22-25; 7 women) participated in the study.

All subjects were right-handed and had normal or corrected-to-normal vision and had no histories of neurological or psychiatric diseases. The data of five participants were excluded from analyses due to artifact components (e.g. head movements) and inadequate performance in the task. The rest of the data from eleven subjects (mean age = 23.4; age range = 22-25; 4 women) were used for analyses. All participants gave a written informed consent for participation, and the study was approved by the local ethics committee.

Design and procedure

All participants went through the main experiment (comparing mimetic words, verbs and adverbs) first. After a break, they went through a control experiment, in which the same locomotion videos were presented without words. For the main experiment, we used 16 video clips showing different manners of locomotion, in which an agent moved from left to right on the screen. Each locomotion video was presented together with sound symbolic mimetic words, non-sound symbolic adverbs, or verbs. In half of the trials, the word and the locomotion semantically matched, while in the other half, they did not (e.g., the verb “aruiteiru” (to walk) was shown together with a skipping locomotion). At the end of each block, a fixation point was inserted for 10 seconds to separate the blocks. In each trial, the stimulus (a video clip with a written word) was represented on the screen for 5 seconds. During the stimuli presentation, the participants were instructed to think about the degree of match between the word and the locomotion, but they were asked not to make a response during this period. After the stimuli presentation, the fixation point appeared on the screen for 3 seconds, during which the participants were asked to respond on a scale from 1 to 5 by pressing an appropriate button. There were 4 blocks for each word class and each block consisted of 4 video-word pairs from the same word class. The order of blocks was rotated in the order of mimetic words, verb, and adverb.

All words were shown at the bottom of the video in *hiragana* (a type of orthography each of which represents a syllable). A block design was employed. In each trial, the participants were asked to judge the degree of matching on the scale of 1-5.

In the control experiment, in addition to the videos used for the main experiment, videos showing unnatural

biological motions (which were created by morphing videos of natural biological motions) were also shown. The procedure of the control experiment parallels to that of the main experiment except that a word was not presented with the video. During the stimuli presentation, the participants were instructed to think whether the locomotion of the video clip was natural or unnatural as a human movement. After the stimuli presentation, the fixation point appeared on the screen for 3 seconds, during which the participants were asked to respond either 1 (natural) or 2 (unnatural) by pressing the appropriate key. There were 8 blocks, each of which consisted of 4 video clips. The “natural” trials in which the videos used in the main experiments served as the baseline for visual recognition of the locomotion without verbal description (words).

Stimuli and stimuli validations

Three rating tests were carried out before the fMRI scanning to check whether words representing the three word classes (mimetic words, verbs, adverbs) do not differ in terms of imaginability, familiarity, and age of acquisition (AOA). All participants were native speakers of Japanese, and none participated in the scanning experiment.

Including the words we used for fMRI scanning task, we prepared 120 words. Twenty-eight participants rated how imaginable each word was. Twenty-seven participants rated how familiar each word was, with a scale from 1 to 7. Finally, we asked other 22 participants to judge around what age they had learned the words to obtain AOA for each word. They were instructed to select the answer from 8 categories; infant period / pre-school age / lower-grade at elementary school / higher-grade at elementary school / junior high school / high school / university or college / do not know the meaning.

The results of the three rating tests indicated that there were significant differences among the three word classes with respect to imaginability (Mimetic words = 5.276 ; Verbs = 6.404 ; Adverbs = 5.616 ; $F(2,81)=3.11$, $p<0.05$) and familiarity (Mimetic words = 5.423; Verbs = 6.511 ; Adverbs = 6.08 ; $F(2,78)=3.11$, $p<0.05$). However, importantly, there was no significant difference between mimetic words and adverbs ($t(1,54)=-1.192$ $p=0.119$). Also, the result of Friedman test indicated that there was no significant difference between the mimetic words and the verbs with respect to AOA (Mimetic words = 1.523; Verbs = 1.545; Adverbs = 2.932, $p=0.763$), although adverbs were judged to have been acquired later than verbs and mimetic words.

Imaging parameters and analysis

Scanning of fMRI data was performed with a 1.5 Tesla MRI scanner. The fMRI images were obtained using multislice gradient-echo planner imaging (EPI) and were used to produce 20 contiguous, 6-mm thick axial slices covering the whole brain [echo time (TE), 50 ms; repetition time (TR), 2000 ms; flip angle, 90 degree; field of view (FOV), 192 mm; 64 × 64 matrix].

The fMRI data were analyzed using SPM2 software (SPM2; Wellcome Department of Cognitive Neurology, UK). The EPI images for each time series were realigned with reference to the first image to correct for head motion. The anatomical images were co-registered with the mean functional images and normalized to the Montreal Neurological Institute (MNI) brain template. Functional data were then normalized using the same transformation parameters and were smoothed in the spatial domain (isotropic Gaussian kernel of 8 mm full width half maximum, FWHM).

Statistical analyses were based on general linear model and activations were modeled using a simple delayed box- car reference vector convolved with a hemodynamic response function (HRF). Low-frequency drifts were removed using a high-pass filter (Holmes *et al.*, 1997) and a first order autoregressive model (AR1) (Friston *et al.*, 2000) was applied for eliminating the temporal autocorrelation of the fMRI time-series data.

Results

Behavioral Results Inside the Scanner

The reaction times for making judgments about the degree of match between the word and the locomotion during the scanning were analyzed. The results indicated that the reaction times for the judgments did not differ across the three word classes, $F(2,20)=0.272$, $p>0.05$.

We also checked if the judged degree of match between the word and locomotion itself differed across the three word classes. No difference was found among mimetics, verb, and adverb conditions.

These results together with the results of the pre-scanning rating studies suggest that the three types of words did not differ in the task difficulty. Hence, if we see differences in the pattern of activations across the three word classes, it cannot be attributed to the task difficulty or processing difficulty of the words.

f-MRI Results

Activation pattern for each word class compared to the baseline

To identify the areas of activation due to processing each type of words, the gross activation for the mimetic, adverb, and verb condition¹ was subtracted by the activation obtained from the motion only (without words) control¹. The usual left hemisphere dominance was observed for the adverbs and verbs. It is important to note that, for all word types including the verbs and adverbs, after removing the activation responsible for perceptual processing of locomotion video, the activation of the motor-premotor areas was identified. This result suggests that, whether the word is sound symbolic or not, words are anchored to direct

perceptual/sensory experiences, in keeping with the embodiment view of concepts and word meanings (e.g., Barsalou *et al.*, 2003, Kemerer, 2010) and in contrast to the formal view of language, which asserts that words are arbitrary symbols.

Interestingly, processing of the mimetic words elicited much broader and stronger activation of the brain than verbs and adverbs. In particular, extensive bi-hemispheric activations were observed when the mimetic word was processed together with the locomotion video, consistent with our hypothesis that mimetic words have dual natures, both as linguistic and non-linguistic gesture-like symbols (Figure 1). Note that the difference between the mimetic words and the other two types of words could not be attributed to familiarity or task difficulty, because the results of pre-ratings and the behavioral results inside the scanner found no difference across them.

Figure1. Unique activations for each word class. The activation map is overlaid onto a rendered SPM normalized brain. Height threshold at $p<0.001$, uncorrected and 0 voxel extend threshold for one sample t-test were applied).

Unique areas of activation for each type of words

Next we examined the unique areas of activation for verbs, adverbs, and mimetic words. For this purpose, the activations observed for the target word class was subtracted by the other two word classes. For example, in order to see the unique regions for the mimetic words, the activations observed for the verbs and adverbs were subtracted from the activations elicited in the mimetic condition.

As is clearly seen in Figure 2, the verb and the adverbs showed virtually no unique regions left, when the activations for mimetics processing were subtracted. In contrast, as expected, activations of the bilateral STG/STS and the MT areas were shown as the specific regions for the mimetics. Also, the mimetics elicited stronger and broader activation in

¹ Here, we only used the blocks of the "natural" motion because we use only "natural" motions for the main experiment. The data from the unnatural motion blocks were discarded from the analysis.

the motor and pre-motor regions than the verbs and adverbs (Figure 2). This finding further supports the hypothesis that mimetic words are more strongly tied to sensory experience than non-sound symbolic verbs and adverbs, and that cross-domain integration between auditory and other (e.g., motor and motor perception) sensory domains are particularly important for processing of mimetic words.

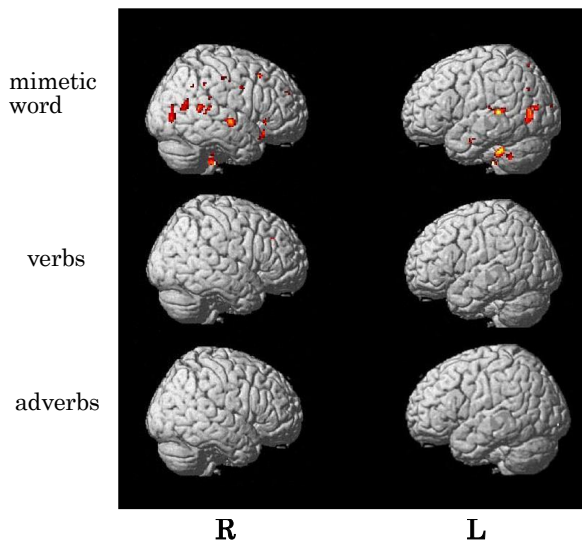

Figure2. The specific regions identified for each word class. The activation map is overlaid onto a rendered SPM normalized brain. Height threshold at $p < 0.001$, uncorrected and 3 voxel extend threshold for one sample t-test were applied).

Correlation between the strength of activation and the degree of semantic match

We further examined if the pattern of brain activity varied as a function of the word-video match or mismatch. The strength of activation in the motor, premotor, and STS areas was correlated with the degree of word-locomotion match. This analysis revealed that when the meaning of mimetic words matched the locomotion, the right motor area was activated more strong ($r = .554$, $p < .05$); when they did not match, the right pre-motor area was activated ($r = -.555$, $p < .05$) (Figure 3).

The shift of the areas of activation between the motor and pre-motor regions along with the change in the degree of the mimetic-locomotion match was intriguing: When the locomotion and the mimetic word semantically matched, the participants presumably mimicked the action easily in the brain; but if the mimetic word and locomotion did not match, the participants might have tried to model the action themselves, and as a result, the activation shifted to the premotor area. In contrast, no such correlation was found in the right STG/STS area, suggesting that the activation of the right STS region was related to the processing of mimetic

words per se, independent of whether the word semantically matched the motion or not.

Figure3. The activations in the right hemisphere as a function of matching (Left) and mismatching (Right) mimetic words. The activation map is overlaid onto a rendered SPM normalized brain. Height threshold at $p < 0.001$, uncorrected and 0 voxel extend threshold for ANOVA were applied).

Discussion and Conclusion

This research investigated the neural representation of mimetic words, verbs and adverbs in the domain of human locomotion using fMRI. In the traditional formal linguistics, sound symbolism has been considered as an unimportant aspect of language (e.g., Saussure, 1986; Sapir, 1921). However, recently, this view has been revisited in linguistics, psychology, language development, and neuroscience.

Researchers have demonstrated that certain phonological and prosodic properties are correlated with the meanings of words (e.g., voicedness are correlated with heaviness), and that people are able to detect this sound-meaning correlates from very early developmental stages (e.g., Maurer and Mondoch, 2005). It has also been suggested that sound symbolism may play a role in language development within a child (Imai et al., 2008; Kita et al., 2010) as well as evolution and origin of language (Ramachandran & Hubbard, 2005). In spite of the accumulating evidence for the presence of universal sensitivity to the sound-meaning correspondence, the neural mechanism behind it has been still at a stage of speculation.

This research was conducted to uncover the neural mechanism of sound symbolism by comparing the activation patterns for sound-symbolic mimetic words, (non-sound symbolic) verbs and adverbs in the domain of locomotion. The results largely support the hypothesis that mimetic words have dual natures, somewhat in between linguistic symbols and non-linguistic gesture, as not only the regions relevant to language processing but also those relevant to non-linguistic iconic gestures were activated. The stronger activation of the MT, motor and pre-motor areas also suggest that mimetic words invoke stronger attention to the motion and invites speakers to mentally simulate the action more strongly than regular, non-sound symbolic verbs.

Ramachandran and Hubbard (2005) speculate that processing of sound symbolic words involves cross-domain mappings in the brain between sound contours and motor patterns. The bilateral activation of the STS area found for the

mimetic word processing strongly indicates cross-domain mappings and integration between sound and motion, and provide support for their speculation. In future research, it is important to see if the pattern is replicated for mimetic words expressing other sensory domains (e.g., touch).

The results are also in great harmony with the embodiment view of language and cognition, demonstrating that words in general invoke activations of relevant sensory areas, consistent with previous neuro-imaging studies (e.g. Martin et al, 1995; Huak & Pulvermüller, 2004; Kemmerer & Tranel, 2008). However, they also suggest that the degree of embodiment depends on word types, with highly sound- symbolic words like mimetic words are most directly and strongly bound to sensory experience.

The issue of the origin of the sensitivity to sound symbolism is extremely interesting. Maurer and Mondloch speculate that sensitivity to sound symbolism is universally present prior to language learning, reasoning that it occurs as a bi-product of over-connectivity among different sensory areas in infants. In our lab, we are currently testing whether pre-semantic infants are sensitive to the sound-vision (shape) correlates and how this can be manifested in the brain. This may open the door to the big quest concerning the origin of language.

Word Order, Case Forms and Structural Priming in Czech Children's Comprehension

Filip Smolík

Institute of Psychology AS CR

Jiří Lukavský

Institute of Psychology AS CR

Abstract: Two groups of Czech children, 3-year-olds (N=28) and 5-year-olds (N=26), participated in a preferential looking experiment testing their comprehension of simple transitive sentences and their susceptibility to structural priming. Four temporarily ambiguous target sentences were presented, two with the canonical SVO word order, two with OVS word order, which is possible but marked in Czech. Each target sentence was preceded by an unambiguous prime sentence with SVO or OVS word order. In 3-year-olds, the presence of OVS primes reduced the garden-path effect observed in the OVS sentences. In 5-year olds, there were no significant effects of structural priming. In unambiguous prime sentences, 5-year olds showed the same level of comprehension in both the canonical and non-canonical sentences. The results suggest that 3-year-olds represent the abstract relationship between agent and patient roles and word order. Results from prime sentences suggest that 5-year-olds can interpret sentences with non-canonical word order.

Modeling Implicit and Explicit Processes in Recursive Sequence Structure Learning

Jamie D. Alexandre (jdalexan@ucsd.edu)

Department of Cognitive Science, 9500 Gilman Drive
La Jolla, CA 92093 USA

Abstract

Recursive structure is viewed as a central property of human language, yet the mechanisms that underlie the acquisition and processing of this structure are subject to intense debate. The artificial grammar learning paradigm has shed light onto syntax acquisition, but has rarely been applied to the more complex, context-free grammars that are needed to represent recursive structure. We adapt the artificial grammar serial reaction time task to study the online acquisition of recursion, and compare human performance to the predictions made by a number of computational language models, chosen to reflect multiple levels and types of syntactic complexity (n-grams, hidden markov models, simple recurrent networks, and Bayesian-induced probabilistic context-free grammars). Evidence is found for a dissociation between explicit and implicit mechanisms of sequence processing, with the SRN more highly correlated with implicit performance, and the PCFG more correlated with explicit awareness of the sequential structure.

Keywords: artificial grammar learning; syntax; recursion; serial reaction time task; simple recurrent network; context-free grammars; implicit/explicit processes.

Introduction

The nature of linguistic structure, and the computational mechanisms by which humans comprehend it, have long been subject to heated debate. Recursion – the ability to hierarchically embed elements within instances of themselves – has been a central point of contention. Although the recursive structure of language was not a new idea at the time, Chomsky formalized the notion of syntactic recursion, touting it as *the* fundamental property that allows for human linguistic ability, a thesis he continues to popularize today (Chomsky, 1956; Hauser, Chomsky, & Fitch, 2002).

In the Chomskyan tradition, the human syntactic system implements a set of rules that allow for theoretically unbounded levels of recursive embedding (“competence”), but this system is then subject to processing constraints, such as working memory limitations, that explain our limited ability to process recursive structures beyond a few levels of embedding (“performance”). Other theorists, particularly from the connectionist camp, have attempted to explain the (limited) human ability to process recursive structure without hypothesizing unbounded competence, by modeling syntactic processing in systems that do not make use of rules or explicit representations (e.g. Elman, 1990; Pollack, 1990; Christiansen & Chater, 1999).

The artificial grammar learning paradigm (initiated by Reber, 1967) has been used to examine processes of syntactic acquisition, but this has been largely restricted to

the class of regular grammars, which doesn’t shed light onto the acquisition or processing of context-free or recursive structure. The goal of the present study is to obtain estimates of a subject’s online string continuation expectancies while responding to sequences generated by a context-free grammar (palindromes), so that these may be compared with the predictions made by a variety of language models trained on the same input history as the subject. The traditional measures of successful acquisition in artificial grammar experiments – such as grammaticality judgments or recall error rates – are not able to provide the incremental (symbol-by-symbol) expectancy data that we require. We adapt a paradigm first employed by Cleeremans & McClelland (1991), known as a serial reaction time task, in which subjects respond to a sequences of stimuli (with a button mapped onto each stimulus class) by pressing the corresponding button as quickly as possible after perceiving stimulus onset. The resulting reaction times are then correlated with the probabilities generated by the competing computational models.

Surprisal

Surprisal, or self-information, is a notion from information theory that quantifies the amount of novel information that a particular event carries with it. An event’s surprisal is defined as its negative log probability:

$$-\log(P(x \mid \text{context}))$$

The concept of surprisal has been used in psycholinguistics as a potential measure of incremental processing difficulty, and is thus expected to correlate with behavioral measures such as reading times in eye-tracking studies, and response times in self-paced reading studies (Hale, 2001; Levy, 2008).

The surprisal model requires that we adopt some measure of the probability of a word’s occurrence given the preceding sentential context. Hale (2001) uses a probabilistic Earley parsing algorithm to generate incremental word probabilities, using the resulting surprisal values to explain the garden path effect. Levy (2008) uses a similar model to explain a wide-range of effects found in the psycholinguistic literature, such as predictability (e.g. effect of Cloze probability), locality effects (e.g. preference for local dependencies), competition/dynamical models (e.g. greater ease in highly constrained contexts), the tuning hypothesis (e.g. effect of structural frequency), and connectionist models (e.g. predictions made by an SRN). The case of the SRN is particularly interesting, because there are significant divergences between the predictions made by an SRN and a

PCFG-based surprisal model, particularly for constructions such as recursive center-embeddings, which PCFGs process flawlessly, and SRNs – much like humans – have difficulty processing beyond a few levels of embedding (Christiansen & Chater, 1999).

Frank (2009) tested a surprisal model against human eye-tracking data from the Dundee corpus, comparing PCFG-with SRN-generated probabilities, and found that the PCFG produced more accurate objective probabilities, but that the SRN produced probabilities that better matched the human data. He concludes from this, firstly, that subjective probabilities diverge from the objective probabilities, and secondly, that the SRN may in fact be a better model of human performance. Other surprisal studies have used n-gram statistics, such as a trigram model with Kneser-Ney smoothing (Smith & Levy, 2008), and also shown close correspondences with human eye-tracking data.

Language Models

A probabilistic language model is a distribution over the strings (sentences) in a language. The models considered in this paper also all support incremental prediction; that is, given a sentence prefix, they assign a distribution over the symbols that might come next.

To allow for comparison with the human data, each of the models is trained on the precise input that a subject has been exposed to at every point in the experiment (rather than training on a larger corpus, or simply using the probabilities assigned by the model that generated the stimuli). This allows us to observe how a subject's predictions change over the course of learning, to gain insight into the rate at which a system is acquired, as well as possible shifts in strategy, rather than simply comparing fully trained systems.

It is also important to note that none of the model parameters are fit to the human data; a model is trained to predict a sequence's continuation based on the set of sequences it has seen up to that point in the experiment, making use of the algorithmic and representational resources at its disposal, but agnostic to human performance.

The models were chosen from amongst those most commonly used within computational linguistics to model sequential structure, at various levels of complexity (some corresponding roughly to levels in the Chomsky hierarchy).

N-grams (bigrams/trigrams)

One of the simplest but most commonly used language models, n-grams calculate the probability of a symbol in terms of the frequency with which it occurs in its immediately preceding context. Here, we will consider bigrams (which take into account the preceding symbol of context) and trigrams (which take into account the 2 preceding symbols). The predictions made by the n-grams at every step were based on training on all preceding sequences (excluding the sequences that had not yet been seen).

Hidden Markov Model (HMM)

Whereas n-gram transition probabilities are defined between sets of adjacent words, the transitions in a hidden markov model (HMM) are defined over a set of "hidden" states, and these states, in turn, generate the individual words. The idea is that there is an underlying "hidden markov process" that we cannot access directly, and all we can observe is the final sequence of words that is produced by this underlying state sequence. Computationally, HMMs roughly correspond to regular languages at the bottom of the Chomsky hierarchy.

We use the standard Baum-Welch algorithm (Baum et al, 1970) to estimate the HMM's transition and emission matrices from the training corpus (the preceding sequences) for an HMM with 5 hidden states. The trained HMM is then used to compute the incremental posterior probabilities of each symbol given its preceding context. As always, the predictions only used the preceding sequences as a training corpus (so as to be comparable to the human data).

Simple Recurrent Network (SRN)

A simple recurrent network (SRN) is a standard three-layer feed-forward network, with the addition of a context layer that maintains a copy of the hidden layer's state from the previous timestep, and then allows the nodes in this context layer to feed back into the hidden layer during the next timestep, alongside the next input (Elman, 1990). The context layer in an SRN effectively implements time-tapped feedback loops from every node in the hidden layer back to each of the nodes in the hidden layer (delayed by one timestep). The addition of recurrent hidden layer connections allows an SRN to learn to use its hidden layer representations to maintain *task-relevant* contextual information over theoretically unbounded (though in most cases, rapidly decaying) distances.

The SRN used in this paper contained 9 input nodes (one for each symbol, plus a sequence boundary marker), 16 hidden nodes, and 9 output nodes. The network was trained using standard back-propagation, with a learning rate of 0.5 and no momentum, on a single pass through the sequences. Output activations at every timestep were converted into probabilities through the Luce choice rule (in effect, normalizing the network's output vector).

Probabilistic Context-Free Grammar (PCFG)

Context-free grammars (CFGs) have played a central role in linguistic theories of syntax ever since Chomsky (1956) proposed them as being necessary (and almost sufficient) to account for the types of recursive phrase structure observed in human language. A probabilistic context-free grammar adds probabilities to the production rules in a context-free grammar, allowing us to calculate a distribution over strings in the language.

Once we know the parameters of the grammar (see below), incremental predictions can be computed as follows (adapted from Jelinek & Lafferty, 1991):

1. The probability of a string is the sum of the probabilities of all its parse trees.
2. The probability of a string prefix is a sum over the probabilities of all possible completions of the prefix.
3. The probability that a particular symbol w_i will appear following the string prefix $w_1..w_{i-1}$ can be computed by dividing the probability of the prefix with that symbol appended, $P(w_1..w_i)$, by the probability of the prefix, $P(w_1..w_{i-1})$

Stolcke (1995) modified the Earley parsing algorithm to compute the above incremental probabilities efficiently, and we use an implementation by Levy (2008) in the present work.

Learning the parameters of a PCFG from an unparsed corpus is not a trivial task, however. Here, we use a Bayesian framework developed by Mark Johnson¹ that uses Gibbs sampling to learn the probabilities for a set of production rules, given a corpus of training sequences. All combinations of production rules with 8 states (in Chomsky Normal Form, e.g. $A \rightarrow BC$) were included in set of candidate rules, and the sampler was given a prior of $\alpha=0.0001$. The counts on the final sample grammar were normalized into probabilities. As with all the other models, the predictions made for every symbol were based on re-training after every sequence, using only on the sequences that occurred prior to that point in the experiment, so that the models have precisely the same information available to them at each timestep as the human subjects. This entire process was repeated 5 times, and the resulting sequences of probabilities were averaged together.

Experiment

Methods

Interface Care was taken in designing and constructing an interface device for the task, due to concerns about measurement noise. The button box (Figure 1) consists of 8 finger-sized push buttons arranged in a 2x4 array, with each button containing its own separately controllable LED for use as a response cue. The buttons and LEDs are interfaced to the PC via a USB-powered LabJack U3 DAQ device, which has very high sampling rates and low command-response latencies, allowing for RTs to be measured to millisecond accuracy.

Figure 1: Button box used in experiment.

Participants Eight subjects (mean age 20.5, all right-handed), drawn from the UCSD undergraduate subject pool, received 2 hours of course credit for their participation.

Stimuli Sequences were generated from the following grammar in Table 1.

Table 1: Context-free grammar used to generate stimuli.

Probability	Production Rule
0.193	$S \rightarrow T0 S T0$
0.146	$S \rightarrow T1 S T1$
0.112	$S \rightarrow T2 S T2$
0.128	$S \rightarrow T3 S T3$
0.077	$S \rightarrow T4 S T4$
0.082	$S \rightarrow T5 S T5$
0.159	$S \rightarrow T6 S T6$
0.103	$S \rightarrow T7$

This grammar generates palindromes, a particular type of “mirror recursion” in which the right-hand side of the sequence is a mirror image (flipped left-to-right) of the left-hand side. The 7th symbol serves as a consistent center marker, making the grammar deterministic. An example sequence would be “0 4 1 3 7 3 1 4 0”.

Palindromes are the canonical example of context-free structures, and possibly the simplest type of grammar that is context-free and thus cannot be fully captured by finite state models such as an HMM, or by n-gram statistics.

An experimental session consisted of 16 blocks of 25 sequences each, with sequences ranging in length from 5 to 15. Each of the 8 subjects were presented with the same set of sequences, but with a different mapping of symbols to buttons, shuffled in a Latin-square design such that every symbol was mapped onto each of the 8 buttons for exactly one subject (to balance out any effects of button location or between-button distances).

Procedure Subjects were told that the purpose of the experiment was to study the “effects of practice on reaction times”, and were told to “hit each button as quickly as possible when that button’s light goes on”. No mention was made regarding the structured nature of the stimuli; as far as the subjects were concerned, the sequences were entirely random.

Sequences were presented rapidly, with the next light in a sequence turning on 120ms after the previous button had been released. After the end of an individual sequence there was a 2 second pause before the next sequence began.

In between blocks, subjects were presented with a feedback screen indicating their performance on the block relative to their performance on earlier blocks (plotting their RT contour over time), and also relative to previous subjects, by means of a highscores list derived from earlier pilot testing. Subjects were given a chance to take a short break in between blocks.

After completing the experiment, subjects were interviewed about the strategies they had employed in the

¹ <http://www.cog.brown.edu/~mj/Software.htm>

task, the factors they thought affected their performance, and what sorts of patterns (if any) they had noticed in the sequences.

Results and Analysis

Reaction times longer than 1000ms (greater than ~ 4.2 std above mean) were excluded from analysis, to eliminate extreme outliers caused by events not related to the task (such as distractions, subject sneezing, etc). Only 0.2% of the trials were excluded by this criterion. In addition, the first trial of every sequence was excluded from correlation analyses, as earlier pilot testing using random sequences showed that mean reaction times for these sequence-initial trials were ~ 70 ms slower than for the remainder of the sequence. Reaction times for error trials (when the incorrect button was pressed) were measured from when the light went on to when the correct button was pressed, ignoring the intervening erroneous button press. Subjects made an average of 65 errors each (1.7% of the trials), and these trials were not excluded from the analysis, but doing so has no noticeable effect.

The median reaction time for each trial is calculated across subjects, and then the resulting sequence of reaction times is correlated with the sequences of surprisal values (negative log probability) generated by each of the models. The experiment is divided up into four parts to visualize how the correlations change over the course of training. Standard correlation coefficients and 95% confidence intervals are plotted in Figure 2. Note that each of the models is significantly correlated with the human reaction time data throughout the experiment, though with no model clearly dominating (except perhaps a slight preference for the SRN).

Figure 2: Correlations between models and human reaction times over the course of the experiment.

Several possible interpretations exist at this point. Since the models themselves are quite strongly inter-correlated, it is possible that the correlations for each of the models could be explained by a common shared component. In particular, each of the models is capable of representing n-gram statistics, so perhaps this could explain some portion of the correlation in the other models. To investigate this

possibility, partial correlations between the human reaction times and the models are computed after regressing out the bigram and trigram statistics. The residual correlations are plotted in Figure 3.

Figure 3: Partial correlations between model probabilities and reactions times, regressing out n-gram probabilities.

As is to be expected, the bigram and trigram correlations become insignificant. The HMM correlations are also eliminated after the first couple of blocks (at which point none of the models have learned very much), suggesting that the HMM was not explaining anything significant about the human behavior beyond n-gram statistics. Both the SRN and PCFG, however, maintain significant correlations throughout, suggesting that they are capturing more about the human reaction times than simply a sensitivity to n-gram statistics.

We might then wonder whether a common component is responsible for both the SRN and PCFG correlations, or if they are each accounting for distinct aspects of the human behavior. To test this, we regress out all models except for the model of interest, and see how much of the variance remains for that model to explain.

Regressing out all the models besides the PCFG reduces its correlations very slightly, but they remain highly over the course of a session, as can be seen in Figure 4 below.

Figure 4: Partial correlations, regressing out all but PCFG.

Similarly, regressing out all models other than the SRN has very little effect on the SRN correlations, which remain strong throughout, despite declining somewhat towards the end (Figure 5).

Figure 5: Partial correlations, regressing out all but SRN.

These results seem to suggest that multiple simultaneous processes are playing a role in human behavior on the task; on the one hand, an associative, incremental component captured by the SRN, and on the other hand, a more rule-based, recursive component exemplified by the PCFG. As SRN models have frequently been used to model implicit learning (e.g. Cleeremans, 1993; Misyak et al, 2009), whereas PCFGs are more often associated with explicit rule-based knowledge, we examined individual differences between subjects with regards to implicit and explicit learning, to see if this might help to explain this dissociation.

In the post-testing questionnaire, 3 of the 8 subjects identified some type of structure within the sequences; some referred to it as a “circular” or “mirror” pattern, and one also gave explicit palindromic examples. The 5 remaining subjects had not noticed any regularity to the sequences, even when probed further (2 of these “felt” like there might be some pattern, but could not articulate any details). We separated these two groups from one another and once again calculated partial correlations (regressing out n-grams and the hmm).

Figure 6: Subjects with no explicit awareness of structure; partial correlations, regressing out n-grams and hmm.

Figure 7: Subjects who were explicitly aware of structure; partial correlations, regressing out n-grams and hmm.

The subjects who were able to report explicit knowledge of aspects of the palindromic structure, by the end of the experiment, showed the strongest correlation with the PCFG (Figure 7), whereas the SRN correlated more strongly with the group that gained no explicit awareness of the structure (Figure 6), indicating that the variance explained by the SRN may reflect a more automatic, implicit processing of the sequential structure (as suggested, for example, by Cleeremans, 1993), whereas the acquisition of recursive, rule-like structures may involve more explicit, conscious processing. It was not possible to query subjects partway through the experiment about whether they had noticed any patterns without drawing their attention to the existence of structure, but the sudden divergence between the PCFG and SRN in Figure 7 lines up well with subjects’ comments during the post-test interview that they had begun to notice the pattern somewhere in the “middle of the experiment”.

It is also instructive to examine the pattern of reaction times over the course of an average sequence. As the sequences are of different lengths, position on the x-axis is represented as percentage of the way through a sequence (Figure 8).

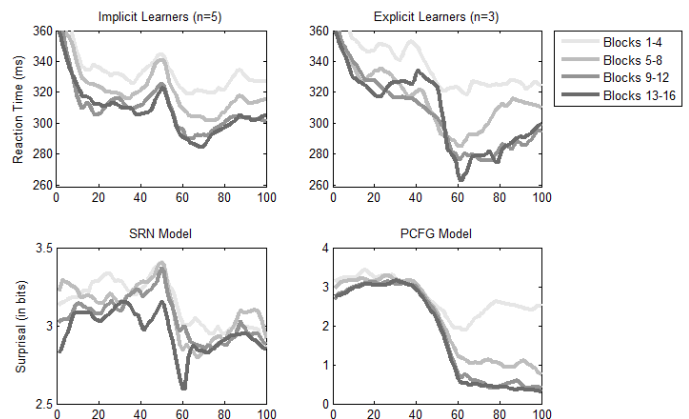

Figure 8: Comparison of RTs and model surprisal over the course of an average sequence (scaled by percentage).

There are several things to note in this reaction time data. Firstly, subjects seem to show a strong advantage in the second half of the sequence, which is consistent with the symbols in the second half being completely determined by the symbols in the first half (due to the palindromic nature of the sequences), and which is seen most strongly both in the PCFG and in the learners with explicit awareness of the structure. Secondly, this advantage is greater immediately following the center symbol and reaction time and then increases slightly as the sequence continues. This is consistent with the fact that later symbols in the second half involve longer-range dependencies, and thus may reflect working memory limitations. The reason for the peak seen halfway through the sequences in both the implicit learners and the SRN is at first unclear, but it is tempting to interpret it as reflecting the cognitive load involved in needing to flip around the first half of the sequence in order to predict the second half, although we might expect this to appear in the explicit rather than the implicit subjects.

Discussion

We attempted to shed light on the mechanisms underlying human processing of recursive structure, by extending the artificial grammar serial reaction time paradigm in two ways; firstly, by training subjects on more complex grammars than are typically used (context-free grammars); and secondly, by comparing performance not only to transitional n-gram probabilities and connectionist models, but also to a Bayesian-induced PCFG model, trained on the exact same set of sequences as the subjects. Evidence was found for a dissociation between implicit and explicit modes of processing, and these modes were seen to correlate most strongly with the predictions of the SRN and the PCFG, respectively.

It may also be fruitful to examine the effects of making subjects explicitly aware of the structure prior to beginning the task, as the results of the present study would suggest this would lead to greater correlation with the predictions of the PCFG. It would also be useful to provide a longer training period, to shed light on how these processes change over the course of more extensive exposure.

Abstract

Recursion is argued to be the crucial property distinguishing human and non-human primates language learning faculty (Hauser, Chomsky, & Fitch, 2002). Recently, 2 studies (Bahlmann & Friederici, 2006; de Vries, Monaghan, Knecht, & Zwisserlood, 2008), which investigated the learnability of a recursive artificial grammar of the type of A^nB^n , used the same material but reported divergent results. We propose that the organization of the linguistic environment crucially determines learnability of the recursive structure, and that this factor might offer some explanation to the incompatible findings. In a grammaticality judgment task using the same materials as in Bahlmann and Friederici (2006) and de Vries et al.'s (2008), we found significantly better performance when the training input was arranged in a starting small fashion, than when it was organized randomly.

Keywords: Starting small; Recursion; Artificial grammar learning; Statistical learning.

Introduction

Exploring the mechanism behind language learning has been the focus of an enormous body of research in linguistics, psychology and education. The question is how children can possibly acquire such an astonishing complex system so rapidly, while the linguistic environment input is noisy and limited. Sentences like *The rat the cat the dog chased killed ate the malt*. (Chomsky & Miller, 1963) with two recursive center embedding clauses are nearly unintelligible, even for native English speakers (Bach, Brown, & Marslen-Wilson, 1986; Hudson, 1996; Newmeyer, 1988; Vasishth, 2001), due to the associated elements in the sentence being distant from one another (e.g. “the rat” and “ate”). Moreover, recursion is a self-referential principle that can be applied an infinite number of times, producing sentences with numerous embeddings being cognitively very hard to process. Among all syntactical characteristics of natural language, recursion has therefore been argued to be the most fundamental and challenging to acquire (Hauser, Chomsky, & Fitch, 2002).

A recent experimental study (Fitch & Hauser, 2004) using an artificial language has reported that cotton-top tamarins could master the *finite state grammar* (FSG) with the $(AB)^n$ type, but not a higher-level recursive *phrase structure grammar* (PSG) with the A^nB^n type, which could be learned by human participants. Using a familiarization-

discrimination paradigm, Fitch and Hauser (2004) first presented the animal participants two auditory sets of consecutive consonant-vowel nonsense syllables (e.g. *la, pa, ba*). Category A syllables were spoken by a female speaker, while Category B syllables by a male. The two sets were identical except for the underlying structure, as well as the pitch. The $(AB)^n$ set in FSG was formed by local transitions between A and B, while the A^nB^n sentences were made according to a center embedding recursive rule (see Figure 1). After this training phase, a discrimination task was performed by the tamarins using the familiarization paradigm. It showed that tamarins could detect the ungrammatical sequences from the grammatical ones in FSG, but not in PSG. Contrastively, humans demonstrated clear discrimination in judging grammaticality of both grammars. This study has raised a renewed interest concerning the inductive learnability of recursive structures, using *artificial grammar learning* (AGL) paradigm (Bahlmann & Friederici, 2006; Bahlmann, J., Schubotz, R.I., & Friederici, A.D., 2008; de Vries, Monaghan, Knecht, & Zwisserlood, 2008; Kersten & Earles, 2001; Perruchet & Rey, 2005). Nevertheless, a study (Gentner, Fenn, Margoliash, & Nusbaum, 2006) concerning song birds' capability of processing A^nB^n structure posed a challenge to this “uniquely human” claim.

Finite State Grammar $(AB)^n$

Phrase Structure Grammar A^nB^n

Figure 1. Structures of Finite State Grammar $(AB)^n$ and Phrase Structure Grammar A^nB^n used by Fitch and Hauser (2004). The phrase structure grammar is recursive, center-embedded, and generates long-distance dependencies.

Bahlmann and Friederici (2006, henceforth B&F) and Bahlmann et al. (2008) carried out an fMRI study to probe into the neural basis of processing center-embedding

structures in AGL. Significantly stronger activation in Broca's area, involved in natural language processing, was observed in processing of hierarchically recursive structure A^nB^n , than for the $(AB)^n$ grammar. By contrast, de Vries et al. (2008) replicated this study by B&F but reported no learning of center-embedding structures. De Vries et al. (2008) first trained all participants on the same stimuli as B&F, and required participants to judge the grammaticality of new items violating the center-embedding rule. However, participants were tested with different types of violations, namely: *scrambled* (e.g. $A_xA_yA_z\mathbf{B_xB_yB_z}$)¹ sequences and *scrambled + repetition* sequences ($A_xA_yA_z\mathbf{B_xB_yB_x}$). As they predicted, their participants could detect the scrambled + repetition violations, but not the scrambled ones. Therefore, de Vries et al. (2008) argued that successful performance in the study of B&F was due to alternative heuristics, such as counting or repetition-monitoring, instead of learning the abstract center-embedded principle. Indeed, B&F applied *replacement violations* (e.g. $A_xA_yA_zB_z\mathbf{A_yB_x}$) and *concatenation violations* (e.g. $A_xA_yB_y\mathbf{B_z}$) in their testing materials, which could possibly also be detected without any knowledge of the center-embedding rule, by merely counting the A's and the B's, or by simply detecting a B that was unrelated to any of the A's in a sequence. De Vries et al. (2008) concluded that surface features of A^nB^n sequences were learned by humans, such as repetition patterns and the match between the number of A's and the number of B's, but not the abstract recursive principle determining the long-distance dependencies between each A and each B in such a sequence. In sum, the learnability of center-embedded structures by mere exposure to input exemplars could not unambiguously be established in research using artificial materials, thus far. It seems still inconclusive to which extent AGL studies could help us understand the mechanism of learning recursion.

Here we propose that two fundamental properties of the training set might point at an alternative account of the inconclusive findings. One crucial property is *starting small*, which is the way learning input is ordered. The notion of starting small was first raised by Elman (1991, 1993). He trained a connectionist network to parse complex structures which contained embedded subordinates. The network succeeded in learning only if it was provided with a staged training input (starting small), but not after exposure to the entire random input as a whole. A number of empirical researches showed supporting evidence for this study (Cochran, McDonald, & Parault, 1999; Kareev, Lieberman, & Lev, 1997; Kersten & Earles, 2001), while some other findings yielded contradictory results (Rohde & Plaut, 1999). Possibly the diverging findings might be explained by the highly different methodologies, such as type of study (experimental designs versus simulation studies), stimulus

¹ In the figure of Fitch and Hauser (2004), there were no indices for $(AB)^n$ or A^nB^n , because any A could be related with any B. Contrarily, in B&F, de Vries et al. (2008) and the current study, indices were used to indicate dependencies between specific A's and B's.

set, input size, training and testing procedures, or the type of grammar used. An input 'growing' gradually, might be especially efficient for learning a complex recursive structure, when the input contains sequences with long distance dependencies, as in the study of B&F.

The second property is *frequency distribution* of the input. In natural language, simple phrases or sentences with zero-level-of-embedding (0-LoE) appear much more frequently than those with several levels of embeddings (Poletiek & Chater, 2006). In real life, this type of short and typical sentences with only adjacent-dependencies, is encountered much more often than more complex compound sentences with several sub-clauses. Sentences with simple structures occur frequently (Philips, 1973; Pine, 1994; Poletiek & Chater, 2006; Snow, 1972). We propose that the distribution of simple and complex sentences in the input set might play a role in rule induction. In our experiment, we presented the input stimuli of our artificial grammar in a distribution that reflected the unequal occurrence of simple and complex sentences in natural language.

To a large extent, both properties of the input we hypothesize to help learners, also occur in the natural linguistic environment of children. Compared to adult-directed speech, child-directed speech has shorter linguistic constituents, simpler structures, and mainly adjacent-dependencies (Pine, 1994). A large amount of repetitions of syntactically short utterances help children learn the basic structure of language. As children grow, child-directed speech develops into more mature speech types (Bellinger, 1980; Garnica, 1977) because more complex constructions are gradually introduced. Therefore, if we can demonstrate experimentally successful grammar learning with a growing environmental input and unequal frequencies for simple and complex exemplars, this might help understanding environmental factors involved in the mechanism of natural language learning.

In the present study, we tested whether participants could learn the hierarchical recursive rule when the learning set was organized 'starting small' rather than randomly, and when unique simple exemplars were repeated, whilst the complex ones were not. We predict that participants will show learning under these conditions.

Experiment

Method

Participants. Twenty-eight students (20 female), from Leiden University participated in the experiment for course credit or payment. All were native Dutch speakers. All had normal or corrected to normal vision.

Materials and design. The same stimuli were used as in B&F and de Vries et al. (2008). There were two sets of syllables, categorized by their vowels. Syllables in Category A contained vowels -e/-i, i.e. {be, bi, de, di, ge, gi}, whereas syllables in Category B contained vowels -o/-u, i.e. {po, pu, to, tu, ko, ku}.

Each syllable in Category A was associated with its counterpart in Category B according to the onset consonants. For instance, any A_x could be related with any B_x . There were two possible syllables for A_x , i.e. “be” or “bi” and two for B_x , “po” and “pu”. Therefore, the associated pairs were {be/bi-po/pu}, {de/di-to/tu} and {ge/gi-ko/ku}. Syllable strings were made out of two, four, and six paired-syllables following the hierarchical center-embedded rule A^nB^n . The resulting grammar G is schematically displayed in Figure 2. Frequencies of syllable occurrence were controlled for.

Figure 2. Grammar G , a recursive A^nB^n center-embedded structure. $A_x=\{\text{be, bi}\}$; $A_y=\{\text{de, di}\}$; $A_z=\{\text{ge, gi}\}$; $B_x=\{\text{po, pu}\}$; $B_y=\{\text{to, tu}\}$; $B_z=\{\text{ko, ku}\}$. Examples of strings generated by G are: bi pu (0-LoE), de ge ko tu (1-LoE), be di ge ku to po (2-LoE). “ G ” in the loops at states S_1 , S_2 and S_3 refer to Grammar G , indicating that a center-embedded clause can legally be inserted at that state.

There were 12 blocks in total. Each block consisted of two phases, i.e. learning and testing. All learning and testing blocks together contained 144 strings respectively. Each learning phase was made of 12 syllable strings. After each learning phase, a testing phase followed with 12 novel syllable strings, of which six syllable strings were grammatical and six were ungrammatical.

Note that grammar G generates 12 unique 0-LoE items, $12^2 = 144$ unique 1-LoE items, and $144 \times 12 = 1728$ unique 2-LoE items. The 12 unique 0-LoE items were presented four times each (48 in total). Forty-eight 1-LoE items were sampled from the 144 possible ones and presented each once, without repetition. Finally, 48 2-LoE items were sampled from the 1728 unique exemplars of G , and not repeated. In this manner, the differential frequencies of repetitions of ‘simple’ vs. ‘complex’ exemplars of a grammar were represented in the input.

Participants were randomly assigned to one of the two experimental groups: the starting small (henceforth SS) group or the random group. All participants were exposed to

the same items, i.e., syllable strings, generated by the grammar G in Figure 2. The learning items for the SS group were ordered by their levels of embedding (LoE). In the first four blocks of the SS group, only 0-LoE items were presented during learning. The following four blocks displayed 1-LoE items only. In the last four blocks, 2-LoE items were presented. In this manner, the learning phase was comprised of three consecutive stages, each of which contained four blocks. The ordering of syllable strings within one block was counterbalanced over participants. The random group would see exactly the same set of strings but in a random order. In the random group, each block and each stage contained an equal number of each LoE-category items.

Both groups were presented the same blocks of test items, in the same order. The grammatical test items were novel items with 0-, 1-, or 2-LoE. Ungrammatical items were made by mismatching syllables from Category A and their counterparts from Category B. To control for as many confounding surface cues as possible, the violations satisfied a number of demands. For two-syllable strings, violations appeared necessarily in the second position (e.g. A_xB_y); for four-syllable strings, violations appeared in the fourth position (e.g. $A_xA_yB_zB_x$, $A_xA_yB_yB_z$); and for six-syllable strings, violations appeared in the fifth or sixth position (e.g., $A_xA_yA_zB_zB_xB_x$, $A_xA_yA_zB_zB_xB_x$, $A_xA_yA_zB_yB_zB_x$, $A_xA_yA_zB_zB_yB_x$). In this way, no adjacent AB violations (illegal bigrams) were presented except for the two-syllable test items, in which violations were necessarily an illegal bigram, i.e. an illegal AB pair.

Secondly, in contrast to B&F, no adjacent repetition of syllables appeared in the same sequence. All grammatical and ungrammatical test strings had an equal number of A’s and B’s. Hence, violations were not detectable by matching the number of A’s to the number of B’s. Thirdly, only one illegal pair was allowed in the same string to keep the global level of difficulty constant for each test item. As a result of these constraints, three types of violation were generated: first, violations of type $A_xA_yA_zB_xB_yB_z$ with A’s and B’s from the same subsets but not equally distributed; second, violations of type $A_yA_yB_zB_z$, or $A_xA_yA_yB_yB_z$ with one B that could not be paired with any of the A’s; third, violations of type $A_xA_yB_yB_y$, or $A_xA_yA_zB_zB_yB_y$, with one A missing a B from the same subset. Constructing the violations in this manner, violations detection by superficial heuristics could be largely excluded and categorization performance could be reasonably attributed to knowledge of the hierarchical structure.

Procedure. At the beginning of every learning trial, a fixation cross appeared in the center of the screen for 500 ms. Then, each syllable was presented separately for 800 ms, with no interval in-between. Participants were instructed that there was a rule underlying the sequences that they had seen. After presentation of 12 syllable strings, the testing phase followed, in which the sequences appeared in the same fashion. When the last syllable of each test item had disappeared, participants had to press the keyboard buttons

indicating “YES” or “NO”. They were required to make a judgment whether the novel syllable string was grammatical or not, according to the rule underlying the sequences in the learning phase. After each judgment, appropriate feedback was given for 500 ms as B& F and de Vries et al. (2008) did. Approximately, the task took about 30 minutes.

Results and analysis

First, we estimated the mean proportion of “YES” responses to all test items. There was a small response bias favoring positive responses ($M = .53$, $SE = .01$, $p < .01$). Accordingly, d' -values were calculated and used as a measure for sensitivity to grammaticality of the responses, i.e. performance. We conducted an independent-samples t -test on mean d' -values for all test items, to compare performance between these two groups. Overall, the SS group ($M = 1.51$, $SE = .36$) highly outperformed the random group, $M = .08$, $SE = .05$, $t(26) = 3.94$, $p = .001$. Moreover, as indicated by a one-sample t -test comparing mean performance with chance level in both groups, only the SS group performed above chance, $t(13) = 4.21$, $p = .001$.

Figure 3. Experiment 1: Mean d' -values for all blocks in both conditions. Points represent mean d' -values per block. The dotted line represents chance level performance ($d' = 0$).

To evaluate the development over time, in both learning conditions, we compared performance on the first block (Block 1) with the last block (Block 12) for both groups. For the SS group, mean d' -values in Block 1 was $M = .73$ ($SE = .30$) and in Block 12, $M = 1.59$ ($SE = .33$). Performance had improved in the last block as compared to the first block as revealed by a t -test for means of paired samples, $t(13) = 2.59$, $p < .05$. In the random group, however, performance did not improve: in Block 1, $M = .01$ ($SE = .21$); in Block 12, $M = .33$, ($SE = .29$), $t(13) = -.98$, n.s.. Although in Block 1 the SS group performed slightly better than the random group in the same block, this difference was not

significant, $t(26) = 1.98$, n.s.. However, in the last block, the SS group clearly outscored the random group, $t(26) = 2.87$, $p < .01$. In Figure 3, mean d' -values are displayed for all blocks in both conditions, showing learning in the SS group over time, but no learning for the random group.

To explore more in detail how the center-embedding recursive principle was learned, we looked into performance on test items with different LoEs. Performance on different types of test items (0-, 1-, and 2-LoE) was compared between conditions, at several stages of exposure. For this analysis, exposure was divided into three stages (Stage 1 consisted of Block 1-4, Stage 2 consisted of Block 5-8, and Stage 3 consisted of Block 9-12.). For the SS group, the stages of training reflected increasing LoE in the stimuli (Stage 1 comprised 0-LoE learning items only; Stage 2, 1-LoE items only; Stage 3, 2-LoE items only). In the random group, all LoEs were presented in the learning phases of every stage. To test the development of performance over time for test items with increasing LoEs, we carried out an ANOVA, with stage and LoE as within-subject factors, and condition as between-subject factor. The $LoE \times Stage \times Condition$ interaction was significant, $F(4, 104) = 2.94$, $p < .05$, indicating that performance for different LoE test items developed differently in each learning condition.

Subsequently, an ANOVA was conducted with LoE as the within-subject factor and d' performance as the dependent variable, for each group separately. For the SS group, a main effect of LoE was found, $F(2, 26) = 10.86$, $p < .001$. As can be seen in Figure 4, learning for test items with 0-LoE was quite high ($M = 1.89$, $SE = .39$) and significantly better than learning for items with higher LoE in the SS group, $M = 1.45$, $SE = .37$, $t(13) = 3.14$, $p < .01$ and $M = 1.29$, $SE = .33$, $t(13) = 4.19$, $p = .001$ for 1-LoE and 2-LoE, respectively. This indicates that participants acquired fundamentally solid knowledge of the adjacent-dependencies of grammar G, under the SS learning condition. Violations of 0-LoE items were observed to be easier to detect than 1-LoE and 2-LoE ones because of their illegal adjacent-dependencies, i.e. bigrams. However, this advantage was only beneficial for the SS group, presented with all 0-LoE training items which clustered in the first stage of exposure. In the random group, participants did not perform differently for various LoE test items. No effect of LoE was found, $F(2, 26) = 1.31$, n.s. Chance level performance was observed in the random group for all types of test items.

Furthermore, our data revealed a main effect of stage in the SS group only: Performance on all types of test items improved along with exposure to increasing LoE items, $F(2, 26) = 3.57$, $p < .05$. The curves of 1-LoE and 2-LoE test items evolved equally (see Figure 4), suggesting that the center-embedding rule was learned and recognized equally well for items with one and two recursive loops. In contrast, no main effect of Stage was found for the random group, $F(2, 26) = .87$, n.s.: Performance was low at the beginning and did not increase significantly over time.

Finally, for the SS group, we compared participants' accuracy on all types of violations with an ANOVA, with Type of Violation as a within subjects factor, to test whether some surface characteristic of the test items (even after careful control for confounding surface cues) might have affected performance. No effect of Type of Violations on accuracy was found, $F(2, 26) = .151$, n.s.. This suggests that participants performed equally well over different types of violations, indicating knowledge of the hierarchical center-embedded structure learned in the SS procedure.

Hence, our findings indicate that center-embedded structures in an AGL could be learned through the SS procedure, but not in the random procedure, in accordance with our hypothesis. Moreover, an incremental exposure to the input in accordance with increasing applications of the recursive rule, correlated with a synchronic improvement in performance. Participants learned the center-embedding principle along with exposure to increasingly more complex exemplars. Robust knowledge of the 0-LoE exemplars could be shown in the SS group only, suggesting that this knowledge was a prerequisite for learning the embedding principle. Furthermore, the SS group did not judge less accurately test items with 2-LoE than items with 1-LoE, suggesting that the recursive rule was learned and recognized equally easily for 1- and 2-LoE strings.

Figure 4. Experiment 1: Mean d'-values for 0-, 1-, and 2-LoE test items at different stages. Points represent mean d'-values of performance per stage. The dotted line represents chance level performance ($d' = 0$).

Discussion

We observed a 'starting small' effect highly facilitating learning a center-embedded recursive grammar. When participants were presented with a randomized input, there was no learning of the underlying hierarchical rule. Moreover, in our training materials as opposed to the materials presented in similar studies using the same unique training exemplars, simple stimuli were presented more frequently than complex ones, possibly contributing to the dramatic learning effect of the starting small ordering found in our study. In the AGL program, it is still under debate whether performance in learning reflects real knowledge of the abstract grammar, or local pattern learning, recognition of repetitions and other surface heuristics (Poletiek & Van Schijndel, 2009). In the present experimental set up, the violations inserted in the test materials were controlled as much as possible for surface cues that would make them easy to detect without knowledge of the structure. Though the use of cues can not be excluded definitely, our data make a strong case for the learnability of a center-embedded structure provided training with a staged input, and sufficient exposure to basic exemplars without embedded clauses.

Our training stimulus set may be regarded as a representation of the child's natural linguistic environment. The input contains not only a huge number of simple adjacent-dependencies (0-LoE items) produced by the grammar, but they were also presented repeatedly. From the complex items produced (1-, and 2-LoE items), a proportionally smaller sample was presented, and no repetitions occurred. This environment with both growing data and repetitions of basic patterns reflects, as we claim, the natural linguistic environment. In the SS group, due to an intensive training with only 0-LoE items, participants might become familiar with the most basic adjacent-dependencies, which might have provided them with a solid foundation for further induction of the recursive operation. Furthermore, the staged ordering helped participants gradually identify the recursive rule and the connections between long-distance dependencies. By contrast, previous studies failing to find recursion learning, trained participants with the whole corpus randomly presented as an entirety, and no 0-LoE items (de Vries et al., 2008). The two factors investigated here seem therefore to play a crucial role in learning complex recursive rules.

As Elman (1993) indicated humans' most amazing achievement in languages occurs in childhood. In this period, children are exposed to continuously repeated simple structures. Furthermore, the *less is more* proposal that the limited cognitive capacity of children is beneficial to language learning (Newport, 1988, 1990) is consistent with the starting small environmental factor found in our experiment.

In sum, the present study reveals crucial roles for staged input and for solid primary knowledge of the basically simple structures in learning a center-embedded recursive structure by induction. The picture raised is that preliminary

simple associative learning mechanisms such as adjacent-dependencies learning might prepare learners for subsequent processing of gradually encountered more complex and more distant dependencies. Our research suggests that the old puzzle of the inductive learnability of recursive structures might benefit from a shift of focus from the formal characteristics of the structure to the stimulus environment and how this environment is nicely shaped to fulfill the needs of the language learner.

Abstract

Previous studies have suggested that individuals use both implicit and explicit, as well as rule and exemplar-based knowledge, to make grammaticality judgments in artificial grammar learning (AGL) tasks. Experiment 1 explored the importance of explicit mechanisms in the learning of exemplar and rule-based information by using a dual-task during AGL training. We utilized a balanced chunk strength grammar, assuring an equal proportion of explicit exemplar-based cues (i.e. chunks) between grammatical and non-grammatical test items. Experiment 2 explored the importance of perceptual cues by changing letters between AGL training and test, while still incorporating the dual-task design and balanced chunk strength grammar used in Experiment 1. Results indicated that participants with a working memory load learned the grammar in

Experiment 1 just as well as the single-task no-load group, presumably by relying solely on implicit learning mechanisms. However, changing the letters from training to test resulted in no significant learning for dual-task participants in Experiment 2, suggesting that exemplar-based perceptual cues may be the major contributor to implicit knowledge. Overall, the results suggest that implicit and explicit mechanisms for learning rule-based and exemplar-based information may both contribute to AGL via four independent, parallel routes, providing a new framework for understanding the complex dynamic of learning in AGL tasks.

Keywords: artificial grammar learning; implicit learning; working memory; dual-task

Introduction

There is widespread agreement that there exist two distinct forms of learning, explicit and implicit. Explicit learning refers to learning that happens actively, consciously, and with effort, such as the type of learning that occurs during much of formal education. Implicit learning, on the other hand, occurs passively, unconsciously, and without effort. Implicit learning is theorized to be involved in procedural motor activities such as riding a bike or typing, as well as in more complex phenomena such as social interaction and language learning (Reber, 1993).

Artificial grammar learning (AGL) has been a useful paradigm for the study of implicit learning. In the typical artificial grammar learning (AGL) paradigm, individuals are shown (or asked to memorize) letter strings that, unknown to them, conform to rules instantiated by an artificial grammar. Following presentation of the training exemplars, participants are able to reliably determine whether a newly presented letter string is grammatical according to the artificial grammar, without being able to explicitly verbalize the rules of the grammar. Originally, it was theorized that individuals rely on an implicit abstract rule-learning system during AGL tasks, with participants' failures to verbalize the rules as evidence that the rules were unconscious (Reber, 1989).

Additional support for implicit rule-based learning in AGL was provided by what are now referred to as "transfer" experiments. In an AGL transfer experiment, the surface features (e.g. letters) of the training exemplars are changed during the test phase, though the underlying grammar stays the same. Clearly, this would make grammaticality decisions based solely on item similarity difficult, if not impossible. Thus, the transfer manipulation is meant to increase reliance on (presumably implicit) rules divorced from the surface details of the exemplars. Impressively, results from multiple studies have indicated that individuals still successfully demonstrate above-chance classification

performance, though the learning is often attenuated (Reber, 1989; Knowlton & Squire, 1996).

In addition to the transfer studies, multiple studies have shown that amnesic subjects, who putatively cannot rely on explicit forms of learning, demonstrate artificial grammar learning similarly to non-brain damaged controls (Knowlton, Ramus, and Squire, 1992; (Knowlton & Squire, 1996). The evidence from both the transfer and the amnesic studies suggest that AGL is mediated by implicit rule-learning mechanisms. Under this view, given that implicit learning is theorized to happen automatically and without effort, executive functions such as working memory (an explicit mechanism, by definition) should have a minimal impact on artificial grammar learning.

Although studies with amnesic patients strongly suggest that AGL can occur without explicit memory, research with non-brain damaged subjects suggests that under normal conditions, explicit processes are also recruited. For instance, test phase classification judgments have been found to be sensitive to the similarity between test and training items, specifically in terms of chunk strength (Chang & Knowlton, 2004; Knowlton & Squire, 1996). Chunks are bigrams and trigrams that are encountered frequently in an artificial grammar due to repetitions in the underlying structure. Studies have shown that individuals do retain some explicit information regarding the chunks of the training items (Dienes, Broadbent, & Berry, 1991; Dulany, Carlson, & Dewey, 1984), and that participants studying only training bigrams can classify the grammaticality of test items correctly at rates similar to controls (Perruchet & Pacteau, 1990). In addition, fMRI studies of AGL tasks have suggested some involvement of the medial temporal lobe (MTL; Fletcher, Buchel, Josephs, Friston, & Dolan, 1999; Opitz & Friederici, 2004). These findings suggest that individuals may rely on a combination of both implicit rule-based knowledge and explicit exemplar-based chunk knowledge to make grammaticality judgments (Vokey & Brooks, 1992; Knowlton & Squire, 1996).

However, although it was originally assumed that rule knowledge is implicit and exemplar-based knowledge is explicit (e.g. Reber 1989), the true picture appears to be much more complex. For instance, participants in a study by Dulany, Carlson, and Dewey (1984) were able to indicate which parts of letter strings were grammatical by crossing out ungrammatical portions, possibly suggesting some explicit knowledge of rules. Similarly, participants in another study demonstrated explicit knowledge of the grammar by being able to complete stems of letter strings to form grammatical strings (Dienes, Broadbent, & Berry, 1991).

Similarly, it appears that implicit learning can also be used to learn both types of information (rule-based and exemplar-based). For instance, Knowlton and Squire (1996) used a balanced chunk strength grammar to show that amnesic patients showed the same pattern of performance as controls, suggesting they were sensitive to both exemplar-based and rule-based information, despite not having explicit knowledge for either. Chang and Knowlton (2004) assessed the importance of low-level perceptual features in AGL performance. Using a balanced grammar, they conducted two experiments: one in which they used a concurrent articulatory suppression task during learning (designed to disrupt perceptual processing), and one where they changed the font and case of letters from acquisition to test. In both cases, participants exposed to the manipulation experienced a disruption in chunk sensitivity, suggesting that exemplar-based knowledge may be more implicit than commonly thought.

In summary, the existing evidence appears to suggest that depending on learning conditions, exemplar and rule-based knowledge may both be acquired implicitly or explicitly. We therefore hypothesized that there may exist at least four separate pathways to learning in AGL (see Figure 1). Exemplar information may be acquired explicitly through memory for chunks (Dienes et al. 1991), or implicitly via perceptual processing (Chang & Knowlton, 2004). Likewise, rule-based knowledge may be acquired via an implicit rule system (Reber, 1967) or via explicit knowledge of rules (Dulany et al. 1984).

The current study aimed to test this proposed four-pathway theory of AGL by attempting to behaviorally dissociate each source of knowledge available to participants. In each of two experiments, we attempted to neutralize one or more of the four hypothesized pathways to knowledge illustrated in Figure 1. In Experiment 1, we incorporated an explicit dual-task during AGL, designed to prevent participants from relying on either form of explicit learning during training (hypothesis generation and item memory), leaving available only implicit sources of knowledge (perceptual fluency and abstract rule-learning). If the four-pathway theory is correct, we should expect that even under this dual-task condition, participants will still demonstrate learning equivalent to single-task participants because they still have access to exemplar-based and rule-based information via implicit learning. In Experiment 2, we

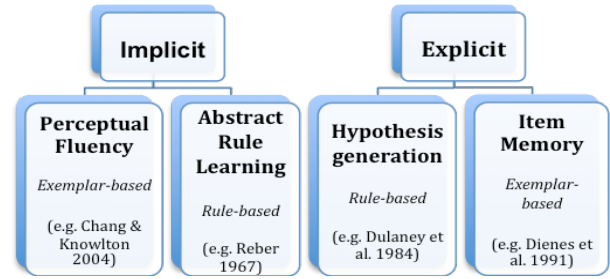

Figure 1: Hypothesized Pathways to Knowledge in Artificial Grammar Learning

furthermore neutralized the implicit perceptual fluency route to learning, leaving dual-task participants only with access to the hypothesized implicit rule-learning mechanism. Unlike Experiment 1, this manipulation is expected to drastically affect learning performance because only the (implicit) rule-based learning pathway is available. Finally, an additional aim of this study is to explore the relationship between individual differences in working memory ability and AGL performance.

Experiment 1: Dissociating Implicit from Explicit Learning

Experiment 1 was designed to address the question of whether learning in the AGL task can take place when explicit mechanisms, specifically working memory, are unavailable. To this end, half of the participants were engaged in a dual-task concurrently with the acquisition phase of the AGL task, designed to make explicit encoding of the stimuli during acquisition very difficult. The dual-task required participants to maintain a series of 6-digit strings in memory at the same time as they were exposed to the letter strings from the AGL task. For the AGL task, we used a balanced chunk strength design (Knowlton & Squire, 1996), which allows us to determine the relative contribution of learning processes to exemplar and rule-based knowledge. In a balanced chunk strength grammar, both grammatical and ungrammatical test items are balanced in terms of the chunks they have in common with the training items, thus ensuring that chunk learning alone cannot account for grammaticality performance. Since we have four categories of test items varying on two dimensions (chunk strength and grammaticality), we are able to determine the impact of processing load from the dual-task on grammaticality and chunk strength separately.

We predicted that individuals with diminished explicit resources (i.e. via the concurrent working memory task during AGL acquisition) would still show learning (compared to a single-task control group) due to the availability of implicit mechanisms (perceptual fluency and abstract rule learning).

Finally, we also had each participant engage in an automated OSPAN task (Unsworth, Heitz, Schrock, & Engle, 2005) to measure their working memory abilities. This provided a way to assess the extent that working

memory ability correlates with AGL performance in the dual- vs. single-task groups. We predicted that OSPAN task performance would be associated with AGL performance for the single-task group only, because unlike the dual-task group, their explicit learning pathways are available.

Method

Participants

Participants were 45 undergraduate students (23 in the single-task condition, and 22 in the dual-task condition) who participated for course credit.

Materials

Automated OSPAN The Turner and Engle (1989) OSPAN task requires individuals to solve math problems while trying to remember a set of unrelated words, and is a common measure of working memory. We used an automated version of the OSPAN, designed by Unsworth, Heitz, Schrock, and Engle (2005). The automated OSPAN (AOSPAN) correlates well with other measures of working memory capacity, demonstrating both good internal consistency and test-retest reliability (Unsworth et al. 2005).

Artificial Grammar The artificial grammar used in this experiment is from Knowlton and Squire (1996), which has the advantage of being a balanced chunk strength design (see Figure 2). To determine chunk strength, Knowlton and Squire (1996) quantified the similarity between learning and test items by determining the number of trigrams and bigrams in a test string that corresponded to those appearing in the learning items. We used the same 23 training items and 32 test items as did Knowlton and Squire (1996). The test items are divided into four chunk-balanced categories of 8 items each: grammatical low chunk (G-LC), non-grammatical low chunk (NG-LC), grammatical high chunk (G-HC), and non-grammatical high chunk (NG-HC).

Procedure

Participants were assigned randomly to the dual-task or single-task condition, with all participants tested individually on a computer in a small, private room. All participants first completed the automated OSPAN task, followed by the AGL task. Participants in the dual-task condition completed a concurrent digit span task during the practice and acquisition phases, as described below.

Dual-Task Group After the automated OSPAN, the dual-task participants first received 3 blocks of practice trials to orient them to the task. Within each block, participants were presented with two or three sets of random letter strings consisting of the letters A, B, C, D, and E. For each string, participants were asked to type the letter string as shown in a space at the bottom of the screen; only after correctly typing the string were they allowed to proceed to the next trial. Participants were asked to use only one hand (their dominant hand) to type the strings. During these practice trials, the dual-task participants performed a concurrent working memory task. At the beginning of each practice block, participants were shown six random numbers

Figure 2: Balanced chunk strength grammar used in current study. From Knowlton and Squire (1996)

presented in the middle of the computer screen for 3000ms. Participants were instructed to maintain the number string in their memory while typing the letter strings as described above. At the end of each block, participants then were required to type the six digits from memory.

Following the practice blocks, participants next completed the acquisition phase, which was nearly identical to the practice phase except for the following differences. Within each block, participants were presented with eight blocks of two or three letter strings each, where each letter string corresponded to one of the 23 training items from the artificial grammar¹. Each training string was presented only once. As with the practice phase, participants were required to type the string correctly before advancing to the next trial, as well as maintain a 6-digit number string in memory, with a different number string given each block.

During the testing phase, participants were informed that the letter strings shown previously conformed to very complex rules, and that they should use their gut feeling to determine whether the letter strings presented next also conformed to these same underlying rules. Participants were then presented with the 32 test strings, and asked to decide whether each was grammatical or not by pressing a corresponding key on the keyboard. Immediately following each grammaticality judgment, participants were asked to rate their confidence regarding the judgment they had just made on a scale of 1-4 with 1 being "I am sure" and 4 being "I am guessing".

Single-Task Group The single-task participants followed the exact same procedure as the dual-task participants, with the only difference being the nature of the concurrent task. The single-task participants saw a line of 6 asterisks instead of 6-digit number strings at the beginning of each AGL practice and acquisition block. They were not required to remember the asterisks during the trials; merely, at the end of each block, they saw each 6-digit number string and were asked to type it. In this way, the concurrent task did not tap working memory resources and thus serves as a good control to the dual-task group.

Results and Discussion

Main results are shown in Table 1. First we consider performance on the OSPAN and concurrent digit span tasks. As shown in the table, both groups performed comparably

¹ Training strings were randomized within blocks, and the blocks were presented randomly for every participant to account for any order effects.

on the OSPAN task, suggesting that the two groups possessed similar working memory abilities. The table also shows that for the concurrent digit span task, the dual-task participants correctly recalled all six digits at the end of each block 67% of the time (note that the single-task participants do not have a digit span score because they were not required to do the concurrent working memory digit span task). This score suggests that the dual-task had the desired effect of being challenging but not impossible to do. Furthermore, to act as a further control, a regression was conducted which indicated that the OSPAN score predicted 17% of the variance in digit span scores, which was marginally significant ($F(1, 20) = 4.13, p = .056$), implying that the effort expended on the dual-task was consistent with what would be expected given participants' working memory abilities. These results suggest that the dual-task had the desired effect of neutralizing or at the very least, attenuating, explicit processing resources for the dual-task group.

For the AGL task, Table 1 shows that both groups demonstrated learning as revealed by their test task performance being significantly greater than chance (single-task group, $t(22) = 5.30, p < .001$; dual-task group, $t(22) = 5.30, p < .001$). In fact, there were no significant differences between the single and dual-task participants on overall accuracy, the tendency to endorse items as grammatical, or classification confidence.

Even more strikingly, Figure 3 shows the test accuracy for each of the four categories of test items separately for each group. There were no differences between conditions on accuracy for each of the four categories. This indicates that both groups showed equivalent learning of the same two primary types of information present in the grammar (exemplar and rule-based information).

Interestingly, bivariate correlations indicated no correlation between accuracy and confidence judgments for either group. There was, however, significant positive correlation between the OSPAN score and accuracy in the single-task control condition ($r = 0.43, p < .05$), and a negative (but non-significant) correlation between the OSPAN score and accuracy in the dual-task condition ($r = -0.23, ns$). These results provide further support that our concurrent task did in fact neutralize working memory resources for the dual-task group; working memory positively contributed to control participants' ability to

Figure 3: Proportion of Correct Grammaticality Judgements by Group and Item Type in Experiment 1.

correctly classify the grammaticality of test items, while it did not contribute to dual-task participants' ability to correctly classify test items. This suggests that the single-group participants were successfully using working memory to learn the grammar, while the dual-task participants were relying on a separate pathway to learning, as indicated by the lack of correlation of OSPAN scores with accuracy in the dual-task.

In sum, the results from Experiment 1 indicate that dual-task participants exhibited equivalent performance on the AGL task, despite having limited explicit resources available due to the concurrent working memory task during encoding. Strikingly, dual-task participants showed a pattern of learning indistinguishable from controls, indicating that explicit information is not necessary for the acquisition of either exemplar or rule-based information. Our results are consistent with the finding that patients with bilateral hippocampal brain damage (who are unable to explicitly encode information) also showed normal learning on an AGL task (Knowlton & Squire, 1996). Thus, one way to conceptualize Experiment 1 is that it provides a way to behaviorally "simulate" hippocampal brain damage using a concurrent working memory task. By forcing participants to engage in the concurrent digit span task, it appears we successfully prevented participants from relying on the explicit pathways to learning (item memory and hypothesis generation as shown in Figure 1); however, even without full explicit resources available for the AGL task, participants still were able to learn both exemplar and rule-based information in a presumably implicit fashion, leading to performance that was identical to the single-task group.

Table 1: Mean (Standard Deviation) Proportion of Correct Responses, Proportion of Items Endorsed Grammatical, Confidence, and OSPAN Score.

	Experiment 1		Experiment 2		
	Single-task	Dual-task	Single-task	Dual-task	Control
Proportion Correct*	.58 (.08)	.58 (.08)	.59 (.06)	.53 (.11)	.49 (.11)
Proportion Grammatical	.58 (.10)	.55 (.12)	.54 (.15)	.49 (.22)	.46 (.15)
Confidence	2.97 (.44)	2.68 (.64)	2.45 (.55)	2.62 (.79)	1.92 (.61)
OSPAN Score	47.64 (15.90)	44.77 (15.83)	44.30 (14.91)	48.38 (12.08)	44.12 (18.04)
Digit Span Score	NA	.67 (.19)	NA	.68 (.21)	NA

*Experiment 2: Between single-task and dual-task: $t(49)=2.51, p<.05$

Experiment 2: Dissociating Implicit Rule-Based from Exemplar-Based Learning

In Experiment 1, we forced the dual-task participants to rely on implicit learning to learn both exemplar and rule-based information. The aim of Experiment 2 was to attempt to remove an additional pathway to learning, namely implicit perceptual fluency, a form of exemplar based knowledge (see Figure 2), leaving only the implicit rule-based system hypothesized by Reber (1967).

In order to remove the availability of perceptual exemplar-based cues, we incorporated the “transfer” methodology described earlier. Specifically, participants were required to do the test classification task on test strings that consisted of an entirely new letter set. With no perceptual similarity between the acquisition and test phases, dual-task participants can only rely on a more abstract form of knowledge gained via the implicit abstract rule-learning route.

We therefore predicted that single-task participants would show some learning even without exemplar-based cues, since explicit rule-based sources of information would still be available. For dual-task participants, however, only the hypothesized implicit rule-based information will be available. Therefore, dual-task participants should still be able to make correct grammaticality judgments, but they may lose the sensitivity to chunk strength due to lack of exemplar-based cues. Alternatively, dual-task participants may fail to learn the grammar entirely if exemplar-based cues are crucial to learning, as suggested by some accounts (Johansson, 2009; Vokey & Higham, 2005).

Method

Participants

Participants were 84 undergraduate students (26 in the single-task condition, 25 in the dual-task condition, and 32 in the control condition) who participated for course credit. A non-trained control condition was used to ensure that any learning that takes place was not due to the test materials themselves.

Materials& Procedure

The materials and procedure for the single and dual-task groups were identical to Experiment 1, with the exception that the test strings used letters F, Z, N, and C in place of X, T, V and J, respectively. The replacement letters were chosen to be perceptually dissimilar from the training letters, and vowels were avoided so that words could not be formed from strings. Care was also taken to ensure that the letters used for test strings did not result in common acronyms that may interfere with the expression of learning.

The control group completed the same procedure as the dual and single-task conditions, with the exception that they were not given the AGL training. During test, they were told that the letter strings they were about to see were created using a complex set of rules, and that they should

Figure 4: Proportion of Correct Grammaticality Judgments by Group and Item Type in Experiment 2

use their gut feeling to decide if each string belonged to the rules or not.

Results and Discussion

Again, we consider OSPAN and digit span scores first. As Table 1 shows, OSPAN results were equivalent between the two groups, suggesting that the groups' working memory abilities were evenly matched. In addition, performance on the dual-task (68%) was similar to Experiment 1.

As Table 1 also shows, accuracy on AGL test items was significantly greater than chance for the single-task participants only (59%, $t(25) = 6.86$, $p < .001$); dual-task test accuracy (53%, $t(22) = 1.08$, $p = ns$) and control accuracy (49%, $t(32) = -0.47$, $p = ns$) were not significantly greater than chance, indicating that only the single-task participants successfully learned the grammar. Further, single-task accuracy was significantly greater than dual-task accuracy ($t(49) = 2.51$, $p < .05$). As in Experiment 1, there were no significant differences between conditions on tendency to endorse grammaticality or classification confidence.

There were however significant differences between conditions on accuracy for the four categories of test items (See Figure 4). Though overall learning for dual-task participants was not significantly above chance, participants did show greater than chance accuracy for the NG-LC category of test items ($t(22) = 2.07$, $p < .05$). Nonetheless, control participants also demonstrated greater than chance accuracy on NG-LC items ($t(22) = 2.07$, $df = 32$, $p < .05$) suggesting that accurate performance on these items may reflect test item artifacts rather than implicit learning.

Bivariate correlations indicated no relationship between confidence, accuracy, and OSPAN scores for any group. This is in contrast to Experiment 1, in which there was a significant correlation between OSPAN scores and accuracy for single-task participants. It is unclear why this relationship would not persist in Experiment 2 given that access to explicit knowledge is presumably still available for single-task participants. It is possible that lack of perceptual information resulting from the transfer manipulation made explicit information regarding

exemplars more difficult to utilize during grammaticality judgments at test.

Experiment 2 demonstrates that without explicit learning mechanisms and perceptual features, no learning takes place. We hypothesized that using a combination of concurrent dual-task and transfer methodology, the only pathway to learning left to participants would be the hypothesized implicit abstract rule-learning route. If true, then our results suggest that the kind of implicit rule-based learning originally hypothesized by Reber (1967) does not occur, at least not for transfer tasks. Instead, it appears that explicit mechanisms may be the sole source of knowledge in AGL transfer experiments (Redington & Chater, 1996).

General Discussion

The goal of this study was to attempt to dissociate implicit from explicit learning in artificial grammar learning by selectively neutralizing one or more of the four pathways that we hypothesized are available to learners. In Experiment 1, a concurrent dual-task was used during AGL acquisition to diminish explicit forms of learning. Participants in the dual-task showed strikingly similar test classification performance to the single-task control group, suggesting that they relied on a different – and presumably implicit – set of learning mechanisms at training to demonstrate the same learning as the single-task group. In Experiment 2, we added an additional manipulation – changing the letter set used in the test phase – in order to remove exemplar-based information. Without three of the four hypothesized learning routes, dual-task participants showed patterns of performance similar to non-trained controls, indicating that little to no learning occurred. Therefore, our results bring into question the idea of a rule-based implicit learning system proposed by Reber (1967). Instead, our results are more consistent with recent proposals that implicit knowledge is acquired primarily through exemplar-based perceptual mechanisms (Chang & Knowlton, 2004; Vokey & Higham, 2005). Alternatively, if an implicit rule-learning mechanism does exist, it does not appear to be recruited during AGL transfer tasks.

These results are consistent with the existence of independent implicit and explicit learning mechanisms operating in parallel. Interestingly, access to both implicit and explicit learning systems (e.g. single-task in Experiment 1) does not substantially enhance learning relative to when only implicit learning is available (dual-task in Experiment 1). This suggests that these systems do not operate synergistically. Future work investigating the development of these hypothesized pathways to knowledge in young children, as well as neuroimaging studies to specifically isolate the underlying neural circuits, may prove fruitful. Furthermore, we anticipate that this framework may have ramifications for understanding the nature of certain cognitive and neuropsychological disorders, especially cases in which cognitive learning mechanisms may be disturbed, such as dyslexia or other language impairments.

Why Streaks Are Special: The Time of Patterns

Abstract

People seek for patterns and pay particular attention to streaks even when they are generated by a random process. The present paper examines statistics of pattern time in sequences generated by Bernoulli trials. We demonstrate that streak patterns possess some statistical properties that make them uniquely distinguishable from other patterns. Because of the uncontaminated continuity, streak patterns have the largest amount of self-overlap, resulting in the longest waiting time and the largest variance of interarrival times. We then discuss the psychological implications of pattern time such as in memory encoding and perception of randomness.

Keywords: Perception of randomness; representativeness; hot hand belief; gambler's fallacy; waiting time; patterns.

Introduction

When faced with temporal sequences of events, people often attempt to make sense out of apparent patterns even when they are completely random. Among the most perceptible patterns, "streaks" or "runs," defined as continuous series of the same outcomes, are notorious for they not only yield counterintuitive statistical properties but also inspire extensive investigations on the biases in human perception of randomness and probabilistic judgment and reasoning.

One well-known example is the hot hand belief. Many basketball fans believe that some players have the "hot hand" and tend to make successful shots in streaks. However, in a seminal study, Gilovich, Vallone, and Tversky (1985) find no significant statistical evidence to distinguish the actual shooting sequences from the sequences of Bernoulli trials. This finding has been controversial but withstood several critical attacks (for a comprehensive summary on the hot hand study, see, Bar-Eli, Avugos, & Raab, 2006). In explaining the hot hand belief, Gilovich et al. (1985) use the representativeness heuristic, which has also been used to explain the gambler's fallacy (Tversky & Kahneman, 1974). By such heuristic, people expect the essential characteristics of a chance process to be represented not only by the entire global sequence but also by local subsequences. For instance, when tossing a fair coin, a streak of four heads—which is quite likely in even relatively small samples—would appear to be

non-representative.¹ Thus, in the gambler's fallacy, a tail is "due" to balance a streak of heads. In the hot hand belief, a streak of successful shots may lead people to reject the randomness of sequences and signal the existence of a hot hand. Several researchers have questioned the representativeness heuristic for its incompleteness in accounting for two opposite psychological dispositions, but their arguments are still based on the evidence that the hot hand belief is false (e.g., Ayton & Fischer, 2004; Burns, 2004). Together, the hot hand belief and the gambler's fallacy have been considered as two outright fallacies in people's perception of streak patterns, and this stance has a great impact on studies in other disciplines such as behavioral finance and economics (e.g., Camerer, Loewenstein, & Prelec, 2005; Gilovich, Griffin, & Kahneman, 2002; Rabin, 2002).

Moreover, studies on people's judgment and generation of random sequences show that people expect fewer and shorter streaks when observing sequences produced by an independent and identically distributed process (i.i.d.) and they tend to avoid long streaks when instructed to generate such sequences (e.g., Budescu, 1987; Falk & Konold, 1997; Nickerson, 2002; Olivola & Oppenheimer, 2008). Besides behavioral evidence, the salience of streak patterns is also indicated by the results from a functional magnetic resonance imaging (fMRI) study (Huettel, Mack, & McCarthy, 2002). In a "pattern violation task," participants were informed of the random order of the sequences. However, greater activation was found in prefrontal cortex (PFC) when participants observed violations of streak patterns (e.g., [AAAA] vs. [AAAB]) than violations of an alternating pattern (e.g., [ABABAB] vs. [ABABAA]) in a random binary sequence. In addition, the amplitude of fMRI hemodynamic responses (HDR) started increasing at lengths 2 for streak patterns (i.e., [AAB]) but only started increasing at lengths 6 and larger for alternating sequences (i.e., [ABABAA]). (Oskarsson, Van Boven, McClelland, & Hastie, 2009, provided a comprehensive review on judgments of random and nonrandom sequences of binary events.)

Given the unique role of streaks in people's perception and judgment of temporal sequences, an inevitable question is what is so special about streaks? To answer this question, we have to examine the statistics of patterns more carefully

¹ The probability of observing four heads in a row at least once in 20 tosses is 0.48.

since they are widely known for producing counterintuitive results (for the same reason, many people are surprised by the results of the runs test in the hot hand study).

It would seem too obvious to mention once again the unique composition of a streak: a streak is composed of an *uncontaminated* run of the same elements, which makes it exceptionally stand out from other non-streak patterns (such as alternation and symmetry) or any composition without an apparent order. While this property does not affect *how often* a streak occurs, it does affect *when* a streak *first* occurs. To exemplify, we compare two patterns HHH and THH (where H = heads and T = tails in tossing a fair coin). Governed by the independence and stationarity assumptions of Bernoulli trials, these two patterns have the same *probability of occurrence* in any three consecutive tosses (hence the fallacy in the gambler’s fallacy and the hot hand belief). However when the coin is tossed repeatedly, the *probability of first occurrence*—the probability that a pattern first occurs at the n^{th} toss, given that the pattern has not occurred before—can be different for different patterns (see Figure 1). For example, both patterns THH and HHH are equally likely to occur or not occur in the first three tosses. If THH has not occurred before, it will have a probability of 0.125 to first occur at the 4th toss. In contrast, if HHH has not occurred before, its probability of first occurrence at the 4th toss is only 0.0625, half of that for THH (for a method of calculating the probability of first occurrence, see Sun, Tweney, & Wang, 2010a). Overall, it will on average take 14 tosses to observe the first occurrence of HHH but only take 8 tosses to observe the first occurrence of THH. Moreover, if we monitor these two patterns simultaneously, it is more likely that we first encounter THH than we first encounter HHH (the odds are 7:1). In other words, it appears that the first occurrence of the streak pattern HHH has been “delayed.”

The time it takes for the first occurrence of a pattern (measured by the number of trials) is a statistical property known as *waiting time*. Compared to the long history of studies on the gambler’s fallacy (see, Ayton & Fischer, 2004), the development of waiting time and its related properties is fairly new (see, Gardner, 1988; Graham, Knuth, & Patashnik, 1994). Most recently, this development has received attention in psychological literature. Hahn and Warren (2009) argue that given people’s limited exposure to the environment (i.e., the number of coin tosses is finite), the longer waiting time of streak patterns would have made them less likely to be observed, thus, “there is something right about the gambler’s intuition that the longer the run, the more likely, by contrast, is a sequence with a final tails” (p. 458). Sun et al. (2010a) criticize Hahn and Warren’s interpretation, and argue that it is the particular composition of patterns, rather than the length of the global sequence, that plays an essential role in both the statistics of waiting time and people’s perception of randomness (also see Sun, Tweney, & Wang, 2010b).

Notwithstanding the debate above, the unique composition of a streak and its “delayed” first occurrence

may provide a new prospective in the investigations on human perception of randomness. Particularly, different compositions of patterns may be directly related to memory encoding due to the limited working memory capacity (e.g., Falk & Konold, 1997; Olivola & Oppenheimer, 2008). For example, a streak of HHH can be easily memorized as “3Hs.” In addition, different waiting times in effect indicate different variances in the distribution of pattern occurring times (Sun & Wang, 2010), and this fact may have direct consequence in people’s intertemporal choices as it has been suggested that human brains are sensitive to time discounting (e.g., Ainslie & Monterosso, 2004; McClure, Ericson, Laibson, Loewenstein, & Cohen, 2007; McClure, Laibson, Loewenstein, & Cohen, 2004). In the following, we demonstrate some interesting properties in the statistics on the time of patterns and discuss the psychological implications.

Figure 1: Probabilities of first occurrence for patterns HHH, HTH and THH when a fair coin is tossed repeatedly.

Mean Time and Waiting Time

The time of patterns has been studied by several different methods and different terminologies exist (e.g., Graham, et al., 1994; Li, 1980; Ross, 2007). To be consistent, here we clarify some basic concepts. In a process of coin tossing, the *interarrival time* (T) is the number of trials (tosses) between any two successive occurrences (arrivals) of the pattern, and the *first arrival time* (T^*) is the number of trials required to encounter the first occurrence of the pattern since the beginning of the process². Then, *mean time* ($E[T]$) is the expected value of the interarrival time, and *waiting time* ($E[T^*]$) is the expected value of the first arrival time. We also distinguish the variance of interarrival time and the variance of the first arrival time by $\text{Var}(T)$ and $\text{Var}(T^*)$,

² T and T^* may have different distributions, so that the process of counting patterns is also called a general renewal process or a delayed renewal process (Ross, 2007).

respectively. To simplify the discussion, here we only discuss the case of a fair coin (i.e., $p_H = p_T = 1/2$) and focus on pattern length $r = 3$. Unless specified, the discussion in the following will extend to patterns for all $r \geq 3$. (A more general treatment can be found in Sun & Wang, 2010.)

Overlap and Waiting Time

We first note that when generated by an independent Bernoulli process, a pattern will have a mean time that is the inverse of its probability of occurrence. Thus, any pattern of the same length will have the same mean time. For example,

$$E[T_{HHH}] = E[T_{HTH}] = E[T_{THH}] = (1/2)^{-3} = 8.$$

However, waiting time can be different for different patterns. Compared to other patterns of the same length, streak patterns always have the longest waiting time. For example,

$$E[T_{HHH}^*] = 14, E[T_{HTH}^*] = 10, \text{ and } E[T_{HHT}^*] = 8.$$

Table 1 lists the mean and variance of interarrival time T and the first arrival time T^* for all possible patterns of length 3. Extra caution should be taken to properly explain these results. An example is given in Figure 2, which depicts pattern time in two different contexts where individual patterns are monitored either independently (panel A) or simultaneously (panels B and C). Note that the colored circles in Figure 2 highlight the position where individual patterns have occurred and they actually represent the values of an “indicator variable” for pattern occurrence. In addition, arrows represent the minimum interarrival time between successive occurrences of patterns—the “minimum succeeding distance” for a pattern to occur given a previous occurrence of either the same pattern or another pattern.

Table 1: Mean and variance of interarrival time T and the first arrival time T^* for patterns of length $r = 3$. Note that for non-overlapping patterns such as HHT, the two pairs of statistics are identical (shown in bold).

Patterns	$E[T]$	$\text{Var}[T]$	$E[T^*]$	$\text{Var}[T^*]$
HHT	8	24	8	24
HTT	8	24	8	24
THH	8	24	8	24
TTH	8	24	8	24
HTH	8	56	10	58
THT	8	56	10	58
HHH	8	120	14	142
TTT	8	120	14	142

Figure 2: Visualization of pattern occurrences. Each circle represents the outcome of a single toss and the colored circle indicates one occurrence of the corresponding pattern. Arrows represent the “minimum succeeding distance” between successive occurrences of patterns, which also inversely indicate the levels of self-overlap (A) and inter-overlap (B and C).

Figure 2A illustrates the essence of waiting time as it is defined independently for each individual pattern. When the coin has been tossed exactly 3 times, the probability of occurrence for any pattern is the same, $1/8$ (also see Figure 1)³. However, interesting phenomena will happen at the 4th toss (or, an observational window of size 3 starts moving from the beginning towards the end of the sequence one position a time). For example, if pattern HHH has occurred at $n = 3$, it can have an immediate reoccurrence at $n = 4$. In contrast, if pattern HTH has occurred at $n = 3$, its earliest next occurrence will have to be 2 tosses away at $n = 5$. More extremely, if we are monitoring pattern HHT and it has occurred at $n = 3$, then its earliest next occurrence will have to be 3 tosses away at $n = 6$. An intuitive explanation for this is that the reoccurrences of HHH can *self-overlap* with each other thus tend to be mostly clustered and the

³ Alternatively, we can imagine that a coin is tossed repeatedly and a long sequence of heads and tails is generated. Then, an observational window of width $r = 3$ randomly lands on any position of the sequence and captures exactly 3 trials. Given the independence assumption of Bernoulli trials, the probability that the observational window will capture any pattern is the same $1/8$, as if the process starts from scratch (i.e., the window lands at the beginning of the sequence).

reoccurrences of HHT cannot overlap thus tend to be mostly dispersed.

The difference in waiting time can be viewed as one type of *precedence relationships* in which individual patterns are monitored independently and only the self-overlap within each pattern is considered. For example, suppose two players are betting on two patterns HHH and HHT, respectively, then each player tosses a coin of her own in isolation (i.e., the “solitaire game” in Sun, et al., 2010a). Because of the different waiting time, the player who bets on HHT will be more likely to get her desired pattern earlier than the player who bets on HHH.

The result above might give an impression that pattern HHT is always more likely to occur earlier than pattern HHH, thus the gambler’s fallacy might actually have a valid statistical basis. However, such precedence relationship may not hold if two patterns are monitored simultaneously in the same sequence and both self-overlap and inter-overlap are involved (the “interplay game”). The fact is that although HHT is faster than HHH in the solitaire game, in the interplay game, HHT overlaps with the end of HHH (two positions) more than HHH overlaps with the end of HHT (none) (see Figure 2B). Overall, it can be calculated that in the interplay game, we are equally likely to first encounter HHH as to first observe HHT.

⁴ It might seem counterintuitive that overlapped occurrences (hence faster reoccurrences) are associated with a longer waiting time. However, a reoccurrence of the pattern has to be based on a previous occurrence. Since a pattern of length $r \geq 2$ is more likely to have not occurred in the first r tosses than it has occurred, faster reoccurrences actually signify a delay in the waiting time.

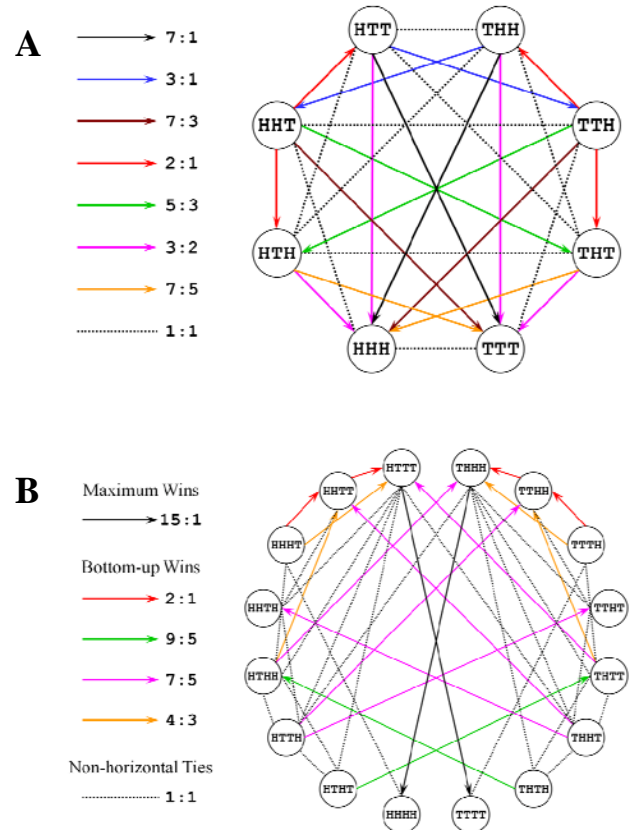

Figure 3 shows the pair-wise precedence relationships in the interplay game for pattern length $r = 3$ and 4. Close examinations of Figure 3A confirm that the precedence relationship does not exactly follow the order of waiting time listed in Table 1. Particularly, a pattern with a shorter waiting time may not be necessarily encountered earlier than a pattern with a longer waiting time. Nevertheless, it appears that streaks are still the slowest patterns—at best, a streak pattern can tie with its “end-reversal” counterpart or its reciprocal streak (e.g., HHH vs. HHT, or, HHH vs. TTT), and it can never “beat” any other pattern. In other words, nontransitivity in the interplay game does not mean the

equivalence (or indifference) between patterns in a circular fashion. Considering all possible pair-wise comparisons, streak patterns are still unique for their delayed first occurrences.⁵ This fact holds for all pattern length $r \geq 2$. Figure 3B shows the pair-wise comparison in the interplay game when pattern length $r = 4$, in which streak patterns are still at the bottom of the game.

Discussion

We have examined several types of pattern time statistics in different contexts and demonstrated that streak patterns indeed possess some unique statistical properties. Here we discuss their psychological relevance and implications in the investigations on human perception of randomness.

First, the particular unbroken continuity of a streak leads to the maximum amount of self-overlap. As a consequence, successive occurrences of a streak tend to be clustered and such tendency would make it harder for human memory to keep an exact count of the actual number of occurrences. By contrast, successive occurrences of other patterns have to be either partially or completely separated (e.g., Figure 2A) and much more evenly distributed (indicated by the small variance of interarrival time in Table 1). For example, in Figure 2A, if the observational window is in size 4 instead of 3, two consecutive instances of 3Hs can be captured by one window. If the memory is encoded as the number of the windows containing the streak (at least once), two instances of 3Hs captured in the same window would have the same weight as one instance of 3Hs. Alternatively, two instances of 3Hs could be replaced by one instance of 4Hs. In either case, the remembered number of occurrences of 3Hs will be less than it actually is.

Moreover, compared with all other patterns, a streak is the slowest pattern to occur, determined by either self-overlap alone (*solitaire*) or a combination of self-overlap and inter-overlap with another pattern (*interplay*). In other words, as a random sequence unfolds over time, we are more likely to first encounter another pattern other than a streak. The only exception is the case in interplay where a streak can tie with its end-reversal counterpart or another streak (e.g., Figure 3). Even in this exception, a streak retains an inferior status because of the “minimum succeeding distance” (see Figure 2B). Although it is equally likely HHH preceding HHT as HHT preceding HHH, if HHH occurs first, HHT can immediately follow. If HHT occurs first, the next best shot for HHH has to be 3 tosses away. That is, the discrepancy in the minimum succeeding distance can obscure people’s experience of HHH more than it does to HHT.

Together, although streak patterns have the same mean time as any other pattern, their longest waiting time and maximum clustering tendency can leave them

underrepresented in people’s experience thus make them appear rare or “non-representative” in recollection. Actually, a recent study by Olivola and Oppenheimer (2008) seems to confirm our speculation: when participants recalled the studied binary sequence, the lengths of streaks present in the original sequence were underestimated. Even more interestingly, Olivola and Oppenheimer found that when a streak was present *early* or *late* in a 25-event sequence, the overall sequence was judged as less likely to be random, compared to when the same streak occurred in the middle of the sequence. It appears that people may actually have an intuitive and accurate response to waiting time such that a streak is unlikely to occur early in sequences generated by a random process.

It should be noted that besides the delayed first occurrence, the particular composition of streaks can manifest itself in many other forms. One example is the probability of occurrence at least once and its complementary “probability of nonoccurrence,” whose roles in affecting people’s perception of event likelihood have been discussed (Hahn & Warren, 2009; Sun, et al., 2010a). Another example is the shear disparity in the variance of interarrival times between different patterns. When time is essential in predicting future events, different levels of variance may have direct consequences in people’s risk preference (e.g., Lopes, 1996; Markowitz, 1991; Sun & Wang, 2010).

Last but not least, in the examples discussed throughout the paper, the sequences of coin tosses are generated by Bernoulli trials (hence inter-event independent and memoryless). However, the process of counting patterns, particularly streak patterns, are not exactly memoryless (this is implied by the unequal mean time and waiting time, see Table 1). As human memory plays essential roles in predicting and planning future events, studies on such process can be useful in order to untangle the interaction of human memory and perception of randomness. Among these different statistics of the similar nature, people can be more sensitive to one form of manifestation than to another or even completely indifferent. We may not be able to use these statistics to vindicate a certain type of bias or fallacy. Nevertheless, these statistics can aid us to better understand the task environment so that we may eventually be able to more precisely pinpoint the source of the error.

Abstract

We used a simple problem-solving game task to study imitation and innovation in groups of participants. Guesses were composed of multiple elements with linear and interactive effects on score, and score feedback was provided after each of a number of rounds. Participants were allowed to view and imitate the guesses of others during each round, and the score information accompanying others' guesses was either shown or hidden in two conditions. When scores were not visible, social learning was impeded; participants were less efficient in their searching of the problem space and achieved lower performance overall. When scores were visible, higher performance was observed, and results indicated a more equitable sharing of productive exploration among participants within groups as a result of selective imitation and cross-participant cumulative mutual innovations.

Keywords: Social learning; distributed cognition; innovation; imitation; problem solving; innovation diffusion.

Background

The act of learning about the world from others permeates human life. This is evident upon casual reflection about how people gather information and make choices about restaurants or movies, candidates for a job or political office, a new city to live in or a large household purchase, not to mention direct collaboration. Such "social learning" has been defined broadly as "the acquisition of behavior by observation or teaching from other conspecifics" (Boyd & Richerson, 2005). Social learning is a well-studied phenomenon in non-human animals, including foraging choices in starlings (Templeton & Giraldeau, 1996), food preferences in various rodent species (Galef & Giraldeau, 2001), and mate choices in black grouse (Höglund, Alatalo, Gibson & Lundberg, 1995). Humans' rare talent among animals for direct and flexible imitation has been called "no-trial learning" (Bandura, 1965), because it is even faster than the one-trial learning observed in animals with a strong built-in tendency to form certain associations (e.g. between the taste of a food and a subsequent stomach ache). This talent allows an imitator to add new behaviors to his or her repertoire without the costs of trial-and-error learning.

Social Learning Strategies

Tendencies toward individual and social learning depend on the availability and reliability of information in the environment, including other learners. Laland (2004)

reviews strategies for *when* social learning is chosen, and *who* social learners choose to imitate. The first class of strategies (when to imitate) often uses the relative cost or uncertainty of asocial learning as criteria. For example, learning about predators on one's own can be very dangerous, so many animals have adapted to learn predator responses from others; in at least one instance this learning has occurred across species (Krause, 1993). The second kind of strategy (who to imitate) often relies on absolute or relative performance of candidate solutions (such as *copy the best* or *copy if better* strategies, respectively), or their relative popularity (such as the *copy the majority* strategy); each of these strategies has been shown in several species (Laland, 2004).

Consequences of Social Learning

Rogers (1988) performed simulations showing that in a temporally unstable environment, the extent to which imitation is beneficial depends on how recently the target of imitation has directly sampled the environment. Therefore, the addition of random social learners (information scroungers) to a population of asocial learners (information producers) does not improve the overall fitness of the population, because the costs of learning avoided by imitators will be offset by costs resulting from the increased use of outdated and inaccurate information. Boyd and Richerson (1995) and Kameda and Nakanishi (2003) confirmed and extended these results to show that when social learners can imitate selectively (e.g. imitating when individual exploration is relatively unreliable and thus more costly), the overall fitness of the population can increase, because both individual and social learning can become more accurate.

Of course, these models are greatly simplified in several ways, among them the assumption that social learners cannot discriminate between model solutions of varying quality without adopting them first. Even without this capability, the benefits for social learners (and thus average benefits for their group) in temporally stable environments are often assumed to be evident (Kameda & Nakanishi, 2002), but the mechanisms by which these benefits accrue are not necessarily clear. If social learning is essentially scrounging that only benefits imitators, then creating obstacles to social learning will only decrease the average performance of imitators. However, the results of previous experiments (Wisdom, Song & Goldstone, submitted) give

us reason to believe that imitators are often also explorers, and that social learning serves as a vital component of the creation of cumulative improvements. Thus impeding social learning is expected to lead to decreases in the performance of all participants.

Experiment Overview

The following experiment investigates both the causes and consequences of social learning. We employ a task in which participants in groups consisting of between one and nine persons are instructed to individually build solutions, which consist of multiple elements chosen from a larger set of elements over a series of rounds. These solutions are evaluated according to a score function that takes into account both individual element values and interactions between them. Groups of participants play simultaneously, and each can view the tentative solutions of all others. In one condition, participants may view fellow participants' scores alongside their solutions, and in another condition fellow participants' scores are invisible.

Predictions

We made the following predictions. When evaluative information about peer solutions was unavailable, participants would be unable to be sufficiently selective in imitation, and thus participants employing highly imitative strategies would have relatively lower scores. Imitation strategies in both conditions would be biased toward peers with solutions similar to the imitator's, and toward adopting solution elements that were more popular among peers, but these effects would be more pronounced in the invisible-scores condition in order to compensate for the lack of direct evaluative information. Mean scores would be lower for participants (including successful asocial learners) in the invisible-scores condition because they would be unable to easily take advantage of good solutions found by others through selective imitation and further improve upon them.

Methods

Participants were recruited from the Indiana University Psychological and Brain Sciences Department undergraduate subject pool, and were given course credit for taking part in the study. Participants populated each session by signing up at will for scheduled experiments with a maximum capacity of 9 persons. 234 individuals participated in the experiment, distributed across 65 sessions as shown in Table 1.

Table 1. Distribution of participants across group sizes.

Group size	1	2	3	4	5	6	7	8	9
# Sessions	16	8	11	11	5	2	3	3	2
# Participants	16	16	33	44	35	12	28	32	18

Task Details and Instructions

We implemented the experiment using custom software written in Java and Flash and run in a web browser (a version of the task can be run as "Creature League" at <http://groups.psych.indiana.edu/>). Each participant used a mouse to interact with the experimental game. A central game server recorded data and updated participant displays at the end of each round. In the game itself, participants attempted to maximize the scores earned by their chosen subsets ("teams") from a set ("league") of creature icons over 24 rounds. The display included an area for the participant's own current team, another area that could be toggled to show the participant's previous round team or their best-scoring team so far in the game (along with its associated score), a league area which showed all of the icons that were available for selection, and indications of the current round in the game and the amount of time remaining in the current round. If a session included more than one participant, each participant's display also showed the team and, in the visible-scores condition, the associated score for each other participant in the previous round. The ordering of other participants' teams in the display was not kept constant across conditions, to avoid imitation based on past behavior. Icons could be copied from any part of the display to a participant's current team by dragging and dropping them with the mouse, except for those already on the participant's current team. The current team could be replaced entirely by another team by using the score box above it as a "handle" to drag it to the current team area. A screen capture of the task interface is shown in Figure 1.

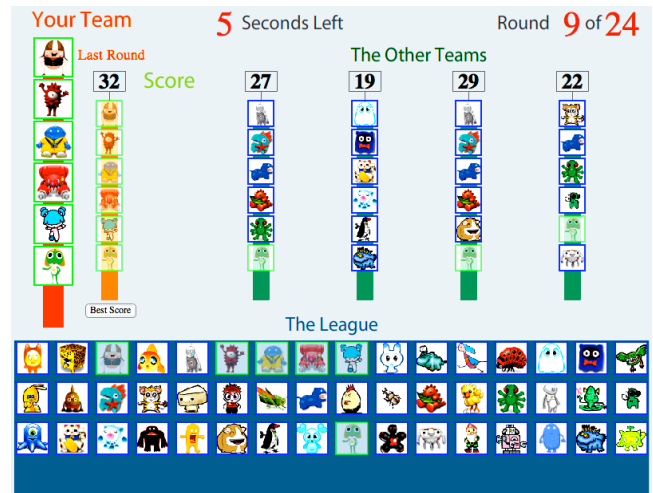

Figure 1: Example of experiment task display.

At the beginning of each session, players were given a hands-on demo of the game (including the various ways to move creatures to one's current team), and further informed about the mechanics of the game and what to expect in the remainder of the experiment session, including the following information. Each game consisted of 24 rounds, and each round was 10 seconds long. Score feedback was

given after each round: if the participant's score had improved from the previous round, the numerical score display counted up to the new score and turned green, and if it had worsened, the display counted down to the new score and turned red. At the end of each game, the display showed the player's final score, along with a table of the scores of each player in each round of the game, sorted by average score. The player's own score was highlighted to show their relative performance without placing competitive emphasis on it. Players were instructed to do their best to maximize their teams' scores over all 24 rounds. At the beginning of each game, each player's team was a random selection of creature icons from the league. Each group played 6 games; in 3 of the games, other participants' scores were visible, and in the other 3 they were not. These were called the visible-scores and invisible-scores conditions, respectively, and were played in random order in each session.

In each game, each icon was associated with a certain positive number of points, and several special pairs of icons were associated with separate score bonuses or penalties that captured interactions between icons. The score for a team was computed by summing the individual point values for each icon, and then adding or subtracting the value of any special pairs present. The pairs did not overlap, and the distribution was designed to be challenging: pairs which gave large positive bonuses were distributed among icons with small individual point values, and pairs which gave large negative penalties were generally found among icons with large individual point values. There was a greater number of positive interactions than negative ones, to give the score distribution a larger upper tail. For ease of comparison and analysis, all scores were normalized to the range [0,1] according to the minimum and maximum possible scores. The combinations of individual and pair values described above resulted in the probability distribution of scores among all possible teams shown in Fig. 2. Participants were not given explicit information about the maximum score, the score distribution, or the position of the interaction terms. The icons' display position and associations with the point distribution were shuffled randomly for each game, so that their appearance and placement in the display did not give clues as to their point values during the course of an experiment session.

Dependent Variables and Definitions

In each round, the following data were recorded for each player: the icons (*choices*) on the team at the end of the round, the *source* of each icon, and the resulting score. The *source* information indicated whether an icon was unchanged from the previous round (Retained), copied from the player's own best-scoring team so far (Retrieved), chosen from the league display (Innovated), or copied from another player's team (Imitated). When Imitation was chosen, the persistent identifier of the copied player was recorded to allow further analyses of imitation decisions. In the case of a player replacing the entire team with Imitated icons, only the choices that were not already present on the

Figure 2: Distribution of scores for all possible teams.

team were counted as Imitated. Similar criteria applied to replacement of an entire team with Retrieved icons, or removing an icon and then returning it to the team via an Innovation choice. *Choice similarity* was defined as the proportion of icons that two teams have in common. An *improvement* was defined as an instance of a participant obtaining a score higher than all prior scores of all players within a particular game. Each participant's *normalized improvement share* was defined as their individually achieved proportion of the total improvements achieved by all participants in a condition, multiplied by the number of participants. A value of 1 indicated a "fair" share, e.g. a participant achieved one-third of the improvements in a three-person session. *Guess diversity* for a group in a particular round was defined as the proportion of icons in the league represented on one or more participants' teams in that round. This value was normalized by the average expected value of this proportion for each participant group size, generated by a Monte Carlo simulation.

Results

Differences in Performance

Grouped participants achieved mean overall (across all rounds) and final normalized scores of .398 and .481 respectively in the invisible-scores condition, and significantly higher scores (.463 and .546) in the visible-scores condition (see Figure 2). Isolated participants achieved mean overall and final scores of .356 and .395. Linear mixed-effects models revealed that score increased significantly with group size in the visible-scores condition ($F(1,63)=79.75$, $p<.0001$, $B=0.354$), as well as in the invisible-scores condition ($F(1,63)=14.94$, $p=.0003$, $B=0.129$), though the latter trend was not as strong. Of all grouped participants, 81.7% had higher mean scores in the visible-scores condition than in the invisible-scores condition (see Figure 3).

Figure 3: Scattergram of individuals' mean scores in each condition, labeled with their participant group size.

Linear mixed-effects models were used to examine trends across rounds for score and guess diversity, with a random effect of participant group. Analysis of score versus round showed a strong positive trend in the visible-scores condition ($F(1,1494)=295.96$, $p<.0001$, $B=.534$, mean increase=0.188), and a slightly shallower positive trend in the invisible-scores condition ($F(1,1494)=251.93$, $p<.0001$, $B=.615$, mean increase=0.145; see Figure 4). Guess diversity showed a similarly strong decrease across rounds in the visible-scores condition ($F(1,1126)=304.78$, $p<.0001$, $B=-.443$, mean change=-0.468), and a weaker decrease in the invisible-scores condition ($F(1,1126)=97.31$, $p<.0001$, $B=-0.453$, mean change=-0.271; see Figure 4).

Grouped participants achieved an average of 1.21 improvements per person in the visible-scores condition, and 0.95 in the invisible-scores condition. Isolated participants achieved an equivalent average of 2.44 improvements per person. Mean proportions of each choice source for improvement and non-improvement guesses in each condition are shown in Table 2. In both conditions, the proportion of Innovation choices was higher for guesses that yielded improvements relative to non-improvements (invisible-scores: $t(733.20)=-14.03$, $p<.0001$; visible-scores: $t(907.73)=-17.14$, $p<.0001$). In the invisible-scores condition, the proportion of Imitation choices was significantly lower for improvements than non-improvements ($t(916.77)=11.54$, $p<.0001$), while in the visible-scores condition, the proportion of Retention choices was significantly lower for improvements than non-improvements ($t(916.33)=9.34$, $p<.0001$). Overall there was significantly higher Retention in the visible-scores condition ($t(360)=-2.218$, $p=.027$, indicating that guesses changed more slowly.

Figure 4: Change in score and guess diversity across rounds in each condition.

Analyses of relationships between mean individual score and mean individual choice source proportions showed a strong negative correlation in both conditions between score and prevalence of Innovation choices (invisible-scores: $F(1,196)=64.16$, $p<.0001$, $B=-0.497$; visible-scores: $F(1,196)=153.5$, $p<.0001$, $B=-0.663$) and a strong positive relationship between score and Retention (invisible-scores: $F(1,196)=15.27$, $p=.0001$, $B=0.269$; visible-scores: $F(1,196)=62.87$, $p<.0001$, $B=0.493$), while a strong positive relationship was shown for Imitation only in the visible-scores condition ($F(1,196)=9.70$, $p=.002$, $B=0.217$), and a strong positive relationship was shown for Retrieval only in the invisible-scores condition ($F(1,196)=14.28$, $p=.0002$, $B=0.261$).

Of all improvements in the invisible-scores condition, 14.5% resulted from guesses that included Imitation, versus 28.4% in the visible-scores condition. In a large majority (>70%) of those cases across both conditions, the focal player imitated at least one peer who had previously imitated the focal player. In other words, a player who was imitated by another player often later imitated the same player in the course of creating an improvement.

Table 2: Mean choice source proportions for (non-) improvement guesses in each condition. (Significant differences within a condition are in **boldface**, and significant differences between conditions are in *italics*.)

Condition	Improvement?	Imit.	Innov.	Retain	Retr.
Invisible Scores	No	.100	.133	.712	.044
	Yes	.039	.216	.705	.035
Visible Scores	No	.091	.114	.763	.022
	Yes	.082	.194	.695	.021

Normalized improvement share showed a relatively equitable distribution of improvements within groups in the visible-scores condition, with the distribution peaked near a "fair" share of 1. In the invisible-scores condition, however, the distribution had a strongly inequitable skew, with a modal share of zero (see Figure 5). A Kolmogorov-Smirnov test of equality of distributions indicated that these distributions were significantly different ($D=0.171$, $p=0.006$). Mean overall score showed a strong positive correlation with improvement share in the invisible-scores condition ($F(1,148)=34.94$, $p<.0001$, $B=0.329$), but this relationship was not evident in the visible-scores condition.

Differences in Strategy

In the visible-scores condition, approximately 79% of imitation events were of the highest-scoring player, while in the invisible-scores condition, all players were approximately equally likely to be imitated with regard to score. A comparison between the mean choice similarity of participants' most recent guesses to those whom they imitated, and to those whom they did not imitate, revealed a slight but significant positive difference in the visible-scores condition: a similarity value of .563 for imitated and .524 for non-imitated guesses ($t(5084.88)=-5.47$, $p<.0001$). The opposite was true in the invisible-scores condition: .317 for imitated and .346 for non-imitated guesses ($t(4041.53)=4.02$, $p<.0001$). In other words, when scores were visible, imitation was biased toward similar guesses, and when scores were invisible, imitation was biased toward dissimilar guesses.

In order to measure the bias of participants to choose an icon according to its frequency in peers' teams, we tallied the number of players in the group whose teams included each icon in the previous round (N_{R-1}), as well as the

number of the remaining players who added it to their team in the current round via Imitation. To convert these figures to normalized frequencies, the first number was divided by the participant group size (N), and the second number was divided by the number of participants who did not possess the icon in the previous round ($N - N_{R-1}$). If a participant had decided to imitate an icon at random from among all neighbors' teams, a certain chance correlation with choice frequency would be expected simply because more high-frequency icons are present. However, a linear mixed-effects analysis of imitation probability versus choice frequency showed a positive frequency bias that was significantly greater than chance in the visible-scores condition ($F(1,604)=943.25$, $p<.0001$, $B=.741$) and significantly below chance in the invisible-scores condition ($F(1,604)=231.67$, $p<.0001$, $B=.470$). This indicates that in the visible-scores condition, participants were biased toward imitating higher-frequency icons at a rate greater than expected by chance, but not in the invisible-scores condition.

Discussion

When scores were visible, participants were heavily biased toward imitating higher-performing peers (displaying the *copy the best* strategy discussed in Laland (2004)), and performance was correlated with the average amount of Imitation in a participant's choices. Participants also showed a bias toward imitating solution elements that were possessed by larger proportions of their fellow participants, similar to the *copy the majority* strategy. Another bias evident in the score-visible condition was toward imitating more similar guesses, which allowed the imitator to make use of social learning while keeping a solution partially compatible with previous solutions and existing knowledge of the problem space, a phenomenon explored in studies of innovation propagation (Rogers, 2003).

As expected, hiding other participants' score information strongly impeded social learning: when others' scores were not visible, the choice of whom to imitate was approximately random with respect to score, and performance was correlated with the average amount of Retrieved information on a participant's team, showing the incentive to focus on previously-acquired information rather than that of others. Surprisingly, participants in the score-invisible condition also seemed to be slightly biased against peer solutions that were similar to their own, as well as icons which were more popular among their peers, perhaps indicating a bias toward novelty, which would help explain the overall decrease in individual Retention in this condition.

However, participants in the invisible-scores condition still showed a slight bias toward imitating more popular icons, indicating that the lack of score information did not cause them to disregard the guesses of their fellow players entirely. Though it conflicts with the finding that imitation in this condition occurred without regard to score, this may explain some of the improvements using Imitation and the

Figure 5: Histograms showing relatively equitable achievement of improvements within groups in the visible-scores condition, and an inequitable distribution in the invisible-scores condition.

positive relationship of score with participant group size in this condition. When players have relatively high incentives to explore for themselves rather than imitate, and yet have some solution elements in common, it is reasonable to conclude that those common solution elements may produce good scores. This is also consistent with many participants' self-reported strategies.

As seen in the increasing score and decreasing guess diversity trends across rounds, average performance increased via the convergence of group members on regions of the problem space that contained high-quality teams. This convergence combined with a small amount of individual exploration caused such regions to be explored more thoroughly and still better solutions to be found. However, in the invisible-scores condition, when imitation was not focused on a small group of better-performing neighbors (because performance information was not available), or similar guesses, this convergence happened much more slowly, search was more diffuse and less efficient, and lower performance resulted.

The significant correlation of improvement share with mean scores in the score-invisible conditions shows that individuals who were relatively more successful at individual exploration were rewarded with proportionately better overall scores compared to others, because their fellow players could not easily copy their improvements and achieve their scores. In the score-visible conditions this relationship disappeared, but mean scores increased significantly such that nearly all participants did better.

In other words, when social learning was unimpeded in the visible-scores condition, high and low individual achievers had approximately the same payoffs, but absolute payoffs were higher for both compared to the invisible-scores condition. This is because imitators were not merely scroungers; the substantial proportion of Imitation present in improvements shows that imitated guesses were often the basis for further cumulative innovations. The cumulative innovation hypothesis is supported by the fact that a large proportion of improvements which used Imitation involved mutual Imitation and improvement, in which solution elements were passed between players via copying and built into better solutions in the process. This enabled a more equitable sharing of the "labor" of producing improvements, and produced more improvements overall.

Gabriel Tarde, one of the founders of social psychology, considered innovation and imitation to be "the fundamental social acts" (Tarde 1903/1969). Cultural conventions can be thought of as a form of large-scale imitation of behaviors that evolve along with their associated populations, subject to accompanying adaptive pressures (Boyd & Richerson, 2005). Innovations are necessary to adapt to the challenges of changing environments, and when members of a group imitate them, adaptive solutions to problems can be effectively preserved within a culture.

The findings of this study point to new avenues for understanding how innovations are generated and spread, as well as how information, incentives and the dynamic

behavioral interactions of individuals create higher-level consequences for the groups to which they belong.

Abstract

We explore whether social context affects how labels (relative to other features) affect category learning. We taught 104 participants four novel categories using a feature inference task. In a between-participants design, we manipulated: 1) the social context of the task (social context vs. on the computer); and 2) which dimension of the category members could be used to perfectly predict the target feature: the category label, a biased feature (which is salient and already associated with the target feature in the correct way) or a non-biased feature (which is less salient and not already associated with the target feature in any way). Learning curves were used to assess whether participants assumed that labels were uniquely helpful compared to other features. The results suggest that the extent to which labels are privileged depends on the context in which the category learning task is presented. When the task is social, people learn quickly regardless of whether a label or another feature is the most informative. When the task is not, both novel labels and biased features are more useful than non-biased features.

Keywords: categorization; feature inference; labels; features; social context.

Introduction

There is a Chinese proverb that says, “The beginning of wisdom is to call things by their right names.” Category labels feel like an important and special part of our conceptual knowledge. We need labels to communicate about classes of objects, and labels (often unlike other features) are a property that all members of a category share. One might expect that labels help learners pick out the category members that have important similarities to each other, and that are different from members of other categories. However, although this has been the topic of study for decades, it remains unclear whether there is a psychological distinction between category labels and other types of features. It is also unknown (especially for adults) whether the effect of a label is affected by the social-referential context in which it is offered.

Work with children broadly supports the notion that labels have a privileged psychological status, although it is still debated what the source of that privilege is. Verbal labels appear to facilitate infant category learning (e.g., Balaban & Waxman, 1997), with shared names highlighting commonalities between objects (Waxman & Braun, 2005). Labels influence the number of categories formed by infants, overriding the categories that are suggested by perceptual similarity (Plunkett, Hu & Cohen, 2008). Additionally, when making decisions about whether a

category feature can be generalized to a new object, preschool children rely more on category membership conveyed by a label than they do on perceptual similarity (Gelman & Markman, 1986; 1987). These experiments suggest that labels are special in some way, but these studies do not address whether a single salient feature possessed by all category members might produce the same effects.

The question is further complicated by the fact that, for children at least, the social and linguistic context influences the effects of category labels. Fulkerson and Haaf (2003) found that labels can help infants to form categories that are otherwise *not* formed when only a non-labeling sound or no sound is used in their place. However, for older infants (15 rather than 9 months) the source of the label matters: these infants formed categories when the labels were presented orally, but not when they were presented by a voice recorder. Consistent with this, Campbell and Namy (2003) found that infants learned object names only when the label was presented in a normal social-referential interaction. The names were learned when the label was verbalized by the experimenter and embedded in a familiar naming routine, such as, “Look at what you have! *Tillen*. That’s what we call that one.” Learning was unsuccessful when the label was emitted from a baby monitor and was not timed with the naming routine.

It is unclear whether we should expect similar effects of social context in adults, or whether any differences between adults and children are due to differences in the social context of label presentation. Unlike for children, most adult category learning experiments do not incorporate a social element: category labels are presented in written form on screen or on paper, or (at most) as a recorded sound. Grice’s conversational maxims (Grice, 1975) suggest that labels presented in a social context should especially be presumed to be relevant and informative to the task at hand. Alternatively, since educated adults are well practiced at using labels, social context may not significantly change how labels are treated.

Labels do seem to play an important role in adult categorization. Categorical perception research suggests that learning that stimuli share a label can be sufficient to increase perceptions of similarity of the stimuli (e.g., Goldstone, Lippa & Shiffrin, 2001). In addition, Yamauchi and Markman (1998; 2000a) have begun to directly address the issue of whether category labels have a privileged status over other features for adults. They claimed that people employ different strategies to make feature inferences or classifications (i.e., infer labels), and that learning novel

categories through a classification task or a feature inference task will produce different category representations. However, the experimental tasks used were unfair as a test of a general distinction between labels and other features, because the category structures of the classification and inference tasks were not equivalent: labels were a diagnostic feature in the inference task, which seemed to drive the differences between conditions (see also Johansen & Kruschke, 2005). However, the studies could suggest that people expect labels to be useful in a feature inference task (see also Yamauchi, Love & Markman, 2002).

In a further series of experiments Yamauchi and Markman (2000b) showed adults a set of labeled exemplars of two categories and asked them to compare novel stimuli to the exemplars. Classifications of the novel stimuli were generally made according to the total number of features consistent with the appropriate category prototype, but feature inferences for novel stimuli were strongly influenced by the observed category label. As a result, when similarity and category membership were placed in opposition, participants were more likely to base their inferences on the label. This effect was decreased when the labels referred to a feature rather than to category membership, or when the label was replaced by a perceptual feature. These studies suggest that to the extent that labels convey category membership, they are privileged over other features. However, the experimental tasks used in these experiments were fairly unnatural, since participants did not have to learn the categories: they simply compared stimuli on a sheet in front of them.

This work has two aims. First, it contributes one of the first explorations in the adult literature focused on the question of whether social context has an impact on the status of labels. Second, it investigates whether labels have a privileged status over other category features for adults. Are people biased to assume that labels are uniquely helpful compared to other stimulus features when learning about novel categories? If so, they should assume that labels are important to pay attention to and therefore categories should be easier to learn when the labels are useful predictors. However, categories should be more difficult to learn when another feature is the more useful predictor (depending on the type of feature). Are these effects mitigated or amplified depending on the nature of the social context in which the labels are presented? Are labels assumed to be especially important in a social category learning context, involving communication with a knowledgeable human teacher?

Method

Participants learned about four novel categories during a feature inference task. Two between-participants experimental factors were manipulated to form a 3x2 design. The first factor was which aspect or dimension of the category members could be used to perfectly predict the target feature. This diagnostic feature dimension could be the CATEGORY LABEL, a BIASED FEATURE or a NON-BIASED FEATURE. The second factor was whether the category

Figure 1: Two sample images used in the category learning task. The image on the right includes the feedback of the hammer.

learning task was performed alone on a personal computer (PC), or in a more social context with the experimenter (SOCIAL).

Participants

106 adults (either undergraduates at the University of Adelaide, or people recruited from the general community; 41 males) took part in the experiment. Ages ranged from 18 to 57 years. They received course credit or AU\$10. One participant's data was removed from the SOCIAL, NON-BIASED FEATURE condition because the participant withdrew from the study before training was completed. An outlier was removed from the PC, LABELS condition for taking 26 blocks to complete the training task (this was more than 3 SDs above the mean for that condition). 16 to 18 people remained in each condition.

Materials

The category learning task was designed to be realistic and engaging, in order to encourage ecologically valid responses. Participants learned about four novel "alien people" categories, each of which contained four members. Images for the categories were created using *World of Warcraft*, an online computer game produced by Blizzard. Examples of the images are shown in Figure 1, and the category structure used across all conditions is shown in Table 1.

Participants were asked to predict the nature of a certain target feature: which item each alien wanted to buy (options were a timber axe, a dagger, a hammer or a staff). The four category members varied on five dimensions, which could each take one of four values. The five dimensions and their possible values were:

- 1) category labels, presented as community names: Goloth, Bragen, Lathor and Durgal
- 2) clothing: leather warrior-like garb, a robe, tradesperson-like overalls and "lumberjack" attire
- 3) hair style: long, cropped, bald and ponytail
- 4) skin color: red, cream, brown and blue-grey
- 5) facial hair: short square beard, long plaited beard, medium pointed beard and broad beard with upturned moustache.

Table 1: Category structure for the feature inference learning task, for all conditions. The diagnostic feature dimension perfectly predicts the target feature dimension, and demarcates the four categories. (F = feature)

Target features	Diagnostic features	F1	F2	F3	F4
Timber axe	1	1	3	2	1
	1	1	1	3	2
	1	2	1	1	3
	1	3	2	1	1
Dagger	2	2	4	3	2
	2	2	2	4	3
	2	3	2	2	4
	2	4	3	2	2
Hammer	3	3	1	4	3
	3	3	3	1	4
	3	4	3	3	1
	3	1	4	3	3
Staff	4	4	2	1	4
	4	4	4	2	1
	4	1	4	4	2
	4	2	1	4	4

As Table 1 demonstrates, four of the feature dimensions contributed to a family resemblance category structure, but one “best predictor” or diagnostic dimension perfectly predicted the target feature. Thus all conditions had rule-based categories: only a single dimension was needed to solve the categorization problem. One experimental factor was *which* dimension was the best predictor of the target feature. In the LABEL conditions, the community name was the diagnostic dimension. Thus participants could learn to perfectly predict which item an alien wanted to buy using only its community name. Alternatively, in the BIASED FEATURE conditions, the clothing was the diagnostic dimension. In these conditions, the clothing “value” corresponded to the target item one might expect based on prior background knowledge: the aliens wearing the robe wanted the staff, the aliens with the leather garb wanted the dagger, the aliens in the overalls wanted the hammer, and the aliens with the “lumberjack” attire wanted the timber axe. Finally, in the NON-BIASED FEATURE conditions, the facial hair was the diagnostic dimension, arbitrarily matched with the target items.

Procedure

Participants were randomly allocated to one of the six conditions. All participants were asked to imagine they were a space traveler who began working in a general store on another planet and needed to learn about the customers of the store. Participants were told that they needed to learn to predict which item each of 16 customers wanted to buy. They learned by trial and error, and the learning task continued until they made the correct prediction for all 16 customers. This criterion was chosen to encourage optimal performance: participants knew that the task would continue until no errors were made.

On each block the 16 trials were presented in random order. For each trial, participants were presented with an image of a customer with a label. In the SOCIAL conditions, the experimenter displayed a card with the image and verbally presented the label (e.g., “This is a Goloth”). In the PC conditions, the label was written in bold blue capital letters above the image on the screen. Participants were then asked to predict the target feature, either verbally to the experimenter in the SOCIAL conditions, or by clicking the appropriate button on the screen in the PC conditions. They were given immediate corrective feedback after each trial consisting of an image of the customer holding the correct item, with the community name written above the image and the name of the correct target item below the image. Participants also received additional feedback after each block of 16 stimuli about their total number of correct responses for that block.

Design

There were two factors of interest in this experiment. One factor was whether the target feature dimension was best predicted by: 1) the community LABEL; 2) the NON-BIASED feature (facial hair), which participants should not have expected to be useful *a priori*; or 3) the BIASED feature (clothing), which people should have had a prior bias to find useful for predicting what the creatures wanted to buy, since the sets of clothing each corresponded to the appropriate target item. This experimental factor tests whether people are biased to assume that labels are uniquely useful features, or whether they are similar to highly salient or useful features (like the BIASED feature). In each level of the factor, the diagnostic feature dimension plays an identical role in the category structure, allowing a fair test of the relative status of labels and features. If labels are not special, all else being equal, learning performance should be equivalent regardless of whether labels or other features are the diagnostic dimension. However, if labels have a special status, participants should be quicker to learn to predict the target feature when the LABEL is the diagnostic dimension. Learning should be slowest in the NON-BIASED FEATURE conditions, where labels are less useful and an unexpected feature *is* useful. Learning should be more rapid in the BIASED FEATURE conditions, where an unsurprising feature *is* useful, and it is relatively easy to remember which particular feature value (i.e., particular outfit) matches with each target item. Of critical importance, then, is whether learning in the LABEL conditions is closer to learning in the BIASED or in the NON-BIASED FEATURE conditions.

The other experimental factor was whether the labels were presented in a social context or not. In the PC conditions, participants worked on a computer; the labels and images were presented on the screen. In the SOCIAL conditions, participants learned by interacting with the experimenter, who presented the images on cards and verbally presented the category labels. This manipulation tests whether people assume labels to be particularly special when the context is more social and interactive.

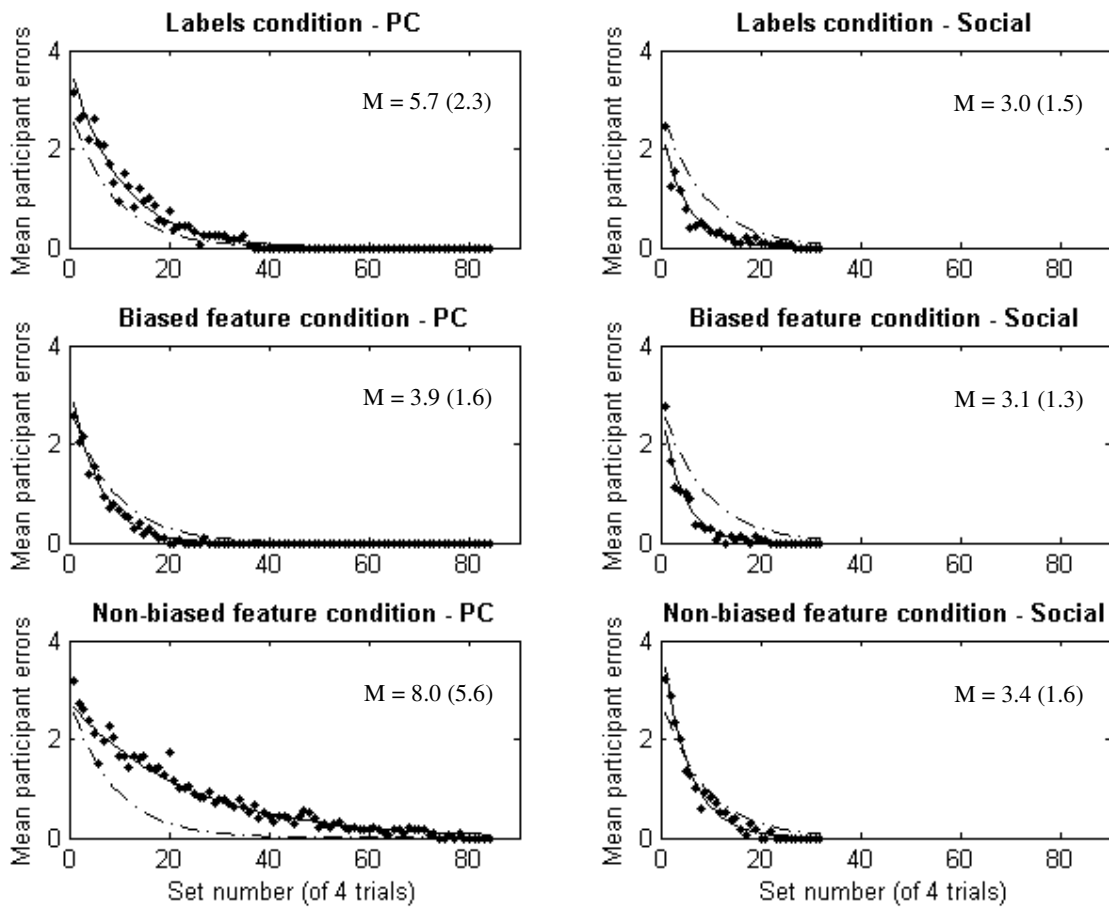

Figure 2: Learning curves averaged across sets of 4 trials, and averaged across participants in each condition. Two models using an exponential function are fit to the error data using BIC: a model with unique parameter values for each condition (solid line) is preferred over a model with the same two parameter values for all conditions (dashed line). M = the mean (SD) number of blocks taken to complete the learning task.

Results

Our results suggest that the extent to which labels are privileged depends on the context in which the task is presented. When the task is social, people learn quickly regardless of the nature of the diagnostic dimension. When it is not, labels are as useful as biased features.

Figure 2 shows the learning curves with error data averaged across sets of four trials, and across all participants in each condition (the black dots). Exponential functions of the form $Y = a \exp(-bX)$ (see Heathcote, Brown & Mewhort, 2000) were fit to the data of each condition. Model parameters were fit using maximum likelihood estimation, and Bayesian Information Criterion (BIC; Schwarz, 1978) was used for model selection. BIC is a measure that considers the data fit, but penalizes models for having excessive parameters (Myung & Pitt, 1997). The model that minimizes BIC should be preferred.

Two (of several¹) simple models that were fit to the mean error data are also shown in Figure 2. Both models used the exponential function, but one model allowed unique parameter values for each condition, while the other model used the same two parameter values for all conditions. These two models were compared, using BIC to estimate the Bayes Factor (see Myung & Pitt, 1997), which provides the odds in favor of the model with the lower BIC score. The model that allowed unique parameter values was preferred according to this criterion (BIC for unique parameters model = 186.0 vs. BIC for same parameters model = 1499.1; according to the Bayes Factor approximation, a difference between BIC scores of such a large magnitude translates to extremely strong evidence in favor of the full model). This suggests that each condition

¹ Other models that were compared with the “unique parameter values” model to test for interaction effects were also found to be inferior according to BIC. (For instance, a model that allowed the PC, NON-BIASED FEATURE condition to have different parameter values to the other five conditions.)

had different learning curves – that is, that participants did not behave identically in each condition.

As Figure 2 demonstrates, the main effect was that learning was faster overall when the task occurred in a social context than when it was presented on a computer. Presenting the category learning task in a social context led to improved learning performance overall². It seems that participants were much more engaged, and thus solved the task quite quickly across all three of the SOCIAL conditions.

There was a more pronounced difference between the LABEL, BIASED FEATURE and NON-BIASED FEATURE conditions when the stimuli were presented on the PC than when they were presented in a social context. That said, in both the SOCIAL and PC conditions, learning was slowest in the NON-BIASED FEATURE conditions, and fast in the BIASED FEATURE conditions, as expected. Of primary interest is to compare performance in the LABEL conditions with that of the other conditions. For both the SOCIAL and PC conditions, learning speed in the LABEL condition was closer to that of the BIASED FEATURE condition than to that of the NON-BIASED FEATURE condition. However, while on the PC, learning in the LABEL condition was slower than learning in the BIASED FEATURE condition. In contrast, in the SOCIAL conditions, the learning curves of LABEL and BIASED FEATURE conditions were very similar. This suggests a weak effect that labels were more privileged in the social context than on the computer. Nonetheless, in either context, diagnostic labels did not help category learning beyond help that could be given by a diagnostic biased feature.

Why was learning not *fastest* in the LABEL conditions? Let us consider the difference in the learning task between the LABEL and BIASED FEATURE conditions. To successfully complete the category learning task, participants in all conditions needed to: 1) notice that one particular feature dimension was diagnostic (e.g., the labels); and 2) learn the match between each particular diagnostic feature value and a target feature value (e.g., that “Bragens” wanted the dagger, and “Lathors” wanted the hammer). However, the BIASED FEATURE condition was easier: the diagnostic feature dimension (clothing) was not only salient and meaningful (and thus easy to notice), but each outfit also meaningfully corresponded to an item (e.g., the robe outfit matched with the staff). Thus, participants could essentially come to the task already knowing the correct answers. The LABEL condition was actually a more difficult task, because although the diagnostic feature dimension was perceptually salient, people needed to learn an arbitrary match between the novel names and the target features. It is interesting that despite the added difficulty, learning in the LABEL

² Exponential functions for LABEL, BIASED FEATURE and NON-BIASED FEATURE conditions were $Y = 3.75\exp(-0.10X)$, $Y = 3.37\exp(-0.17X)$, and $Y = 2.76\exp(-0.04X)$ for the PC conditions, and $Y = 2.53\exp(-0.20X)$, $Y = 2.90\exp(-0.24X)$, and $Y = 4.14\exp(-0.19X)$, for the SOCIAL conditions, respectively. Note that the two parameters vary between conditions; larger a indicates more errors at the beginning of training and larger b indicates faster learning.

Figure 3: Learning curve averaged across sets of 4 trials, and averaged across participants in this condition. The exponential function is fit to the error data.

conditions was similar to that of the BIASED FEATURE conditions. However, the added difficulty might explain why learning in the LABEL conditions was not fastest.

To determine whether this explains the observed similarity between the LABEL and BIASED FEATURE conditions, we ran another experimental condition on the PC with 17 new participants³. The category learning task was identical⁴ to that of the PC, BIASED FEATURE condition, with clothing as the diagnostic feature dimension; however, the feature values no longer matched with the expected target feature values. Counterintuitively, the “lumberjack” wanted the dagger, the “warrior” wanted the hammer, the “tradesperson” wanted the staff, and the “wizard/priest” wanted the timber axe. This new condition still had the salient and expectedly meaningful clothes features as the diagnostic dimension, but the match between feature values was arbitrary. As Figure 3 shows, learning was slowed nearly to the same level as in the PC, NON-BIASED FEATURE condition. This suggests that the fast learning in the BIASED FEATURE condition was due to the pre-existing knowledge of the mapping between outfits and target items. Learning could be fast in the LABEL condition because the names were completely novel and “blank”; unlike the clothes in the new condition, the LABEL condition did not require any unlearning of associations between the diagnostic dimension and the target feature dimension.

Discussion

We set out to explore whether social context has an impact on the status of category labels for adults. We investigated whether people would pay special attention to labels presented in a social context, and hence learn quickly when these labels *are* most informative. While there was some suggestion that labels were more privileged in a social context than they were on a computer, the main result was

³ Participants were undergraduates at the University of Adelaide, or recruited from the general community (9 males). Ages ranged from 17 to 38 years. Participants received AU\$5.

⁴ Feedback was slightly different in this condition, due to the availability of images: participants did not see an image of the correct target item being held by the alien creature.

that people can solve a category learning task much faster when they are in an engaging, social context, regardless of whether a label or another feature is actually more informative. We suspect that the participants were more motivated to do well in the presence of a human teacher and with a more enjoyable, interactive task. When the task is not social, novel labels are privileged over non-salient and arbitrarily-matched features, but are no more useful than biased features. Nonetheless, it is interesting that learning in the LABEL conditions was fast, despite participants having to learn an arbitrary match between each novel label and the target feature. Presumably, if the labels were *not* novel and were appropriately matched (e.g., “Wizard” and “Warrior”), the task would become trivially easy and participants would learn even faster.

The results of this study support an intermediate view between labels being “just another feature” and having a unique, privileged status. Novel labels can aid category learning better than arbitrary (or biased but arbitrarily matched) features can: labels are salient, and novel labels permit new associations with features to be learned without being hindered by knowledge about existing feature associations. However, context matters: if people are already fully engaged with the category learning task, there is less scope for labels to aid learning beyond other features. One caveat to this finding is that perhaps the influence of labels in the social context was somewhat hidden by a ceiling effect, since our rule-based category structure was a simple one, quickly solved by most participants. More challenging category structures may reveal a larger influence of labels within a social context.

Further work is required to determine whether adults *process* labels differently to other features, or simply weight them more heavily. Gliozzi, Mayor, Hu and Plunkett (2009) contrast an *unsupervised feature-based account* and a *supervised name-based account* of category formation. According to the latter account, objects given the same name belong to the same category, and so labels act as invitations to form categories and highlight commonalities between objects. The unsupervised feature-based account says that labels have the same status as other features. Labels may vary in salience, just like other features, but are handled with the same statistical inference processes as are other features. The model by Gliozzi et al. (2009) suggests that for infants, labels play a mundane but powerful role as simply additional features. Our study, and the experiments by Yamauchi and Markman (e.g., 1998; 2000a) are consistent with this view.

Finally, this experiment has implications for adult category learning studies that are not presented in an engaging, social context. We found that presenting a category learning task in the absence of a social context does not encourage optimal learning behavior. Category learning on a computer may not reflect category learning in the more engaging situations typically encountered in real life, so it is worth understanding category learning in more naturalistic, social contexts.

Abstract

A hallmark of human cognition is the ability to learn from others—both via language and via non-linguistic cues. Children are sensitive to actions done for their benefit, treating pedagogical acts as conveying important information (Csibra & Gergely, 2009). The current research tapped children's exploration to investigate whether seeing a causal property either demonstrated pedagogically or produced accidentally influences children's expectations about that property's extension to other kind members. Experiment 1 found striking differences in 3- and 4-year-olds' exploration when a property was demonstrated intentionally rather than accidentally. Experiment 2 replicated this effect while also investigating possible influences of the emotional valence of causal events and the salience of property information. These experiments reveal that preschoolers use pedagogical cues to make inferences about generalizability and guide their exploration.

Keywords: Pedagogy; Exploratory Play; Inductive Inference; Causal Learning.

Introduction

One fundamental aspect of human cognition is our ability to learn from and teach others. Our abilities to read others' intentions and engage in collaborative learning may provide the necessary foundation for human culture, from law and government to industry and education (Gergely & Csibra, 2005; Tomasello, 1999). Children's understanding of intentions is inherent to many domains, including word learning (Baldwin, 1991, 1993a, 1993b) and imitation (Carpenter, Akhtar, & Tomasello, 1998; Meltzoff, 1995). Recent work has elaborated on the importance of explicit teaching and demonstration, which fundamentally rely on children's ability to read intentions. Tomasello and Carpenter (2007) argue that "instructed learning" is key to acquiring cultural knowledge, such as what we call objects and how we use them, and Csibra and Gergely (2006, 2009) suggest that humans have adapted a faculty for "natural pedagogy," enabling efficient social learning. On this account, children should treat pedagogical cues (e.g., eye gaze, pointing) as signaling that information is not only important, but that it is culturally agreed-upon and generalizable.

Indeed, pedagogical cues appear to influence processing of information even in infancy. For example, 8-month-olds

expect eye gaze to be directed at referent objects when accompanied by pedagogical cues (Csibra & Volein, 2008). Further, pointing leads 9-month-olds to privilege a novel objects' identity over current location in memory (Yoon, Johnson, & Csibra, 2008). And when 14-month-olds see a person pedagogically convey affective information (e.g., disgust) about an object, they treat it as a stable property of the object (Gergely, Egyed, & Király, 2007), and expect others to react similarly towards it (Egyed, Király, Krekó, Kupán, & Gergely, 2007).

Thus, even infants treat pedagogy as communicating important information about novel objects. However, it is as yet unclear whether children take such information as generalizable to a kind, rather than merely to a particular object. Assessing whether novel information should be generalized to a kind is critical in category and concept formation, where children rely on others to impart often otherwise unknowable information (Gelman, 2009; Harris, 2002; Harris & Koenig, 2006). Such knowledge transmission is often linguistic, using language that refers to kinds and categories, and children make a variety of inductive inferences on the basis of kind-referring language. For example, children take labels as referring to kinds that share nonobvious properties, and generalize novel properties on the basis of shared labels—which signal shared category membership—rather than perceptual similarity (e.g., Booth & Waxman, 2002; Gelman & Coley, 1990; Gelman & Markman, 1986, 1987). Moreover, recent work has demonstrated that preschoolers expect novel objects that share a label to share a novel causal property, and selectively explore those objects more when that property fails to extend to additional kind members (Schulz, Standing, & Bonawitz, 2008). Children also understand that information conveyed in a generic statement (e.g., "dogs bark") has greater inductive potential than information conveyed non-generically (e.g., "this dog barks") (Cimpian & Markman, 2008; Gelman, Star, & Flukes, 2002; Hollander, Gelman, & Raman, 2009), and information conveyed generically becomes more central to their kind representations (Cimpian & Markman, 2009).

However, it is important to note that while linguistic cues such as kind labels are powerful in driving generalization, they are not always used pedagogically. One can use object or kind labels without having any intention of pedagogically conveying information, and certainly without intending such information to be taken as generalizable. Thus it might be

important for children to make use of non-linguistic cues when assessing the generalizability of novel information.

Indeed, Gergely and Csibra (2009) suggest that at the core of generic knowledge transmission is pedagogical intent—an intent to explicitly impart new information to a recipient—and that children are sensitive to whether or not information is communicated for the purpose of teaching them something important. Similar to a Gricean view of communication (cf. Clark, 1996; Sperber and Wilson, 1986), in which we expect speakers to be clear and informative, children may infer that when an adult intentionally communicates information for their benefit, it is because the adult intends to teach them something relevant and important, and thus children may use pedagogical cues to gauge generalizability. Given this, we hypothesize that, even given a shared label, children may make stronger inferences about the whether a property is generalizable when it is demonstrated pedagogically, treating it as more conceptually central and inferring that other kind members should share that property.

To test this, our methodology builds on prior research which has established that exploratory play is a window onto children's implicit inductive processes. Having learned that an exemplar of a kind has a causal property, young children, even infants, explore more upon encountering exemplars that share a kind label, but which lack that property (Baldwin, Markman, & Melartin, 1993; Schulz et al., 2008). In the current research, we tapped children's natural exploration to investigate whether, even given objects that share a kind label, they would form different expectations about generalizability depending on whether a novel property was demonstrated intentionally or produced accidentally. If so, then when a property is intentionally demonstrated for them, but fails to obtain for other kind members, children should explore more than when that same property is produced accidentally.

Experiment 1

In Experiment 1 we taught children a name for a novel object, and either intentionally demonstrated or accidentally produced a novel causal property (magnetically picking up paperclips). We then presented children with an identical set of exemplars with the same label but which lacked the property (they were not magnetic), and let them play.

Methods

Participants Thirty-two three-year-olds (16 girls; $M = 42$ months; range = 36–46 months) and 32 four-year-olds (16 girls; $M = 54$ months; range = 48–61 months) from a university preschool participated. Children came from predominantly middle- and upper-middle-class families, representing a variety of ethnic groups. Children were randomly assigned to condition, equating for gender and age.

Materials The novel objects were small wooden blocks. The active block had magnetic tape on one end, while the inert blocks had non-magnetic tape. All were covered with black tape, with green tape covering the magnetic/non-magnetic end.

Procedure All children were tested in a private room in their preschool by a trained experimenter. Children first learned a novel label (blicket) for the active block. When asked for the blicket, all children successfully selected it from 4 distracters on two trials, without error.

After learning the word, children did a short distracter task (making paper houses). This served two goals. First, it distanced the word-learning, which was necessarily pedagogical, from the demonstration. Otherwise, children may have remained in a pedagogical “mindset.” Second, it provided a plausible excuse for placing a pile of paperclips on the table.

The experimenter then started to clean up the toys. He put away each the distracters saying, “Let’s put this away. He then picked up the active block, and again said “Let’s put this away,” which served as an implicit invitation to attend to the blicket. In the intentional condition, he said, “Look, watch this!” He deliberately placed the it on the paperclips, picked it up (with paperclips attached), and looked at it, saying “Hmmm” in a neutral tone. He then placed it next to the paperclips. Next, he placed 10 inert blocks on the table, saying, “here are some blickets.” The accidental condition was *identical*, except that the experimenter appeared to “accidentally” drop the block on the paperclips as he was putting it away, exclaiming “Oops!” As in the intentional condition, he picked it up with paperclips attached, looked at it, said, “Hmmm,” and placed it next to the paperclips.

The experimenter then told the child to “go ahead and play” while he left the table and sat facing away from the child for 60 seconds. Upon returning, the experimenter introduced a puppet and asked the child, “Can you tell Mr. Monkey about blickets?”

Results

None of the 3-year-olds explored the blickets in the accidental condition (leading to zero variance in that cell of the design), precluding parametric analyses. We analyzed 3- and 4-year-olds’ responses separately, using non-parametric Mann-Whitney U and χ^2 tests.

4-year-olds Although there were no differences across conditions in whether or not 4-year-old children explored the blickets, they showed striking differences across conditions in the nature of that exploration, specifically the amount of time they spent exploring and the number of times they tried to elicit the property from the inert blickets. When 4-year-olds saw the property demonstrated intentionally, they spent more time trying to pick up paperclips with the blickets ($M = 46.94$ s, $SD = 21.38$) than when they saw it produced accidentally ($M = 24.69$ s, $SD = 25.02$), $U = 66.0$, $N = 32$, $p = 0.019$.

Four-year-olds also made more attempts to pick up paperclips with the blickets ($M = 9.25$, $SD = 7.62$) in the intentional condition than the accidental condition ($M = 2.94$, $SD = 3.45$), $U = 61.5$, $N = 32$, $p = 0.011$.

3-year-olds Three-year-olds showed an analogous effect of condition, which was even starker than for the 4-year-olds. In the accidental condition, zero out of 16 children explored at all, compared with 8 out of 16 in the intentional condition, $\chi^2(1, N = 32) = 10.67$, $p = 0.001$. Thus, despite lower overall levels of exploration, 3-year-olds were sensitive to how the property was produced, and this guided their inferences and exploration

Discussion

These results provide compelling evidence that children use pedagogical cues to guide their inductive inference and exploration. When 4-year-old children were deliberately shown a causal property of a novel object in a pedagogical manner, they explored more upon discovering that the property did not obtain for additional kind members, indicating that they expected the property to generalize. Furthermore, 3-year-olds explored only in the Intentional condition, suggesting a sensitivity to intentional demonstration even at a younger age.

Two additional factors beyond the pedagogical cues may have influenced children's exploration. First, to convey that it was accidental the experimenter said "Oops!" after producing the property in the accidental condition. But this may have also marked the property as negative, potentially inhibiting exploration. Additionally, the conditions may have produced slightly different evidence—more paperclips may have stuck to the block in the intentional condition, making the property potentially more salient. Experiment 2 explored the possible effect of these factors on children's exploration. We added an enthusiastic exclamation ("Wow!") in both conditions to mitigate any influence of negative affect, and also equated the number of paperclips picked up across conditions.

Experiment 2

The results of Experiment 1 make clear that, even when objects share a kind label, whether or not a property is demonstrated in an intentional, pedagogical manner has a powerful effect on children's inferences about the generalizability of that property and their exploration of novel kind members. Further, as mentioned above, there are other potentially interesting factors that could also be influencing children's exploration—specifically the inherent negativity of accidental events and the varying salience of the property information. If children are sensitive to the affective valence of causal events and attuned to the saliency of particular properties in making inferences and guiding exploration of novel kinds, then we might expect that equating these factors across conditions could dampen

the effect of the manner of demonstration. However, if children's sensitivity to pedagogical cues is singularly important in guiding inference and exploration, equating for other facets of the event might have little impact on the effect of intentional demonstration.

Methods

Participants The participants were an additional 32 3-year-olds (16 girls; $M = 41$ months; range: 39-46 months) and 32 4-year-olds (16 girls; $M = 52$ months; range: 48-57 months), with comparable backgrounds to children in Experiment 1.

Procedure The procedure was identical to Experiment 1 with several modifications. First, while maintaining the manipulation of saying either "Look, watch this" or "Oops!" the experimenter also exclaimed, "Wow!" after producing the property in both conditions, rather than simply saying, "Hmm." This should mitigate any inhibitory effect that exclaiming "Oops!" in the accidental condition might have had on children's exploration. Second, we controlled for the number of paperclips picked up across conditions. The experimenter always picked up 2 paperclips in the intentional condition, while in the accidental condition the mean was 2.41 paperclips.

Results

Unlike Experiment 1, in which not one 3-year-old in the accidental condition explored, some 3-year-olds in both conditions of Experiment 2 did explore. However, violations of assumptions of normality and homoscedasticity precluded parametric comparisons across age groups. Instead, we used non-parametric ordinal logistic regressions (see Cimpian, 2009), with condition and age as predictors, to compare exploration across the two age groups and two conditions.

These analyses revealed a main effect of condition on children's exploration, with children in the intentional condition spending more time exploring (Wald $\chi^2 = 10.05$, $df = 1$, $p = 0.002$) and making more attempts to elicit the property (Wald $\chi^2 = 18.29$, $df = 1$, $p < 0.001$) than children in the accidental condition. The analyses also revealed a main effect of age, with 4-year-olds spending marginally more time exploring (Wald $\chi^2 = 3.21$, $df = 1$, $p = 0.073$) and making significantly more attempts to elicit the property (Wald $\chi^2 = 6.82$, $p = 0.009$) than 3-year-olds. To explore these effects further, we followed up these analyses by conducting Mann-Whitney U tests within each age group.

4-year-olds As in Experiment 1, 4-year-olds spent more time exploring in the intentional condition ($M = 40.63$ s, $SD = 19.57$) than in the accidental condition, ($M = 20.75$ s, $SD = 22.27$), $U = 70.5$, $N = 32$, $p = 0.029$. They also made more attempts to elicit the property in the intentional condition ($M = 7.63$, $SD = 4.53$) than in the accidental condition ($M = 2.81$, $SD = 2.46$), $U = 44.5$, $N = 32$, $p = 0.001$.

3-year-olds As in Experiment 1, significantly more 3-year-olds explored in the intentional condition (12 children; 75%) than in the accidental condition (5 children; 31%), $\chi^2(1, N = 32) = 6.15, p = 0.013$. Additionally, 3-year-olds spent more time exploring in the intentional condition ($M = 32.38$ s, $SD = 23.48$) than the accidental condition ($M = 11.56$ s, $SD = 21.09$), $U = 68, N = 32, p = 0.023$, and made more attempts to elicit the property in the intentional condition ($M = 5.63$, $SD = 6.29$) than the accidental condition ($M = 1.00$, $SD = 2.76$), $U = 59.5, N = 32, p = 0.008$. Thus, as with the older children, 3-year-olds used pedagogical cues to assess the generalizability of new information and guide their exploration.

Discussion

Even when controlling for the emotional valence of the event and the salience of the property, children showed different patterns of inductive inference and exploration on the basis of whether a property was demonstrated intentionally. Having seen a property intentionally demonstrated rather than produced accidentally, 3- and 4-year-olds showed increased exploration when that property failed to obtain for other kind members.

General Discussion

These experiments provide initial purchase on the question of how intentional demonstration influences children's inductive inferences. While previous research has documented an early sensitivity to pedagogy (Csibra & Volein, 2008; Egyed et al., 2007; Gergely et al., 2007; Yoon et al., 2008), the current work directly investigates the role of pedagogical cues in the process of theory-based categorization and concept formation in young children. As early as age 3, children take intentionally demonstrated information as more kind-relevant and generalizable than identical evidence produced accidentally.

Recent work has suggested that pedagogy might be a "double-edged sword," potentially dampening children's natural curiosity and constraining learning to only what is being taught (Bonawitz et al., 2009). However, our data indicate that children do not merely learn exactly what is taught (in our case, that a particular novel object is magnetic), but rather infer from pedagogical cues that this is an important and generalizable property of the novel kind. Upon encountering evidence conflicting with this inference, having seen the property demonstrated pedagogically increased curiosity and exploration. Thus, pedagogy may facilitate deeper learning of socially or culturally important information. Particularly to the extent that children are intuitively geared towards to learning not simply everything one can do with an object, but rather what we as a group or society use such artifacts for (Kelemen, 1999; Kelemen & Carey, 2007), selective use of pedagogical cues in this manner may be particularly important.

It is important to note that in the current research, we have not directly addressed the distinction between *pedagogical* as opposed to simply *intentional* action. In the current studies, the intentional condition was both intentional and pedagogical, while the accidental condition was neither. It is possible that simply seeing an artifact used in an intentional manner is enough to lead children to infer that other objects of the same kind can be used in the same way. However, children may remain particularly attuned to whether or not that action was done with *pedagogical* intent—that is, with the purpose of teaching them something new—or merely with the intent of carrying out a particular function. This is an important question, and one which we are addressing in further research.

Another open question what children are learning from, on one hand, information conveyed by the demonstration, and on the other hand, evidence produced by their own exploration. It is precisely this conflict between inferences about generalizability made on the basis of pedagogical cues and evidence that the property in fact fails to generalize which appears to drive continued exploration. But of course this conflict remains even after exploration, and how children resolve this conflict is as yet unclear.

More broadly, these results support the idea that, as generic language conveys information about the generalizability and conceptual importance of new information (Cimpian & Markman, 2009; Gelman et al., 2002; Hollander et al., 2009), so too does intentional, pedagogical action. When presented with the same novel causal property in a pedagogical manner rather than an accidental one, children make appear to make generic, kind-based inferences that drive their exploration. Furthermore, this obtains even when objects in both conditions share a label. Kind labels are known to license category-based inductive inferences, (e.g., Gelman & Markman, 1986), and having shared versus distinct kind labels does influence exploratory play (Schulz et al., 2008). Our research demonstrates that pedagogical cues play an important role above and beyond that of the kind label.

When facing inductive problems in generalization, children have many sources of information available to them, both non-social (e.g., observation, exploration, and prior knowledge) and social (e.g., labels, generic language, intentional and pedagogical cues). Children's ability to integrate sources of information—especially when they conflict—is an important skill. The current research suggests that this ability is developing during the preschool years, and that by as young as 3 children are particularly sensitive to intentionally communicated information as they form and test hypotheses about the world.

Acknowledgments

This research was supported by a NSF Graduate Research Fellowship to the first author. We are grateful to the teachers, staff, parents, and children at Bing Nursery School

and the Arboretum Child Care Center for their participation, to Hannah Jaycox and Cole Murphy-Hockett for their assistance with data collection and coding, to Andrei Cimpian for comments on a previous draft of this paper, and to Krishna Savani for advice on statistical analyses.

The Facilitative Effect of Context on Second-Order Social Reasoning

Abstract

This paper is about higher-order social reasoning such as “I think that you think that I think ...”. Previous research has shown that such reasoning seriously deteriorates in complex social interactions. It has been suggested that reasoning can be facilitated greatly if an abstract logical problem is embedded in a context. This has not yet been tested for higher-order social reasoning. We presented participants with strategic games that demand higher-order social reasoning. The games were embedded in the context of a marble game. Participants performed really well, that is, almost at ceiling. We argue that context has a facilitative effect on higher order social reasoning.

Keywords: Theory of Mind; Social Cognition; Higher-order Social Reasoning; Strategic Game.

Social Reasoning

In many social situations we need to reason about one another. We do so to plan our actions and predict how our behavior might affect others. The ability to reason about another’s knowledge, beliefs, desires and intentions is often referred to as Theory of Mind (Premack & Woodruff, 1978). It has been extensively investigated in children and seems to develop around the age of 4 years (Wimmer & Perner, 1983; but see Onishi & Baillargeon, 2005). Nevertheless, reasoning about others is very demanding, even for adults, which becomes apparent in more complex interactions. So far, empirical results have shown social reasoning to be far from optimal (Flobbe, Verbrugge, Hendriks, & Krämer, 2008; Hedden & Zhang, 2002). It has been suggested that (social) reasoning might be facilitated if it is embedded in a context (Wason & Shapiro, 1971). In the current study, we investigate whether social reasoning really is difficult and whether embedding it in a context can facilitate it.

When we ascribe a simple mental state to someone, we are applying first-order social reasoning. For example, imagine a social interaction between Ann, Bob and Carol. If Bob thinks “Ann knows that my birthday is tomorrow”, he is applying first-order reasoning, which covers a great deal of social interaction.

However, first-order reasoning is not sufficient to cover more complex social situations. The interaction between Ann, Bob and Carol can easily demand reasoning of one order higher: If Carol thinks “Bob knows that Ann knows that his birthday is tomorrow”, she is making a second-order attribution.

Bob’s first-order attribution and Carol’s second-order attribution are hierarchically structured: Bob applied first-order reasoning by attributing a mental state to Ann, and Carol applied second-order reasoning by attributing first-order reasoning to Bob. A third-order attribution involves

the reader attributing second-order reasoning to Carol, and so forth.

The depth of reasoning in humans is constrained by cognitive resources (Verbrugge, 2009; Flobbe et al., 2008; Hedden & Zhang, 2002). As the order of reasoning increases, the demands on cognitive processing increase as well. Cognitive resources and processing speed seem to increase with age (Fry & Hale, 1996), and that increase could allow for the representation of increasingly more complex mental states. Findings from developmental studies support that idea. Where first-order social reasoning is acquired at the age of around 4 years (Wimmer & Perner, 1983), second-order social reasoning seems to develop some years later, at the age of around 6 to 8 years (Perner & Wimmer, 1985). However, 6- to 8-year-olds do not understand all kinds of mental states, and even adults cannot readily apply second-order reasoning in all kinds of contexts (Flobbe et al., 2008; Hedden & Zhang, 2002).

Paradigms to Test Social Reasoning

There are a few paradigms to test social cognition. Probably the most familiar paradigm is the False-Belief task (Wimmer & Perner, 1983), which has been adapted to test second-order social cognition (Perner & Wimmer, 1985). In a typical second-order False-Belief story, two characters, John and Mary, are independently informed about the transfer of an object, an ice-cream van, from one location to another. In the story, both John and Mary know where the van is, but John does not know that Mary also knows that the van has moved to a new location. Participants are told the story and asked where John thinks Mary will go for ice cream. To answer this question correctly, participants have to be able to represent the second-order false belief “John thinks that Mary thinks the van is still at the old location.”. In Perner and Wimmer’s (1985) study, some children of 6 to 7 years of age were able to make such second-order attributions, but only under optimal conditions; when the inference of second-order beliefs was prompted.

Apart from some concerns about the False-Belief task’s aptness to test for the presence of a Theory of Mind (Bloom & German, 2000), Perner and Wimmer (1985) expressed concerns about the generality of their findings as participants were presented “rather pedestrian problem[s] of knowing where somebody has gone to look for something” (p. 469). They stressed that investigations into higher-order social reasoning will only achieve theoretical importance if a link with other domains can be established.

Various other language comprehension paradigms have been used to test social cognition (e.g., Van Rij, Van Rijn, & Hendriks, to appear; Hollebrandse, Hobbs, De Villiers, & Roeper, 2008; Hendriks & Spender, 2006). Hollebrandse et al. (2008) presented discourse with multiple, recursive

embeddings. In their Experiment 1, no second-order reasoning was observed in children and adults. Hollebrandse et al.'s (2008) findings led them to conclude that "second-order theory of mind is a different milestone than first-order theory of mind." (p. 276).

The problem with the paradigms mentioned above is that they depend heavily on language skills (Apperly, Samson, Chiavarino, & Humphreys, 2004; Bloom & German, 2000), and cannot be adapted easily to investigate higher orders of reasoning. A paradigm that does not depend that much on language skills is that of strategic games (Verbrugge, 2009; Flobbe et al., 2008; Hedden & Zhang, 2002). In strategic games, players have to reason about one another, because a player's payoffs depend on what the other players do, and vice versa. Games are less prone to semantic idiosyncrasies and are as such easier to control. That allows games to be presented repeatedly in different variations to acquire a more accurate measure of second-order reasoning.

Strategic Games

Hedden and Zhang (2002) used a strategic game to study first- and second-order social reasoning. It is a sequential-move game, which is played on a 2-by-2 matrix (Figure 1). In each cell there are separate payoffs for Player 1 and Player 2, respectively. The goal is to attain the highest possible payoff. The players take turns; Player 1 begins. At each turn, a player has to decide whether to stay or to move to the next cell, as indicated in Figure 1. If a player decides to stay in a particular cell, the game ends and both players attain the respective payoffs in that cell. If a player decides to move, the turn passes to the other player.

Figure 1: Schematic overview of a matrix game (Hedden & Zhang, 2002). The first number in each cell is Player 1's payoff, the second Player 2's payoff. The goal is to attain the highest possible payoff. Participants first had to predict what the other player would do at cell B before making a decision what to do at cell A. In this example, Player 1 would have to predict that Player 2 will stay, because Player 1 will move if given a choice at cell C, leading to a lower payoff for Player 2, namely 2 instead of 4. Consequently, the rational decision for Player 1 is to move to cell B.

Hedden and Zhang (2002) asked participants to (1) predict what the other player would do (stay or move) at cell B, and (2) decide whether to stay or to move at cell A. The

first question provides a direct measure of what order of reasoning participants apply. To answer that question correctly, participants have to apply second-order reasoning; think about what the other player (at cell B) thinks that they think (at cell C). The second question measures whether the decisions that the participants make are based on the predictions that they have made. As a consequence of this procedure in which participants first have to predict what the other player will do, the application of second-order reasoning may not be completely spontaneous. Nevertheless, the proportion of games in which participants made second-order predictions is not that high, in the range of 60% – 70% at the end of the experiments 1 and 2, considering that by chance alone that proportion would be 50%, because there are just two predictions possible: either Player 2 stays or Player 2 moves.

Poor performance could imply that second-order social reasoning is difficult or that participants had difficulties understanding Hedden and Zhang's (2002) matrix games. Participants could have had difficulties to comprehend the task, because the games are very abstract. The matrix games of Hedden and Zhang (2002) would be less abstract if embedded in a context. Higher-order social reasoning, which seems to be very demanding in these games, might benefit from a context embedding.

Context Effects

Some studies have investigated whether reasoning can be facilitated if a problem is presented in a (social) context. The Wason Selection Task (Wason & Shapiro, 1971) is an example of a task to investigate effects of context on reasoning. Wason and Shapiro (1971) presented a logical problem in an abstract form to one group of participants and in a "thematic" form (i.e., embedded in a social context) to another group of participants. Ten out of sixteen participants in the thematic group solved the problem, opposed to two out of sixteen participants in the abstract group. That finding implies a facilitative effect of context on reasoning.

However, there is another interpretation of Wason and Shapiro's (1971) manipulation, according to which the abstract and thematic forms are not logically equivalent (Stenning & Van Lambalgen, 2004; Manktelow & Over, 1991). If the logical problem does differ for these forms, Wason and Shapiro's findings do not support the argument that context has a facilitative effect on reasoning. To really appreciate facilitative effects of context on (higher-order social) reasoning, it is important that the context in which we embed the matrix games of Hedden and Zhang (2002) does not change their logical form. Then, improved performance can be attributed solely to context effects.

Not just any context will facilitate (higher-order social) reasoning. Flobbe et al. (2008) embedded Hedden and Zhang's matrix games in a context. Participants played games in which they, together with the computer, drive a car. The games are an adaptation of the Centipede game (Rosenthal, 1981), and are logically equivalent to Hedden and Zhang's (2002) matrix games. In second-order games,

Figure 2: A zeroth-order (a), first-order (b) and second-order (c) Marble Drop game. The participant's payoffs are represented by a1 – a4, the computer's by b1 – b4, both in increasing order of value. The goal is to let the white marble end up in the bin with the highest attainable payoff. The diagonal lines represent trapdoors. At the first set of trapdoors, the participant decides which of both trapdoors to remove, at the second set the computer decides, and at the third set the participant again decides. The dashed lines represent the trapdoors that both players should remove to attain the highest payoff they can get.

the road has three junctions, which correspond with the transitions, from one cell to another, in Hedden and Zhang's matrix games. At each junction either the participant or the computer decides to move ahead (i.e., continue the game) if there is a higher payoff to attain further in the game, or to turn right (i.e., end the game) if there is no higher payoff to be attained further in the game. The participant and the computer alternately take seat in the driver's position; the one in driver's seat makes the decision.

The performance of the adult participants in Flobbe et al.'s experiment was higher than in Hedden and Zhang's study: the mean proportion of games in which the adult participants gave a correct second-order prediction was more than 70%. It is important to note that this proportion is an average over Flobbe et al.'s entire experiment, whereas in Hedden and Zhang's experiments the proportion of games in which the participants applied second-order reasoning did not reach 60% – 70% until the end.

Flobbe et al.'s findings support the idea that context facilitates reasoning. Their findings also show, as did Hedden and Zhang's, that second-order reasoning is not impossible. However, performance was low, considering that the participants were explicitly asked to reason about their opponent. Both Flobbe et al. and Hedden and Zhang asked participants to first make a prediction before making a decision. This procedure is expected to scaffold second-order reasoning, as it prompts the participants to think about the other player (and what that player might think of them).

We expect that performance can be much further improved with a simpler context. In Flobbe et al.'s task, participants alternately change driver's seat with another player, which is not common practice in every day life. In the next section we will present a context that is more intuitive and will require less explanation.

We argue that second-order reasoning is not that difficult if it is embedded in an apt context, and that the facilitative effects of context render the scaffolding effects of making predictions (before making a decision) obsolete.

Experiment: Marbles and Second-order Reasoning

We present games, which we will call Marble Drop, in which the path of a white marble, which is about to drop, can be manipulated by removing trapdoors (Figure 2). Experience with world-physics allows players to see easily how the marble will run through a game. The interface of the game is very insightful; players can quickly see who can change the path of the marble, at what point in the game.

Marble Drop games are logically equivalent to Hedden and Zhang's (2002) matrix games and Flobbe et al.'s (2008) Centipede games (which we show with an informal proof in <http://www.ai.rug.nl/~leendert/Equivalence.pdf>). Marble Drop games only differ in appearance. The payoffs are color-graded marbles, which can easily be ranked according to preference, lighter marbles being less preferred than darker marbles. The ranking makes it possible to have payoff structures similar to those in matrix and Centipede games. The sets of trapdoors in Marble Drop games correspond with the transitions, from one cell to another, in Hedden and Zhang's (2002) matrix games.

We used color-graded marbles instead of numbers (of marbles) to minimize the usage of numeric strategies other than first- and second-order reasoning. We observed such alternative strategies in pilot studies in which we presented Flobbe et al.'s (2008) Centipede games with payoff numbers. Participants reported to use strategies such as maximizing the difference in both players' payoffs, maximizing the sum of both players' payoffs, and obstructing the other player.

Figure 2 depicts example games of Marble Drop. The goal is to let the white marble end up in the bin with the darkest color-graded marble. Note, for illustrative purposes, the color-graded marbles are replaced with codes: a1 – a4 represent the participants' color-graded marbles and b1 – b4 represent the computer's color-graded marbles (which are of another color); 1 – 4 being light to dark grades. (See <http://www.ai.rug.nl/~meijering/MarbleDrop.html> for the

original Marble Drop games.) The diagonal lines represent the trapdoors.

In the example game in Figure 2a, participants need to remove the right trapdoor to attain the darkest color-graded marble of their color (a2). The game in Figure 2a is a zeroth-order game, because there is no other player to reason about.

In first-order games (Figure 2b) participants need to reason about another player, the computer. The computer is programmed to let the white marble end up in the bin with the darkest color-graded marble of its target color, which is different from the participants' target color. Participants need to reason about the computer, because the computer's decision at the second set of trapdoors affects at what bin a participant can end up.

In the example game in Figure 2b, if given a choice at the second set of trapdoors, the computer will remove the left trapdoor, because its marble in the second bin (b2) is darker than its marble in the third bin (b1). Consequently, the participant's darkest marble in the third bin (a3) is unattainable. The participant should therefore remove the left trapdoor (of the first set of trapdoors), because the marble of their target color in the first bin (a2) is darker than the marble of their target color in the second bin (a1).

In a second-order game (Figure 2c) there is a third set of trapdoors at which the participants again decide what trapdoor to remove. They need to apply second-order reasoning, that is, reason about what the computer, at the second set of trapdoors, thinks that they, at the third set of trapdoors, think.

Method

Participants Twenty-two Psychology students participated in exchange for course credit. Two were excluded because of not adhering to the instructions.

Stimuli The colors of the marbles were taken from the HSV (hue, saturation and value) space. A sequential color palette was computed by varying saturation, for a given hue and value. This resulted in 4 grades (with saturation from 1 to .2) for each of the colors orange (hue = .1, value = 1) and blue (hue = .6, value = 1).

The payoff structures are constructed to be diagnostic of second-order reasoning. First- and second-order reasoning should yield opposite predictions and decisions in order to allow us to see at what order participants are reasoning.

All payoff structures in the experiment demand second-order reasoning. Consequently, payoff structures in which Player 1's first payoff is a marble with a color gradient of 1 or 4 are excluded. It is evident that in the former case participants should continue the game and in the latter case participants should end the game, whatever the other player does. The same holds for Player 2's second payoff, because at that bin (underneath the second set of trapdoors), Player 2 decides what to do.

Also, payoff structures in which Player 2's payoffs in bins 3 and 4 are lower or higher than the payoff in bin 2 are

excluded. Player 2 does not need to consider Player 1's payoffs in these structures.

The payoff structures are doubly balanced for the number of left/right (trapdoor removal) predictions about Player 2 and decisions of Player 1.

Design & Procedure Before the experiment took place, participants were tested on colorblindness. They had to be able to distinguish the two colors blue and orange, and the 4 grades of each color. The experiment consisted of 3 blocks: a training block, an experimental manipulation block, and a test block.

The training block consists of zeroth-, first- and second-order Marble Drop games, respectively. In zeroth-order games, participants do not have to reason about another player. They have to find out in what bin the darkest color-graded marble of their target color is, and what trapdoor to remove to let the white marble end up in that bin. The target color is either blue or orange, which is counterbalanced between participants. If a participant's target color is blue, the computer's target color is orange, and vice versa. These games do not require social reasoning but are presented to familiarize the participants with the physics of the Marble Drop game. Participants are presented 4 zeroth-order games.

We assume that in first- and second-order games, participants reason about the decision of the computer at the second set of trapdoors. If a participant removes the left trapdoor of the first set of trapdoors, the white marble will drop into the first bin. If a participant removes the right trapdoor of the first set of trapdoors, the white marble will roll to the second set of trapdoors at which the computer decides what trapdoor to remove. If the computer removes the left trapdoor, the white marble will drop into the second bin. If the computer removes the right trapdoor, the white marble will drop into the third bin in first-order games, it will roll to the third set of trapdoors in second-order games. In the latter case, the turn passes to the participant. If the participant removes the left trapdoor, the white marble will drop into the third bin. If the participant removes the right trapdoor, the white marble will drop into the fourth bin. As soon as the white marble drops into a bin, participants are presented feedback ("correct!" or "incorrect!"). If they fail to let the white marble end up in the correct bin, a green arrow is depicted underneath the correct bin and participants are asked to explain verbally why that bin is the correct one. Participants are presented 8 first-order games and 8 second-order games.

In the experimental manipulation block, participants play second-order Marble Drop games. The participants are asked to decide what to do at the first set of trapdoors. They immediately receive feedback after making a decision. The experimental manipulation involves that one half of the participants is asked first to predict what the computer will do at the second set of trapdoors, before making a decision at the first set of trapdoors. This manipulation is included to investigate scaffolding effects of making predictions. In this block and the next, the games are not continued after the

participants have made a decision. The experimental manipulation block consists of 32 trials, all trials diagnostic of second-order social reasoning.

In the test block, the participants play second-order Marble Drop games. The participants that made a prediction before making a decision in the experimental manipulation block do not have to make predictions anymore. The test block has the same structure as the experimental manipulation block, except that none of the participants have to make predictions anymore.

The participants were randomly assigned to the group that makes a prediction and a decision in the experimental manipulation block and only a decision in the test block, the PD-D group, and the group that makes decisions in the experimental manipulation and the test block, the D-D group.

Results

To account for random effects of individual differences and payoff structures, we performed Linear Mixed-Effects (LME) analyses (Baayen, Davidson, & Bates, 2008). We first analyzed the proportion of games in which participants applied second-order reasoning (Figure 3). The analysis consists of a (logistic) LME with *block* (experimental manipulation and test) and *group* (PD-D and D-D) as fixed factors and *participants* and *payoff structures* as random factors.

Figure 3: Mean proportion of games in which participants applied second-order reasoning, presented separately for the PD-D and D-D groups in the experimental manipulation block and the test block. The standard errors are depicted above and below the means.

The grand mean is 0.94. The factors *block* and *group* are significant: $\beta = .809$, $z = 2.348$, $p = .009$ and $\beta = 5.721$, $z = 1.844$, $p = .033$, respectively. The interaction *group* \times *block* is also significant: $\beta = -1.024$, $z = -1.844$, $p = .033$.

Reaction Times The games in the experimental manipulation block are procedurally different for the PD-D and the D-D groups. We analyzed the reaction times of the games in the test block, because these are not procedurally different for the PD-D and the D-D groups.

After removing the trials in which participants unsuccessfully applied second-order reasoning, a LME analysis was performed, with *group* (PD-D and D-D) as a

fixed factor and *participants* and *payoff structures* as random factors.

Figure 4: Mean reaction times for the PD-D and D-D groups. The standard errors are depicted above and below the means.

The grand mean is 7.82 seconds. The factor *group* is significant: $\beta = 1.523$, $t = 3.09$, $p < .01$. On average, the participants in the D-D group were faster to make a decision than the participants in the PD-D group (Figure 4).

Discussion

The participants performed really well in the Marble Drop games (Figure 3). The proportion of games in which they successfully applied second-order reasoning was very high, at 94% correct. That proportion is much higher than in Hedden and Zhang's (2002) matrix games (60% - 70%) and Flobbe et al.'s (2008) Centipede games (slightly above 70%). This finding supports the idea that a context can facilitate reasoning. It matters in what context reasoning is embedded. Flobbe et al.'s context facilitated higher-order reasoning, but not as strongly as in our experiment, which has a simpler context.

The interaction between *block* and *group* is significant. The performance of the participants that made a prediction before making a decision in the experimental manipulation block, the PD-D group, is almost at ceiling in both the experimental manipulation block and the test block (Figure 3). On the other hand, the performance of the participants that did not make a prediction in the experimental manipulation block, the D-D group, is not yet at ceiling in the experimental manipulation block, but reaches ceiling in the test block (Figure 3). This finding could imply that the D-D group lacked a scaffolding effect of making predictions in the beginning of the experiment. However, the D-D group, which was not explicitly asked to predict what the other player would do (before making a decision), probably did learn to make predictions during the experimental manipulation block. Eventually, there was no difference in performance anymore in the test block.

The main effect of *block* can be mainly attributed to the D-D group. The performance of the participants in the D-D group increases to ceiling in the test block, whereas the performance of the participants in the PD-D groups already

reaches ceiling in experimental manipulation block and remains stable (Figure 3).

The participants not only performed better, they also responded faster in Marble Drop games than in matrix games. Mean reaction times of second-order predictions were approximately 10 seconds in matrix games (Hedden & Zhang, 2002), whereas mean reaction times of second-order predictions took less than 7.5 ($M = 7.1$, $SE = .57$) seconds in Marble Drop games for the PD-D group in the experimental manipulation block. Mean reaction times of second-order decisions (based on second-order predictions) were approximately 3.5 second in matrix games, and less than 2.5 ($M = 2.2$, $S = .77$) seconds in Marble Drop games for the PD-D group in the experimental manipulation block.

Although these comparisons with Hedden and Zhang's (2002) results are informal, the differences are considerable. The better performance in Marble Drop games than in Hedden and Zhang's (2002) matrix games probably is not caused by a difference in our participants' speed-accuracy tradeoff. Our participants applied second-order reasoning more often and faster, which supports the idea that our context facilitated higher-order reasoning.

In the test block, on average, the participants in the D-D group were faster to make a decision than the participants in the PD-D group (Figure 4). In the test block, the behavior of the participants in the PD-D group could still have been constrained in a stepwise procedure of first making a prediction, then a decision. The participants in the D-D group were given more freedom in the experimental manipulation block to naturally interleave a prediction between the steps in their decision-making, which could have caused them to be faster than the participants in the PD-D group.

General Conclusion

Our findings seem to imply that embedding a logical problem in a context greatly facilitates (social) reasoning. Because of the facilitative effects of context embedding, second-order reasoning did not need to be scaffolded by explicitly asking participants to predict the behavior of other players. Second-order reasoning might still be difficult, but participants were able to apply it in Marble Drop games.

The question remains what strategies participants used to arrive at second-order decisions and predictions. We intend to investigate this with computational models (e.g., Van Maanen & Verbrugge, submitted). These models can help us to explore the cognitive mechanism involved in higher-order social cognition, and whether higher-order social cognition will generalize to more complex tasks.

Abstract

Phonology is held to play a central role in typical reading development (Shankweiler et al., 1979) and sensory or phonological deficits are often held to be a primary cause of reading disability (Snowling, 2008). However, little is known about the nature of phonology at the endpoint of atypical reading development -- that is, in adult poor readers. We examined the time course of (auditory) lexical activation, competition, and learning in a community sample with a high proportion of poor readers in two experiments. In Experiment 1, contrary to our expectations, we found that poor readers were *more* sensitive to subphonemic coarticulatory cues than better readers. In Experiment 2, we examined the time course of word learning along with the time course of phonological competition. Poor readers differed from better readers in the trajectory of learning, and also in phonological competition: typical readers exhibited strong competition between rhymes, but poor readers did not. Simulations with a computational model suggest that instability in phonological organization (simulated via reduced lateral inhibition) can explain differences in both studies in counter-intuitive ways, shedding new light on an old problem.

Keywords: phonology; reading; dyslexia; reading disability; spoken word recognition; computational modeling; visual world paradigm.

Introduction

A fundamental principle shared by nearly all theories of reading is that phonology plays a key role mediating the mapping from print to meaning (Harm & Seidenberg, 2004; Shankweiler et al., 1979; Snowling & Hulme, 2005; Ziegler & Goswami, 2005). This follows from repeated findings that impairments in reading are correlated with deficits in phonological abilities (Shankweiler et al., 1977; Snowling, 1981). While multiple hypotheses exist, linking the deficit to poor phonological quality (Joanisse, 1994) or low-level sensory impairments (e.g., Tallal, 1980), the precise nature of the phonological deficit in dyslexia and its causes remains a subject of intense debate.

Fairly little is known about the nature of phonological processing at the endpoint of atypical reading development, since studies of reading disability logically focus on developing samples. An exception is recent work by Szenkovits, Ramus, and colleagues (reviewed by Ramus & Szenkovits, 2008). They point out that deficits in phonological abilities in college-aged poor readers (self-

reported "presumed dyslexics") are most readily detected in tasks with significant working memory demands (phonemic awareness tasks, or verbal short-term memory tasks) or under time pressure (as in rapid auditory naming). However, in tasks that do not impose such demands, poor readers are not strikingly different from typical readers (most notably, they report that poor readers in their sample exhibit phonological similarity effects similar to those exhibited by good readers, contra Shankweiler et al., 1977, who reported that poor readers fail to show such effects). Ramus and Szenkovits suggest that the phonological deficit in dyslexia therefore may not be one of phonological representation, but rather one of phonological *access* -- and so manifests as difficulty in rapidly retrieving phonological forms into working memory. This new take on phonology in dyslexia has the potential to illuminate the nature and basis of the phonological deficit in new ways.

Techniques for examining the time course of on-line language processing provide the means to examine this hypothesis more closely. We report preliminary results of a project investigating the phonological abilities of adult poor readers. We use stimulus manipulations and time course measures that have been used to investigate lexical activation and competition at a fine timescale (Dahan, Magnuson, Tanenhaus, & Hogan, 2001) and lexical learning (Magnuson, Tanenhaus, Aslin, & Dahan, 2003) in typical adults.

Experiment 1

In Experiment 1, we sought a sensitive test of the fine-grained phonological processing of our sample, but in a task that minimizes cognitive demands. The study reported by Dahan, Magnuson, Tanenhaus and Hogan (2001) fits the bill. Dahan et al. investigated the impact of misleading coarticulation (subcategorical -- i.e., subphonemic -- mismatches). They achieved misleading coarticulation by cross-splicing recordings of words. For example, they took the initial consonant and vowel (CV) from "neck", cut as late as possible before the final stop consonant, and spliced it together with the final consonant of "net". This sounds like "net", but the vowel includes coarticulation consistent with /k/. They labeled this sort of item "W2W1" (word 2 spliced to word 1). They also had cases where the initial CV

Figure 1. Left: Sample display. Center: TRACE predictions. Right: Competitor fixations over time from Dahan et al. (2001).

came from a nonword ("nep" + "net" → N3W1). Finally, they included cross-spliced items without misleading coarticulation by splicing together two recordings of a target word like "net" (W1W1).

Dahan et al. presented these items with displays like the one shown in Figure 1, using the Visual World Paradigm (VWP; Tanenhaus et al., 1995). Subjects heard instructions like "point to the net". Eye movements were recorded as subjects followed the spoken instructions.

The motivation for their study was the apparent deficiency in the TRACE model (McClelland & Elman, 1986) identified by Marslen-Wilson and Warren (1994) using these kinds of materials, in that lexical decision reaction times appeared inconsistent with the time course of activation in TRACE. However, the time course measure provided by the VWP (Figure 1, right) showed that the TRACE predictions (Figure 1, center) were remarkably accurate. Crucially, subjects fixated the competitor, "neck," most when there was misleading coarticulation consistent with that word (W2W1 condition), and least when the coarticulation was fully consistent with the target (W1W1). Fixation proportions were intermediate when misleading coarticulation did not map onto a word (N3W1). TRACE predicts the W1W1 and W2W1 patterns intuitively; the word with best bottom-up match is initially activated most strongly. The N3W1 results follow because neither net nor neck has an advantage as the nonword coarticulation is heard; thus, both reach a relatively high level of activation before the disambiguating final consonant.

Predictions What might we predict for our sample? If their linguistic difficulties arise from imprecise phonological representations (e.g., the phonological quality hypothesis of Joanisse, 2004) or slow-to-activate phonological representations (e.g., the generalized slowing hypothesis; Kail, 1994), we might expect them to be less affected by misleading coarticulation, and so show weaker competition effects. On the phonological access hypothesis (Ramus & Szenkovits, 2008), if the task minimizes cognitive demands, our sample ought to look no different from a typical sample.

Methods

Participants The participants were 56 college-aged adults (mean age = 21) recruited from community colleges and

GED programs in the New Haven area. Previously, we have documented linguistic and other cognitive abilities in samples from this population (Braze et al., 2007), and demonstrated that the degree to which reading is subserved by common, supramodal brain areas also subserving speech is correlated with reading ability (Shankweiler et al., 2008). We examine this sample with a battery of 25 linguistic and other cognitive assessments. In this brief report, we only have room to mention that this population tends to lag in language and other cognitive domains, but a wide range of abilities is observed. Our goal is to conduct individual differences analyses. Given space constraints for the current report, though, we will compare the top 50% of readers in our sample with the bottom 50%. The most intuitive measure for conducting this median split is the standardized score from the Peabody Picture Vocabulary Test (which correlates closely with, e.g., a composite score derived from all subtests of the Woodcock-Johnson battery). The bottom 50% had standard scores ranging from 67 to 90, with a mean of 81. The top 50% had scores ranging from 91 to 137, with a mean of 104. The results we report do not differ if we remove, e.g., participants with low approximated IQ, and so the full sample is included.

Materials The auditory materials were those used by Dahan et al. (2001), and consisted of 15 word 1-word 2-nonword 3 triples (W1, W2, N3), such as *net*, *neck*, and *nep* (for the full set, see the Appendix B of Dahan et al.). The visual materials were similar to those used by Dahan et al., except that their line drawings were replaced with photographs.

Procedure The procedure was identical Dahan et al.'s. There were 3 lists, with 5 items assigned to each condition (W1W1 [consistent coarticulation], W2W1 [misleading cohort coarticulation], N3W1 [misleading nonword coarticulation]) in each list. Participants were randomly assigned to lists. On each trial, a fixation cross and four simple shapes appeared on the screen. When the participant clicked the cross, the trial began, and pictures of four objects appeared. A spoken instruction was presented over speakers, such as "point to the net; now click on it and put it below the circle." We tracked eye movements using an SR-Research Eyelink II head-mounted eye tracker, sampling at 250 hz. We tracked the probability of fixating each item

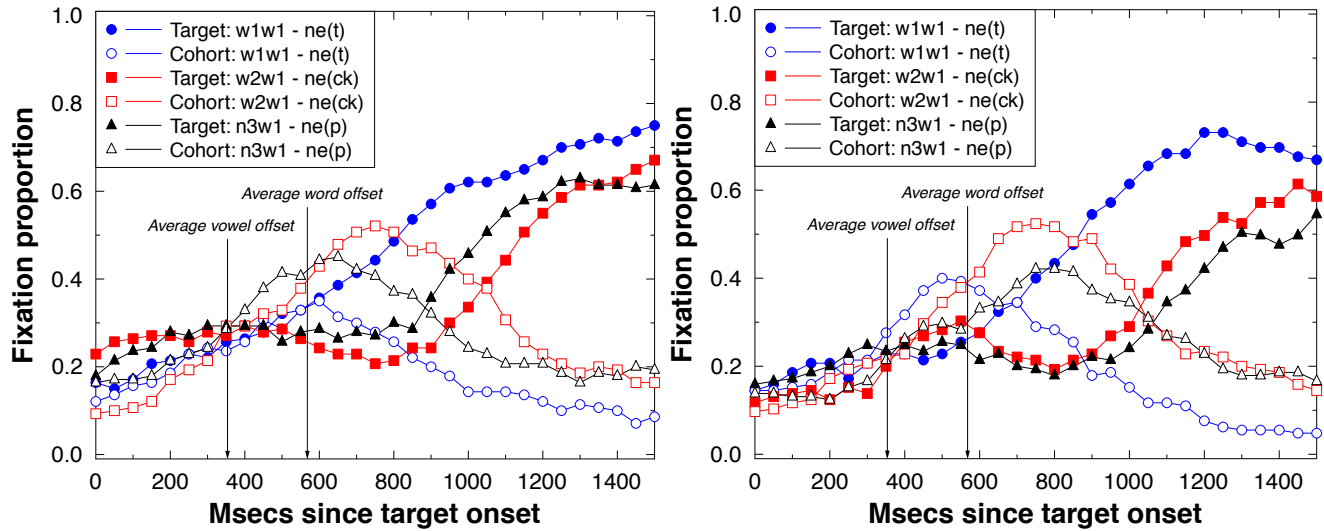

Figure 2: Subcategorical mismatch data for the top 50% (left) and bottom 50% (right) of readers from our community sample.

over time from the onset of the target word (e.g., *net*).

Results and discussion

Eye movements were parsed into saccades and fixations. Saccade time was attributed to the following fixation, since saccades are essentially ballistic; the initiation of a saccade is the earliest indicator of the choice to fixate the next gaze position. Eye tracking results are presented Figure 2. Qualitatively, the observed patterns for both halves of our sample resemble the (competitor) pattern in Figure 1. Notably, there is no apparent delay in the response to the bottom up signal in either half, when compared with the university sample in Figure 1. There are some differences between the two subsets in Figure 2 in the relative magnitude and timing of competitor proportion curves, but the most salient difference between the groups is in the target fixations in the mismatch conditions. The top 50% show the same ordering observed by Dahan et al.: $W1W1 > N3W1 > W2W1$. However, the pattern for the bottom 50% is $W1W1 > W2W1 > N3W1$. We explored this using a 2 (subset) \times 2 ($W2W1$, $N3W1$) ANOVA on mean target fixation proportion in the window from 200 msec after word onset (the expected average latency for a signal-driven saccade) to 1200 msec (approximate target peak latency).

There was a main effect of Subset (top=0.40, bottom=0.32; $F(1,54)=6.8$, $p=.01$), but not Condition ($F < 1$), and a significant interaction ($F(1,54)=4.2$, $p<0.05$). This was due to a reliable effect of condition for the top subset ($W2W1=.37$, $N3W1=.44$; $F(1,54)=5.4$, $p=.03$), but not for the bottom ($W2W1=.34$, $N3W1=.30$; $F<1$).

Thus, there are several interesting patterns. There is no apparent delay in bottom up response. However, the later time course is different in both subsets compared to the sample of Dahan et al. (2001), and the subsets differ from each other. Most notably, it appears that lexical competition differs in the bottom subset. Target proportions for the mismatch conditions are depressed throughout the analysis window in comparison to the top subset, and the two

mismatch conditions do not differ reliably in the amount of target interference they cause for the bottom subset.

Computational modeling To make sense of these patterns, we turned to the jTRACE re-implementation (Strauss, Harris, & Magnuson, 2007) of the TRACE model (McClelland & Elman, 1986) that includes several additional features (graphical user interface, plotting and scripting utilities). Starting with the default parameters used by Dahan et al. (2001) to obtain the simulations shown in the middle panel of Figure 1, we explored a wide range of changes to several parameters, one at a time. The goal was to determine whether any parameter could be changed to produce the observed changes in the bottom subset: increased competition effects without slowing initial lexical access. We tested a variety of parameters in TRACE (feedforward and feedback gain at various points, addition of input and "sensory" [model-internal] noise). *Lexical decay* was of particular interest, as the parameter McMurray et al. (2010) claim best fits individual differences in a lexical competition in a group of adolescents with a range of language and cognitive abilities; however, its influence is too weak and late. Two parameters could simulate the general trends: reducing *phonemic* or *lexical lateral inhibition* by approximately 50% from default levels. Reducing inhibition does not affect initial activation rates, but it allows larger competition effects because it delays the impact of late-arriving bottom-up disambiguation. In particular, it predicts larger cohort competition effects (note slight trends in this direction in the bottom subset) as well as less differentiation in target trajectories for the mismatch conditions.

Experiment 2

In Experiment 2, we continued our exploration of our sample's phonological abilities by examining lexical competition in the context of an artificial lexicon learning task (based on Magnuson, Tanenhaus, Aslin, & Dahan, 2003). This allowed us to simultaneously study

Figure 3: pictures of unusual animals used in the artificial lexicon study (Experiment 2).

phonological competition effects in word recognition (how strongly do "cohorts", like /pibo/ and /pibu/, compete? How strongly do rhymes, like /pibo/ and /dibo/, compete?) and word learning ability. Magnuson et al. (2003) were motivated in part by the goal of precisely controlling lexical characteristics such as phonological similarity, frequency, and neighborhood density. This approach has an added advantage for our sample. To the degree that our sample diverges from the performance of typical participants using real words, it is very difficult to determine the locus of the difference. There may be deep reasons, such as differential organization of processing mechanisms, or shallow ones, like simple differences in vocabulary size. An artificial lexicon paradigm allows us to put participants on maximally similar footing. While participants differ in linguistic and cognitive abilities, the items are equally unfamiliar to all.

Predictions Virtually any variant of the phonological deficit hypothesis might predict poor readers would perform worse in learning the artificial lexicon. With respect to the time course of cohort and rhyme competition, two precedents using familiar words in the visual world eye tracking paradigm suggest possible outcomes. Desroches, Joanisse, and Robertson (2006) examined cohort and rhyme competition in children with dyslexia. Unlike typically developing peers, they did not exhibit rhyme competition effects. In contrast, McMurray et al. (2010) reported that adolescents meeting criteria for SLI showed stronger cohort *and* rhyme effects, though only in the late time course. Thus, we might expect to see typical cohort effects but weak or absent rhyme effects (consistent with Desroches et al.) or late-enhanced cohort and rhyme effects (consistent with McMurray et al.).

Methods

Participants A subset of participants from Experiment 1 participated in Experiment 2: 14 individuals from the top 50% and 20 from the bottom 50%.

Materials 8 artificial words were constructed with one "cohort" (onset) competitor in the artificial lexicon and one rhyme. The words were /pibo, pibu, dibo, dibu, tupa, tupi, bupa, bupi/. The visual materials were pictures of 8 unusual animals (see Figure 3). Names were mapped randomly to pictures for each subject.

Procedure Each trial had identical structure. A fixation cross appeared in the center of the screen. When the participant clicked the cross, the trial began. Two pictures

appeared, to the left and right of the cross. 500 ms later, an instruction was played, such as "find the pibo." At first, participants could only guess. If they clicked on the incorrect object, they heard "try again." When they clicked the correct object, they heard feedback, such as "that's right, that's the pibo!" The experiment consisted of 8 blocks of 24 trials. Each item appeared as the target 3 times per block, once each with its cohort, its rhyme, and an unrelated item. Thus, each block had 8 cohort, rhyme, and unrelated trials. There was no formal test; we measured behavior continuously over learning.

Results and discussion

Accuracy and response time Accuracy and response time (for accurate trials) are shown in Figure 4 for the two groups. We conducted ANOVAs with factors Type (Cohort, Rhyme, Unrelated) and Block for accuracy and RT. In the interest of space, we will only briefly summarize the results. The two subsets were both reliably more accurate for Unrelated than Rhyme trials, and more accurate in Rhyme than Cohort trials. In RT, the main effect of Type was not reliable for the top subset; in planned comparisons, none of the Types differed another. But for the bottom subset, Cohort trials were significantly slower than both Rhyme and Unrelated trials, which did not differ from each other. Thus, the bottom subset seemed to show less rhyme interference.

Fixation proportions over time are presented in Figure 5 by just showing target fixations (competitor fixations are essentially complementary) averaged over all correct trials (as the patterns did not change substantially with training). For qualitative comparison, results from a sample of 14 U. of CT (UConn) undergraduates are presented. Qualitatively, there is a very striking result. There are clear effects of both Cohort and Rhyme for the UConn sample. The Cohort effect is stronger and earlier, as with real words (Allopenna, Magnuson, & Tanenhaus, 1998; Desroches et al., 2006), while the Rhyme effect emerges later. Growth curve analysis (Mirman, Dixon, & Magnuson, 2008) revealed reliable intercept differences for the TD group (Unrelated > Rhyme > Cohort), analogous to differences in mean proportion over the analysis window. In contrast, the two community sample groups shows strong Cohort effects, but delayed Rhyme effects. The Rhyme condition differs reliably from the Unrelated condition for the top 50%, but not for the bottom 50%.

Our results are consistent with those of Desroches et al. (2006), who reported an absence of rhyme effects in children with dyslexia using a similar eye tracking paradigm with familiar, real words. They are partially consistent with the recent report of McMurray et al. (2010) that adolescents with SLI show larger but *later* competition effects than typically developing peers. We again turned to the model in order to explore possible bases for such a pattern.

Computational modeling As with Experiment 1, we used the jTRACE re-implementation (Strauss et al., 2007) of TRACE. Because TRACE is not a learning model (though see the Hebbian version of TRACE version developed by

Mirman, McClelland & Holt, 2006), we treated TRACE as a model of the stabilized system at the end of learning. Again, we changed one parameter at a time, looking for a change that would leave the magnitude and timing of the cohort effect intact while ideally wiping out the rhyme effect. We again tried several parameters. Lexical decay does not selectively affect rhyme effects. Reduced lexical lateral inhibition actually boosts rhyme effects. Only one parameter could generate the correct trends: a *reduction in lateral inhibition at the phoneme layer*. As it is reduced, rhyme effects are weakened and delayed, while leaving the cohort time course largely intact (though cohort effects are somewhat amplified). This counter-intuitive outcome follows from what happens to phonemes other than the initial phoneme of the target word. With inhibition reduced, similar phonemes get much more activated. Even though the phoneme inhibition parameter is lower, there is actually greater inhibitory flow at the phoneme level, putting rhymes that differ from the target in initial phoneme by more than a single feature at a disadvantage. Interestingly, lateral inhibition at the phoneme level was one of two parameters that could achieve the correct pattern to fit the bottom 50% subset behavior in Experiment 1.

Summary In Experiment 2, good and poor readers achieved similar accuracy in artificial lexicon learning. However, the time course of learning was substantially different, with poor readers exhibiting slower learning in early trials. Poor readers showed similar on-line onset (cohort) competition effects as better readers, but failed to exhibit a reliable effect of rhyme competition (instead showing a weak, delayed effect). This converges with a report that children with dyslexia did not exhibit rhyme effects in a similar study using real words (Desroches et al., 2006). In TRACE simulations, the only way to substantially reduce rhyme effects without inappropriately perturbing cohort (onset) effects was to reduce lateral inhibition at the phoneme level -- a parameter change that can also capture the poor reader differences in Experiment 1.

General Discussion

Adult poor readers continue to differ from good readers in phonological processing. Our poor readers showed greater interference effects from misleading coarticulation than better-reading peers in Experiment 1. Poor readers learned new words with a different trajectory than better readers in Experiment 2, and exhibited late, weak rhyme competition effects. The two primary patterns of differences -- enhanced competition due to misleading coarticulation and absence of rhyme effects -- can both be modeled in TRACE via reduced lateral inhibition at the phoneme level. The convergence on phoneme inhibition in the simulations of Experiments 1 and 2 increases our confidence that this parameter manipulation is capturing something important about phonological differences in poor readers. One next step will be to use the re-parameterized model to generate predictions for poor readers in new tasks.

We do not wish to imply that we believe that there are

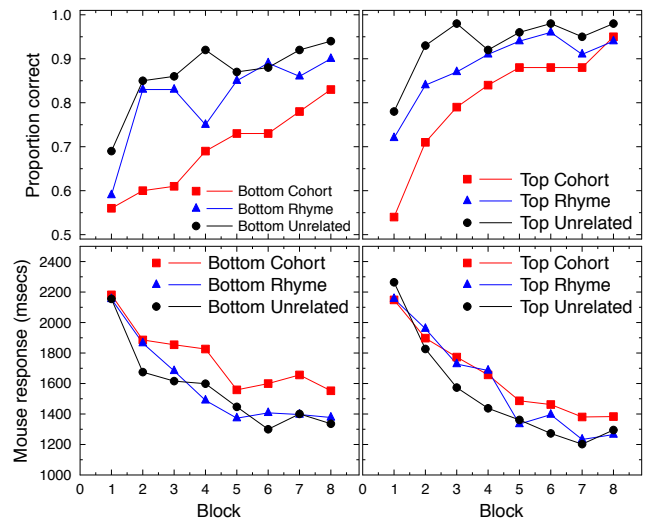

Figure 4: Accuracy (top) and RT for the bottom 50% of readers in our sample (left) and the top 50% (right) by training block.

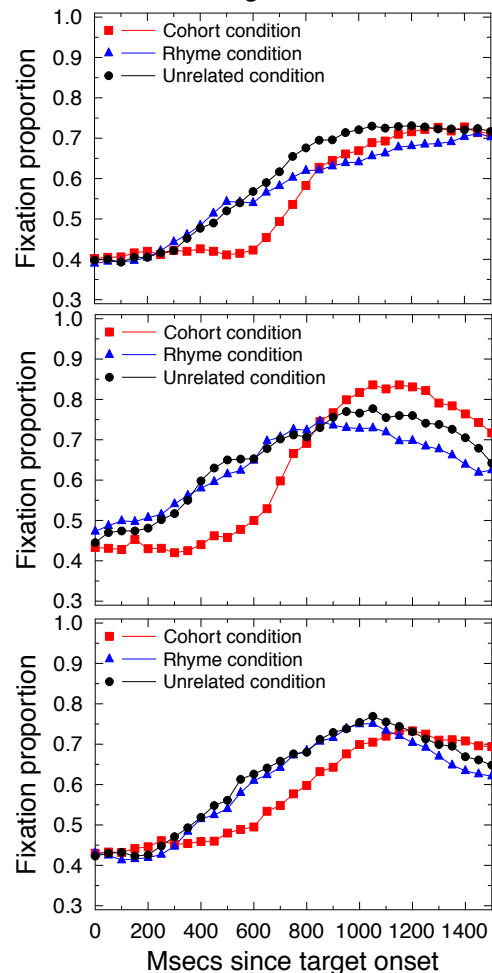

Figure 5: Target fixation proportions over time in Experiment 2, collapsed across block and only including correct trials, averaged over all 8 blocks. **Top:** typical university sample. **Middle:** to 50% of community sample readers. **Bottom:** bottom 50% of community sample readers. Patterns varied only slightly by block.

discrete representations of phonemes in the brain, let alone a discrete parameter controlling lateral inhibition. The ability of TRACE to simulate differences based on reduced phoneme inhibition instead points to the level of phonological organization in the dynamical system it is meant to simulate, i.e., the mechanisms underlying human word recognition. Thus, our simulations may identify the level of the system -- phonological organization -- that appears to be crucially different in poor readers.

Our results are potentially consistent with any form of the phonological deficit hypothesis, although they somewhat favor accounts that assume a typical level of phonetic resolution (given that poor and better readers showed similar timing in early lexical activation), and differences in the stability of phonological representations. In particular, our results may be compatible with the phonological access hypothesis (Ramus & Sjenkovits, 2008). However, our results also suggest differences in phonological access may be more subtle than suggested by Ramus and Sjenkovits, who emphasize working memory demands in conventional tasks that most clearly identify phonological deficits. That we observed differences in the time course of lexical activation, competition and learning in poor adult readers in minimally demanding, naturalistic tasks suggests that the locus of the phonological deficit may be a more low-level property of the system, even though this deficit may require difficult tasks or sensitive measures to be detected. We hope that our continuing exploration of individual differences in adult poor readers will illuminate this possibility further.

Abstract

The process of phonological encoding was investigated in primed word naming and word typing with Chinese monosyllabic words. The target words shared or did not share the onset consonants with the prime words. The stimulus onset asynchrony (SOA) was 100 ms or 300 ms. Typing required the participants to enter the phonetic letters of the target word, which correspond roughly to the onset and the rhyme of the word's syllable. Regardless of SOAs, response times were shorter in the related condition than in the unrelated condition (an onset priming effect) for word typing, but were similar for word naming. The results suggest that naming and typing in Chinese may involve somewhat different phonological encoding processes even though both tasks require accessing the phonological codes. It is hypothesized that phonological encoding in Chinese is syllable driven in word naming, but is segment driven in word typing.

Keywords: Naming, Typing, Phonological Encoding, Word Production.

Introduction

The organization of a production system, natural or artifactual, must be constrained by the kind of outputs it is designed to produce. The production system for a car is organized differently than the production system for an airplane. The production systems for different kinds of cars (sedan vs. truck) are probably also organized differently. For natural languages, it has been shown recently that the word form encoding component of the word production system is organized differently for different languages such as Dutch and Chinese. In the present study, we show that the process of phonological encoding in word production is also somewhat different for naming and typing within the same language, Chinese, even though both tasks involve accessing phonological codes.

The phonological codes of a word may contain the syllables (e.g., /seg/ and /ment/ for the word 'segment'), the individual segments (e.g., /s, ɛ, g, m, ə, n, t/) and the prosodic features (the stress pattern 'σσ) of the word. Theories of word production vary in whether the syllables are hypothesized as stored and retrieved units (Dell, 1986; Ferrand, Segui, & Grainger, 1996; Santiago, MacKay, Palma, & Rho, 2000), or whether they are assembled online during phonological encoding (Levelt, Meyer, & Roelofs, 1999). According to the model proposed by Levelt and colleagues (the LMR model), phonological encoding starts

with retrieving the segmental contents and the wordshape frame of the word to be produced. The segments are then assigned to the slots in the wordshape frame sequentially from left to right according to the phonotactic principles of the language. The result of this segment-to-frame association (called syllabification) is phonological syllables, which are fed to the next stage of processing for phonetic encoding and articulation. In this model (illustrated in Figure 3), the syllables are assembled products of phonological encoding. The model was solely based on empirical evidence from Indo-European languages such as English, Dutch, and German.

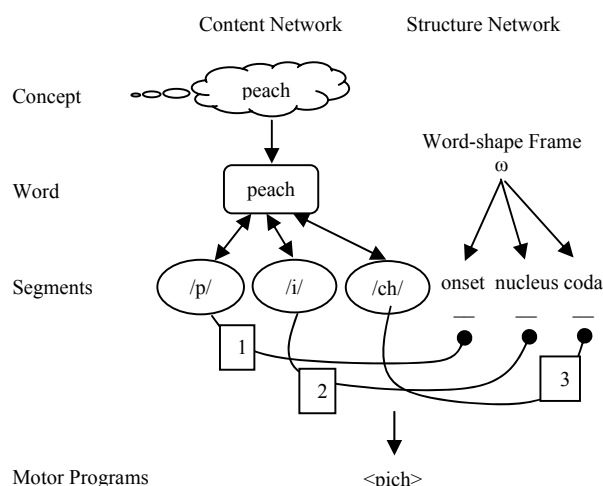

Figure 3: Production of an English CVC monosyllable for naming. Arrows signify activation. Button terminals signify assignment of contents to structures.

Assuming a similar architecture to the LMR model, Chen and colleagues (Chen, Dell, & Chen, 2002; O'Seaghdha, Chen & Chen, 2010) examined Mandarin Chinese recently but proposed that phonological encoding starts with retrieving the stored syllables of the word. The segmental contents and the syllable frame of each syllable are then retrieved for the same kind of segment-to-frame association process as in the LMR model. The difference between the LMR model (Figure 3) and the Chinese model (illustrated in Figure 4) can be characterized as the difference between segment-driven and syllable-driven processes. The difference, as we maintained previously, is due to the

different design characteristics of the phonological systems in the respective languages. The English and the Dutch phonology emphasize words and segments (large number of syllable types, syllable boundaries are often ambiguous, segments may be resyllabified in a different context, syllables carry stress and are not equally weighted), whereas the Chinese phonology emphasize syllables (clear syllable boundaries, syllabification prohibited, simple syllable structures, small number of syllable types).

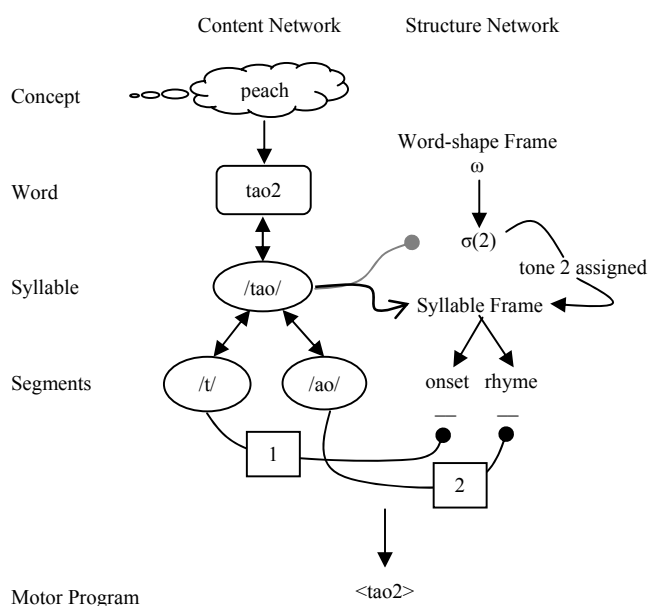

Figure 4: Production of a CV monosyllable in Mandarin for speaking. Arrows signify activation. Button terminals signify assignment of contents to structures. For simplicity, a rhyme is represented as a segment.

Typing is a production task which resembles speaking in many aspects except perhaps for the motor outputs. For speaking, the motor output involves moving several articulators simultaneously and sequentially in a highly coordinated fashion to produce syllable-sized gestures (MacNeilage, 1998). For typing, the motor output involves moving the fingers of both hands entirely discretely and sequentially (even though planning is done in parallel, Rumelhart & Norman, 1982; Salthouse, 1986). Both tasks, however, will need to access the phonological contents of a word, especially true in Chinese. The question we asked was whether the same kind of phonological encoding process operates in speaking and typing.

One hypothesis is that the same kind of phonological encoding process operates in speaking and typing. Although the motor outputs of typing are more discrete and sequential than those of speaking, the individual keystrokes may still be organized hierarchically into chunks of the word and the syllable sizes (Cooper, 1983). Accordingly, the entire process of producing a word would be identical in speaking and typing except that the specific motor muscles involved are different. Recent studies by Damian and colleagues

(Zhang and Damian, in press; Shen and Damian, 2009) with English showed that writing accessed orthographic codes (graphemes) whereas speaking accessed phonological codes (phonemes or segments). However, writing involves a segment driven process just like speaking. In English, writing and typing are similar enough so that Damian and Shen's findings can be taken as the basis for the same-process hypothesis when speaking and typing are being compared. In Chinese, however, writing and speaking are distinctly different, and so are writing and typing (to be explained immediately). Therefore, hypothesizing about the phonological encoding processes in speaking and typing Chinese requires some explanation of the way Chinese characters are typed.

Chinese characters are logographs. Writing a Chinese character involves writing the strokes in a specific order and configuration. In contrast, the most commonly used methods of typing a Chinese character (*zhuyin* in Taiwan and *pinyin* in Mainland China) involve entering the phonetic letters of the word such as the onset consonant, the medial vowel, the rhyme, and the tone (for the *zhuyin* method), which bear no resemblance whatsoever with the strokes in writing. Nevertheless, what displays on the computer screen after phonetic typing is the orthographic form of the character. The phonological form is also shown, but only as an intermediate output before the typist hits the Enter key.

Given the way Chinese characters are typically typed (the phonetic typing method), it can be reasonably assumed that word typing might involve accessing the phonological codes of a word much like word speaking or naming. It can, then, be asked whether the same or different kinds of phonological encoding process underlie Chinese word naming and word typing.

Because previous studies have shown that speaking a word in Chinese is syllable driven, the same-process hypothesis predicts that typing a word in Chinese is also syllable driven. The contrasting hypothesis is that somewhat different kinds of phonological encoding process operate in speaking and typing. Because the individual keystrokes are organized discretely in typing, the process might emphasize the individual keystrokes, and, accordingly, the segments, more than the higher order units like the syllables. Support for the emphasis comes from analysis of typing errors, which, according to Norman and Rumelhart (1983), suggest that words are parsed into single-letter and two-letter units for execution. There may be two consequences of this emphasis. First, syllabification may not be necessary. Once the segmental contents of a word are retrieved, they are mapped to segment-sized motor programs for execution. This is different from speaking, where the initially retrieved segmental contents of a word are assembled back to syllables in order to be mapped to syllable-sized motor programs for execution. Second, the influence of higher-order units such as syllables and words may be weak because the end products are segments. In sum, the different-process hypothesis predicts that typing a word in

Chinese might be segment driven (illustrated in Figure 5), in contrast to the syllable driven process in speaking (Figure 4).

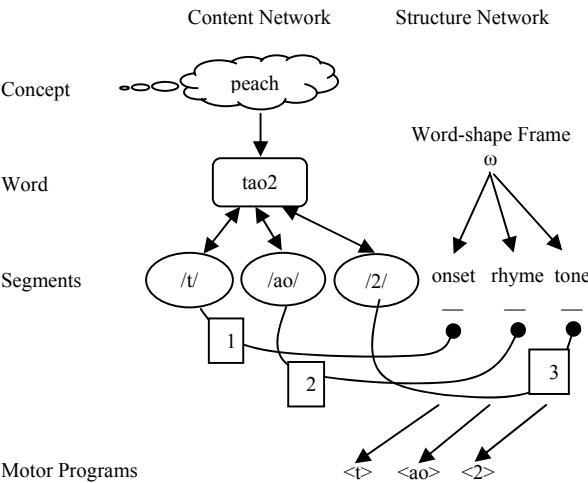

Figure 5: Production of a CV monosyllable in Mandarin for typing as modified from the speaking model of Figure 4 according to the prediction of the different-process hypothesis.

To test the hypotheses against each other, we employed a primed word naming task and a primed word typing task using Chinese monosyllabic words. Typing was performed with the zhuyin method. The target words shared or did not share the onset consonants with the prime words. We compared the onset priming effects (the difference in response times between the related and the unrelated conditions) between the two tasks. Because previous studies have observed no onset effect in Chinese speaking tasks (masked priming and implicit priming, Chen, Chen, & Dell, 2002; Chen, Lin, & Ferrand, 2003; O’Seaghdha, Chen, & Chen, 2010), the same-process hypothesis predicts no onset priming effects for either task, whereas the different-process hypothesis predicts no priming for the naming task but significant onset priming for the typing task.

In addition to manipulating phonological overlap, we also manipulated orthographic overlap such that the prime and the target words shared or did not share the first radical. With an unmasked priming procedure and stimulus onset asynchronies of varying lengths, previous studies showed that an orthographic overlap would produce positive (43 ms), negative (57 and 85 ms) or no (115 ms) priming in a word naming task (Perfetti & Tan 1998). According to one explanation, negative priming is due to form-related competition whereby the episodic memory trace of the prime is reactivated by the shared orthographic form in the target and competes with the target for phonological encoding (O’Seaghdha & Marin, 2000). If the level of competition is lexical, both the same-process hypothesis and the different-process hypothesis predict similar negative priming for naming and typing. If the level of competition is phonological, the same-process hypothesis predicts similar negative priming for the two tasks, while the different-

process hypothesis predicts greater negative priming for naming than for typing (assuming syllable competition is greater than segment competition) or similar negative priming for naming and typing (assuming syllable competition is no greater than segment competition). Due to the uncertainties about the level of competition, the extent of competition, and the effect of SOA, the orthographic manipulation was included more for an explorative purpose than for testing the present hypotheses.

Method

Participants

Twenty-six native Mandarin Chinese speakers were recruited for the typing task and twenty-two for the naming task. They were students from National Cheng Kung University and the surrounding universities. The participants for the typing task were all habitual zhuyin typists with an average typing speed of 62.7 characters per min. All the participants had normal or corrected-to-normal vision and they were paid for participation.

Design and Materials

Thirty characters served as targets. Each was paired with four types of prime characters according to whether it shared the onset consonant or the first radical with the prime. An example is given in Table 1. The frequencies and the stroke numbers were matched among the four types of primes. There were a total of 120 pairs, which were randomly ordered for each participant. The experiment included one between-subjects factor (typing method) and three within-subjects factors (phonological relatedness, orthographic relatedness, and stimulus onset asynchrony), each with two levels. The SOA was either 100 or 300 ms. For each of the four types of prime-target pairs, half was presented with 100-ms SOA and the other half with 300 ms. The half which was presented with 100-ms SOA for half of the participants was presented with 300-ms SOA for the other half of the participants, and vice versa.

Table 1: An example of the prime-target pairs as a function of phonological and orthographic relatedness between the primes and the targets. The mean frequencies and the mean stroke numbers of the prime characters (standard deviations in parentheses) are also given.

		+Onset	-Onset
+Radical	Characters	梯-桃	概-桃
	Pinyins	ti1-tao2	gai4-tao2
	Mean frequency	224 (34)	258 (119)
	Mean strokes	11.6 (2.8)	10.9 (3.6)
-Radical	Characters	泰-桃	棄-桃
	Pinyins	tai4-tao2	qi4-tao2
	Mean frequency	238(87)	276 (112)
	Mean strokes	11.9 (3.5)	12.4 (3.4)

Apparatus and Procedure

The experiment was programmed in Visual Basic for the typing task and in E-Prime for the naming task. Both were run on a personal computer (Intel® Core™2 Quad CPU, Q6600@2.40GHz) with a 20-inch LED screen (32bits, 1400x1050 pixels, 8-ms refresh rate), a standard keyboard, and a microphone. For the typing task, the experiment began with a familiarization phase, followed by a practice block of six trials and the experiment block of 120 trials. To ensure the participants knew the exact phonetic letters of each character used in the experiment, all of the characters (120 primes and 30 targets) were shown one at a time in a random order. The participants had to type in the correct phonetic letters of each character. If a mistake was made, the correct answer was offered. All of the incorrectly-answered characters were presented again at the end of the list. The procedure was repeated until no characters were incorrectly typed.

A trial for the practice and the experimental blocks consisted of a fixation cross appearing at the center of the computer screen for 1 sec. The prime character appeared in the Ximing font for 100 or 300 ms, followed immediately by the target character in the Biaokai font. Each character subtended about 2° visual angle horizontally and vertically from a viewing distance of 50 cm. The participants were asked to type in the phonetic letters of the target character as quickly and accurately as possible. The response time was recorded and measured to the accuracy of millisecond from the onset of the target character to the first keystroke of the typing response. Response accuracy was also recorded.

All of the participants completed the typing task before coming back a month later for the naming task. For the naming task, exactly the same procedure was employed, except that the participants were asked to name the characters out loud. The response time was registered at the onset of the participants' vocal response.

Results

Typing

Errors were infrequent (less than 6%) and were not analyzed. Response times (RT) for the correct trials were analyzed using a linear mixed model (Statistical Analytic System, the PROC MIXED procedure) with subjects and items as random-effect variables and phonological relatedness, orthographic relatedness and SOA as fixed-effect variables. The mean RTs as a function of phonological relatedness, orthographic relatedness and SOA are plotted in Figure 1. The most notable effects in the figure are that of SOA and that of phonological relatedness. Response times were faster under 300-ms SOA than under 100-ms SOA: $F(1, 2895) = 62.4, p < .0001$. Response times were also faster when the prime and the target shared the onset consonant than when they did not (a positive onset priming effect of 30 ms): $F(1, 2895) = 35.3, p < .0001$. Response times were somewhat slower when the prime and the target shared the first radical than when they did not (a negative orthographic priming

effect of 9.5 ms): $F(1, 2895) = 4.2, p < .05$. None of the interactions were significant, p 's $> .2$.

Figure 1: Mean RTs as a function of phonological relatedness, orthographic relatedness, and SOA from the typing task.

Naming

Errors were less than 2%. Response times were similarly analyzed as they were for typing. The mean RTs as a function of phonological relatedness, orthographic relatedness and SOA are plotted in Figure 2. The only significant effect in the figure is that of SOA. Response times were faster under 300-ms SOA than under 100-ms SOA: $F(1, 2516) = 323.9, p < .0001$. Response times were somewhat slower when the prime and the target shared the first radical than when they did not (a negative orthographic priming effect of 5.6 ms), but the effect fell short of the conventional level of significance, $p = .134$. None of the other effects were significant, p 's ranging from .454 to .932.

Figure 2: Mean RTs as a function of phonological relatedness, orthographic relatedness, and SOA from the naming task.

Combined Analysis

When the data from both tasks were included in the analysis with task as an additional fixed-effect variable, the results revealed significant main effects for all fixed-effect variables: $F(1, 5440) = 68.3, p < .0001$ for task, $F(1, 5440) = 259.3, p < .0001$ for SOA, $F(1, 5440) = 21.5, p < .0001$ for phonological relatedness, and $F(1, 5440) = 5.9, p < .02$

for orthographic relatedness. Importantly, the task \times phonological relatedness interaction was significant: $F(1, 5440) = 23.5, p < .0001$, confirming the different findings in the separate analyses. The task \times orthographic relatedness interaction was not significant, $F < 1$, confirming the similar findings in the separate analyses. The only remaining significant effect was that of task \times SOA. All of the other effects were nonsignificant, p 's ranging from .262 to .997.

Discussion

Single word naming and typing in Chinese both involve accessing the phonological codes of the word, but the motor outputs are different. Does word typing involve the same or different phonological encoding processes from word naming? Using an unmasked priming procedure and manipulating phonological and orthographic overlaps between the prime and the target characters, we observed significant positive onset (phonological) priming in the typing task, but no priming in the naming task. At the same time, we also observed significant and comparable negative radical (orthographic) priming in both tasks.

The orthographic priming effects were similar in the naming and the typing tasks. It is important to note that these effects did not vary with phonological relatedness. That is, whether the prime and the target shared the onset consonant did not affect the orthographic priming effect. This could suggest (1) lexical competition whereby the reactivated prime word competed with the target word for phonological encoding, or (2) phonological competition whereby the phonological contents of the prime and the target competed for selection. It is not possible for the present study to determine whether the observed orthographic priming was due to lexical or phonological competition, and whether phonological competition between syllables is equivalent in magnitude to that between segments. As a result, the similar orthographic priming effects are interesting, but uninformative for testing our hypotheses. The following discussion will focus on the different phonological priming effects.

The different phonological priming effects observed in word naming and word typing suggest that the two types of tasks likely involve somewhat different phonological encoding processes, but an alternative account needs to be considered first. The alternative account would argue that the segmental effect in word typing occurred at the stage of motor output. That is, knowing ahead of time the first segment of a word allowed the participants to prepare the motor act of typing that segment, or even to start typing before they had retrieved the response word. Either possibility is highly unlikely because the prime-target SOAs were too short (100 and 300 ms) to allow the processing of the prime to proceed to the motor stage in time to benefit the production of the target at that level. The finding that onset priming in word typing did not vary with SOAs also helps to rule out these possibilities.

The different phonological priming effects can be explained by postulating two different models for word

naming and word typing. Figure 3 illustrates a production model for speaking a monosyllabic Chinese word proposed previously (O'Seaghdha, Chen, & Chen, 2010). The model is applicable to a word naming task if we focus on the production phase of naming and also ignore the concept level. In the model, syllables are retrieved as chunks. The segmental contents and the syllable frame are separately spelled out, followed by the sequential assignment of the individual segments to the categorized slots in the frame. The result of this phonological encoding process is a syllable-sized motor program for articulation. Figure 4 illustrates the same model modified for typing. In this model, tone is assumed to be one of the segmental contents of a syllable and is assigned last; there is no explicit syllable level; and the sequential assignment of the individual segments to their categorized slots leads to several segment-sized motor programs, rather than one syllable-sized motor program.

The segment-sized output characterizes an important feature of the typing model and distinguishes it from the naming model. In fact, it also contrasts with the naming model hypothesized for Germanic languages (Roelofs, 1997; Levelt, Meyer, & Roelofs, 1999). The different characteristics of the outputs for typing and naming serve to constrain the processing at earlier stages differently. Specifically, the syllable-sized output for naming prescribes that phonological encoding address the syllable, whereas the segment-sized output for typing prescribes that it address the segment in the planning process. The segment-addressing system gives rise to the onset priming effect observed in the typing task, whereas the syllable-addressing system produces no onset priming in the naming task.

To summarize, the results of the present study, as far as the onset priming effects go, support the hypothesis that somewhat different phonological encoding processes are involved in speaking and typing. The process is syllable-driven in speaking, but segment-driven in typing. And this is due to the different natures of the outputs the two tasks aim to produce.

In our previous work (Chen, Chen, & Dell, 2002; Chen, Lin, & Ferrand, 2003; O'Seaghdha, Chen & Chen, 2010), we emphasized and investigated cross-linguistic differences in the design characteristics of Chinese and English/Dutch (with respect to the phonological system) and how the processing mechanisms of phonological encoding differ accordingly. In the present study, we highlighted another important factor that might modulate the processing mechanism *within the same language*. The idea that the specific form of the output must in some way drive the form of the intermediate representations in a production system should surprise no one. The input of a production system can differ greatly from the output. Given that production is a process that translates a specific input to a specific output, the final form of the output (the goal state of the production system) must require that the intermediate representations approach that form, or else production would fail. This idea

is consistent with any system that is adaptive and goal-directed.

The hypothesis that the forms of the internal representations are constrained by the form of the output in a production system is consistent with previous models that postulate different modality-specific lexicons for speaking and writing, based on neuropsychological evidence (Ellis & Young, 1988; Caramazza, 1997). It is also consistent with the theoretical concept of embodiment in cognition (Lakoff & Johnson, 1999; Clark & Chalmers, 1998).

Many issues remain and further work awaits researchers. Convergent evidence is needed from other production tasks and procedures (e.g., word naming and picture naming with masked primes, the form preparation task). The difference between word typing in Chinese and word naming in English deserves investigations. Even though both involve segment-driven processes, they may be motivated differently. As mentioned earlier, the well-cited model of word production for English/Dutch assumes syllable-sized outputs. If the assumption is valid, the segment-driven process of phonological encoding must find a different motivation in the English/Dutch speaking system than that in the Chinese typing system. On the other hand, it could be that the assumption has been false. The hypothesis also bears a broader implication for understanding the cognitive system in general.

Finally, word typing (or typewriting) used to be a special skill of a small group of professionals. As a result, research on typewriting has been sparse. With the increasing popularity of computer word processing, typewriting has become a common skill of literacy like handwriting. As a production task, it is time for the production researchers to begin investigating this new technologically-driven skill of the digital age in order to understand its similarities and differences from the speaking task.

Visual and Task characteristics may explain hemispheric asymmetry in visual word recognition

Abstract

Previous studies proposed that the left hemisphere (LH) lateralization in English word recognition is because of the LH superiority in language processing. Nevertheless, Chinese character recognition has been shown to be more bilateral or right hemisphere (RH) lateralized and thus is a counter example of this claim. Through computational modeling, here we show that at least two factors other than language lateralization may influence hemispheric asymmetry in visual word recognition: (1) Visual similarity among words, which can be influenced by the ratio between the alphabet size and the lexicon size and the visual similarity among letters: We show that the more similar the words are in the lexicon, the more high spatial frequency (HSF) information is required to distinguish them, and this leads to more LH lateralization (2) The requirement to decompose a word into letters in order to map them to corresponding phonemes in pronunciation: We show that letter identity mapping requires more HSF information than word identity mapping, and alphabetic reading requires more HSF information than logographic reading; this leads to more LH lateralization in alphabetic languages. These two visual and task characteristic factors alone may explain differences in lateralization between English word and Chinese character recognition, without assuming the influence from language lateralization.

Keywords: visual word recognition, hemispheric asymmetry, computational modeling

Introduction

Lateralization in visual word recognition

Words, which surround us ever since our childhood, have been extensively studied in the research on visual recognition. Previous studies have consistently shown a left hemisphere (LH) lateralization effect in visual word recognition in alphabetic languages such as English. A classical right visual field (RVF)/LH advantage in reading English words (or words in alphabetic languages) has been demonstrated first in tachistoscopic recognition (e.g., Bryden & Rainey, 1963) and consistently reported in other word recognition tasks, such as word naming (Brysbaert & d'Ydewalle, 1990) and lexical decision tasks (Faust, Babkoff, & Kravetz, 1995). Data from fMRI studies have shown a region inside the left fusiform area (Visual Word Form Area, VWFA) responding selectively to words (e.g., McCandliss, Cohen, & Dehaene, 2003). ERP studies also show that words elicit a larger N170 in the LH than strings of symbols (e.g., Maurer, Brandeis, & Dehaene, 2005). This RVF/LH advantage in visual word recognition in alphabetic languages has been argued to be because of the LH lateralization in language processing (e.g., Voyer, 1996).

Nevertheless, this claim has been challenged by at least one counter example, that is, the recognition of Chinese characters. In contrast to the RVF/LH advantage in the recognition of English words, the recognition of Chinese characters, a logographic writing system, has been shown to have a left visual field/right hemisphere (LVF/RH) advantage in orthographic processing, demonstrated in tachistoscopic recognition tasks (e.g., Tzeng et al., 1979; Cheng & Yang, 1989). In addition, Hsiao and Cottrell (2009) showed a left side bias effect in Chinese character perception in Chinese readers (experts), but not in non-Chinese readers (novices). This left side bias effect also suggests the RH involvement in Chinese character processing.

As for phonological processing in Chinese character recognition, Weekes and Zhang (1999) reported phonological priming effects on the recognition of phonetic compounds (i.e. characters with a phonetic radical that has information about character pronunciation) when the characters were presented in the RVF/LH but not in the LVF/RH; this effect was not observed in integrated characters (i.e. characters that do not have a phonetic radical; Weekes, Chen, & Lin, 1998). Thus, research on Chinese character recognition has exhibited a LVF/RH advantage for orthographic processing, and a RVF/LH advantage for phonological processing, especially for phonetic compounds. ERP and fMRI studies of Chinese character recognition have also shown a more bilateral or RH-lateralized activation in the visual system than those of English word recognition (e.g., Tan et al., 2000; Liu & Perfetti, 2003), which is consistent with the behavioral data.

The RH advantage in Chinese character recognition has been argued to reflect the RH superiority in handling holistic pattern recognition (Tzeng et al., 1979). Nevertheless, findings in later studies do not support this claim. For example, Cheng and Yang (1989) showed no laterality effect in the recognition of non-characters and pseudo-characters, suggesting that this RH advantage may be related to lexical knowledge of Chinese characters or learning experience. Also, in contrast to Tzeng et al.'s claim, Hsiao and Cottrell (2009) showed a reduced holistic processing effect in Chinese readers compared with non-Chinese readers. Thus, it remains unclear why Chinese character recognition and English word recognition involve different hemisphere lateralization.

Hemispheric processing model

In order to investigate why Chinese character and English word recognition involve different hemispheric

lateralization, here we adopt a computational approach, aiming to examine potential factors that may influence hemispheric asymmetry in visual word recognition, since computational modeling approaches enable us to have better control over variables.

Anatomical evidence shows that our visual field is initially split along the vertical midline, and the two visual hemifields are initially contralaterally projected to different hemispheres. In order to examine at which processing stage this split information converges, Hsiao, Shieh, and Cottrell (2008) conducted a hemispheric modeling study of face recognition, aiming to account for the left side bias effect in face perception. They proposed three models with different timing of convergence: early, intermediate and late convergence models (Figure 1). They showed that both the intermediate and late convergence models are able to account for the left side bias effect in face perception, whereas the early convergence model fails to show the effect.

Hsiao et al.'s hemispheric processing model (2008) incorporates several known observations about visual anatomy and neural computation: Gabor responses are used over the input images to simulate neural responses of cells in the early visual system (Lades et al., 1993); Principal Component Analysis (PCA), a biologically plausible linear compression technique (Sanger, 1989), is used to simulate possible information extraction processes beyond the early visual system. This PCA representation then is used as the input to a two-layer neural network (Figure 2).

In addition, the model implements a theory of hemispheric asymmetry in perception, Double Filtering by Frequency theory (DFF, Ivry & Robertson, 1998). The DFF theory argues that information coming into the brain goes through two frequency filtering stages: The first stage involves attentional selection of a task-relevant frequency range. At the second stage, the LH amplifies high frequency information, while the RH amplifies low frequency information. This differential frequency bias in the two hemispheres is implemented in the model by using two sigmoid weighting functions to assign different weights to the Gabor responses in the two hemispheres (Figure 2).

Here we apply Hsiao et al.'s hemispheric processing model (2008) to the modeling of visual word recognition, in order to examine whether visual and task characteristics alone are able to account for the differences in hemispheric lateralization in different languages, without assuming the influence of language processing being LH-lateralized. We introduce our hypothesis below.

Figure 1: Hemispheric models with different timing of convergence (Hsiao et al., 2008)

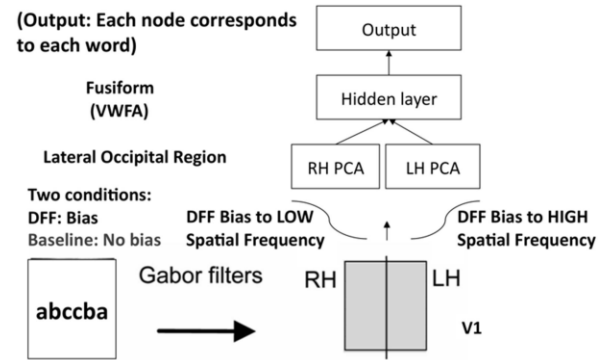

Figure 2: Hsiao et al.'s hemispheric processing model (2008)

Visual and task characteristics of a writing system

Here we test the hypothesis that differences in visual and task characteristics of a writing system alone are able to account for differences in hemispheric lateralization in visual word recognition in different languages. We hypothesize that at least two factors other than language lateralization may influence hemispheric lateralization in visual word recognition:

(1) Visual similarity among words in the lexicon:

The more similar the words look visually in the lexicon, the more high spatial frequency (HSF) information is required to recognize them; this leads to more LH lateralization. We hypothesize that at least two factors may influence visual similarity among words in the lexicon:

- (i) Number of letters shared among words in the lexicon: The more letters are shared among words in the lexicon, the more similar the words look visually in the lexicon. This factor is influenced by the ratio between the alphabet size (i.e. the number of letters in the alphabet) and the lexicon size (i.e. the number of words in the lexicon); that is, given a fixed lexicon size, the smaller the alphabet size is, the more number of letters may be shared among the words in the lexicon, and thus the more similar the words look visually in the lexicon.
- (ii) Similarity among letters in the alphabet: The more similar the letters in the alphabet look visually, the more similar the words look visually in the lexicon. This factor may be influenced by the number of letters in the alphabet; that is, given a fixed representational space for all possible letters, when we gradually increase the number of letters in the alphabet, it becomes more likely that some letters will look similar to each other (i.e. closer to each other in the space).

According to these two factors, we predict that with a fixed lexicon size, when we gradually increase the alphabet size, the model will first exhibit more and more low spatial frequency (LSF) reliance since the words will share fewer and fewer common letters (factor (i)); when the letters in the alphabet start to look visually similar to each other because of the alphabet size increase, the model will start to exhibit reduced LSF reliance (factor (ii)). In other words, we expect

that there will be an inverted-U-shaped curve in LSF reliance/RH lateralization in the model when we gradually increase the alphabet size given a fixed lexicon size.

(2) The requirement to decompose a word into letters in order to map them into corresponding phonemes in pronunciation

Maurer and McCandliss (2007) proposed the phonological mapping hypothesis to account for the difference in ERP N170 lateralization between faces and words: N170 has been found to be larger in the RH compared with the LH in face recognition, whereas in the recognition of English words, it has been found to be larger in the LH compared with the RH. They argued that given phonological processes are typically left-lateralized (e.g., Price et al., 1997; Rumsey et al., 1997), specialized processing of visual words in visual brain areas also becomes left-lateralized. Accordingly, the LH lateralization of N170 may be specifically related to the influence of grapheme-phoneme conversion established during learning to read. According to this hypothesis, this phonological modulation should be less pronounced in logographic scripts such as Chinese (Maurer & McCandliss, 2007).

In contrast to the phonological mapping hypothesis, here we hypothesize that the LH lateralization in English word recognition is due to the requirement to decompose a word into letters, without assuming phonological processes being left-lateralized. We test this hypothesis through two simulations. In the first simulation, we contrast two mapping tasks using the same stimuli: word identity mapping and letter identity mapping. In the word identity mapping task, the model learns to distinguish different words, whereas in the letter identity mapping task, the model learns to identify the constituent letter in each letter position of an input word. We expect that the letter identity mapping task will require more HSF information (i.e. LH lateralization) compared with the word identity mapping task¹.

In the second simulation, instead of mapping word image input to either word or letter identities, we model visual word recognition more realistically by mapping them to pronunciations. We use an artificial lexicon with Korean-character-like pseudo-characters as the orthography. Two pronunciation conditions are created: in the alphabetic reading condition, each component (letter) of a character maps to a consonant or vowel in pronunciation systematically, whereas in the logographic reading condition, each character maps to a pronunciation randomly without a systematic relationship between its orthographic components (letters) and the phonemes in pronunciation. We expect that the alphabetic reading condition will require more HSF information (i.e. more LH lateralization) compared with the logographic reading

condition.

Figure 3: Images used in the current study: (a) palindrome English pseudo-words; (b) Korean pseudo-characters (from left to right, vertical structure, top heavy structure, and bottom heavy structure); (c) & (d) Left and right damaged images of the English pseudo-words and the Korean pseudo-characters

Modeling Method and Results

To test our hypotheses, we applied the intermediate convergence model proposed by Hsiao et al. (2008) to visual word recognition. In the model, the input word images were first filtered with a rigid grid of overlapping 2D Gabor filters (Daugman, 1985) to obtain Gabor responses. At each grid, we used Gabor filters of eight orientations and a fixed number of scales. The number of scales used depended on the task-relevant frequency range, which was determined according to the smaller dimension of the images; the highest frequency scale did not exceed the smaller dimension of the images (following Hsiao et al., 2008). In the current simulation, the dimensions of the two types of images used were 35 x 100 for the English pseudo-words and 70 x 80 for the Korean pseudo-characters (see Figure 3); thus the number of scales for English pseudo-word images was five ($2^5 = 32 < 35$, and $2^6 = 64 > 35$) and that for Korean pseudo-character images was six ($2^6 = 64 < 70$, and $2^7 = 128 > 70$). We applied the Gabor filters to a 5x18 grid of points on each English pseudo-word image, and to a 12x14 grid of points on each Korean pseudo-character image. So each English pseudo-word image was transformed into a vector of size 3600 (5x18 sample points x 8 orientation x 5 scales) while each Korean pseudo-character image was transformed into a vectors of size 8064 (12x14 sample points x 8 orientations x 6 scales).

After obtaining the Gabor magnitudes, two conditions were created: the baseline condition and the biased condition. In the baseline condition (the control condition), Gabor responses in different scales were given equal weights (i.e. no frequency bias), while in the biased condition, we implemented the second stage of the DFF theory by using a sigmoidal weighting function to bias the Gabor responses on the left half word (RH) to LSFs, and those on the right half word (LH) to HSFs (Figure 2). The perceptual representation of each of the left and right half

¹ Note that we reported some pilot data in Hsiao & Cottrell (2009b). Compared with Hsiao & Cottrell (2009b), here we have revised the hypotheses and modeling methods, and presented brand-new and more complete simulations.

words was compressed by PCA into a 50-element representation each (100 elements in total, following Hsiao et al., 2008)². This PCA representation then was used as the input to a two layer neural network, as shown in Figure 2 (see Hsiao et al., 2008, for more simulation details).

We trained our neural network model to recognize the input images until the performance on the training set reached 100% accuracy. The training algorithm was gradient descent with an adaptive learning rate. To test hemispheric asymmetry effects, in contrast to the previous hemispheric models of face and word recognition (e.g., Hsiao et al., 2008, Hsiao & Cottrell, 2009b), here we did not use “chimeric images” (Figure 3(a) & (b)) as a way to give noise to one side of the stimulus in order to test the model’s reliance on either the left or right half of the representation. A potential problem in using this kind of chimeric images for words is some letters may have a similar shape as their mirror images (such as ‘o’ and ‘m’ in the English alphabet), while others do not; thus these letters will give non-uniform noise distribution over the mirror-image sides of the chimeric words. Here we avoided this problem by using damaged images (Figure 3(c) & (d).) It was made by setting one half of the PCA representation to zero, so that when mapping these damaged images to their identities, only one of the visual hemifields was used for recognition. The left side bias effect thus was measured as the difference between the accuracy of recognizing a right-side-damaged word (carrying LSF/RH information only) as the original word and the accuracy of recognizing a left-side-damaged word (carrying HSF/LH information only) as the original word.

Visual similarity among words in the lexicon:

We first used images of six-letter English pseudo-words to examine how visual similarity among words in the lexicon influences lateralization in visual word recognition. To counterbalance the information carried in the two visual fields, we used palindrome pseudo-words as the stimuli (e.g., Figure 3(a)). We created artificial lexicons with an increasing alphabet size (a-c, a-e, a-g...), and trained the model to learn each lexicon 50 times. In each of the 50 simulations, 26 palindrome words were chosen randomly from all possible combinations of letters in the alphabet to form the artificial lexicon. In the model, each output node corresponded to a word identity.

In the first lexicon with letters from ‘a’ to ‘c’, there were 27 possible combinations: aaaaaa, aabbaa, aaccaa, abaaba, abbbba... The randomly chosen 26 words thus looked very similar to one another. When we increased the alphabet size to include ‘a’ to ‘e’, the number of combinations became 125, and the randomly chosen 26 words became more dissimilar visually to one another (i.e. the similarity among words decreased). In other words, the larger the alphabet size was, the lower the visual similarities among words in the lexicon were. Here we examined how the model’s

lateralization changed when we gradually increased the alphabet size.

In the datasets, we used 8 different fonts for each word, with 4 of them used as the training data, and the other 4 used as the testing data (counterbalanced across the simulations). Thus, in both the training and testing datasets, each word had 4 images of different fonts.

Figure 4: RH/LSF preference in the models trained with lexicons with different alphabet sizes in the word identity mapping task (* $p < 0.01$; ** $p < 0.001$; *** $p < 0.001$).

The results are shown in Figure 4. The RH/LSF preference was defined as the difference in the left side bias effect between the biased condition and the baseline condition; it reflected how much the model preferred the RH/LSF-biased representation over the LH/HSF-biased representation compared with the control condition when no frequency bias was applied (Hsiao et al., 2008). As shown in Figure 4, when the alphabet size was small (e.g., ‘a’ to ‘c’), the model had low RH/LSF preference. When we increased the alphabetic size, the RH/LSF preferences became stronger, and then decreased after the peak at around ‘a-g’ (i.e., an inverted-U shape in Figure 4).

Thus, the results showed that, when gradually increasing the alphabetic size of the lexicon, the visual similarity among words decreased, and the model relied more on LSFs to distinguish the words. But when the alphabetic size kept increasing, more and more letters with similar shapes were used in the alphabet (e.g., ‘c’ and ‘o’, ‘b’ and ‘h’, ‘m’ and ‘n’), and the visual similarity among words in the lexicon increased; as the result, the model required more HSFs to distinguish the words.

The requirement to decompose a word into letters

When reading words in alphabetic languages, the readers have to decompose the visual input of a word into its constituent letters/graphemes and map them to the corresponding phonemes. This decomposition may require details of the word image and thus rely more on the HSF information. Here we examined lateralization effects in a letter identity mapping task using the English pseudo-words. Instead of learning to map word images to word identities, the model was trained to map a word image to its constituent letter identities. The output layer of the model

² In a separate simulation, we found that using 100 components each made the representation noisier and deteriorated the model’s performance.

was divided into 3 parts corresponding to the first 3 letter positions in a word (the end 3 letters were the same as the first 3 since they were palindrome words). The number of nodes in each part was equal to the alphabetic size (see Figure 5).

Figure 5: Output layers of the letter-position identity mapping task (Hsiao & Cottrell, 2009b).

Figure 6: RH/LSF preference in the letter identity mapping task (in red) in the models trained with lexicons of different alphabet sizes, compared with the word identity mapping task (in blue; * $p<0.01$; ** $p<0.001$; *** $p<0.001$).

Figure 6 shows the results. The results showed that compared with the word identity mapping task, the letter identity mapping task required more LH/ HSF information. In addition, in the letter identity task, as the alphabet size increased, the model relied more on LH/HSF information.

In another simulation, we used artificial lexicons with Korean-character-like pseudo-characters to examine hemispheric asymmetry effects in recognizing square-shape characters, and more importantly, to examine hemispheric processing difference between logographic and alphabetic language reading. In this examination, we modeled visual word recognition more realistically by mapping each word input into its pronunciation with a consonant-vowel-consonant structure.

In the datasets, there were also 8 different fonts for each Korean-character-like pseudo-character. Each character consisted of three Korean-alphabet-like letters, arranging in three different structures: vertical, top-heavy, and bottom-heavy (Figure 3(b)). The frequency of each letter appearing in either side of the characters in the lexicon was balanced. In the alphabetic reading condition, each letter systematically mapped to either a vowel or a consonant in pronunciation, whereas in the logographic reading condition, each character mapped to a randomly assigned pronunciation without a systematic letter-phoneme mapping.

Figure 7 shows the results. As shown in the figure, the RH/LSF preference in the logographic reading condition was always stronger than that in the alphabetic reading condition. This result suggests logographic reading requires more LSF information compared with alphabetic reading, and is consistent with the visual word recognition literature showing a more RH lateralization in reading logographic languages such as Chinese compared with alphabetic languages such as English.

Character Format

Conclusion and Discussion

Visual word recognition in alphabetic languages such as English has been reported to be LH lateralized, and argued to be due to the LH lateralization of language processes. Nevertheless, a RH/LVF advantage has been reported in orthographic processing of Chinese character recognition. In this study, by applying the hemispheric processing model (Hsiao et al., 2008) to visual word recognition, we examined whether visual and task characteristics alone are able to account for differences in hemispheric lateralization in different languages without assuming the influence from language processing being LH-lateralized.

We first showed that visual similarity among words in the lexicon can influence lateralization in visual word recognition. We used artificial lexicons with the same number of words and word length, but with different alphabetic sizes, and trained the model to map word image input to their word identities. The results showed an inverted- U -pattern (Figure 4): When the alphabet size increases, the model initially relies more and more on the RH/LSF information, because words in the lexicon share fewer and fewer common letters and the visual similarity among words in the lexicon decreases. Nevertheless, with further increase of the alphabet size, the model's RH/LSF reliance starts to decrease, because of the increase of visual similarity among letters in the alphabet.

We then showed that the requirement to decompose a word into its constituent letters can also influence lateralization in visual word recognition. We used the same artificial lexicons but trained the model to perform a letter-identity mapping task instead of the word identity mapping

task. The results showed that decomposition of words into letters requires more HSF information and thus results in more LH lateralization. In addition, we used Korean pseudo-characters to examine lateralization differences between logographical reading and alphabetic reading. The results showed that logographical reading requires more LSF information compared with alphabetic reading, and thus results in more RH-lateralization.

The two factors related to visual and task characteristics of a writing system we proposed here are able to account for the lateralization differences between English word and Chinese character recognition. Compared with Chinese, words in the English lexicon may look more similar to one other, because of the smaller alphabet size (only 26 letters) and a much larger lexicon size (more than 20,000 words). In contrast, Chinese has a smaller lexicon size (about 4500 characters for a native speaker), but a much larger “alphabet” (i.e., more than 1000 stroke patterns). In addition, English is an alphabetic language whereas Chinese is a logographic language. Chinese logographic reading may require more LSF information that leads to more RH-lateralization compared with English alphabetic reading, since logographic reading does not require a decomposition of words into letters in order to map them to corresponding phonemes.

In summary, here we show that visual and task characteristics of a writing system alone may account for lateralization differences in visual word recognition in different languages. Specifically, they are (1) visual similarity among words in the lexicon, and (2) the requirement to decompose a word into letters for performing grapheme-phoneme conversion during learning to read.

Abstract

Many studies have examined the effects of co-activation of similar words (“neighbors”) during processing, with some reporting facilitative effects and others reporting inhibitory effects. Attractor dynamics has provided a promising integrated account in which distant semantic neighbors (moderately similar words) tend to facilitate processing and near semantic neighbors (highly similar words) tend to inhibit processing. This framework was extended to phonological neighbor effects on the accuracy of word production. For aphasic patients (N=62) and speeded young controls (N=32), picture naming was more accurate for words with many distant phonological neighbors (words with matching onsets) and less accurate for words with a near phonological neighbor (homophones). In addition, the sizes of the facilitative and inhibitory effects were correlated, suggesting that the mechanisms responsible for both effects are functionally integrated. These results extend an attractor dynamics framework that predicts facilitative effects of distant neighbors and inhibitory effects of near neighbors.

Keywords: phonological neighbors; cohort density; homophones; neighborhood density; word production; attractor dynamics.

Introduction

Theories of language processing agree that similar words are co-activated during processing. Such co-activation provides a simple account of classic priming effects: processing *cat* partially activates *dog* (due to semantic similarity) and *can* (due to form similarity), facilitating responses to those words (Marslen-Wilson & Zwitserlood, 1989; Meyer & Schvaneveldt, 1971; Zwitserlood, 1996). Co-activation is also consistent with findings from studies using the visual-world paradigm: when instructed to click on a picture of a *cat*, participants are more likely to fixate images of a *dog* or a *can* (Allopenna, Magnuson, & Tanenhaus, 1998; Huettig & Altmann, 2005; Magnuson, Tanenhaus, Aslin, & Dahan, 2003; Mirman & Magnuson, 2009; Yee & Sedivy, 2006). Co-activation of similar words has also been used to account for global similarity effects: the number of similar words that are likely to be co-activated given a particular similarity metric, called “neighborhood density”. In this report, we examine the effects of two kinds of phonological neighbors on word production in aphasic patients and speeded young controls.

The effects of neighborhood density on word processing are complex and poorly understood. Neighbors defined by form similarity (spelling or sound) have been found to facilitate printed word recognition (e.g., Sears, Hino, & Lupker, 1995) and spoken word production (e.g. Vitevitch, 2002). However, phonologically similar neighbors consistently produce inhibitory effects in many tasks involving spoken word recognition (e.g., Luce & Pisoni, 1998; Magnuson, Dixon, Tanenhaus, & Aslin, 2007). Neighbors defined by semantic similarity can also exert effects in both directions. Near neighbors (concepts with very similar meanings) inhibit word recognition and distant neighbors (concepts with moderately similar meanings) facilitate visual word recognition (Mirman & Magnuson, 2008). Mirman and Magnuson suggested that this contrast between the impact of near and distant neighbors on word processing may be a general property of word processing. For example, although orthographic neighbors (*salt* - *halt*) generally facilitate visual word recognition, transposed-letter neighbors (*salt* - *slat*) exert inhibitory effects (Andrews, 1996).

The attractor dynamics framework for cognition represents each concept as a stable state (“attractor basin” or simply “attractor”) in a high-dimensional space of possible mental states (for an accessible introduction see Spivey, 2007). Word processing is a matter of traversing this space in order to reach the correct attractor. When the system has reached a stable state, it is deemed to have “settled” and the accuracy of the system’s final state can be compared relative to the target attractor. Neighbors are other attractors and distance between attractors is determined by similarity. The critical insight from attractor dynamics is that different similarity relations between neighbors can exert different effects on the settling process (Mirman & Magnuson, 2008). Distant neighbors create a broader attractor basin, which facilitates settling to the correct attractor. In contrast, near neighbors are too few to substantially change the overall size of the attractor basin, but because of their high similarity (i.e., proximity) to the target, they function as conflicting subbasins, which slows the completion of the settling process.

An alternative to the attractor dynamics account would be to simply stipulate that neighbor effects are different in

different contexts or tasks. For example, Vitevitch and Luce (1998; 1999; see also Luce & Large, 2001) proposed that, in speech perception, sub-lexical neighbor effects are facilitative and lexical neighbor effects are inhibitory. However, there are three arguments against this view as a general account of neighborhood effects. First, the empirical data have been challenged (Lipinski & Gupta, 2005). Second, semantic neighbor effects appear to emerge at a single level of processing (i.e., semantics), thus, assigning different effects to different levels cannot account for the facilitative effects of distant semantic neighbors and the inhibitory effects of near semantic neighbors (Mirman & Magnuson, 2008). Third, it is unparsimonious to propose that neighbor interactions have fundamentally different properties at different levels of processing.

Attractor dynamics provide a parsimonious, integrated account in which neighbors can have different, context-dependent effects. However, the existing data have only examined the key attractor dynamics prediction in the domain of semantic neighborhoods. The present studies examine these same predictions in the domain of phonological neighbor effects on word production.

As noted above, previous studies have found facilitative effects of phonological neighbors on word production. Vitevitch (2002) found that healthy young controls produced more errors in an error-elicitation paradigm and were slower to name pictures for words with few phonological neighbors compared to words with many phonological neighbors. Similarly, aphasic patients produce more errors when naming pictures with low phonological neighborhood density names (Gordon, 2002; Kittredge, Dell, Verkuilen, & Schwartz, 2008).

Given the facilitative effect of phonological neighbors in picture naming tasks, one might expect that greater phonological similarity would strengthen this effect. In the extreme case, words with different meanings but identical phonological forms, that is, homophones (e.g. *can* [container] vs. *can* [able]) might be particularly easy. After all, the naming target's homophone is maximally phonologically similar to target's phonology. However, if both meanings are activated during an attempt to retrieve the name of one meaning of a homophone, those meanings may compete, consequently producing slower responses and higher error rates. Thus, there is reason to expect the opposite result. Indeed, this is the critical prediction from the attractor dynamics account of neighborhood effects.

There is an extensive experimental literature investigating homophony in word production, most of which is concerned with whether word frequency effects on picture naming arise from syntactic-semantic representations or phonological form representations (e.g. Caramazza, Costa, Miozzo, & Bi, 2001; Jescheniak & Levelt, 1994). Although there is no consensus among these studies, it is likely that production latencies for a homophone are influenced by the frequency of both its meaning and its form. More relevant to

our analysis are findings that both meanings of a homophone are activated during word production. For example, priming the non-pictured homophone meaning affects response latency and accuracy in picture naming tasks (Cutting & Ferreira 1999; Ferreira & Griffin, 2003). Moreover, picture naming studies with aphasic patients have shown that training on one homophone meaning generalizes to the other meaning (Biedermann, Blanken, & Nickels, 2002; Biedermann & Nickels, 2008a; Biedermann & Nickels, 2008b).

These studies suggest that homophone production involves some degree of interaction between the target and its homophone mate. Given this, if homophones are viewed as very near phonological neighbors, the attractor dynamic approach of Mirman and Magnuson (2008) predicts that having a homophone should be associated with some kind of cost. Alternately, if the extreme similarity of the homophone just exaggerates the positive effect of having a similar neighbor, then the expectation is for a benefit. These conflicting predictions were tested by examining the accuracy of picture naming in aphasic patients and in speeded young controls.

Experiment

Methods

Participants. There were two sets of participants: aphasic patients and speeded young controls. The patients were 62 unselected aphasic patients recruited from the MRRI Cognitive Rehabilitation Research Registry (Schwartz, Brecher, White, & Klein, 2005) on the basis of chronic aphasia secondary to left cerebral vascular accident. They had a mean age of 58 (range 26–78), mean years of education of 14 (10–21), and most (over 90%) were at least 6 months post-onset. The patients were all premorbidly right-handed, had English as the primary language, adequate vision and hearing, and unilateral left hemisphere damage (not restricted to subcortical areas). These patients included all aphasia subtypes and covered a wide range of performance (2%-97% correct naming). The young controls were 32 healthy college students with no known history of neurological, visual, or auditory impairments, who were recruited from the University of Illinois participant pool.

Materials. The 175-item Philadelphia Naming Test (PNT; Roach et al., 1996) was used to measure word production in picture naming. The black and white pictures represent objects from varied semantic categories and have high familiarity, name agreement, and image quality. Names range in length from 1 to 4 syllables and in frequency (normalized to occurrences per 1 million word tokens) from 1 to 100.

Our concern is with the effects of “near” and “distant” phonological neighbors on picture naming in order to test

the general attractor dynamics prediction that the effect of neighbors will depend on their impact on the attractor landscape. Distant phonological neighbors were defined as words that share onsets with the target word. These words are described as “cohorts” because they form the cohort of partially activated words during spoken word recognition (e.g., Allopenna et al., 1998; Magnuson et al., 2007; Marslen-Wilson & Zwitserlood, 1989). There are many possible phonological neighborhood measures, which are all strongly correlated with one another. The cohort density measure (the summed log frequency of the target word and all of its cohorts) was chosen because word onsets are particularly important for spoken word processing.

Lexical variables (phonological neighborhood, word frequency, etc.) were assessed using the American National Corpus (Ide & Suderman, 2004), a large-scale, representative corpus of American English containing over 3.2 million spoken word tokens. The words in the PNT were divided into “few” and “many” neighbor conditions based on the median cohort density (31.5) and a few words were eliminated to ensure that the conditions had an equal number of words and were matched in word frequency and length (the resulting conditions were composed of 85 words each). Table 1 shows that the two conditions were matched in word frequency and length and strongly different in cohort density as well as differing on other phonological neighborhood measures. For the purpose of this experiment, it was not necessary to isolate a particular measure of phonological neighborhood; rather, it was sufficient that words in the two conditions strongly differed in their number of phonologically similar words.

Table 1. Mean (standard deviations in parentheses) properties of stimuli for cohort density manipulation.

	Few neighbors	Many neighbors	t	p<
Phonological neighborhood measures				
Cohort Density	14.9 (8.7)	73.2 (36.0)	14.5	0.0001
Neighborhood Density	10.2 (8.8)	14.1 (11.3)	2.5	0.05
Number of Neighbors	11.8 (12.8)	16.2 (15.2)	2.0	0.05
Posit. Prob.	.211 (0.1)	.263 (0.1)	3.2	0.01

Control Variables				
Num. Words	85	85	-	-
Log Frequency	1.07 (0.7)	1.16 (0.7)	0.94	0.35
Num. Letters	5.51 (1.9)	5.11 (1.9)	1.4	0.17
Num. Phonemes	4.33 (1.7)	4.35 (1.5)	0.09	0.93

Near phonological neighbors were defined as words with identical phonological forms and unrelated meanings, that is, homophones. The 175 words in the PNT include 14 homophones for which the pictured meaning is the dominant meaning (meaning dominance was assessed based

on proportion of associated words in the USF free association norms (Nelson, McEvoy, & Schreiber, 2004): $M=73.6\%$, $SD=10.5$, $Range=50.4-86.7$). Number of meanings (homophony) was assessed based on the number of distinct entries in the online Wordsmyth dictionary (<http://new.wordsmyth.net/>). For each of these homophones a control (unambiguous) word was selected from the PNT that was matched to the homophone on word frequency, length, and phonological neighborhood variables (see Table 2).

Table 2. Mean (standard deviations in parentheses) properties of stimuli for homophony manipulation.

	Homophones	Control Words	t	p<
Num. Meanings	2.21 (0.58)	1.0 (0)	-	-
Control Variables				
Num. Words	14	14	-	-
Cohort Density	50.6 (41.1)	46.7 (36.0)	0.87	0.40

Procedure. The patients were tested using the standard PNT procedure (<http://www.ncrm.org/assessment/pnt>; Roach et al., 1996; see also Dell et al., 1997; Schwartz et al., 2006): each picture was presented one at a time and the first complete (i.e. non-fragment) response produced within 20 s was scored. The young controls were tested using the tempo picture naming procedure (Hodgson & Lambon Ralph, 2008). This task provides a valuable source of converging data for comparison with the patient data because it has been shown to induce some characteristic aspects of aphasic picture naming errors. In the tempo picture naming task, participants heard a series of beeps set to a tempo (500 ms). On the fourth beep they were also presented with a picture (one of the PNT items), which they were to name and to time their response to coincide with the fifth beep.

Results

Cohort Density. The left panel of Figure 1 shows that picture naming accuracy was lower for low cohort density words than for high cohort density words (Patients: 66.7% vs. 70.4%, $t(61)=5.5$, $p<0.00001$; Speeded controls: 79.7% vs. 81.7%, $t(31)=2.37$, $p<0.05$). Patients also produced more nonword errors for low cohort density words than high cohort density words (8.24% vs. 6.62%, $t(61)=3.23$, $p<0.01$). Speeded controls produced very few nonword

errors ($M=0.68\%$, $SD=0.89\%$) and the numerical trend in the same direction as the patients (0.77% vs. 0.63%) was not significant ($t(31)=0.49$, $p>0.6$). There were no significant effects on any other error type. The cohort density finding is consistent with previous findings that words with many phonologically similar words are easier to produce (Gordon, 2002; Kittredge et al., 2008; Vitevitch, 2002).

Figure 1. Picture naming accuracy for high and low cohort density words (left panel) and for homophones and control words (right panel). Error bars reflect 1 SE.

Homophony. The right panel of Figure 1 shows that participants were more accurate for the control words than for the homophones (Patients: 77.0% vs. 71.7% , $t(61)=3.45$, $p<0.001$; Speeded controls: 83.5% vs. 79.4% , $t(31)=5.43$, $p<0.00001$). This finding is consistent with previous results that indicate slowed processing due to competition between different meanings of homophones (e.g., Shatzman & Schiller, 2004; see also Ferreira & Griffin, 2003). The increased errors for homophones did not aggregate to a specific error type (i.e., no reliable differences for any error type).

Relation between effect sizes. We tested the correlation between cohort density and homophony effect sizes across participants to examine whether there is a possible relationship between them. Figure 2 shows each participant's homophony effect size (homophones – control) plotted against that participant's cohort density effect size (high – low). The effect sizes were reliably correlated for patients ($r = -0.25$, $p<0.05$) and for speeded controls ($r = -0.76$, $p<0.0001$).

One possible explanation for this effect size correlation is that there is simply an effect of overall accuracy. That is, participants who make more errors show bigger differences between any conditions. To test this hypothesis, we examined correlations between overall accuracy for the critical conditions and the effect size. For patients, neither correlation approached significance (homophony: $r = 0.0032$, $p > 0.98$; cohort density: $r = 0.0937$, $p > 0.46$). The

same was true for controls (homophony: $r = 0.1124$, $p > 0.54$; cohort density: $r = -0.2616$, $p > 0.14$). Since it is not due to overall accuracy, the correlation between cohort density and homophony effect sizes suggests that the mechanisms involved in producing the benefit of similar-sounding words (cohort density effect) are closely tied to those involved in producing the cost of identical-sounding words (homophony effect).

Figure 2. Relationship between homophony and cohort density effect sizes. Open circles correspond to patients, filled triangles correspond to speeded controls.

General Discussion

We examined the effects of phonological neighbors on picture naming in aphasic patients and speeded young controls. Two kinds of phonological neighbors were considered: similar-sounding words defined as words with matching onsets (i.e., cohorts) and identical-sounding words (i.e., homophones). These different phonological neighbor types capture the important distinction between distant and near neighbors. Mirman and Magnuson (2008) found that distant semantic neighbors facilitated word recognition and near semantic neighbors inhibited word recognition. Andrews (1996) found a similar contrast between the effects of (distant) orthographic neighbors and (near) transposed-letter neighbors on visual word recognition. Based on these results, we predicted facilitative effects of phonological neighbors and inhibitory effects of homophony.

The results were consistent with these predictions: both participant groups exhibited a facilitative effect of cohort density and an inhibitory effect of homophony. In addition, the effect sizes were correlated across participants; that is, participants who showed larger cohort density advantage effects also showed larger homophony disadvantage effects. This suggests that the mechanism or mechanisms that produce these effects are functionally integrated.

To account for the contrasting effects of near and distant semantic neighbors, Mirman and Magnuson (2008) proposed an account based on attractor dynamics. On this view, distant neighbors create a broader attractor basin,

which facilitates settling to the correct attractor. In contrast, near neighbors are too few to substantially change the overall size of the attractor basin, but because of their high similarity (i.e., proximity) to the target, they function as conflicting subbasins, which slows the completion of the settling process. These distinctions are shown schematically in Figure 3. Mirman and Magnuson confirmed this account using simulations of a computational model.

Figure 3. Top: Schematic diagram of narrow and broad attractor basins resulting from few and many distant neighbors, respectively. Bottom: Schematic diagram of a single attractor basin and an attractor with a subbasin formed by a near neighbor.

To extend this framework to word production it is helpful to consider picture naming as a process of settling to an attractor in a multidimensional space that combines semantic and phonological dimensions. For a given target word, cohort neighbors and homophone neighbors are equally semantically unrelated to the target (the cohort pair *can* – *cat* and the homophone pair *can* [container] – *can* [able] are equally semantically unrelated). On the phonological dimensions, the homophone neighbors have substantially more similarity to the target word than cohort neighbors do (i.e., complete phonological overlap vs. shared onsets). Therefore, a large number of cohort neighbors can increase the gradient and facilitate settling to the correct attractor. In contrast, a single homophone neighbor will not have a substantial impact on the gradient, but can form a competing subbasin, which can delay the settling process.

If the settling process is disrupted by damage or a time constraint, the system may fail to settle completely (no

response) or may settle to an incorrect attractor (error). Since settling is facilitated by distant (cohort) neighbors and inhibited by near (homophone) neighbors, this account captures the observed pattern of facilitative effects of cohort density and inhibitory effects of homophony. The correlation between effect sizes could reflect the average sharpness of attractor basins in the landscape. In a landscape with relatively sharp attractor basins, distant neighbor attractors would have a relatively small impact on slope steepness and near neighbors would be less likely to act as a competing subbasin. Attractor dynamic models generally develop sharper attractors over the course of learning, so this individual difference variable could reflect language skill. Further research is required to test this hypothesis or other possible explanations of the correlation between effect sizes.

In sum, the present results demonstrate contrasting effects of near and distant phonological neighbors on picture naming and provide a new perspective on the mechanisms involved in word production. Furthermore, they contribute to the creation of a unified theory of neighborhood effects in lexical processing.

Abstract

This paper presents an experimental study of the influence that the anxiety state may have on analogical mapping. Contrary to the well-known study of Tohill & Holyoak (2000), where the anxiety state impeded the analogical mapping, in this study participants in the anxiety state were significantly more inclined to produce a relational choice which is structurally consistent with the target, even though this alternative was more superficially dissimilar to the target. This result was obtained in a match-to-sample paradigm. The implications for the theory of how anxiety influences analogy-making are discussed and it is argued in favor of a more detailed and specific approach to studying the influence of anxiety on each component mechanism of analogy-making.

Introduction

Imagine that you are in a stressful situation and you feel anxious. Will that make you more or less successful in making good analogies? Some researchers believe that this emotional state will impede the analogy-making process (Tohill & Holyoak, 2000), while others (Richert, Whitehouse, Stewart, 2005) argue that you will make more or better analogies and that is why some religious rituals are deliberately designed to increase your anxiety. This controversy has motivated our study.

The interplay between analogy and emotions has been studied from two opposite perspectives.

Thagard and Shelley (2001) have argued that analogy may influence emotions, since people may use analogies to convey emotions to others like in the famous “Saddam is like Hitler” example (Spellman & Holyoak, 1992). This theoretical account was empirically supported in a recent study using simple proportional analogies (Bliznashki & Kokinov, 2009) which demonstrated that the negative or positive attitude towards an item in one domain can be transferred to the corresponding item in the other domain via the analogy and that this transfer is bidirectional.

Several researchers explored the influence of emotions on the analogy-making process itself. Thus a series of studies was devoted to the influence of anxiety on analogy (Leon and Revelle, 1985; Keinan, 1987; Tohill and Holyoak, 2000). Why anxiety? The specific line of reasoning was that since it is well known that anxiety influences several cognitive processes, including working memory, one should expect also an influence on analogy. Thus Tohill and Holyoak (2000) provided evidence that state anxiety impedes the relational mapping and anxious participants prefer a more superficial attributive mapping. In their study anxiety was induced prior to the task by a serial subtraction task with a negative feedback. Participants were instructed

to count aloud from 1000 backwards with a decrement of 13. One experimenter corrected participants’ mistakes and another – urged participants to count faster. Moreover, participants in the anxiety group were informed that they would have to repeat this task at the end of the experiment, i.e. after the analogy-making task. The influence of anxiety on analogy-making was tested with a cross-mapping task, where participants were asked to indicate which object, presented on one of the pictures “goes with” the object, pointed to by the experimenter. The trick was that the object pointed to in the first picture could “go with” two different objects in the second picture for two different reasons, i.e. with the object which is similar in its physical appearance to the pointed object or with the object that participates in similar relations as the pointed one. Based on Eysenk’s working memory restriction theory (Eysenk and Calvo, 1992) it was assumed that anxiety restricts working memory capacity which in turn impedes higher-order relational mapping needed for finding the relational mappings in the cross-mapping task used in this particular study. Correspondingly, anxious participants¹ indicated fewer relational mappings than non-anxious participants (Experiment 1) even in the presence of explicit instruction to find them (Experiment 2) (Tohill and Holyoak, 2000).

It was also shown that state anxiety impedes the range of generated analogies to a given base problem (Feldman and Kokinov, 2009). Anxious participants generated a significantly smaller amount of drastically different analogies, i.e. most of their analogies belonged to one domain, while non-anxious participants were more flexible and generated analogies belonging to two or three different domains. In addition, non-anxious participants produced analogies with remote domains, while anxious ones produced mainly close analogies. At the same time no difference was found between the quality of mapping and convincingness of the analogies produced. So, no direct evidence was produced neither in favor, nor against the hypothesis that anxiety impedes analogical mapping. It was only demonstrated that anxiety impedes analogical retrieval (in an analogy generation task).

On the other hand, it has been shown that people in negative mood are more likely to choose the relational match rather than the attribute matches compared to people in positive mood in a simple matching-to-sample task (Hristova, 2009). In this study both the relational and the attribute mappings were possible, but curiously people in negative mood prefer the former ones, i.e. they choose the

¹ state anxiety is used here, not trait anxiety.

relationally similar target as being more similar to the base stimulus. Hristova (2009) argues that the triples of figures used as stimuli in this experiment presuppose that the relational mappings were harder than the attribute ones, since they require an extra effort for encoding of relations, which were not explicitly drawn between figures. Hence participants in negative mood invested more effort while doing the task than participants in positive mood, consistent with the cognitive tuning hypothesis (Schwarz, 2002) that has inspired this experimental work. Since the core of analogy-making is exactly the mapping between relations, rather than attributes (Gentner, 1983) the straightforward inference from this work is that negative, rather than positive mood may enhance analogy-making by facilitating the encoding of relations.

In conclusion, it seems that there is controversial evidence for the role of emotions on analogical mapping. Tohill and Holyoak (2000) have found that state anxiety may change analogical mapping from relational toward attribute based one, while Hristova (2009) has found that negative mood, which can be considered as similar in valence to the state of anxiety (i.e. anxiety is a kind of negative emotional state) facilitates relational mapping compared to positive mood.

It could be that anxiety exerts a completely different influence on analogical mapping than negative mood: an interesting hypothesis that insists on fine grade distinction between the negative emotions themselves and therefore, between the cognitive mechanisms that these emotions may change. This hypothesis however, cannot fully explain the variety of results obtained in the field of analogy-making, since two experiments that manipulate state anxiety report different results with respect to analogical mapping: Tohill and Holyoak, (2000) demonstrated less relational mappings due to anxiety, while Feldman and Kokinov (2009) did not report any effect of anxiety on analogical mapping.

The present research aims to further explore the influence of anxiety on analogical mapping by exploiting the anxiety-inducing procedure used by Feldman and Kokinov (2009) and the analogical mapping task used by Hristova (2009). If anxiety impedes relational choices in this task rather than facilitate them, as shown under negative mood (Hristova, 2009), then it would be relatively safe to conclude that the diverse negative emotions (to be more specific, anxiety compared to negative mood) exert different effects on analogy-making. If the opposite trend is observed then the picture of influence of anxiety on analogical mapping is more complicated.

Experiment

Method

The main idea of this experiment is to test whether an induced state of anxiety will change the type of relational processing performed by the participants and in particular whether the proportion of relational choices will be higher or lower than in a non-anxiety state.

Design

This experiment has a between-subject design with one independent variable – the state of anxiety (an anxiety and a non-anxiety group), and one dependent variable the proportion of relational choices made. Two other variables were used for control purposes only – the state of anxiety as measured by a self-report on a scale and the response times.

Stimuli

22 stimuli were used in this experiment. Each of them was a match-to-sample-triple consisting of a base item B and two target items T1 and T2. The question that the participants had to answer was “whether T1 or T2 is more similar to B”. The stimuli were prepared in such a way that one of the targets was sharing the same objects or the same color of the objects as the base, i.e. was superficially similar to the base, while the other one shared some spatial or transformational relations but consisted of different objects, i.e. was structurally similar. Both choices make perfect sense. Three groups of stimuli were used in the experiment and representatives of each group are presented in Figure 1. There is a forth group of stimuli which are only partially analogous (i.e. none of the two is a good match) since only some of the relations/attributes are shared (Figure 2). These stimuli were used by Hristova (2009) and are variations of the stimuli used by Medin, Goldstone, and Gentner (1990) and Sloutsky and Yarlas (submitted). We have used them for replication purposes.

Figure 1. Three examples of items from the Match-to-Sample task, one example from each category of stimuli. In all three cases T1 is the relational choice, while T2 is the superficially similar one. Of course, in the experiment the order of T1 and T2 presented as relational/superficial choice has been contra balanced.

Figure 2. An additional type of examples used in the Match-to-Sample task for replication purposes. Neither T1, nor T2 makes perfect analogy to B, but T2 keeps the spatial relationships, while T1 keeps the relations between textures.

Procedure

The participants were tested individually by an experienced experimenter in a sound proof booth on a personal computer running e-Prime automated script.

Participants were enrolled in a matching-to-sample experiment for about 5 minutes. Their task was to judge whether “T1” or “T2” are more similar to the standard “B” by pushing the respective button on a BBOX: the left button “T1” and the right button for “T2”. When participants gave their answer the next stimulus appeared on the screen. The presentation order of the stimuli was randomized across participants. A fixation cross was presented for 50 ms before each trial.

In the Experimental group the state anxiety was induced by a “public speech” procedure which was used successfully

to induce state anxiety in a number of other studies (Graeff1, Parente, Del-Ben, Guimarães, 2003; Pertaub, Slater & Barker, 2002; Feldman & Kokinov, 2009). The participants in the Anxiety group when invited were instructed that at some point they will be interrupted and will be asked to make a presentation on a topic that they will not know in advance. The task will be to argue in favor of a specific claim. They will have to talk spontaneously and without interruption for 5 minutes. Their presentation will be video recorded and then later on their communication skills will be evaluated. In that moment the experimenter installed a camera in front of the participant, but no recording was initiated. They were asked meanwhile to participate in another experiment and they were given the match-to-sample task described above. The participants were never asked to make the public speech and were never recorded, however, they were constantly expecting that this was going to happen. At the end the participants were debriefed about how they were feeling and they also rated on a 5 point scale how nervous they were during the experiment.

Participants

38 participants (15 male and 23 female) took part in the experiment. All of them were students at the New Bulgarian University some in psychology and some in other programs. Their age varied from 17 to 37 years and the average was 22.95. The participants were randomly assigned in equal numbers to the two conditions, maintaining equal ratios between female and male participants in each group.

Results

First of all, our manipulation of anxiety seems to be successful. The two groups differed significantly on their self-evaluation of how nervous they had felt during the experiment on a 5 point scale ($t(36)=4.624$, $p<0.001$, $d=1.50$) – the Control group ($M=0.79$, $SD=1.134$) and the Anxiety group ($M=2.32$, $SD=0.885$).

The mean proportion of the relational choices was higher in the anxiety group (35%) than in the control group (24%) and this difference turned out to be significant tested with a t-test when the data were aggregated by item – ($t(42)=5.695$, $p<0.001$, $d=0.31$) (Figure 3). At the same time importantly, RT did not differ significantly between the two experimental conditions: $t(42)=0.397$, $p=0.693$, (Figure 4). Thus, the influence of anxiety cannot be attributed to spending more time and more careful inspection of the task in the anxiety group.

Figure 3. Mean proportion of relational choices per condition.

Figure 4. Mean RT per condition.

The same trend was observed for the six stimuli of Hristova (2009), included in the item pool of this experiment: the anxiety group made significantly more relational choices (38%) than the control group (25%) ($t(10)=0.424$, $p=0.016$, $d=1.78$), while the difference in the mean RT was again not significant ($t(10)=0.782$, $p=0.452$). This result is comparable to the one obtained by Hristova (2009) with the same task and stimuli, where people in negative mood also made significantly more relational choices than people in positive mood.

Discussion

The goal of this research was to clarify the role of anxiety for analogical mapping. Two conflicting findings were discussed at the beginning: anxiety may impede relational mapping (Tohill and Holyoak, 2000) or anxiety, as a kind of negative emotional state, may facilitate relational mapping (Hristova, 2009). The present research supports the latter prediction, i.e. anxiety facilitated relational mappings.

The question now is why we have obtained results opposite to the ones by Tohill and Holyoak (2000)? There are two important differences between the two studies: the

procedure of anxiety inducement and the tasks of the participants. Each of them could potentially cause the difference.

With respect to the anxiety inducement procedure there are a number of differences. It could be that one of them is inducing stronger anxiety than the other. We cannot say this with certainty, since we have not used the same instrument for measuring the anxiety state of the participants, however, there are reasons to believe that the current procedure induces stronger anxiety since making a public speech and being recorded and then your communication skills being analyzed seems more stressful than counting backwards at high speed and being corrected. In addition, in the current procedure the participants were warned that they can be interrupted any time and asked to make the public speech, while the participants in the Tohill & Holyoak (2000) study knew that they will be counting again only after the analogy task is over. Of course, these are only speculations, it is also possible that the current procedure has produced much less anxiety than the Tohill & Holyoak (2000) study and the results are due to the classical Yerkes-Dodson law (1908) that describes the inverted U shaped relationship between arousal and performance: maybe we have found the optimal level of arousal for the matching-to-sample task used in our experiment, while Tohill and Holyoak (2000) did not. In other words anxiety may both increase and decrease relational mappings depending on the degree of arousal. This explanation is unconvincing since the very same procedure has been applied by Feldman & Kokinov (2009) and it has significantly reduced the number of *different* analogies generated and their *scope*. Also additional analysis of the data shows that there is a trend: the higher the self-reported anxiety is, the more relational choices participants make, i.e. there is no point above which the relational choices have declined.

Alternatively, the difference might be due to the difference in the analogy tasks used in both experiments. This would be an interesting avenue for research since it would require task analysis and decomposition of the “analogy-making process” into simpler mechanisms and exploring the role of anxiety for each of these components. Thus, for example, in both tasks – the cross-mapping corresponding task used by Tohill & Holyoak (the subject has to point to the corresponding object of a hinted one) and the match-to-sample task used in the current study (the subject has to chose which of two alternative situations is more similar to the sample) – the participants have to encode certain relations and attributes of the objects and than build the two alternative mappings, and finally chose the better one. According to some models of analogy-making like ARCS (Holyoak & Thagard, 1989), AMBR (Kokinov, 1994, Kokinov & Petrov, 2001), CopyCat and TableTop (Hofstadter, 1995), LISA (Hummel & Holyoak, 1997) there are at least 3 subprocesses of analogy-making: perceiving (encoding) the relations, forming hypotheses of possible correspondences, and competition between them (constraint satisfaction), other models like SME (Gentner,

1983, Falkenhainer, Forbus, Gentner, 1989) offer alternative but analogous subprocesses. Anxiety may influence each of these subprocesses specifically. Since Tohill & Holyoak (2000) allow their subjects to observe the two pictures for 15 sec before the question was asked, this would mean that all relations are already encoded and possibly also most of the hypotheses are formed and after the query mostly the constraint satisfaction process continues. Thus the influence of anxiety would be mainly on the constraint-satisfaction outcomes. In our study participants used on average 4 sec for the whole task of encoding, hypotheses building, and constraint satisfaction. Therefore, it is reasonable to assume that they do not have the time for full relational encoding, building all possible hypothesis, etc. Most probably they encode only a few relations and form a few hypotheses and therefore the constrain-satisfaction process is quite straightforward. Thus most probably the anxiety state influences mostly the process of relational encoding in this case. According to the DUAL architecture and the AMBR model (Kokinov, 1994, Kokinov & Petrov, 2001) anxiety concentrates the activation over a smaller area of Long-Term Memory thus causing a smaller search space but faster processing within this space (Feldman & Kokinov, 2009). Thus maybe the anxiety state in our task causes a speeded search for relational encoding (especially given the restricted number of relations used in the stimuli) and hypotheses formation and that is how anxiety enhances relational choices.

Such a possibility is potentially and indirectly backed up by neuroscience approaches to anxiety and its influences on cognitive processes. Posner, Rueda, and Kanske (2007) distinguished 3 main attentional neural networks – *alerting network* (associated with the right frontal and parietal brain areas which contributes to the maintenance of the sensitivity level needed for perceiving and processing stimuli), *orienting network* (associated with the superior parietal lobe, frontal eye fields, and temporoparietal junction which contributes to the selection of information from among numerous sensory stimuli), and *executive control network* (associated with midline frontal areas, anterior cingulate gyrus, and lateral prefrontal cortex which contributes to the conflict resolution and voluntary action control) which could be somehow related to the three processes described above: encoding relations, building hypotheses, and constraint satisfaction. The encoding of relations would depend on the alerting network allowing bottom-up recognition of relations; the hypotheses formation – on the orienting network selecting potential correspondences; and the constraint satisfaction depending on the inhibitory capacity of the executive control. A recent study by Pacheco-Unguetti, Acosta, Callejas, Lupianez (2010) found that the anxiety state enhances the work of the alerting and orienting networks, while no significant effect was found on the executive network, while the trait anxiety has no effect on the alerting and orienting networks, but severely diminishes the executive control and its possibilities for inhibition. Thus “state anxiety is related to greater orienting

and alerting effects, thus making participants more sensitive to bottom-up processing” (Pacheco-Unguetti et al., 2010). This might mean that in an anxiety state people are more rapidly encoding the relations which are otherwise difficult to be perceived and this could explain why the anxiety-induced subjects made more relational choices in our experiment. This hypothesis can be potentially backed up also by the study of Becker (2009) who found that in the presence of threatening stimuli people are faster in visual search also for non-threatening stimuli, i.e. faster encoding is performed. It is true that the search he has studied is for objects, not relations, but we plan an experimental study to test whether this speeded processing will also be extended to relations as we assume. At the same time the anxiety-induced subjects in the Tohill and Holyoak (2000) study had the necessary time to encode all relations in advance and therefore the effect could be due either to the limited capacity of working memory (Eysenck & Calvo, 1992) or to impoverished constraint satisfaction. Of course, all these are wild speculations and further studies are necessary to test these hypotheses.

The main conclusion from this study is that the influence of anxiety on analogical mapping is much more subtle and complicated than previously thought and that we need to study more carefully the influence of anxiety on each of the components of the analogy-making process before jumping to bold conclusions.

Acknowledgments

Abstract

The durations of negative events are overestimated when compared to the actual amount of time passed (Langer, et al, 1961; Meck, 1983). Similarly, emotionally valenced faces are temporally overestimated when compared to neutral ones (Droit-Volet, Bruno, & Niedenthal, 2004). In the current study, participants embodied emotion via mood induction prior to temporal estimation of neutrally valenced faces. Valenced mood induction led to overestimation of the duration of neutral faces. Results support the claim that embodiment of emotion can cause subjective temporal distortion.

Introduction

Several movies, advertisements, and societal icons portray the old adage, ‘Time flies when you are having fun’, but only recently did science begin investigating the legitimacy of this statement. Does subjective experience of duration really change when in emotionally valenced situations? Experiencing emotional events such as foot shocks (Meck, 1983) and approaching threatening stimuli (Langer, et al., 1961) results in overestimation of event duration, implying that subjective experience of time speeds up when participating in negative events. Simply put, negative situations produce the feeling of more time going by than has actually passed.

The current paper investigates the impact of emotions on temporal perception and the scalar theory of timing (Gibbon, 1977). Past research has found that humans overestimate the duration of emotionally valenced faces (Droit-Volet, Bruno, & Niedenthal, 2004), and the current study evaluates an embodied emotion

premise for this subjective temporal bias. After mood induction, participants evaluated the duration of neutrally valenced faces. We hypothesized that participants in valenced moods would overestimate the duration of these neutral events, supporting the impact of embodied emotions on subjective temporal perception.

The Scalar Theory of Timing

A predominant theory of timing is the scalar timing theory (Gibbon, 1977) which comprises two fundamental properties: (1) the internal clock is, on average, accurate in estimating stimulus durations, and (2) the greater the mean duration of time has passed, the larger the variability of the internal clock’s estimation. Three stages are outlined in scalar timing theory: (1) the clock stage, (2) the memory stage, and (3) the decision stage. During the clock stage, a pacemaker emits pulses that are stored in an accumulator, with more pulses representing longer durations. The accumulator is opened or closed with a mode switch, allowing specific events to be separated for temporal estimation. Once event timing is complete, the contents of the accumulator are stored for later use in the decision stage in working memory, where they are compared to previously experienced durations stored in long-term memory. The decision stage allows for appraisal of relative values in order to make an assessment of time.

In this scalar model of timing, an attentional system—which can allocate differential resources to incoming stimuli based on perceived importance—is added to the modal switch of the clock phase, helping explain erroneous time estimation. While scalar timing theory posits that the internal clock is generally accurate, over and under-estimation of time does occur. For example, previous research suggests

that attentional distraction can either delay the mode switch closing or prematurely open it, resulting in a net loss of pacemaker pulses. This loss results in an underestimation of time (Buhusi & Meck, 2006; Coull, et al., 2004; Lejeune, 1998; Macar, 2002; Meck & MacDonald, 2007).

Effects of Emotion on Attention and Timing

Emotional salience can significantly impact attentional priority, with highly emotional stimuli directing both conscious and unconscious attention away from neutral stimuli (Taylor & Fragopanagos, 2005). Emotional stimuli have been shown to: (a) be detected faster and more accurately than neutral stimuli, regardless of the number of distracters (Ohman, Flykt, & Esteves, 2001), (b) remain more detectable within an attentional blink paradigm, even persisting past the point at which neutral stimuli become minimally detected (Anderson & Phelps, 2001), and (c) capture automatic attention earlier than neutral stimuli when measured by event-related potentials (Carretie et al., 2004). Furthermore, affective priming's impact on emotional judgment (Murphy & Zajonc, 1993) and amygdala activation of backwards-masked emotional stimuli (Whalen, et al., 1998) also demonstrate how both detected and undetected emotional stimuli impact cognitive and neural processes involved with attention.

Recent findings have provided substantial evidence that emotions also impact temporal processing by causing overestimation of the duration of emotional: (a) events (Langer, et al., 1961; Meck, 1983; Stetson, Fiesta, & Eagleman, 2007), (b) faces (Droit-Volet, Brunot, & Niedenthal, 2004; Gil, Niedenthal, & Droit-Volet, 2007), and (c) other stimuli (Angrilli, et al., 1997; Noulhiane, et al., 2007). When experiencing stressful events, such as foot shocks (Meck, 1983), approaching threatening stimuli (Langer, et al., 1961), and forcing eye contact with an angry face (Schiff & Thayer, 1970), higher arousal level is hypothesized to increase the pacemaker's speed, thereby impacting the number of pulses acquired in the accumulator. In addition, a significant interaction between emotional valence and arousal has been found, with the duration of high

arousal, negative stimuli being overestimated when compared to high arousal, positive stimuli (Angrilli, et al., 1997). The relationship is reversed when low arousal stimuli are presented, with the duration of negative stimuli being underestimated when compared to positive stimuli (Angrilli, et al., 1997). Finally, the durations of emotionally valenced faces (i.e. angry, happy, and sad) are significantly overestimated when compared to neutral faces in a duration bisection task (Droit-Volet, et al., 2004). These results are consistent with those of Schiff and Thayer (1970), who found that perceived duration of forced eye contact with an angry face was significantly longer than perceived duration of eye contact with a neutral face.

Together, these findings suggest that emotional stimuli, events, and faces impact the speed of the pacemaker invoked by scalar timing theory. Other research suggests that the impact of emotional faces on temporal processing may also involve embodied cognition of perceived emotion.

Embodiment of Emotion

Viewing emotional events, stimuli and faces similarly affect temporal processing, but a remaining question is whether the experience (embodiment) of emotions affects temporal estimates of neutrally valenced stimuli. Studies suggest that embodiment of emotions occurs when exposed to valenced faces (Chambon et al., 2008; Effron, et al., 2006). Embodiment of other groups' physiological behavior has been demonstrated by Bargh, et al (1996) with participants: (a) walking slower when exposed to elderly stereotype words in a word search, and (b) being more likely to interrupt when exposed to rude stereotype words. Similarly, Chambon, et al. (2008) hypothesized slowing down of the internal clock speed when exposed to elderly faces versus younger faces. Effron, et al. (2006) investigated if an embodied cognition approach could specifically explain the impact of emotional facial stimuli on temporal processing; indeed, inhibiting imitation of viewed facial expressions (by having participants hold a pen between their lips) eliminated any overestimation of the duration of valenced faces. These results suggest that imitation of facial

expression may influence timing processes, though additional evidence for the role of embodied emotion on temporal processing is needed.

The current study will thus further investigate the role of embodied cognition through evaluation of the implication set forth by Effron, et al. (2006). If perceived mood is embodied, and as such impacts temporal perception, similar effects should be seen when mood is induced and neutral stimuli are evaluated as when valenced stimuli are evaluated in a neutral mood. Induction of positive, negative and neutral moods was utilized to determine whether emotionally valenced mood leads to duration overestimation of neutral faces similar to the effect seen when timing valenced stimuli. If overestimation of neutral facial stimuli were found for those in a positive and negative mood, compared to participants in a neutral mood, results would indicate that subjective temporal distortion could occur via embodiment of emotion. The current study also evaluated the influence of emotion on the scalar timing theory, specifically the impact of emotional arousal and attention prioritization. Differences in point of subjective equality between moods revealed a bias shift, seen in previous literature, implicating an increase in pacemaker speed during emotionally arousing situations. Furthermore, attentional prioritization of any emotional stimuli used in previous studies was decreased through the use of neutral stimuli in this study, thereby allowing for the exclusive analysis of embodied emotional arousal on temporal perception.

Methods

Participants

Participants consisted of 32 undergraduates (males: $n = 14$, females: $n = 18$) in psychology classes at Utah State University (neutral mood: $n = 12$, positive mood: $n = 7$, negative mood, $n = 13$). Participants received course credit for participating.

Material: Apparatus and Stimuli

All participants were asked to complete a computer-based bisection task taking approximately 30 minutes. The experiment was run on a Dell Optiplex 755 computer with a 21

inch monitor in a dimly lit room. Participants sat approximately 45 cm from the display. The task stimuli were presented and data were recorded using E-prime, and participants made all responses using a keyboard. The stimulus presented for the practice trials was a white oval (9 x 10 cm) similar to that used by Droit-Volet, et al. (2004). One photo of a female face with a neutral expression, which had been coded using the Facial Action Coding System (Tracy, et al., 2009), was used for the testing trials (44x .32 cm).

Procedure

Before the bisection task, a mood induction procedure was run in which each participant was presented with a series of either positive ($n = 25$), negative ($n = 24$), or neutral ($n = 35$) Velten statements (Velten, 1968) that progressed automatically on the computer screen over the course of 8 minutes. Participants were instructed to “read each and think about them as if you were experiencing them.” This procedure has been used to induce both positive and negative moods in many previous studies (Jennings, et al., 2000; Sinclair, et al., 1994; Strickland, et al. 1974).

Immediately following the mood induction, participants completed a temporal bisection task similar to the one used in Droit-Volet et al. (2004) with two trial phases: (1) practice, and (2) testing. Participants pressed the space bar to initiate each trial. In the practice phase, a white oval was presented for the longest (1600 ms) and shortest (400 ms) durations. Participants had to press the ‘d’ key if the duration was closer to 400 ms or the ‘k’ key if the duration was closer to 1600 ms. Each stimulus was presented 8 times, for a total of 16 trials. Accuracy feedback was given after each trial; positive feedback consisted of ‘Correct!’ displayed visually for 1500ms, while negative feedback consisted of ‘Incorrect’ displayed visually for 1500ms. Participants were then instructed to press the spacebar to begin the next trial. In the testing phase, participants were presented with a neutral face rather than a white oval as the stimulus to be timed, and feedback was eliminated. This face was presented for 18 trials each at each of 7 durations in random order, including the shortest and longest durations from the training phase and various

intermediate durations (400, 600, 800, 1000, 1200, 1400, and 1600 ms) for a total of 126 trials.

Results

For the training phase, participants in all mood conditions demonstrated accuracy on the bisection task prior to starting the test trials (neutral = 91.67%, positive = 98.43%, negative = 93.75%). For the testing phase, the mean proportion of long responses was calculated for each stimulus duration and separated by mood condition (see Figure 1).

To evaluate any significant differences between groups, a non-linear regression analysis was performed [model: $Y=1/(1+[x/T50]^E)$] followed by a statistical comparison of the slopes (E) and subjective mid-point (T50) using a student's t-test. No significant differences between slope were found across groups. The following significant differences between subjective mid-point (T50)—the stimulus duration that the participant is equally like to categorize as 'short' or 'long'--were found: (a) those in a positive mood had a significantly lower T50 than those in a neutral mood ($t(15) = -4.414$; $p < .01$; positive: T50 = 893; neutral: T50 = 948.6), and (b) those in a negative mood had a significantly lower T50 than those in a neutral mood ($t(21) = -3.187$; $p < .01$; negative: T50 = 904.8; neutral: T50 = 948.6). Thus, lower points of subjective equality were found in the positive and negative mood groups, as compared with the neutral mood group, supporting the premise that induction of valenced moods causes overestimation of the duration of neutral events.

Figure 1. Proportion of 'long' responses for the duration of neutral facial stimuli for participants in neutral, positive, and negative moods.

As evidenced in Figure 1, this produces a leftward shift for the psychophysical functions of participants in valenced moods compared with neutral moods, and results in a bias to respond 'long'.

Discussion

The present findings replicate the effect of emotion on temporal perception found by Droit-Volet, et al. (2004) with emotionally valenced mood causing overestimation of neutral stimuli duration compared to duration estimation in neutral moods. The current use of mood induction, instead of emotional stimuli, supports the claims set forth by Effron et al. (2006) outlining the embodiment of perceived emotion significantly impacting temporal perception. The impact of experienced mood on temporal perception being identical to the impact of observed mood on temporal perception endorses the idea that embodying perceived emotion causes temporal bias when judging stimulus duration.

The current findings also speak to the influence of arousal on the scalar timing theory by illustrating a significant difference in point of subjective equality as well as no significant difference in sensitivity – slope- between groups. The use of neutrally valenced stimuli, as well as no slope differences between groups, indicates little if any impact of attentional demands on temporal perception. Furthermore, significant differences in point of subjective equality supports previous findings that arousal can impact pacemaker speed (Droit-Volet, et al., 2004; Gil & Droit-Volet, 2009). Positive and negative moods increase arousal levels, thereby causing faster pulse emission from the pacemaker and resulting in longer subjective judgment of time passed. Overall, in conjunction with previous research examining the effects of emotionally valenced stimuli on temporal perception, the current findings: (a) reveal the same impact via valenced mood induction on timing of neutral stimuli, and (b) suggest that

embodiment of emotions may distort temporal perception via increased arousal.

A body of research on depression and temporal perception suggests that the slowing of pacemaker speed in depressed individuals causes time to pass subjectively slower and underestimation of time (Blewett, 1992; Gil & Droit-Volet, 2009). There is a deceleration of general motor function in depression (Lemke, et al., 2000), however, manifested in reports of helplessness and resignation and not seen in non-depressed patients in a sad mood. This difference in motor function speed could account for the disparity in temporal perception in depressed and non-depressed patients. Regardless, differences in temporal perception between clinical populations with affective disorders (i.e. depression, bi-polar disorder) should be further addressed in future research.

Whether temporary valenced mood increases pacemaker speed or depression slows it, both support the idea that embodiment of emotions can drive temporal biases. When imitation of viewed facial expression is inhibited, for example, stimulus valence fails to impact temporal perception, suggesting that merely *perceiving* emotions in others is not sufficient to impact timing (Effron et al., 2006). The current finding that temporary mood induction produces the same effect on temporal perception as perceived mood further supports the claim that embodiment of emotions may play a mechanistic role in the influence of valence on timing.

Abstract

The studies examine the role of *hot cognitions* alongside *cold cognitive appraisal* within the framework of *coherence-based reasoning*. In two simulated legal cases we find that emotions towards the suspect and motivation with respect to the outcome of the case are strongly correlated with the cognitive appraisal of the facts of the case, the judged credibility of the witnesses, and the overall judgment of the suspect's blame. Moreover, emotion and motivation partially mediate the effect of experimental manipulations on decisions.

Keywords: Decision-making; constraint satisfaction processes; coherence based reasoning; legal decision-making.

Introduction

Decision making in real-world situations characterized by complex patterns of facts often involves *coherence-based reasoning*; as decision makers consider a pattern of evidence and come to a conclusion, judgments about the facts of the case and the conclusion shift to become more coherent with each other (Holyoak & Simon, 1999; Simon, 2004; Simon et al., 2004a; Simon et al., 2004b). We sought to extend this research by investigating the role of *hot cognitions* in the *cold* cognitive appraisals involved in such judgments. We were particularly interested in whether and how emotions and motivation are implicated in conclusions about a suspect's guilt. Considerable research has recently examined the role of emotions in decision-making (Rick & Loewenstein, 2008). Particular attention has been directed at anger, which leads to systematic distortions in a variety of judgments. These distortions are especially problematic when the anger is aroused by a source that is unrelated to the person being judged. Observers aroused by such *incidental anger* are more likely to attribute blame to the person being judged, to perceive her conduct as intentional, to lower the required threshold of evidence, to neglect alternative explanations and mitigating circumstances (Lerner, Goldberg, & Tetlock, 1998; Goldberg, Lerner, & Tetlock, 1999; Quigley & Tedeschi, 1996), and to increase the desire for retaliation (Ferguson & Rule, 1983).

Social judgment has also been shown to be affected by motivation. As noted by Kunda (1990), reasoning processes

under *directional goals* often lead to results that comport with those goals, whereas *accuracy goals* tend to lead to more objective conclusions (Balcetis & Dunning, 2006; Ditto & Lopez, 1992; Piercey, 2009).

In the current studies we sought to study the impact of *directional goals* by giving some subjects a specific role as either prosecutor (or investigator) and other subjects the role of defender. Taking on such *adversarial roles* may lead to biased information search and hypothesis testing. We also hypothesized that such *adversarial roles* may lead to negative emotions, such as anger.

Unfortunately the research demonstrating the effect of emotion and motivation on reasoning offers little insight into how these effects occur. How do emotion and motivation interact with the variables on which the judgments are supposed to be based: facts, preferences, values, etc.? One possibility is that emotion and motivation override these underlying variables. Another possibility is that emotion and motivation influence the underlying variables in the corresponding direction, which makes the corresponding judgments feel natural and obvious. The latter explanation is consistent with the Gestaltian notions that underlie *coherence-based reasoning*: the mental model of the task settles at a state of equilibrium at which all relevant elements—the underlying variables, conclusion, motivation, and emotion—all cohere with one another. Thus, we hypothesized that the constraint satisfaction processing that underlies *coherence-based reasoning* would engulf both the cold cognitions (as observed previously) and the hot cognitions. This prediction dates back to Heider's Balance Theory, in which liking for a person or an object was theorized to affect the overall balance of the structure (Heider, 1958). More recently, researchers have modeled hot and cold cognitions within the framework of constraint satisfaction processing (Nerb, 2007; Thagard, 2006).

Overview of Studies

In both studies, participants judged a quasi-criminal case concerning an allegation of academic misconduct by a university student. Participants were asked to imagine that they worked at a state university in the Office of Student

Disciplinary Affairs, which deals with allegations of academic misconduct. The Office investigates and adjudicates the allegations and, where appropriate, recommends disciplinary actions. The procedure consisted of an investigation followed by an adversarial-like disciplinary hearing, in which a University Representative prosecutes the case, and the student is defended by a Student Representative. The cases are ultimately decided by the university's Chief Judicial Officer.

The case involved an allegation that a student, Debbie Miller, cheated on a closed-book exam by copying from her notes. Participants received the case information, and were asked to make a variety of judgments about the incident. All participants received the same case information and instructions, except for assignment instructions, as described below. None of the manipulations provided any information pertaining to whether she cheated or not. In all conditions, participants were instructed to be "fair and objective."

The first study examines whether the objectivity of investigation is affected by directional motivations and emotions that are elicited by the adversarial nature of the process. Participants were asked to play the role of the investigator, and assigned to investigate the case for one of the two parties (the two adversarial assignments) or for both (the non-adversarial assignment).

The second study examines the effects of the intensity of adversarialism. Participants were asked to role-play a prosecutor-like role in a case of alleged academic misconduct. Half of the participants were given background information intended to induce low intensity (*non-partisan*) (e.g., you feel that most of the time, the disciplinary process reaches correct decisions), while the other half were given information intended to induce high intensity (*partisan*) (e.g., you believe that many of the students who were cleared by the disciplinary process did in fact cheat).

Study 1: Adversarial and Inquisitorial Investigations

This study tested whether and how investigations conducted in an adversarial framework might lead to different outcomes than investigations conducted in a non-adversarial mode. Participants were assigned to investigate the case for either one of the parties (two adversarial conditions) or for both parties (the non-adversarial condition). We predicted that relative to the non-adversarial assignment, the adversarial assignments would result in views of the case that would be tilted towards the respective assignments and that these views would be mediated by motives and emotions elicited by the role assignment.

Method

Participants. Participants were 296 individuals who completed the study via the Internet. The sample was 62% female, with an average age of 43.

Procedure. Participants went through a series of web pages containing the instructions, the case information, and the measures. They were informed that the assigned role of

investigator entailed preparing the evidence to be submitted to the disciplinary hearing. All participants received the same case information and instructions, except for assignment instructions, as described below.

Assignment. Participants were randomly assigned to one of three conditions. The "university-assignment" condition was designed to simulate a police investigation. Instructions emphasized that the individual was performing the investigation on behalf of the University and their reports were central to the case. They were also told that someone would be fulfilling a similar function for the other side.

The "Debbie-assignment" condition was designed to simulate a private investigation for the defense. The instructions for this assignment were identical to the university assignment, but the sides were reversed.

The "Sole Investigator" condition was designed to mimic a non-adversarial investigation; participants were told that they were the sole investigator in the case. The instructions emphasized that they were the only investigator working on the case and that both sides would rely on their report.

All participants were exposed to the same case and instructed to be fair and objective. Participants performed the study alone, and there was no other investigator.

Case. The case was intricate and ambiguous. From the university files, participants learned that Debbie, a junior, was an "A" student, and was considered hardworking and ambitious. At high school, she was charged with cheating on an exam, but the file did not indicate whether she was disciplined or not. An interview with the examination room proctor revealed that Debbie sat against a wall, close to the back corner of the room. The proctor noticed that Debbie sat crouched over her papers, as if she was hiding something. At the end of the exam, she noticed also that Debbie stuck something into the pocket of her sweater, which later turned out to be a note with a summary of the course. Brad Loomis, a fellow student who sat behind Debbie, claimed to have seen her pull out the note from her sweater pocket and copy from it throughout the exam. The professor reported that Debbie was anxious about the exam, but did not believe that she cheated. He did mention that she was the only student to respond correctly to one of the questions. Debbie denied the allegations adamantly. She stated that as an A student, she had only to lose by cheating. She explained that she crouches when sitting for long periods of time because of a back injury she sustained while playing on the college volleyball team.

Dependent Variables. 1. *Overall Judgments.* Participants estimated the likelihood that Debbie cheated on the exam (0-100%), how they would decide the case, how they expected the Chief Judicial Officer to decide the case, and which side their view supported.

2. *Case facts and related beliefs.* Participants evaluated 13 factual issues involved in the case, and 9 belief questions that corresponded to 9 of the factual questions (1 - 11 scale).

3. *Judgments of Liking, Emotions, and Motivation.* Participants indicated how much they liked Debbie (0-100). Next, they reported how much they felt three positive

emotions (sympathy, compassion, and sorrow) and three negative emotions (anger, scorn, disgust) towards Debbie. Another question gauged participants' motivation towards the outcome of the case by asking participants which side they wanted to see win the case. (all on a 1-11 scale)

4. *Objectivity and Distrust.* The questions measured participants' assessments of the objectivity of their own view of the case; the objectivity of the other investigator; how their own objectivity would be judged by the other investigator; and how the Chief Judicial Officer would assess their own objectivity and the other investigator's. (all on 1-11 scale).

Results

The prediction was that role assignment would influence participants' judgments of all aspects of the case.

1. *Overall Judgments.* The assignment had the predicted effects on overall judgments of the case. The estimates of the probability that Debbie cheated were 33%, 43%, and 53% for the Debbie-Assignment, Sole Investigator, and University-assignment conditions, respectively, $F(2, 292) = 12.75, p < .001$. A similar pattern was found in participants' judgments as to which side of the case was supported by their view: 3.5, 5.0, and 5.8, with higher numbers meaning more University support, ($F(2, 292) = 15.17, p < .001$). A chi-square analysis, $\chi^2(2) = 6.99, p < .05$, revealed that the assignment also influenced how participants would decide the case themselves (23%, 37%, and 40% would decide that Debbie cheated, respectively).

2. *Case facts and related beliefs.* First, consistent with prior research on *coherence-based reasoning* (Holyoak & Simon, 1999; Simon et al., 2001; Simon et al., 2004b), views of these items clustered around a coherent mental model of the case. The 13 fact items formed a reliable composite ($\alpha = .88$). Participants developed globally coherent structures that tended to view the factual pattern as indicative either that Debbie cheated or that she did not. We found a similar clustering of the 9 beliefs that were related to the facts of the case ($\alpha = .60$). This weaker alpha is understandable given that background knowledge is more stable than ad hoc judgments of specific events.

Second, the assignment influenced the facts and related beliefs as predicted, Facts $F(2, 292) = 15.87, p < .001$; Beliefs $F(2, 292) = 14.11, p < .001$. Those assigned to the university-condition were more prone to interpret the facts as incriminating Debbie (Fact $M = 5.7$, Belief $M = 5.4$), whereas those assigned to the Debbie condition interpreted them as least incriminating (Fact $M = 4.4$, Belief $M = 4.5$). The judgments in the Sole Investigator condition were in between (Fact $M = 5.2$, Belief $M = 5.0$),

3. *Judgments of Liking, Emotions, and Motivation.* The assignment also influenced liking and emotional reactions to Debbie, as well as motivation with respect to the outcome. Participants in the university-condition were consistently the most negative toward Debbie, whereas those in the Debbie assignment condition were consistently most positive, with Sole Investigator in between: (Liking: 56 vs. 60 vs. 65;

Negative emotions: 4.0 vs. 3.5 vs. 3.1; Positive emotions: 5.4 vs 6.0 vs. 6.8; Motivation to see University win: 5.7 vs. 4.6 vs. 3.7), all $ps < .05$.

4. Coherence: Correlations and Mediation

All the primary variables, whether cold (facts, likelihood, decision) or hot (liking, emotions, motivation), were strongly inter-correlated, $r_s = .57-.76, p < .01$, two tailed. These widespread correlations capture the essential core of the network that underlies constraint satisfaction processing.

Mediational analyses of the potential causal paths among the variables provided additional evidence to support the *coherence-based* mechanism. They were conducted with an SPSS macro by Preacher and Hayes (2004).

The first set of mediational analysis analyzed the relationship between the three primary variables—role assignment (“condition”), judgments of the case facts (“facts”), and the “likelihood” item (“likelihood that Debbie Miller did cheat on the exam”). Case facts were shown to be a significant mediator between assignment and likelihood, ($p < .001$). The assignment manipulation influenced the participant's perceptions of the case facts, which, in turn, influenced perceptions of guilt. A significant mediational effect was also observed in the reverse direction, with judgments of likelihood mediating the effect of assignment on the evaluations of the facts ($p < .001$). This is consistent with the bi-directional nature of *coherence-based reasoning*, in which all the elements in the network should mutually influence one other.

Another set of analyses examined whether participants' emotions and motivations mediated their “likelihood” judgments. Four Sobel tests were conducted, one for each mediator: facts, liking for Debbie, motivation (which side participant wanted to see win), and emotion. The effect of the assignment on the likelihood judgments was mediated significantly by each variable, all in the predicted directions. Similar mediation was observed when the “facts” were treated as the dependant variable.

To explore the relative strength of each mediator we conducted multiple mediational analysis. We included the four significant mediators (facts, liking, motivation, and emotion) simultaneously in the same analysis. The analysis revealed that two of the four remained significant, with the case “facts” being the strongest mediator ($z = 4.59, p < .001$), then “motivation” ($z = 4.00, p < .001$), while the emotion composite was marginal ($z = 1.79, p = .07$).

5. *Perceived Objectivity – The Adversarial Mindset.* The findings provide insight into the participants' metacognitive judgments. First, participants felt that their views of the case were equally objective in the adversarial conditions (7.9 and 8.0, on a 1 to 11 scale) as in the non-adversarial condition (7.9). They were unaware that the adversarial manipulation biased their judgments. Second, participants' in the two adversarial conditions had different views of their own and their adversary's objectivity. Participants deemed their adversary to be less objective, $M = 6.45$, than they deemed themselves, $M = 8.0, t = 6.80, p < .001$. They also deemed him or her to be less trustful of themselves, $M =$

6.2, than they believed themselves to be, $M = 8.0$, $t = 8.46$, $p < .001$. Participants also believed that the other investigator's distrust was unwarranted, in that it was less credulous, $M = 6.2$, than the Chief Judicial Officer's evaluation of themselves, $M = 7.2$, $t = 5.06$, $p < .001$.

Discussion

The adversarial role strongly influenced people's perception of an ambiguous case. Relative to the non-adversarial assignment, adversarial role assignments skewed participants' views of the case in a self-serving manner. Participants in the condition that simulated police investigators were more likely to conclude that Debbie was culpable, whereas those simulating investigators for the defense were more prone to infer that she did nothing wrong. Most likely both conditions had a biasing influence on participants' judgments. Indeed, participants in the Sole Investigator condition viewed the case to be very close to the middle between the two adversarial conditions. The biasing impact of the adversarial assignment was manifested also by the arousal of mistrust towards their adversary.

Finally, the study provides the first experimental evidence of the interrelationship between hot and cold cognitions in *coherence-based reasoning*. More evidence for this relationship will be presented in Study 2.

Study 2: Partisanship and Coherence

Study 2 tested the effects of *strength* of *partisanship* on people's perceptions of a case and the role of motivation and emotion. We compared participants primed with a *non-partisan* manipulation with participants primed with a *partisan* one. We also examined whether the assignment would influence assessments of the trustworthiness of the witnesses. *Coherence-based reasoning* would lead to the prediction that judgments of the evidence would be positively related to judgments of the source's credibility.

We also sought to test *coherence shift* of beliefs. Study 2 introduced a pre-test instrument that tested participants' responses to the "belief" items, which were later included in the body of the study. This repeated-measures design enabled us to test within-subject shifts in the participants' responses to the belief items.

Method

Participants. The study used the same procedure as in Study 1. 163 individuals participated via the Internet. The sample was 48% female, with an average age of 46.

Procedure. We used the same case of Debbie Miller (with minor changes). The instructions described the adversarial hearing and the role of the University Representative ("University Rep"), which was substantively very similar to the role of a prosecutor, and role of the Student Advocate. All participants were assigned to the role of University Representative. After receiving the case, participants made a variety of judgments about it. All participants received the same case and instructions, except for information that was designed to manipulate the degree of partisanship.

Dependent Variables. Most of the variables were identical to those in Study 1. In addition, we measured participants' responses to the belief items on the pre-test and the judgments of the trustworthiness of the witnesses. To obtain a baseline measure for testing *coherence shifts*, participants received a pre-test questionnaire prior to the presentation of the case, containing questions probing their beliefs on a number of seemingly unrelated social issues. These questions were identical to the "belief" questions administered later on. Each of the belief items probed for a background belief that pertained to an ambiguous fact of the case (e.g., "In general, people who have lower back pain tend to crouch when they sit for extended periods of time"). We predicted that responses to the belief items would shift from pre-test to post-test, ultimately cohering more strongly with the view of the case (see Simon, Snow, & Read, 2004).

Treatment. Participants were assigned to one of two conditions differing in their *partisanship*. Participants in the *non-partisanship* condition were told that for the most part they felt the process was fair. They were also provided with positive information about the Student Advocate assigned to represent Debbie Miller, Jim Cooper. He was said to be fair and professional and interested in the truth.

Participants in the *partisanship* condition were told that they had become frustrated by the number of students who had been cleared, despite being almost certainly guilty. They were upset about the impact of this on the University's reputation and the harm inflicted on students who did not cheat. Participants in this condition also received negative information about their adversary, Jim Cooper, being told that he was overzealous, strongly biased toward students, and responsible for many of the recent cases in which cheaters were cleared.

Results

The prediction was that participants in the *partisan condition* would be more inclined to believe that Debbie did cheat than participants in the *non-partisan condition* and that this would influence a range of different judgments.

1. **Overall Judgments.** The estimates of the likelihood that Debbie cheated were 40% in the *non-partisan* condition and 53% in the *partisan* condition, $F(1, 161) = 6.93$, $p < .01$. The assignment also influenced how participants would decide the case themselves, *non-partisan*: 33% Guilty vs. *partisan*: 49%, Chi-square (1) = 4.23, $p = .04$.

2. **Case facts and related beliefs.** Those in the *partisan* treatment perceived the case to be more consistent with the conclusion that Debbie cheated (Facts $M = 5.6$; Beliefs $M = 5.4$) than did participants in the *non-partisan* condition (Facts $M = 4.8$; Beliefs = 5.0), where higher numbers are more consistent with Debbie cheating, $F(1, 160) = 9.65$, $p = .002$ and $F(1, 160) = 6.14$, $p = .014$, respectively. The 13 "fact" items cohered to make a reliable composite ($\alpha = .86$), as did the related "beliefs" ($\alpha = .61$). Also partisanship affected the perceived trustworthiness of the witnesses. Both witnesses who testified that Debbie cheated were deemed more trustworthy by *partisan* participants

(Proctor: 6.8 v. 6.0; Brad Loomis: 6.0 v. 4.9), $F(1, 160) = 4.96, p = .027$ and $F(1, 160) = 10.0, p = .001$, respectively.

3. *Judgments of Liking, Emotions, and Motivation.* The partisanship manipulation also influenced participants' emotions and motivations. Compared with *non-partisan* participants, *partisan* participants liked Debbie less ($M = 53$ vs. 59), had stronger negative feelings ($M = 2.7$ vs. 2.1) and weaker positive feelings towards her ($M = 3.3$ vs. 4.0), and were more motivated to see the university prevail ($M = 5.8$ vs. 4.3), all differences $p < .05$.

4. *Coherence Shifts of the Belief Items.* Despite the initial ambiguity (as denoted by the non-significant differences at pre-test), by the time of the decision, the beliefs shifted to cohere with the decision and with one another, creating a strongly interconnected mental model (Holyoak & Simon, 1999; Simon et al, 2004a, Simon et al, 2004b). Figure 1 shows the coherence shifts in the belief items, plotting the data separately based on participants' response to the question: "if you were the Chief Judicial Officer, how would you decide the case?" (regardless of partisanship). A test of the interaction confirmed that these shifts were highly significant, $F(2, 158) = 91.5, p = .000$.

Figure 1. Coherence shifts in belief measures

5. *Mediations and Structural Equation Modeling.* We used SEM to perform simultaneous testing of the interrelationships among the study variables to identify which of the competing models best accounts for the relationships. The first analyses contained the four primary *cold cognitions*: partisanship assignment ("condition"), judgment of the case facts ("facts"), "likelihood" that Debbie Miller cheated on the exam, and the "decision" ("how would you decide the case?").

Two models (see Figure 2) show that partisanship predicts the primary variables. Model 1 shows that partisanship affected the judgment of the facts, which affected likelihood, which affected the decision. This is compatible with rational models of inference. Model 2 suggested that the inference chain may also run in reverse. These opposing models capture the bi-directionality of *coherence-based*

reasoning; a central feature of the mutual influence in constraint satisfaction processes.

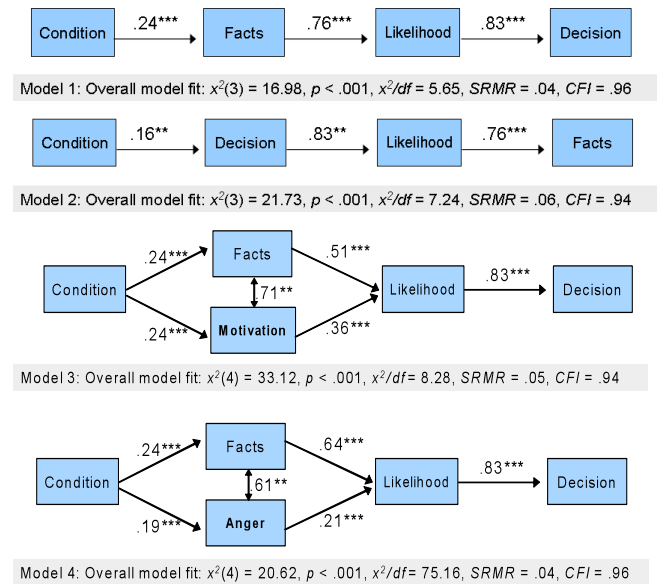

Figure 2: SEM models of hot and cold cognitions

Our primary question was whether hot cognitions are involved in the constraint satisfaction processes that drive the representation towards coherence. We first tested mediational relationships between the three hot cognitions (anger towards Debbie, motivation, and liking) and a central cold cognition: decision, (See Figure 3). A simultaneous mediational analysis between the condition and the decision revealed effects for "anger" and "motivation", but not for "liking". Mediation by hot and cold cognitions was also observed using SEM (see bottom of Figure 2), which found good fitting models for both "motivation" and "anger" as joint mediators, with "facts," of "likelihood", and decision.

Figure 3: Multiple mediation model

Discussion

Judgments were influenced considerably by the intensity of partisanship. As in Study 1, the treatment assignment resulted in coherent mental models of the case, in which the wide range of variables involved in the judgment all cohered with the manipulated conclusion. Participants' assessments of the trustworthiness of the witnesses were also influenced by the assignment. Partisan participants were more likely to trust the witnesses who claimed to have seen Debbie cheat. Most important, we observed that hot cognitions mediated the effect of the assignment on the cold cognitions.

General Discussion

The studies show that the perception of a factually ambiguous case depends on the conditions under which the judgments are made. Study 1 simulated a police investigation and found that the perception of the case was strongly influenced by the participants' role assignment. Relative to the non-adversarial assignment, adversarial role assignments skewed participants' *hot* and *cold* cognitions in a manner that supported their assigned side. The non-adversarial assignment led to judgments close to the midpoint between the two adversarial conditions. The symmetry of the polarization supports the conclusion that adversarialism results in a distorted perception of the case. Participants in all conditions deemed their perception of the case to be equally objective, suggesting that the participants in the adversarial conditions were unaware of the influence of the assignment on their judgments. Study 2 simulated a prosecutorial view of the same case and found that both hot and cold cognitive judgments are influenced considerably by the intensity of the partisanship.

These studies provide further corroboration for the *coherence based reasoning* framework (Holyoak & Simon, 1999; Simon, 2004; Simon et al., 2004a; Simon et al., 2004b). We found again that participants' views of a complex task tend to cluster into large and coherent mental representations that encompass the overall judgments of the case as well as of the entire set of facts and related beliefs.

However, the most important contribution is the novel finding of the interrelationship between the hot and cold cognitive aspects of the task. While a great deal of research has observed the effect of emotion and motivation on cognitive processing (e.g., Kunda 1990; Slovic, Finucane, Peters, & Macgregor, 2002; Zajonc, 1980), that research has not provided much insight into the mechanisms by which these effects occur. Mediation analyses and SEM revealed that emotion, motivation and to some degree also liking, mediated the effect of the assignment on the various cold cognitive judgments of the case, while similar mediations were observed in the reverse direction. While one ought to be cautious drawing causal conclusions from these data, these observations are strongly consistent with the Gestaltian features of high interconnectivity and bidirectional influence that characterize constraint satisfaction processing and *coherence-based reasoning*.

Comparison-Induced Sequence Effects on Hedonic Evaluations

Jessica M. Choplin (jchoplin@depaul.edu) & Megan M. Lombardi (mlombar7@depaul.edu)

DePaul University Department of Psychology
2219 North Kenmore Avenue
Chicago, IL 60614-3504

Abstract

Hedonic evaluations and emotional reactions to experiences depend not only upon the conditions being experienced, but also upon the sequences in which conditions are experienced. The authors propose a comparison-induced distortion (CID) model of sequence effects on evaluation in which to-be-evaluated exemplars are verbally compared (Choplin & Hummel, 2002; Choplin, 2007) to the most similar, recent exemplars. Predictions of this model were tested and pit against Helson's (1964) adaptation-level theory, Parducci's (1995) range-frequency theory, and Haubensak's (1992) consistency model using a paradigm in which sequences periodically improved (i.e., improved for n trials, returned to the original state on a single trial, and improved for n trials again) or periodically deteriorated by small or large amounts. The results were consistent with the predictions of the proposed CID model of sequence effects and inconsistent with adaptation-level theory, range-frequency theory, and the consistency model.

Sequence Effects

Most theories of the causes of emotions posit that people's emotional reactions to the conditions they experience (e.g., prices, salaries, pain, tastes, wait times, and so forth) depend in part upon their hedonic evaluations of those conditions—how good or bad they judge those conditions to be (e.g., Kahneman, 1999; Lazarus, 1991; Tesser & Martin, 1996). While some researchers conceptualize these evaluations as measurements on a single good/bad dimension (Kahneman, 1999) and other researchers conceptualize these evaluations as separate measurements of how good conditions are and how bad conditions are (Cacioppo, Gardner, & Berntson, 1999; Watson & Tellegen, 1985), the general idea underlying this common notion is that these evaluations play a central role in the emotions people experience. If people judge conditions to be good, then their emotional reactions will generally be positive. That is, the evaluation that a condition is good will evoke emotions such as happiness, delight, and relief. If people judge conditions to be bad, then their emotional reactions will generally be negative. That is, the evaluation that a condition is bad will evoke emotions such as anger, frustration, and worry.

A challenge for research on emotion and hedonic evaluation arises from the fact that evaluations are not a pure function of the objective conditions being evaluated. Rather, hedonic evaluations depend upon the context in which conditions are experienced (see, for example, Parducci, 1995). Predicting people's emotional reactions, therefore, requires an understanding of the contextual factors that affect evaluations. The research reported here

investigated one type of context effect on evaluation, namely, the effect of the sequence in which conditions are experienced. Paying \$2.85 per gallon of gasoline, for example, might seem more reasonable if recent prices have been over \$2.85 than if recent prices have been under \$2.85. Waiting 5 minutes for a bus might seem more reasonable if one has lately been waiting more than 5 minutes than if one has been waiting less. The purpose of the research reported here was to develop and test an account of how the sequences in which conditions are experienced affect evaluations. We will propose a comparison-induced distortion (CID) account of sequence effects on evaluation and pit this account against Helson's (1964) adaptation-level theory, Parducci's (1995) range-frequency theory, and Haubensak's (1992) consistency model.

Comparison-Induced Distortions

The basic idea underlying the CID model of sequence effects is that people will verbally compare to-be-evaluated items to the most similar items they have recently encountered. The model selects previous exemplars to be compared to the to-be-evaluated item using two criteria: 1) giving more weight to exemplars that are more similar to the to-be-evaluated item and 2) giving more weight to more recent items (the 1-back item is weighted higher than the 2-back item, the 2-back item higher than the 3-back item, etc.). Although the proposal that these two criteria determine recall and comparison processes has not previously been applied to sequence effects on hedonic evaluations, it has been applied to other domains in which recall of previously presented exemplars affects judgment (see, for example, Nosofsky & Palmeri, 1997; Smith & Zarate, 1992).

After a comparison item is selected, we hypothesize that the to-be-evaluated item is verbally (often sub-vocally, not out loud) compared to the comparison item. CID theory predicts that verbally comparing items causes people to exaggerate small differences and under appreciate the size of large differences. The reason for this pattern of evaluation is that evaluations are biased toward the central tendency (i.e., mean or median) of values associated with a comparison word (Huttenlocher, Hedges, & Vevea, 2000).

For example, a longer wait for a bus could be 1 extra minute or 30 extra minutes, but when we consulted city bus schedules we found that the most common wait time between buses was 10 minutes. That is, there is a distribution of differences in wait times between busses where the central tendency of the distribution of "longer wait times" is around 10 extra minutes. Huttenlocher et al. (2000) demonstrated that judgments of values are typically

biased towards the central tendency of categories. If so, then a “longer wait time” of 5 extra minutes (i.e., less than the central tendency of the category of “longer wait times” which is 10 extra minutes) would be biased towards the evaluation of 10 extra minutes. That is, the difference would be exaggerated. Likewise, a “longer wait time” of 15 extra minutes (i.e., more than the central tendency of 10 extra minutes) would also be biased towards the evaluation of 10 extra minutes. This time, however, the bias would cause the size of the difference to be under appreciated.

The experiment described below was designed to test the predictions of this model. To do so, participants were asked to rate their aversion to several fictional wait times for a bus in the winter. Participants evaluated wait time sequences that improved or deteriorated in large or small increments, returned to a value near the original value, and then improved or deteriorated again. CID theory predicts that there will be an amount of change (small or large) by direction of change (improving or deteriorating) interaction effect. Specifically, wait times in the small-increment deteriorating sequence will be rated as worse than wait times within the small-increment improving sequence, because these small differences will be exaggerated. A little worse will seem like a lot worse and a little better will seem like a lot better. Conversely, wait times in the large-increment deteriorating sequence will be rated better than items in the large-increment improving sequence, because people will under appreciate the sizes of the differences. A lot worse will seem as if it is only a little worse and a lot better will seem as if it is only a little better.

Adaptation-Level Theory

Models of sequence effects on evaluation commonly start with Helson’s (1964) proposal that evaluations are made relative the conditions to which people have adapted—that is, the conditions to which they have become accustomed, consider normal, and continue to expect (see Briesch, Krishnamurthi, Mazumdar, & Raj, 1997; Frederick & Loewenstein, 1999; Kalyanaram & Winer, 1995, for reviews). Helson (1964) modeled the conditions to which people adapted as the running average of all previously experienced conditions (see also Kalwani, Yim, Rinne, & Sugita, 1990; Rajendran & Tellis, 1994; Wedell, 1995). These running averages then serve as reference points against which all other conditions are evaluated. Models that appeal to this explanation of sequence effects on evaluation assume that sequence effects occur when the conditions people consider normal change as they experience more instances. If people experience additional favorable conditions, they will start to consider these favorable conditions to be normal. If people experience additional unfavorable conditions, they will start to consider unfavorable conditions normal. This change in what is considered normal, thereby, causes sequence effects wherein the same conditions might be evaluated as better (or worse) depending upon whether the previously experienced values were better or worse.

Contrary to CID theory, AL theory predicts that items in deteriorating sequences will always be judged worse than items in improving sequences regardless of the size of the

difference between items. Since items are evaluated in comparison to the adaptation level—which is the average of all previous items—the same item (e.g., 36 minutes) will be evaluated differently based on the average of the items that precede it in the sequence. For a deteriorating sequence, the to-be-evaluated wait time will be worse than what people have gotten used to, the average that they consider normal. For an improving sequence, the to-be-evaluated wait times will be better than what they are used to and consider normal. This pattern would be true regardless of the sizes of the differences between wait times. That is, adaptation-level theory predicts that wait times will be evaluated as worse in deteriorating than in improving conditions.

Range-Frequency Theory

One of the most important models of hedonic evaluation is Parducci’s (1995) range-frequency theory. Range-frequency theory is based on the idea that judgments are made based on a compromise between range and frequency principles. According to the range principle, individuals evaluate items relative to the smallest and largest values that they have previously encountered. The individual’s evaluation is based on a calculation of the range value for the to-be-evaluated item, which is the proportion of the range at which the to-be-evaluated item is located relative to the smallest and largest values. The midpoint between the highest and lowest values would be 50% of the way to the largest value from the smallest; half way between the smallest value and the midpoint would be 25%; and half way between the midpoint and the largest value would be 75%. According to the frequency principle, individuals evaluate to-be-evaluated items by calculating their percentile rank among all of the items that they have seen. Individuals compromise between these two principles when making evaluations.

Unlike comparison-induced distortion theory, range-frequency theory predicts that there will be no effect of the amount of change between wait times as long as there are no changes in the range or frequency values of the to-be-evaluated wait times. The experiment described below controls for this issue by keeping range and frequency values constant across the amount of change manipulation. Furthermore, the frequency values (percentile ranks) of the to-be-evaluated wait times would be larger (worse) in the deteriorating sequence than in the improving sequence, because better previous exemplars would be included in the context of judgment. Like adaptation-level theory, then, range-frequency theory predicts that wait times will be evaluated as worse in deteriorating than in improving conditions.

Consistency Model

Similar to comparison-induced distortion theory, Haubensack’s (1992) consistency model of evaluation relies on the basic assumption that recalled exemplars affect judgment. According to the consistency model, people strive for internal consistency in their responses since judgments are subjective in that the mapping between the real-world dimension and the category-rating dimension is

arbitrary. In attempting to maintain internal consistency in their responses, people often constrain their responses based on the first few exemplars they encounter. By making judgments about preceding stimuli in a sequence, for example, the person is confining subsequent judgments to a specific response scale. If the person evaluates the first few items in a sequence, doing so commits them to giving subsequent judgments that are consistent with the previous judgments. Evaluations that are consistent with those previous judgments can be calculated by linearly interpolating from previous evaluations.

To control for the effects of early judgments and the requirement that participants' evaluations be consistent with these judgments, an initial sequence was held constant across the direction of change manipulation for the current study. If participants linearly interpolate from the initial judgments they make, then evaluations should be the same for the deteriorating and improving conditions. To control for memory effects, a high and a low value were always present within the previous five trials (less than the seven represented in Haubensak's model) and these high and low values were constant across the direction of change conditions. Since this model predicts that the initial sequence will be the basis for wait time evaluations, this model predicts no effects of the amount of change between exemplars.

Experiment

To pit the predictions of the CID model of sequence effects against the predictions of the other models, we used a paradigm in which participants imagined that they had to wait for the bus in a rural town in northern Minnesota on each of 36 fictional winter days (manipulated within a single session). Wait times either periodically improved (i.e., times became successively shorter on each of n trials, returned to a value near the original state on a single trial, and then became successively shorter on each of n trials again) or periodically deteriorated (i.e., times became successively longer on each of n trials, returned to a value near the original state on a single trial, and then became successively longer on each of n trials again). Participants rated how aversive each wait time would be.

This sequence is effective in pitting the CID model against the other models. The CID model predicts that the size of the difference between consecutive exemplars will matter such that exemplars within periodically deteriorating series will be rated as worse than exemplars within periodically improving series when there is a small amount of change between consecutive exemplars. Additionally, exemplars within periodically deteriorating series will be rated as better than exemplars within periodically improving series when there is a large amount of difference between consecutive exemplars. Adaptation-level and range-frequency theories, by contrast, predict that exemplars within periodically deteriorating series will always be judged worse than exemplars within periodically improving series. The consistency model predicts no effects of the amount of change manipulation.

Method

Participants. An experimenter, who was blind to the hypotheses, approached individual prospective participants on a university campus or in the surrounding community. Two hundred and five people volunteered after being approached in this manner. Approximately half of the participants ($n = 101$) experienced wait times that changed (improved or deteriorated) by small amounts (i.e., 5 minutes) on each trial, excluding periodic large changes. Of these, 50 participants were in the periodically improving condition and 51 were in the periodically deteriorating condition. The other half of the participants ($n = 104$) experienced wait times that changed (improved or deteriorated) by large amounts (i.e., 15 minutes) on each trial, excluding periodic larger changes. Of these, 54 participants were in the periodically improving condition and 50 were in the periodically deteriorating condition.

Materials and Procedure. Participants imagined that they were spending 36 days in northern Minnesota during the middle of the winter and had to rely upon an erratic bus for transportation. The amount of time they spent waiting for the bus each day was presented aloud and participants rated how aversive that wait time for each day would be on a scale from 0 ("not bad") to 10 ("extremely bad").

CID hypothesized that participants would overreact to differences smaller than 10 minutes (i.e., 5 minutes) and under-react to differences larger than 10 minutes (i.e., 15 minutes), because the median of values from the category of "longer wait times" for busses was 10 minutes in local bus schedules for the campus community. Furthermore, the results of the experiment (presented shortly) suggest that participants did overreact to 5-minute differences and under-react to 15-minute differences. Sequences of presented values were constructed by dividing the middle 26 days of the experiment into two 13-day periods. Within each 13-day period, periodically improving and deteriorating sequences like those in Table 1 were presented. The order of the three series shown in Table 1 (i.e., Series A, B, and C) was fully counterbalanced to produce six counterbalanced groups for each of the four—2 (amount of change: 5 minutes or 15 minutes) \times 2 (direction of change: improving or deteriorating)—conditions. The sequence of wait times in the second 13-day period was identical to the sequence in the first 13-day period.

To control for primacy effects and introduce participants to the range of values they would see prior to the sequence manipulation, a sequence of 5 days was inserted at the beginning of the experiment. The sequence on these 5 days was 22, 35, 50, 35, and 22 minutes respectively in the small-difference condition and 2, 35, 70, 35, 2 minutes respectively in the large-difference condition. To make peak and end values equivalent across periodically improving and deteriorating sequences before asking participants to make a retrospective evaluation (Kahneman, Frederickson, Schreiber, & Redelmeier, 1993; Redelmeier & Kahneman, 1996), a sequence of 5 days was added to the end of the

Table 1. Wait Time Sequences (all values are in minutes)

Initial Sequences:			
For Participants Experiencing Small Changes	22, 35, 50, 35, 22		
For Participants Experiencing Large Changes	2, 35, 70, 35, 2		
Manipulated Sequences:	Series A	Series B	Series C
Deteriorating in Small Increments	26, 31, 36, 41, 46	27, 32, 37, 42	29, 34, 39, 44
Improving in Small Increments	46, 41, 36, 31, 26	42, 37, 32, 27	44, 39, 34, 29

Final Sequence:			
For All Participants	35, 35, 35, 35, 35		

experiment. The wait time for each of these 5 days was 35 minutes.

After evaluating wait times for all 36 days, participants retrospectively evaluated all of the wait times they had seen in the experiment on a scale from -50 (not bad at all) to +50 (extremely bad).

Results

We first analyzed the ratings participants gave for each of the 36 days as they went through the experiment. To reduce variance caused by idiosyncratic reactions to wait times, participants' judgments during the initial 5-day sequence were used as a baseline. Each participant's judgments on trials 6 through 31 were divided by the average of her or his average judgment on days 1 and 5, days 2 and 4, and her or his judgment on day 3. The results are presented in Figure 1.

As shown in Figure 1, of the participants in the small change condition, those who experienced periodically deteriorating sequences rated wait times more aversive than did those who experienced periodically improving sequences for 11 of the 13 wait times. This proportion (.85) was significantly greater than .50, $\chi^2(1, N = 13) = 4.92, p < .05$. This effect was very weak, however. In fact, a 2 (direction of change: improving or deteriorating) \times 2 (portion of sequence: days 6-18 and days 19-31) \times 13 (wait times) Mixed-Factors Analysis of Variance (ANOVA) on the evaluations of participants in the small-difference condition failed to find a difference due to the direction of change, $F(1,99) = 0.04, MSE = 28.61, p > .05$.

The participants in the large change condition showed a very different pattern of evaluations. Of these participants, those who experienced periodically improving sequences rated wait times more aversive than did those who experienced periodically deteriorating sequences for all 13 of the 13 wait times. This proportion (1.00) was significantly greater than .50, $\chi^2(1, N = 13) = 4.92, p < .01$. A 2 (direction of change: improving or deteriorating) \times 2 (portion of sequence: days 6-18 and days 19-31) \times 13 (wait times) Mixed-Factors ANOVA on the evaluations of

participants in the large-difference condition also found a main effect of the direction of change, $F(1,102) = 8.92, MSE = 24.07, p < .05$.

The interaction between amount of change and direction of change was also significant as revealed by an omnibus 2 (amount of change: small or large) \times 2 (direction of change: improving or deteriorating) \times 2 (portion of sequence: days 6-18 and days 19-31) \times 13 (wait times) Mixed-Factors ANOVA, $F(1,201) = 8.25, MSE = 26.3, p < .05$. This finding is consistent with the predictions of the CID model presented above and inconsistent with the predictions of adaptation-level theory (Helson, 1964) and range-frequency theory (Parducci, 1995) and not predicted by the consistency model (Haubensak, 1992). Post hoc least significant difference analyses found that participants who experienced periodically improving large differences rated wait times more aversive than did the other three groups. Evaluations on days 19-31 did not significantly differ from evaluations on days 6-18, $F(1,102) = 0.11, MSE = 2.32, p > .05$.

A 2 (amount of change: small or large) \times 2 (direction of change: improving or deteriorating) Between-Subject ANOVA on participants' retrospective evaluations showed no main effect of the amount of change [$F(1,201) = 3.18, MSE = 621.1, p > .05$], no main effect of the direction of change [$F(1,201) = 0.46, MSE = 621.1, p > .05$], and no interaction between them [$F(1,201) = 0.87, MSE = 621.1, p > .05$] suggesting that the algorithms responsible for retrospective evaluations might be different from the algorithms responsible for online evaluations. This result also suggests that the finding that people prefer improving to deteriorating sequences (Hsee & Abelson, 1991; Hsee et al., 1991; Schifferstein & Frijters, 1992; Varey & Kahneman, 1992) might not generalize to online evaluations of periodically improving and deteriorating sequences such as the sequences investigated here.

Discussion

Theories of sequence effects on hedonic evaluation were assessed using a paradigm in which values periodically

Figure 1. Results

improved or deteriorated by small or large amounts. When values changed by small amounts, participants evaluated periodically improving sequences more positively than periodically deteriorating sequences; but when values changed by large amounts, participants evaluated periodically deteriorating sequences more positively than periodically improving sequences.

Helson's (1964) adaptation-level theory cannot explain the finding that evaluations differed based on the size of the difference between exemplars since AL theory makes the prediction that items in deteriorating sequences will always be judged worse than items in improving sequences regardless of the size of the difference between items. Since wait times in the large change deteriorating sequence were preferred over wait times in the large change improving sequence it seems as though participants' evaluations were not based on a comparison of the to-be-evaluated wait time and the average of the preceding wait times, which would result in the opposite finding.

Since the range and frequency values of each wait time in the small change condition mapped onto the range and frequency values of each wait time in the large change condition, range-frequency theory (Niedrich, Sharma, & Wedell, 2001; Parducci, 1995) cannot explain the finding that the amount of change between items influenced wait time evaluations. Furthermore, range-frequency theory cannot explain the finding that wait times were evaluated as better in the large change deteriorating condition than in the large change improving condition; the frequency principle predicts that wait times will be worse in the deteriorating condition than in the improving condition since there would be more positive exemplars in the context of judgment. Based on the current findings, it seems as though range and frequency principles were not used to make evaluations of

wait time since these principles would produce the opposite pattern of evaluations.

Haubensak's (1992) consistency model of judgment also cannot explain the finding that the amount of change between wait times influenced evaluations. The consistency model predicts that evaluations are based on linear interpolations from initial items in a sequence. Because linearly interpolating between the evaluations made during the initial sequence would have made evaluations in the periodically improving and deteriorating sequences identical, the finding that there were differences in the evaluated wait times in these sequences suggests that participants did not base their evaluations off of the initial sequence of wait times that was presented.

Of the four evaluation models presented in this paper, only the CID model proposed above was able to predict and explain the observed results. The finding that participants preferred periodically improving to periodically deteriorating sequences when wait times changed by small amounts is consistent with the CID prediction that differences will be exaggerated toward the central tendency of values that have been associated with a comparison word (Huttenlocher et al., 2000). Similarly, the finding that participants preferred periodically deteriorating to periodically improving sequences when wait times changed by large amounts is consistent with the CID prediction that differences will be under appreciated when the central tendency of values associated with a comparison word is smaller than the amount of change.

The results reported here have implications for how managers, price strategists, administrators, politicians, and other bearers of good and bad news ought to present news to others. Consistent with research on hedonic editing (Thaler & Johnson, 1990), if circumstances (e.g., prices, salaries, service quality, and so forth) are going to become better,

perhaps it is best to present the good news a little bit at a time. People will appreciate the good news; and they will be likely to exhibit positive emotions such as happiness, delight, and relief each time that good news is presented. If circumstances were going to become worse, however, perhaps it would be best to present all of the bad news at once. People might not realize how bad circumstances have actually gotten; and while they will likely exhibit negative emotions such as anger, frustration, and worry, the sum total of these negative emotions might be less than if the bad news were presented a little bit at a time. The CID model builds on this previous research by offering guidance on the size of the changes that will be underappreciated or exaggerated. Changes that are larger than the central tendency of the distribution of previously observed changes will be underappreciated; and changes that are smaller than this central tendency will be exaggerated.

The Effect of Cognitive Load and Meaning on Selective Attention

Abstract

Nillie Lavie's Load Theory of selective attention suggests that the size of the cognitive load affects selective attention ability: the larger the cognitive load, the poorer the selective attention performance. Other authors have found that the relationship between distracting and relevant information can influence how well distractors are ignored. Our study hypothesized that a) larger cognitive load would (as previously shown) hinder reaction time on a selective attention task, b) that distractors (words) semantically related to the words being held in memory (as part of the cognitive load manipulation) would be more distracting than unrelated and neutral distractors. The findings instead showed that unrelated distractors were more distracting.

Lavie's Load Theory of selective attention suggests that the quantity of stimuli presented to a person determines how their selective attention system will function – whether they will be more or less distractible (Lavie, Hirst, de Fockert, & Viding, 2004). The Load Theory suggests that selective attention consists of two mechanisms: a passive, perceptual system, and an active mechanism of cognitive control. The perceptual system functions in line with the early selection model, where the number of stimuli modulates the effectiveness of attentional selection. When there is a low load on the perceptual system – as in a visual search task with few (1-3) items to search through – there is extra, unused perceptual capacity that involuntarily picks up other (irrelevant, distracting) environmental information, and the person is more likely to perceive distractors. In a high perceptual load condition, the opposite is true: the task uses up all attentional capacity, and extra environmental elements can't interfere. In this model, the second stage of selective attention is an *active*, cognitive process. In conditions of high cognitive load, where most of the person's cognitive capacity is consumed with a difficult working memory task, for example, the person has few cognitive resources available to resist distraction by irrelevant information. The person can better disregard distractors in a low-cognitive load condition. When the working

memory (or other task) contains fewer items, there is more cognitive capacity available to focus on relevant information, while effectively weeding out perceived distractors. This cognitive system only comes into play in conditions of low perceptual load, when distractors have been perceived and need to be actively suppressed (Lavie, Hirst, de Fockert & Viding 2004; Lavie & Cox, 1997; Lavie, 1995).

Many studies have addressed the intricacies of this model, usually using simple, single letter or digit stimuli. Past studies used stimuli that are unrelated to each other and that carry as little semantic information as possible. Presumably, they do this to get at the attention issue in its purest form, with the simplest stimuli possible. Stimulus material used in past studies includes letters, numbers, colors, and simple black and white symbols. Few have examined the model in relation to the semantic content of the stimuli. This raises the obvious questions: are distractors more distracting when they are meaningfully related to task-relevant information? Is this effect modulated by cognitive load?

Most of the work done to test Load Theory has focused on the perceptual mechanism of selective attention. Lavie and colleagues have investigated the effect of cross-modal distractor presentation in a decision task, and the possible relationship between the cognitive load resulting from task-switching between and within sensory modalities (Rees, Frith & Lavie, 2001; Brand-D'abrescia & Lavie 2008). Only Lavie's 2004 study has really addressed the effect of cognitive load on selective attention tasks. This makes sense; the question of involuntary attention grabbing by stimuli is a more direct way to study selective attention, and according to the Lavie model, the cognitive system plays only a supporting role in attention control. However, we wanted to investigate the effect of cognitive load further. The current study investigated the impact of the cognitive load on selective attention. More specifically, we examined what effect, if any, the semantic content of the information being held in working memory has on distractibility when

distractors are related to the information in working memory. Lavie et al.'s 2004 study used digits to compose their memory sets, the current study used words. By using words instead of digits, the memory set words could be related to each other, and could allow for distractors to also be related (or not) to the words in the memory set. By manipulating the meaningful relationships between memory set and distractor we hoped to have an effect on distractor interference.

One study has examined the effects of distractors with semantic meaning (words) when that meaning is either task congruent or non-congruent. Fabrice Parmentier (2008) found that task-relevant and task-irrelevant novel distractor words modulated performance of a decision task in a way that suggested that the words were semantically analyzed immediately following presentation. Specifically, when an auditory distractor word (either 'left' or 'right'), presented simultaneously with a target arrow, was incongruent with the direction of a target arrow, it took longer than with a congruent distractor word for participants to identify the direction of the arrow. This suggests that task relevant information can be more distracting than task irrelevant information. It should be noted, however, that this interference did not occur when the congruent and incongruent distractors were standard distractors (presented on every trial). The authors conducted two different manipulations of the neutral:word distractor ratio, and observed interference only when a neutral distractor was used (a sinusoidal tone) on 80% of trials, and congruent and incongruent distractors each appeared in 10% of trials. This indicates that interference occurred only when the meaningful distractors were novel as well. (The current study also examined the interference caused by semantically relevant and irrelevant distractors, but in a uni-modal design. Parmentier (2008) used a bimodal design, with auditory distractor words and a visual decision task.)

Lavie and colleagues have also manipulated the similarity of the distractor and the target in a visual search task. For example, in sections of her study outlining the two-part attention model, half of the distractors would be the same as the target (X and X), and half of them would be different (X target with N distractor) (Lavie et al., 2004). These studies have shown that task non-congruent distractors cause greater interference with attention control than congruent distractors. Still, these studies used only stimuli and distractors without semantic meaning.

Lavie and Forester (2008) noted that most selective attention studies (including most of Lavie's own) utilize the same or similar stimuli as the distractor item and target item (i.e. black and

white letters, numbers, symbols, etc.). Therefore, the experimenters focused on the effects of truly-task irrelevant distractors, distractors that were completely unrelated to the target stimuli. Such studies are valuable because they aim to more closely simulate real-world distraction and selective attention in a controlled clinical setting. During a visual search task, participants had to identify whether an X or an N was present. During the task standard distractors (X or N) were presented in 80% of trials, related distractors (similar to target items) were presented in 10% of trials, and unrelated distractors (images of cartoon characters) were presented in the remaining 10%. They found that these novel distractors could create more disruption of performance than standard distractors, but only when participants had a longer period of time to identify the target. When a time pressure was added to the search task—they were given 500 ms to respond rather than no time limit—the extra interference of irrelevant distractors was eliminated in high perceptual load conditions, in agreement with the Load Theory's prediction.

Belke, et al. (2008) also investigated the effects of target-similar distractor items in a visual search task. Their experimental tasks presented participants with a target, presented as a single word, followed by an array of images. In some trials the array would contain the target, and some trials would contain an item semantically related to the target (target: "shirt," related item: an image of a pair of pants). Using an eye-tracker, they found that when the target was present, even in trials where the related item was also present the participant's first fixation would fall on that target significantly more frequently than non-target items. When the target was absent, however, the first fixation would fall on the related item significantly more than the other items in the array (Belke et al., 2008). These results suggest that, when primed with a target item, the participant is more likely to look at an item related to that prime than an item unrelated to that prime.

Finally, Belke et al. (2008) found that items semantically related to a target are more attention-grabbing than unrelated items. This, along with the broad finding that task-congruent distractors are more distracting than neutral distractors (Lavie et al. 2004; Parmentier, 2008; Lavie & Forester 2008), and Parmentier's findings that semantic information can be obtained from novel distractors, lead us to four hypotheses. First, we hypothesized that distractors with semantic content related to the semantic content of the memory set would cause more interference (more distraction, slower RTs) than either distractors unrelated to the memory set, or neutral distractors (which should have caused the

least interference). Second, we also expected to see an effect of load on distractibility compatible with the Load Theory: we expected to see greater distractibility (slower RTs) in the high cognitive load condition. Third, based on the Load Theory we hypothesized that there would be no interaction between cognitive load and distractor type; past studies produced no results that would suggest an interaction either way. Finally, we expected to see a higher rate of false positive identifications in the memory probe in the high load condition, as there should have been less cognitive capacity available to actively ignore distractor words.

Methods

Thirty-four Introduction to Psychology students from Franklin and Marshall College participated, in exchange for course credit. Participants volunteered for participation via sign up sheet. No demographic factors were recorded or controlled for.

Stimulus images were generated using Graphic Converter software, and sets of stimuli (trials) were constructed and ordered manually (although a random order was generated by computer to guide the organization of the trials). Stimulus sets were presented using Generic Psychology Lab software. All software was run on Mac OS9. Accuracy and mean reaction times for each participant were recorded by the software and analyzed using SPSS statistical software.

Each trial consisted of three phases that were presented serially at fixed time intervals: part 1, the memory set presentation, part 2, the selective attention task, and part 3, the memory probe. The memory set consisted of a small set of words the participants were asked to remember. The selective attention task was a simple decision task. Each attention task presentation consisted of a target letter (N or X) and a non-target (an O), one above the fixation point and one below. The target appeared randomly and equally in each location. The trials were also split evenly between the two target letters, each target letter appeared equally. One and only one of the two targets were present on every trial. Participants were asked to identify which of two target letters were present (X or N). During this time, a distractor presented simultaneously with the selective attention task, in the periphery of the screen aligned horizontally with the fixation point. The target and non-target stimuli (the N or X, and O) appeared, along with a flanker distractor, for 250ms. This display was followed immediately by a blank screen. Participants had from the offset of the selective attention screen (the onset of the blank screen) onward to make their response, either pressing the N key if the N was present, or the X

key if the X was present. Finally, participants were shown a word, and asked if it was present in the original set.

This study had a 2x3 within subjects design: cognitive load x semantic content of distractors. Cognitive load was defined here (as in Lavie et. al. 2004) as the number of items presented in the memory set. The two conditions, high and low, were defined as memory sets containing 5 and 2 items respectively. In the low load condition, the memory set was presented for 2s and in the high load condition it appeared for 4s. These presentation times were meant to eliminate extra search/reading time from the low load condition, while still allowing enough time in the high load condition for the participant to read and process all memory set words. A similar method was used in Lavie (2004) when manipulating cognitive load. The two levels of cognitive load, as manipulated by memory set size, were presented in separate experimental blocks. Participants were assigned one of two groups at the start of the study, and group assignments alternated every-other participant. Presentation order was counterbalanced between groups.

In order to allow distractors to be semantically related (or not) to the words in the memory set, all memory sets consisted of either 2 or 5 words meaningfully related to each other. Our study's 3 distractor conditions were 1) a "neutral" distractor: a single symbol (#) without semantic meaning; 2) "related" distractors: words that are in the same semantic category as the words in the memory set; and 3) "unrelated" distractors: words that carry semantic meaning but are unrelated to the words in its trial's memory set. Words were semantically related based on broad categorization by meaning, or words were grouped under one broad category. For example, a high load memory set could consist of the words "apple, pear, grape, orange, cherry." A related distractor word would be "plum," and an unrelated distractor could be "truck."

The memory probe could have either been one of the words from the memory set (apple), or a word still related to the set, but not present (peach). While words were recycled between the two trial blocks, no words were presented more than once in the same trial block. Words were only used if they contained less than three syllables, and were easily recognizable.

In order to preserve the novelty of the meaningful distractors (which, according to Parmentier, 2008, was essential to the recognition of the distractors), a longer string of meaningless symbols (ex. #S%!?) was not used as the neutral distractor. Within each block of trials, 50% of distractors were neutral

distractors (#), 25% were related, and 25% were unrelated.

Reaction times on the decision task and accuracy rates in the memory probe were collected. A 2 x 3 within subjects ANOVA (cognitive load x relatedness of distractor) was run to analyze the possible effects of our variables as they pertain to the first three hypotheses, and appropriate post-hoc tests were run as necessary. Error rates were also calculated, and a 2x2 within subjects ANOVA (presence of the memory probe x cognitive load) was run to examine any patterns regarding false positives or false negatives (as discussed in our fourth hypothesis).

Results

The 2 x 3 ANOVA (cognitive load x relatedness of distractor) results indicated a significant main effect of relatedness, $F(2,62)=16.008$, $p<.001$, partial $\eta^2=.341$. However, there was no main effect of cognitive load, $F(1,31)=.018$, $p=.894$, and partial $\eta^2=.001$. The interaction between cognitive load and relatedness was statistically significant, $F(2,62)=.028$, $p=.028$, and partial $\eta^2=.109$. Fisher's LSD post hoc test was conducted to determine which groups of relatedness were significantly different in reaction times. Results revealed that all three groups differed significantly.

Figure 1: Mean reaction time as a function of cognitive load and distractor type.

A 2 x 2 ANOVA (presence of memory probe x cognitive load) indicated significant main effect of cognitive load, $F(1,31)=6.779$, $p=.014$, and partial $\eta^2=.179$, as well as a significant main effect of presence, $F(1,31)=30.998$, $p<.001$, and partial $\eta^2=.500$. There was no interaction between cognitive load and presence, $F(1,31)=.005$, $p=.943$, and partial $\eta^2<.001$.

Post-hoc t-tests were conducted to look at differences among related and neutral distractors in different cognitive loads. The results revealed a significant difference between mean reaction times of high related distractors and high neutral

distractors, $t(31)=3.123$ and $p=.004$. There was not a significant difference between mean reaction times of low related distractors and low neutral distractors, $t(31)=.371$ and $p=.713$.

Figure 2: Mean error rate (%) as a function of cognitive load and memory probe condition.

Discussion

The first hypothesis was not supported. While a significant main effect of distractor type was found, the unrelated distractors caused more interference than related distractors. Neutral distractors caused the least interference, in line with the hypothesis. The background literature leading to this hypothesis was not cohesive, and at the time the hypotheses were written, the literature suggesting the greater interference capacity of related, rather than unrelated, distractor items was more compelling than the other findings available. Given the current findings, a second examination of the background information highlights several studies that do support the present results. As noted, Lavie et al. (2004) found that task non-congruent distractors were more distracting than task congruent distractors, Lavie & Forester (2008) found that novel, task irrelevant image distractors were more distracting than familiar or relevant distractors, and Parmentier (2008) found that task relevant items presented simultaneously with a task facilitated performance, while irrelevant items interfered.

These results might suggest a sort of priming effect. Perhaps the memory set primes some larger category or group meaning, and as a result the participant is not surprised by the presence of a related distractor; an unrelated distractor, then, is unexpected and more attention-grabbing. This is not completely satisfactory, however, because it might imply that related distractors would produce faster RTs than even neutral distractors would. This is only partially supported by our results. While in the high load condition, the neutral distractor caused significantly less interference than the related distractor, in the low load condition the two distractor categories produced mean RTs that were

virtually the same. If priming were involved, we would have expected to see related distractors produce significantly faster RTs than both unrelated and neutral distractors, or very similar RTs to neutral distractors. While these results have interesting implications in the broader discussion of priming effects and working memory, further discussion of the topic is beyond the scope of this study.

Although our results are not consistent with our original predictions, they still build on the previous literature in valuable ways. All previous work cited here related their distractors only to the items in their selective attention or perceptual load tasks; the related (or unrelated) information appeared all on the same screen. The current study sought to examine relatedness between the attention task and the cognitive load, to manipulate relatedness across tasks and attention mechanisms. Because of this the results were slightly unpredictable, but valuable nonetheless.

The second hypothesis was also not supported: no main effect of cognitive load was observed. This result was unexpected, as the effect of cognitive load has been observed in past work. A trend towards significance was observed—high load RTs were slower than low load RTs—but only in the ‘related’ and ‘unrelated’ condition. This suggests that, possibly, the cognitive load manipulations were not adequate representations of ‘high’ and ‘low’ cognitive load. One possible explanation of this involves the related nature of the stimuli. Perhaps the fact that all memory set items fell under one broad category or meaning provided a strategy for remembering them: maybe participants remembered the group rather than each individual word (consciously or not) in an effort to reduce the load on the cognitive system. The results regarding our fourth hypothesis provide more evidence to this effect.

Our fourth hypothesis was supported. We observed significantly more false positives in the high load condition than in the low load condition: participants were failing to accurately remember the words in the larger memory sets. After considering the related nature of the memory set words, this result suggests that participants noted the category of the words presented along with individual words. As all memory set words, present and absent, were related to their memory set (it would have been too obvious had the probe words been unrelated) false positives indicate that participants recognized the category membership/ semantic meaning of the probe word and responded accordingly.

The results concerning the second and fourth hypotheses point to semantic grouping as a

characteristic that can mitigate the effects of cognitive load in both directions. In high load conditions, it appears that semantic grouping reduces the load that would otherwise be placed on a cognitive system by trying to retain five unrelated or meaningless items. Relating memory set provides a crutch, a strategy for the participant to make remembering easier. By relating the high load memory set items to each other, we may have created a pseudo-high cognitive load, not high enough to mimic previous results. The current manipulation of low load does differ from past studies’. In Lavie et al. (2004), the low cognitive load condition contained one item: a single letter. In Belke et al.’s (2008) manipulation of cognitive load a single number was used in the low load memory sets. To compare, the current study used two one- or two - syllable words. Setting aside the extra item in our low load condition, words have meaning, single letters do not. It is possible that the combination of these two factors brought the low load condition’s difficulty closer to that of the high load condition. Adding the factor of meaningfully related memory sets, seems to have knocked the significance out of the effect of cognitive load.

Our third hypothesis was, again, not supported. A significant interaction occurred between cognitive load and distractor relatedness. The relationship between the two variables was very similar between the two conditions with meaningful distractors (the ‘related’ and ‘unrelated’ conditions). The interaction appears between these conditions and the neutral distractor condition: neutral distractors were more distracting in the low load condition than in the high. This is not consistent with load theory, which would predict faster RTs in the low cognitive load condition all around. Most of the background studies cited here disregard their neutral data, there isn’t much in the literature to compare our results to. The degree of the difference between RTs of contentful and non-contentful distractors—the fact that the trend is reversed in the neutral condition—may indicate a different mechanism is at work when the distractor and the memory set information are presented in the same form (all words, as opposed to words and symbols). This interpretation is not fully compatible with the past findings, however. Lavie and Forester (2008) found that when target stimuli were letters and distractors were images of cartoon characters, the images were still significantly distracting (when compared to letter distractors). This study, though, did not manipulate cognitive load; the novel distractors were not novel to cognitive load content, as in the current study, they were novel to perceptual load items. Perhaps, as the current results suggest, the interaction *between*

attention mechanisms is qualitatively different than that *within* mechanisms. This qualitative difference is interesting and warrants further study.

The size of the sample may have limited the study. Using additional participants was not feasible, however, and because of the within-subjects design was not essential. The software used to present stimuli, and record reaction times, responses and error rates also limited our ability to fully explore the data. A more sophisticated program like E-Prime could alleviate these technological issues.

The current study is incomplete in that it does not compare related memory sets to unrelated memory sets. Further exploration is necessary to determine whether the results seen here are truly attributable to the semantic relatedness of the memory set and the distractor, or if they are simply a product of using whole words as stimuli. Adding a third independent variable, that of memory set relatedness, would enhance the literature in this area.

More detailed data regarding error rates and the type of distractor task would shed further light on the issue of false memories: it is possible that the greater the interference of the distractor in the selective attention task, the higher the error rates would climb. If unrelated distractors are more distracting, it follows that error rates in the unrelated distractor condition would be significantly higher than those in the related or neutral conditions.

Because of technological limitations, it could be valuable to re-examine the interaction between distractor type and cognitive load. Validating the current results regarding neutral distractors could point to different mechanisms used in ignoring extraneous information.

Conclusion

A desire to better understand what interrupts or facilitates selective attention continues to drive research in cognitive psychology. While Lavie's Load Theory provides a valuable theoretical explanation of the phenomena, it is also vital that studies explore selective attention in real-world settings using real-world stimuli. The present results indicate that while the Load Theory provides a strong theoretical base, there are stimulus characteristics, like meaning and relationships between stimuli, that can alter the general pattern,

but not without a cost. While it is possible that relating stimuli to one another reduces the cognitive capacity required to retain it, retention and recall suffer when such strategies are used. Knowing how attention and working memory are disrupted and aided could be particularly applicable in the field of education, and could be used to teach strategies for better retention and more effective methods of teaching and information presentation.

Is perceptual acuity asymmetric in isolated word recognition? Evidence from an ideal-observer reverse-engineering approach

Abstract

An asymmetrical optimal viewing position (OVP) effect in isolated word recognition has been well documented, such that recognition speed and accuracy are highest when the point of fixation within the word is slightly to the left of center. However, there remains disagreement as to the source of the asymmetry in the OVP effect. One leading explanation is that perceptual acuity in isolated word recognition is asymmetric, falling off more rapidly to the left than to the right. An alternative explanation is that of lexical constraint: perceptual acuity may be symmetric, but that the distributional statistics of the lexicon are such that the letters near the beginning of a word are on average of greater value in discriminating word identity than the letters near the end. On both these accounts, a left-of-center fixation point optimizes the efficient accrual of perceptual input from the word string, but for different reasons. These accounts have been difficult to tease apart experimentally due to the ubiquitous potential influence of lexical constraint. Here we take a novel approach, constructing an ideal-observer model of isolated word recognition which takes into account word frequency information and thus intrinsically accounts for the role of lexical constraint. Within this model, the shape of the perceptual acuity curve is governed by free parameters that can be estimated from purely behavioral response data from word recognition experiments. Fitting our model to the experimental data of Stevens & Grainger (2003), we find that the asymmetric version, in which perceptual acuity can differ to the left and to the right, fits human behavioral responses significantly better than symmetric versions in which the perceptual acuity curve is constrained to be the same to the left and to the right. Furthermore, in both parametric and nonparametric versions of the asymmetric model, perceptual acuity falls off more rapidly to the left than to the right. These results support the position that the perceptual acuity curve in isolated word recognition is indeed asymmetric.

Introduction

Literate native speakers are exquisitely adapted to the visual and linguistic processing of written text in their language. The naturalistic task underlying most of this adaptation is reading (Rayner, 1998). In the study of eye movements in reading, one of the most striking examples of this adaptation in the last several decades has been discovery of *asymmetry of the perceptual span*: in languages which are written from left to right, readers are more sensitive to material to the right of the center of fixation on the page than they are to material on the left. In languages which are written from right to left,

however, this sensitivity is reversed (Rayner, Well & Pollatsek, 1980). Since visual acuity per se is not itself asymmetric (as evidenced by experimental work on perception of non-linguistic visual inputs), the most intuitive interpretation of this finding is that, in ordinary progressive reading, because readers of languages written left to right have already seen what lies to the left of their eyes, they differentially attend to what lies to the right (and vice versa for languages written right to left).

However, the discovery by O'Regan, Lévy-Schoen, A., Pynte, J. & Brugailière (1984) of the optimal viewing position (OVP) in *isolated* word recognition makes the picture more complex. The OVP in isolated word recognition can be succinctly described as follows: word recognition is fastest and most accurate when the initial fixation point of the eyes is slightly to the left of the center of the word (Figure 1a). The discovery of the OVP launched considerable discussion as to its nature and implications, since it cannot be obviously accounted for by an asymmetry in perceptual acuity that would be adaptive for the task.

At present, there are two leading explanations that have been proposed for the OVP in isolated word recognition. One is that the asymmetry of perceptual acuity to the left and to the right within reading may affect *all* processing of visual linguistic input. If acuity drops off more rapidly to the left of the fixation point than to the right, then the best strategy to recognize a word would be to fixate at a left-of-center location, maximizing average acuity across the word as a whole. Evidence supporting this position has been adduced by Nazir, O'Regan & Jacobs (1991) and Nazir, Heller & Sussman (1992), who demonstrated left-right acuity differences in tasks involving the detection of a target letter at a variable position within a masking letter string (e.g., *kkkkkykk*). They found that the drop-off in performance was a monotonic function of visual eccentricity, and the left visual field showed steeper drop-off than the right visual field (Figure 1b).

The other leading explanation was put forth by Clark & O'Regan (1999), who argued that a better way to understand the contributions of these different mechanisms may lie in the distributional statistics of the written lexicon itself. They investigated the contributions of orthographic constraints, con-

Figure 1: The OVP effect in isolated word recognition and possible explanations for it.

structuring a simple measure of residual lexical ambiguity that would hold assuming only that two letters near the fixation point and at the end of the word are known. For a range of word lengths in both French and English, this ambiguity measure is minimized just to the left of the word's center, capturing the OVP effect through lexical constraint without resorting to an asymmetric perceptual acuity curve (Figure 1c).

It is difficult to adjudicate between these two possible explanations through purely experimental means, because well-established effects on word recognition such as those of word frequency and neighborhood density make it is fairly clear that lexical constraint plays a ubiquitous role in the process but varies slightly for every word in the lexicon, making it difficult to design a word-recognition experiment that controls for lexical constraint while testing perceptual acuity. Conversely, our understanding of precisely how the perceptual acuity curve affects word recognition remains limited, making it difficult to hold it constant and test only lexical constraint as a possible source of OVP effects. In this paper, we take an alternative approach, constructing an ideal-observer model (Marr, 1982; Anderson, 1990) of isolated word recognition in which lexical constraints are assumed to be available. The perceptual acuity curve in this model is determined by a set of parameters which are free and can be fit to behavioral data using well-established techniques of statistical inference. Our ideal-observer model thus allows us to “reverse-engineer” the perceptual acuity curve active in isolated word recognition on the basis of a lexicon (with word frequencies) and a behavioral data set, and assess whether and how the reverse-engineered acuity curve may be asymmetric.

Data

The dataset used in our study is from Experiment Two of Stevens & Grainger (2003). In this experiment, words were presented for 50ms each at various positions relative to the center of the fixation. After presentation of each word, the participant was asked to type the presented word back into the computer. The dataset contains 75 five-letter words and 105 seven-letter words and the human performance (correctness of the response) for each word from seventy subjects, for a total of 12,600 observations balanced across word identity

and fixation position. We obtained a word frequency database from the Agence France Presse (AFP) French Corpus, which contains French journal articles from 1993-1996. Since the human dataset has both five-letter and seven-letter French words, we extracted frequency counts for all five-letter and seven-letter words in the corpus. The resulting lexicon contains 14,379 five-letter French words and 21,569 seven-letter French words.

Model

The Bayesian Reader

We use an ideal-observer model of isolated word recognition, the Bayesian Reader (Norris, 2006, 2009). Our version of the Bayesian Reader introduces several key assumptions regarding the nature of word recognition which determine the form of the probabilistic model:

- Word recognition is a Bayesian hypothesis test in which prior expectations regarding what word is likely to be presented are combined with perceptual evidence \mathbf{d} to determine posterior beliefs about what word w is being seen:¹

$$P(w|\mathbf{d}) = \frac{P(\mathbf{d}|w)P(w)}{P(\mathbf{d})};$$

- The prior probability of each word $P(w)$ is proportional to its corpus frequency of occurrence;
- Perceptual evidence consists of a sequence of independent identically distributed (i.i.d.) input samples $d^{(1)}, \dots, d^{(N)}$ drawn from a NOISE DISTRIBUTION $P(d|w)$, where samples accrue at a constant rate over time;
- If we denote the letters of a word w of length L as w_1, \dots, w_L , then an input sample d can be decomposed into L samples d_1, \dots, d_L , with d_i conditionally independent of d_j given w_i and w_j for all $i \neq j$, so that

¹Tasks in which the decision to be made is something other than the identity of the word—e.g., a lexical decision about whether the input string is a word in the participant's language—can be formulated as Bayesian hypothesis tests among the possible choices (Norris, 2006; del Prado Martin, 2008).

$$P(d|w) = \prod_{i=1}^L P(d_i|w_i).$$

We will refer to the term $P(d_i|w_i)$ as the noise distribution for letter w_i .

Thus far, this version of the Bayesian Reader is simpler and more general than that introduced by Norris (2006), who assumed (a) a specific representation of each sample d as a point in a high-dimensional space; (b) a multivariate Gaussian form for the noise distribution $P(d|w)$; and (c) a specific estimate of the noise variance used by the ideal observer in computing the posterior distribution over words given perceptual evidence.

Adaptation to modeling visual acuity curves

In order to adapt the Bayesian Reader to the task of estimating visual acuity curves, however, we need to introduce a dependence of the noise distribution for each letter on its physical positioning. In particular, we assume that the noise distribution for each letter is dependent on its eccentricity as measured in number of characters from the point of fixation, with negative values corresponding to left-of-fixation and positive values to right-of-fixation; and on its proximities v^L and v^R to the left and right edges of the word, also measured in characters. If we define these physical positioning characteristics of a letter w_i as $k_i \equiv \langle e_i, v_i^L, v_i^R \rangle$, then its position-contingent noise distribution can be denoted as $P(d_i|w_i, k_i)$.

For the empirical modeling studies presented here, we make the additional assumption that the value of

$$E_{d_i|w_i^*, k_i} [P(d_i|w_i, k_i)], \quad (1)$$

where $E_{d_i|w_i^*, k_i}$ denotes expectation under the conditional distribution $P(d_i|w_i^*, k_i)$ for the true letter w_i^* being presented, depends only on k and on whether $w_i = w_i^*$. This assumption can be interpreted as stating that every letter is equally confusable with all letters other than itself; the quantity in (1) for $w_i \neq w_i^*$ can be interpreted as the level of confusability of a letter as a function of its physical positioning. This assumption is not necessary within the overall framework, and indeed could be relaxed in order to incorporate letter confusability matrices (Engel, Dougherty & Jones, 1973; Geyer, 1977) into the model and even to learn them directly from behavioral word-recognition data. In the present studies, however, this assumption greatly simplifies and facilitates both the statistical learning problem and its computational implementation.

Learning visual acuity from word identification data

Recall that in their word-identification study, Stevens & Grainger (2003) presented experimental participants with five- and seven-letter words one at a time for a brief, fixed interval too short to permit refixation, with fixation position varying across trials. The behavioral response r in each trial

was the participant's guess as to which word they saw. Our goal is to use these behavioral responses to learn the dependence of the visual acuity of a letter—as quantified by confusability in (1)—on its physical positioning.

We model the naming task using the assumptions outlined in the previous two sections. In general, the experimental participant must choose their response r through some possibly stochastic decision process based on their posterior beliefs $P(w|\mathbf{d}, k)$ about what word they saw. We further assume that the participant makes their choice of response through probability matching, so that the probability of any response r given the word w^* actually being presented is given by its expected posterior probability:

$$P(r|w^*, k) = E_{\mathbf{d}|k, w^*} [P(r|\mathbf{d}, k)] \quad (2)$$

where $E_{\mathbf{d}|k, w^*}$ represents the expectation marginalizing over possible perceptual input samples given the true word and its physical positioning. For notational simplicity, we omit the subscript on the expectation whenever it is clear from context.

Equation (2) can be rewritten using Bayes' rule as

$$P(r|w^*, k) = P(r) E \left[\frac{P(\mathbf{d}|r, k)}{P(\mathbf{d}|k)} \right]. \quad (3)$$

Equation (3) is the expectation of a ratio of random variables $E[Y/X]$, an expression which cannot in general be manipulated exactly. Using the method of propagation of error, however, a second-order approximation for the expectation of a ratio can be found (Rice, 1995):

$$E \left[\frac{Y}{X} \right] \approx \frac{E[Y]}{E[X]} + \frac{1}{E[X]^2} \left(\text{Var}[X] \frac{E[Y]}{E[X]} - \text{Cov}[X, Y] \right).$$

We now turn our attention to the rightmost part of this expression, the covariance between the numerator and the denominator—in Equation (3), these terms are $P(\mathbf{d}|r, k)$ and $P(\mathbf{d}|k)$ respectively. Insofar as any individual word plays only a small part in the calculation of the marginal probability $P(\mathbf{d}|k)$, we would expect the covariance of this marginal probability with $P(\mathbf{d}|r, k)$ to be small (with the important caveat that because words tend to look more like each other than like non-words, there will generally be some positive covariance, and its magnitude may depend on the orthographically typicality of w^* and r). Dropping the covariance from the above approximation allows us to approximate our posterior probability as

$$P(r|w^*, k) \approx P(r) \frac{E[P(\mathbf{d}|r, k)]}{E[P(\mathbf{d}|k)] + \frac{\text{Var}[P(\mathbf{d}|k)]}{E[P(\mathbf{d}|k)]^3}}.$$

Ignoring the denominator (which is constant with respect to r) and decomposing the perceptual input \mathbf{d} into its component independent samples at each time j and letter position i , we obtain

$$P(r|w^*, k) \propto P(r) \prod_{i,j} E_{d_i^{(j)}|k_i, w_i^*} [P(d_i^{(j)}|r_i, k_i)].$$

We take advantage of the identical distribution of the N samples to obtain the approximate unnormalized probability

$$P(r|w^*, k) \propto P(r) \prod_i \left(E_{d_i|k_i, w_i^*} [P(d_i|r_i, k_i)] \right)^N.$$

We are now ready to take advantage of our assumption from the previous section that each letter is equally confusable with all letters other than itself—that is, the value of each of the above terms $\left(E_{d_i|k_i, w_i^*} [P(d_i|r_i, k_i)] \right)^N$ depends only on k_i and on whether $w_i = w_i^*$. For each k_i , let us denote the value taken when $w_i = w_i^*$ as p_i , the value taken when $w_i \neq w_i^*$ as q_i , and the ratio $\frac{p_i}{q_i}$ as l_i . Substituting these terms in and dividing the entire expression by $q_1 \dots q_L$ gives us our final approximate expression for the probability of the participant's response:

$$P(r|w^*, k) \propto P(r) \prod_{i: w_i = w_i^*} l_i \quad (4)$$

where l_i is dependent on the physical positioning of the letter in question. On the original assumption of the Bayesian Reader that the number of input samples N accumulates at a constant rate over time, the value $\log l_i$ can be interpreted as the average rate at which perceptual information accrues at position i .

Model parameterization and estimation

Within the context of our model, the goal of inferring a visual acuity curve from behavioral word-recognition data entails estimating these input-accrual rate parameters $\log l_i$. In the studies presented here, we assume as stated before that the $\log l_i$ for each letter is a function of three properties of its physical position: its eccentricity from the fixation point, its proximity from the left edge of the word, and its proximity from the right edge of the word. All measurements are made in characters. We consider two functional forms for the eccentricity parameters: a PARAMETRIC form in which the values of $\log l_i$ is assumed to follow a Gaussian curve centered at the fixation point with maximum value α and standard deviation σ ; and a NONPARAMETRIC form in which each eccentricity has its own arbitrary parameter value. For each form, we consider a SYMMETRIC version in which the eccentricity parameters $\log l_i$ are determined by the absolute eccentricity, and an ASYMMETRIC version in which the parameters for negative and positive eccentricity values of the same magnitude can be different (in the parametric Gaussian case,

the asymmetric model allows different standard deviations σ_L and σ_R to the left and the right of the fixation point). Additionally, all models include one left-edge and one right-edge “bonus” parameter, b_L and b_R , added to the eccentricity parameters to determine the input-accrual rate parameters $\log l_i$ for the first and last letters of a word respectively. That is, if the fixation position is on the f -th character of the word and the function $e(\cdot)$ maps eccentricities to values in $\log l_i$ space, we have

$$\begin{aligned} \log l_1 &= e(1 - f) + b_L && \text{(first letter)} \\ \log l_i &= e(i - f) && \text{(middle letters; } i \notin \{1, L\}) \\ \log l_L &= e(L - f) + b_R && \text{(last letter)} \end{aligned}$$

In all cases, we fit the parameters of our models using maximum likelihood estimation. Fortunately, the gradient of our model is readily calculable and allows estimation using standard gradient-descent techniques.

Results

For each of our nonparametric (−PAR) and parametric (+PAR) models, we fit a symmetric (+SYM) and an asymmetric (−SIM) variety to the 12,600-observation dataset of Stevens & Grainger (2003, Experiment 2) estimation. This dataset contains presentations of both five-letter and seven-letter words, with every letter of each word serving as the fixation point for an equal number of trials. For each model, we used a single set of eccentricity and edge-bonus parameters to cover all trials, giving us four parameters in the symmetric parametric case (one maximum acuity parameter, one standard deviation, and two edge bonuses), five in the asymmetric parametric case (two standard deviations instead of one), nine in the symmetric nonparametric case (seven eccentricity parameters and two edge bonuses), and fifteen in the asymmetric nonparametric case (thirteen eccentricity parameters instead of seven). These models are nested in the classical statistical sense as follows:

$$[-\text{PAR}, -\text{SYM}] \prec \{[-\text{PAR}, +\text{SYM}], [+ \text{PAR}, -\text{SYM}]\} \prec [+ \text{PAR}, +\text{SYM}]$$

Since we use maximum likelihood estimation with far more observations than parameters, we can use likelihood-ratio tests for pairwise comparisons of all models except between $[-\text{PAR}, +\text{SYM}]$ and $[+ \text{PAR}, -\text{SYM}]$. These tests indicate that asymmetric models explain participant response behavior far better than symmetric models in both parametric ($\chi^2(1) = 250, p \ll 0.001$) and non-parametric cases ($\chi^2(6) = 345.7800, p \ll 0.001$). Among asymmetric model variants, the nonparametric model explains participant response behavior significantly better than the Gaussian model ($\chi^2(10) = 564.7, p \ll 0.001$).

For the asymmetric nonparametric model, we estimated standard deviations for our parameter estimates using 100 bootstrap replicates. Figure 2 graphs the value of $\log l$ as a function of eccentricity, together with edge-bonus parameter

Figure 2: Symmetric (dashed blue lines) and asymmetric (solid black lines) non-parametric model parameter estimates. Error bars on the asymmetric model parameter estimates are standard deviations estimated from bootstrap replicates. b_L and b_R are “edge bonus” parameters added to the appropriate eccentricity parameters to obtain $\log I$ for the leftmost and rightmost letters in a word.

estimates (and error bars to indicate bootstrapped standard deviations for the asymmetric variant), for the two varieties of the nonparametric model. Figure 3 graphs these quantities for the two varieties of the parametric model. In both figures, eccentricity falls off to the left more rapidly in the asymmetric model than in the symmetric model, and to the right more rapidly in the symmetric model than in the asymmetric model.² This consistent pattern suggests that the data of Stevens & Grainger (2003) provide evidence for an asymmetry in the perceptual acuity curve in visual recognition of isolated words even when lexical constraint is taken explicitly into account.

Conclusion

The results of our modeling studies provide additional evidence for the idea that an asymmetric visual acuity curve contributes to the OVP effect documented in many studies on isolated word recognition (O’Regan et al., 1984; Vitu, O’Regan & Mittau, 1990; O’Regan & Jacobs, 1992; Stevens & Grainger, 2003). Even while explicitly accounting for the role of lexical constraint, we consistently found that the models which best accounted for the distribution of response accuracies found in Experiment 2 of Stevens & Grainger (2003) had an asymmetric perceptual acuity curve in which acuity dropped off more slowly as a function of visual eccentricity to the right than to the left. Although Stevens & Grainger (2003) also presented results of another experiment using the letter-within-mask identification task which called into ques-

²In the nonparametric model, the most extreme eccentricities have oddly-behaving parameter estimates that indicate possible problems with model specification, perhaps because the edge bonus parameters are so often implicated in model predictions for these extreme eccentricities. We expect that fitting the nonparametric model to behavioral data involving presentation of words of a larger variety of lengths would be likely to reduce or eliminate this problem.

Figure 3: Symmetric (dashed blue lines) and asymmetric (solid black lines) parametric model results, assuming that eccentricity is piecewise Gaussian centered around the fixation point. b_L and b_R are “edge bonus” parameters added to the appropriate eccentricity parameters to obtain $\log I$ for the leftmost and rightmost letters in a word.

tion the generalizability of the findings of Nazir et al. (1991, 1992) regarding asymmetry of the perceptual acuity curve, the fact that an asymmetric perceptual acuity curve is required to provide the best account for their word-recognition data by an ideal observer with the knowledge of lexical statistics of the language calls into question the strong position staked out by Clark & O’Regan (1999) that the left-of-center position of the OVP may derive purely from lexical constraint. In our view, the most plausible theoretical position reconciling our modeling findings with empirical findings from the reading literature on the asymmetric perceptual span (Rayner et al., 1980) and with those of Stevens & Grainger (2003) on character-within-mask recognition is that isolated word recognition does indeed involve an asymmetry of perceptual acuity, but that it is a parasitic byproduct of cognitive adaptation to the naturalistic task of reading. The character-within-mask recognition task may be sufficiently unlike naturalistic reading that it does not trigger this asymmetric perceptual span. It is worth noting that the experiments of Nazir et al. (1991) and Nazir et al. (1992) always involved fixation on the leftmost or rightmost character of the word, and used a letter (instead of the hash mark # used by Stevens & Grainger) as the mask character. It is possible that the lower overall visual acuity due to fixation at the word’s right or left edge together with the letter mask may have induced the language and perceptual systems to categorize input in this experiment more like that obtained in natural reading, inducing asymmetric perceptual acuity.

Although we believe our modeling approach represents an important step forward in resolving these issues, it is important to emphasize that several simplifying assumptions we introduced which led from the general ideal-observer formulation to the specific, highly tractable model of Equation (4) have the potential to significantly affect our modeling results and deserve more careful consideration in the future. The first

of these simplifying assumptions was equal confusability of letter pairs. Of course, it is well known that some letter pairs are more confusable than others (e.g., *o* is much more confusable with *e* than with *l* for native English speakers; Geyer, 1977). It is possible that the assumption of equal confusability could interact with the lexical statistics of French and the items chosen by Stevens & Grainger (2003) to create a confound in the explanation of our modeling results—for example, such a confound might arise if the letters near the end of their items were more highly confusable than the letters near the beginning of their items. This possibility can be explored in future work by relaxing the assumption of equal confusability and using established letter confusion matrices to scale our model parameters, or even to allow our model to learn confusability parameters directly from word-recognition behavioral data.

The second simplifying assumption deserving discussion is that participants' behavioral responses arose from probability matching. In other cognitive domains, this assumption seems to have reasonable theoretical and empirical support (Vulkan, 2000; Mozer, Pashler & Homaei, 2008; Vul & Pashler, 2008; Vul, Goodman, Griffiths & Tenenbaum, 2009). That being said, it is entirely possible that participants' responses may reflect maximization or some other similar decision process, and that most inter-trial response variability derives from the variation inherent in noisy perception. The consequences of this possibility may be explored in future work within our framework by explicit simulation of inter-trial noise instead of marginalizing over perceptual input as we have done here.

The final simplifying assumption is that of minimal covariance between the probability of noisy perceptual samples given the word under consideration and the marginal probability of those perceptual samples. As discussed earlier, this assumption is clearly wrong insofar as words in any given language tend to look more like each other than like non-words; but the sheer number of words in the lexicon, combined with the considerable variability that does exist among wordforms, implies that this covariance should in general be rather small. It is also not obvious to us how this simplifying assumption might introduce a confound to our specific result of an asymmetric perceptual acuity curve in isolated word recognition. Nevertheless, there are two ways that this simplifying assumption could be relaxed in future work. First, explicit simulation of inter-trial noise would permit us to quantify the discrepancy between the simplified results we report here and the results which would obtain under the model more generally. Alternatively, we might try to quantify the covariance between $P(\mathbf{d}|w, k)$ and $P(\mathbf{d}|k)$ through explicit simulation, and then use these covariance estimates to adjust our expectation-based model directly. This latter alternative might have the added benefit of giving us more direct insight into the full range of top-down effects that are present in word recognition. Intuitively, this covariance should be larger for more "prototypically word-like" words, which should de-

crease the expected posterior belief for such words relative to less word-like words, a sort of second-order neighborhood-density effect. Further elucidation of all these issues awaits future research.

Acknowledgments

We are grateful to Michaël Stevens and Jonathan Grainger for graciously sharing their experimental data with us; and to Rebecca Colavin for her expertise in French. This research was partially supported by NIH Training Grant T32-DC000041 to the Center for Research in Language at UCSD to NJS, by a Taiwan Graduate Fellowship of government sponsorship for overseas study to WHC, and by NSF grant 0953870 to RL.

Abstract

There is a chorus of complaints that many professional tennis players who grunt when striking the ball gain an unfair advantage because the sound of the grunt distracts their opponent. However, scientific investigations of human attention and performance, specifically with regard to sound-vision interactions, would seem to predict that a grunting sound should help because it will draw attention to the visual event of a ball being struck. We tested the argument that a grunt has a negative impact by requiring participants to view videos of a professional hitting a ball to either side of a tennis court with or without a grunt. The task was to respond as quickly as possible to the ball's direction. Grunting interfered with performance making responses slower and less accurate. The competitive advantage afforded to the grunting player is potentially profound. The findings will be discussed in relation to current theory on multisensory integration.

Keywords: Attention; multisensory integration; distraction; tennis; action perception.

Introduction

Last year, for the first time, a Portuguese women's tennis player, Michelle Larcher de Brito, made it to the third round of the 2009 French Open. Unfortunately for Michelle she lost to Frenchwoman Aravane Rezai in a match where Michelle was heavily criticized for executing a loud and long grunt each time she hit the ball. The complaint is that Michelle, and many of the best players in tennis like her, such as Maria Sharapova (who grunts at over 100 decibels) and the Williams sisters, gain an unfair advantage by distracting their opponents with their grunts. Indeed, there is a growing chorus of critics who complain that many of the top-ranked professional women tennis players are cheating when they grunt. This complaint has been voiced not only by the media and fans, but also by the athletes themselves

(Flatman, 2009; Navratilova, 2009). Indeed, further exemplifying the notion that grunting might distract an opponent, the governing body of the rules of tennis (International Tennis Federation, ITF) explicitly states (rule 26) that purposeful and excessive grunting is a hindrance and reason for a point penalty (International Tennis Federation, 2009).

Unfortunately, the scientific evidence to support these complaints and rules is less than compelling. While there is evidence that performance on a visually based task can be interfered with when a rare and unexpected distracting sound occurs, such as a phone ringing during an exam (Shelton, Elliott, Eaves, & Exner, 2009), a predominant complaint is that tennis players grunt too frequently (i.e., on every shot), so the grunts can hardly be unexpected. Furthermore, there is also evidence that when a sound and visual event occur at different moments and/or locations, attention may be drawn to the sound and away from the visual event (Morein-Zamir, Soto-Faraco, & Kingstone, 2003; Sekuler & Sekuler, 1997). However, that situation does not apply to tennis, as the sound of a grunt and the visual of a ball being struck share a common place in time and space. Accordingly, laboratory research indicates that when audio-visual events share a common origin, they are often integrated, thereby helping to focus attention on the visual event (Calvert & Thesen, 2004; Stein, London, Wilkinson, & Price, 1996). In fact, in some situations a certain degree of temporal and spatial disparity in the multimodal signals can actually be tolerated (Jones & Jarick, 2006). The science therefore suggests that a player who grunts while making a shot may help their opponent focus attention on the shot. This notion can be further bolstered by evidence that having a sudden, short sound can increase one's general level of alertness (Nickerson, 1973). Thus past research does not support the complaint that grunting puts an opponent at a competitive disadvantage.

Nevertheless, it would be the height of arrogance to dismiss the complaints from opponents and experts alike that the grunts have a negative impact. Indeed, past audio-visual studies have generally been limited to detecting flashes of light, and may not apply to the more complex situation of perceiving a tennis ball being struck. To take an initial step toward studying the effect of grunting in tennis we presented videos of a tennis player executing a forehand or backhand groundstroke to the left or right side of the court. Critically, half of the videos included a grunt whereas the other half did not. If the sound of the grunt is indeed distracting, longer response latencies and higher error rates would be expected when participants judged the direction of the tennis shot when a grunt was included.

Method

Participants

Thirty-three undergraduate students from the University of British Columbia participated in exchange for course credit. All reported normal hearing and normal or corrected-to-normal vision.

Materials

Participants sat approximately 60 cm from a computer screen in a dimly lit and sound attenuated testing room. The experiment was programmed and presented using DMDX software (<http://www.u.arizona.edu/~jforster/dmdx.htm>).

A total of 384 video clips were made of a professional tennis player hitting the ball (either forehand or backhand) to either the left or right of a video camera (Canon ZR10 digital video (DV) camera; 10x optical zoom, 200x digital zoom, image stabilizer, and 460K CCD pixel level) set up on the baseline of the court opposite the player. To be included as a video clip, the player had to hit the ball in a 2 X 2 meter target extending from the sideline and the baseline. The video clips were edited so as to include forehands hit crosscourt and down the line, and backhands hit crosscourt and down the line. There was a total of four clips for each shot type that were then edited such that each clip was played with or without a grunt and ended either at contact or 100 ms after contact. Each clip type (i.e., 32 total for each shot type, total of 128 video clips ranging in length from 1230 ms – 1666 ms) was repeated three times for a total of 384 trials. To mimic the sound of the grunt, while at the same time controlling for individual grunt types, white noise (500 ms; a very conservative and uniform grunt) was played for the last portion of the clips that included the ‘grunt’.

Procedure

Participants were required to respond as quickly and accurately as possible indicating the direction of the shot in each video clip (3 blocks of 128 separated by breaks for rest). They were required to use the M key on a keyboard

with their right hand if they thought that the shot was going to their right, and the X on a keyboard with their left hand if they thought that the shot was going to their left. Each trial began with a fixation cross (1250 ms), followed by the video. The experiment lasted approximately 25 minutes.

Results

Clips that ended at contact (Hard decision) were analyzed separately from clips ending 100 ms after contact (Easy decision). The data were analyzed for reaction time (RT) and accuracy. When the grunt was present and the video stopped at the time of contact, the participants were consistently 33 ms slower to respond to the direction of the ball (496 ms versus 463 ms; $t(32) = 3.7$, $p = .001$), and they made 4% more decision errors (39% vs. 35%; $t(32) = 2.7$, $p = .012$; see Figure).

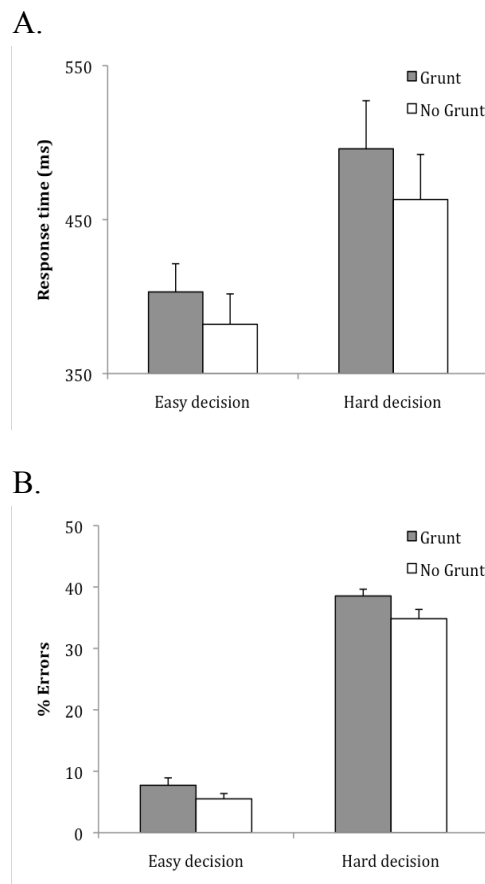

Figure: Dark grey bars represent when the grunt was present and clear bars when the grunt was absent for easy- and hard-shot decisions (A – response time in ms; B – total percentage of decision errors). All differences are significant.

When the video ended 100 ms after contact the exact same pattern was observed. If the grunt was present, participants

were 21 ms slower to respond to the direction of the ball (403 ms vs. 382 ms; $t(32) = 3.7$, $p = .001$), and they made 3% more errors (8% vs. 5%; $t(32) = 3.5$, $p = .001$). That a grunt had the same effect for hard and easy judgements was confirmed by analyses of variance of the overall RT and error data, which directly compared Grunt (Present vs. Absent) and Decision (Hard vs. Easy). The RT results revealed main effects of Grunt and Decision, reflecting the fact that participants were slower to respond when a grunt was present, $F(1,32) = 31.1$, $p < .001$, and the decision was hard, $F(1,32) = 21.8$, $p < .001$, but there was no interaction between grunt and decision, $F(1,32) = 1.74$, $p = .196$. Similarly, for response accuracy, there were more errors for grunts $F(1,32) = 16.0$, $p < .001$, and hard decisions, $F(1,32) = 525.8$, $p < .001$, but no interaction, $F < 1$.

Discussion

The findings are clear-cut. When a grunt occurs opponents are significantly slower (21-33ms) and make significantly more decision errors (3-4%) regarding the direction of the ball both for easy and hard decisions alike. Despite serve speeds now frequently exceeding 100mph (Miller, 2006), if a very conservative estimate that a professional tennis shot travels at 50mph during a rally, a 21-33ms response delay equates to a ball travelling two extra feet on every shot before an opponent can respond. This is a tremendous advantage given that rallies on average last five to seven seconds, with opponents executing generally four directional changes per point with approximately three strokes per rally (the precise values will of course vary with factors like game strategy and court surface; Fernandez, Mendez-Villanueva, & Pluim, 2006). Furthermore, based on data focusing exclusively on 481 matches played at Wimbledon from 1992-1995, an average of 6.4 points played per game can be calculated (Magnus, & Klaasen, 1999). Therefore, between the average number of points played per game and the average number of strokes per point, the additional 3-4% errors observed here could be equivalent to an opponent being wrong footed by a grunting-shot nearly once every game. Given that only four points are required to win a game, this is a definite advantage.

One can only speculate at present as to why a grunt affects the speed and accuracy of responding to a tennis shot. Because a tennis shot and grunt originate from the same location (i.e., the same person), contemporary evidence suggests that visual perception of the shot should be enhanced (see for example Calvert & Thesen, 2004; Sekuler & Sekuler, 1997). Yet we found the opposite. One possibility, suggested by past and present players, is that the sound of a ball making contact with a racket helps to indicate where a shot is going, and a grunt masks this crucial audio-visual integration. We are currently pursuing this issue by manipulating systematically the time of a grunt and the moment that a ball strikes a racket; benchmarking the data against past studies of audio-visual integration. An

additional avenue for future research is to manipulate the sound of the grunt and the expertise of the observer. The latter idea is of particular interest, as it might be possible that tennis experts may attempt unique strategies to circumvent the negative impact of a grunt that we have demonstrated here. However, given the self-reports from the tennis players that an opponent's grunting interferes with their play, and our data showing that negative effects of grunting arise for both response latency and accuracy measures regardless of decision difficulty, it is likely that the negative effect of grunting persists for expert tennis players. Indeed, current research suggests that many multisensory phenomena are highly resistant to top-down processes (Driver, & Noesselt, 2008).

It is difficult to ascertain whether many of the most prolific grunTERS intentionally grunt to distract their opponent. There is little doubt, however, that they are cheating their opponents. Grunting not only decreases their opponent's ability to judge the direction of a shot, it also reduces the amount of time they have to respond to every shot. These consequences on faster tennis surfaces, such as the grass courts of Wimbledon, or the hard courts of the Australian and US Open, are likely to be profound.

Abstract

Prior research indicates that young children can generalize object properties on the basis of category information when it is conveyed by identical labels or semantically similar labels at the same level of taxonomy (i.e., synonyms) (Gelman & Markman, 1986). However, in previous research semantic similarity was confounded with co-occurrence probability. Therefore, it is possible that synonym-based induction observed in prior research stemmed from children relying on cues other than the semantic similarity of labels. The present study investigated synonym-based induction with labels that do and do not co-occur in child-directed speech. Results indicated that adults made inferences on the basis of the semantic similarity of labels regardless of co-occurrence probability. In contrast, 4-year-old children generalized based on synonymous labels at above chance levels only when synonyms co-occurred in child-directed speech.

Keywords: Labels. Synonyms. Word Learning. Induction. Cognitive Development. Categories.

Introduction

Labels are pervasive in thought. Within the first six years of life, a child may learn up to 14,000 labels (Markman, 1990). It has been suggested that labels convey an object's category, thereby facilitating knowledge generalization (Gelman & Markman, 1986). For example, if a sheepdog has a certain property, would a bulldog be likely to share the same property? Though this question has no definitive answer, one might surmise that, both the sheepdog and the bulldog are likely to possess the property because both are referred to as 'dogs.'

It is well documented that adults rely on category information conveyed by labels to generalize from the known to the unknown, however, it remains contested when children begin to do so. Some research has suggested that children can rely on category information conveyed by labels as early as 13 months of age (Welder & Graham, 2001). Numerous studies have indicated that toddlers and preschool-age children view labels as communicating objects' kind, and that identical labels elicit category-based induction in young children as well as adults (Gelman 1988; Gelman & Coley, 1990; Gelman & Markman, 1986; Jaswal, 2004).

This interpretation has recently been challenged on the grounds that children may treat labels as perceptual attributes of objects rather than as category markers (Sloutsky & Fisher, 2004). Under this view, when two objects share a label, children engage not in *category-based* induction, but instead in *label-based* induction. In other words, children may rely on shared labels in the course of induction not because they understand that labels refer to categories, but because auditory information (including category labels) has a higher attentional weight than visual information early in development (Robinson & Sloutsky, 2004; Sloutsky & Napolitano, 2003). Indeed, there is ample evidence that auditory modality dominates the visual modality in infancy (Lewkowicz, 1994; Robinson & Sloutsky, 2004, 2007) and that these effects extend into early childhood (Napolitano & Sloutsky, 2004). Furthermore, there is evidence that a similarity-based account of early induction (which considers labels to be features of objects contributing to the overall perceived similarity) can readily account for children's reliance on identical labels in the course of property induction as well as categorization tasks (Sloutsky & Fisher, 2004; Sloutsky, Lo, & Fisher, 2001).

Both label-based and category-based accounts predict that children should rely on identical labels during the course of induction. One way to tease apart these two perspectives, is to convey category membership via non-identical semantically similar labels: If it is the case that children perceive labels as windows into categories, then children's generalizations based on semantically similar labels should be similar to their generalizations based on identical labels. If however, children are willing to generalize based on identical labels but not on semantically similar labels, then induction early in development can be label-based without necessarily being category-based.

There are two ways to convey semantic similarity using non-identical labels: by using hierarchically-related labels (e.g., *poodle-dog*) or semantically-similar labels at the same level of taxonomic hierarchy (e.g., *puppy-dog*). For the purpose of brevity, semantically similar labels at the same level of taxonomic hierarchy will be henceforth referred to as *synonyms*. It has been shown that the ability to base

inferences on familiar labels organized into taxonomic hierarchies does not mature until 7- to 8-years of age (Gelman & O'Reilly, 1988; Johnson, Scott, & Mervis, 1997). This finding could suggest that preschoolers' induction with identical labels is unlikely to be category-based. However, it is possible that children's difficulty using hierarchically-related labels stems from the lack of understanding of class inclusion relations, rather than from the lack of understanding that labels denote categories. Indeed, children have been shown to master class inclusion relations by 7- to 8-years of age (Klahr & Wallace, 1972) – the same age at which children can use hierarchically-related labels in the course of induction. The argument presented above suggests that preschool-age children should be successful in performing induction with synonyms, because these labels denote objects of similar kind at the same level of taxonomic hierarchy. At present, however, few studies have examined this possibility.

In a now classic study, Gelman and Markman (1986, Experiment 2) presented 4- to 5-year-old children with triads of pictures consisting of a target item and two test items: one test item looked similar to the target and the other belonged to the same category as the target. Category information was communicated by either identical or synonymous labels. Children were asked to generalize a property from one of the test items to the target. For example, children could be told that a 'rabbit eats bugs' whereas a 'squirrel eats grass', and asked whether the target item (referred to as a 'rabbit' in the Identical Labels condition and as a 'bunny' in the Synonyms condition) 'eats bugs like the rabbit' or 'eats grass like the squirrel.' Gelman and Markman found that children generalized properties to categorically similar items at above chance level in both labeling conditions. Notably, children's performance with synonyms was no different than their performance with identical labels (63% and 67% of category-based responses, respectively).

Gelman and Markman's (1986) study provided support to the notion that children utilize category information conveyed by linguistic labels. However, it has recently been suggested (Fisher, in press) that some label pairs in the Synonyms condition consisted of labels that were not only semantically similar, but also likely to co-occur as compound nouns in child-directed speech (e.g., *bunny-rabbit*, *puppy-dog*) according to the CHILDES database (MacWhinney, 2000). Co-occurrence of words in natural language has been argued to give rise to strong lexical associations (Brown & Berko, 1960; McKoon & Ratcliff, 1992); therefore in Gelman and Markman's (1986) study it is possible that when children were told that a 'bunny' had a particular property and were asked whether this property would be true of a 'rabbit' or a 'squirrel', children's responses were based not on the understanding that bunnies and rabbits are the same kind of animal, but on the fact that the word 'bunny' primed the word 'rabbit', whereas the word 'squirrel' did not.

A recent study by Fisher (2010) provides preliminary evidence to support this possibility. In this study participants were presented with a label extension task, in which they were taught a familiar label for a novel target object (e.g. "on a different planet, this one is called a *rock*"), and then asked which of the three test objects would likely be referred by a synonymous label (e.g., "which one do you think is called a *stone* on a different planet?"). The three test objects varied in perceptual similarity to the target: one test object looked similar, one looked less similar, and one looked dissimilar. The Co-occurring Synonyms condition included labels that co-occurred in child-directed speech (e.g., *bunny-rabbit*, *puppy-dog*, *kitty-cat*), whereas the Non-co-occurring Synonyms condition included labels that never co-occurred in child-directed speech in the CHILDES database (e.g., *rock-stone*, *couch-sofa*, *child-kid*; MacWhinney, 2000). Fisher found that adults and six-year-old children inferred that objects referred to by synonymous labels were likely to look similar, exhibiting a high proportion of choices of similar test items in both labeling conditions. In contrast, 4 year-old children were more likely to choose similar test items in the Co-occurring Synonyms condition than in the Non-co-occurring Synonyms condition. Moreover, young children's performance in the Non-co-occurring condition did not exceed chance.

The present study was designed to directly examine the possibility that label co-occurrence may play a role in inductive generalization. Four-year-old children and adults participated in a triad induction task; on half of the trials participants were asked to make inferences based on non co-occurring synonyms and on the other half of the trials participants made inferences based on co-occurring synonyms. An Identical Label condition was also included as a control condition

Method

Participants

Participants were 33 4-year-old children ($M = 4.52$ years, $SD = .40$ years, 18 females, 15 males) recruited from local preschools and 30 undergraduate students from a local university who received partial course credit.

Design

The experiment had a 2 (Label condition: Synonymous vs. Identical Labels) by 2 (Co-occurrence condition: Non-co-occurring vs. Co-occurring Labels) by 2 (Age: Preschoolers vs. Adults) mixed design. Labeling condition was a between-subject factor: participants were randomly assigned either to the Synonymous or Identical Labels condition. Co-occurrence probability of labels was a within-subject factor: every participant performed induction both with co-occurring and non-co-occurring labels.

Materials

Language materials consisted of nine label triads, with each triad comprised of a target item, a semantically related test

item and an unrelated test item. Related test items could be conveyed either by identical or by semantically similar labels (in the Identical and Synonymous Labels conditions, respectively). Unrelated items consisted of labels that a separate group of adult participants judged to be unrelated to the target items (see details below). To-be-generalized properties consisted of two-syllable blank predicates. A full list of linguistic stimuli is provided in Table 1.

Visual stimuli consisted of three sets of doors, with each set including three identical doors. Participants were told that objects were hiding behind each of the doors. This procedure was used to provide participants with conditions that were maximally favorable to relying on semantic information conveyed by labels as there was no perceptual conflict that participants had to resolve to perform category-based induction. Since visual stimuli were identical, category information conveyed by labels was the only basis for induction. Additionally, a set of 27 pictures was used for a Picture Identification task that all children completed after the experiment proper. The goal of this task was to ensure that children were familiar with all of the labels used in this study, and that children were willing to use semantically similar labels to refer to the *same* object (see the Procedure section below for details).

Label Selection

Assignment of label pairs to the Co-occurring and Non-co-occurring conditions was similar to the procedure used in Fisher (2010). Five different databases in the CHILDES corpus were analyzed (i.e., Bates, Brown, Gleason, HSLD, and Wells). Children’s ages ranged from 1 ½ to 9 years, and, across all databases a total of 2,264,722 words were included. To obtain normalized co-occurrence scores, the number of raw co-occurrences was divided by the sum of instances of each word occurring individually minus the number of times the two words co-occurred. For example, the word “kitty” occurred in the analyzed databases 847 times, the word “cat” occurred 2,319 times, and these words co-occurred 131 times. Using the normalization procedure the probability of the words “kitty” and “cat” co-occurring was calculated as $131 \div [847 + 2,319 - 131] = .04$.

Four co-occurring synonyms were selected based on their above-zero co-occurrence probability and their likelihood of being known to young children. Because all four co-occurring label-pairs referred to natural kinds, only non-co-occurring synonyms referring to natural kind objects were selected for this study. We did not use some of the non-co-occurring label pairs used by Gelman and Markman (1986) (e.g., *cobra-snake* and *rose-flower*) because these labels were hierarchically related, and thus unlikely to generate category-based induction in 4-year-old children (Gelman & O’Reilly, 1988; Johnson, Scott, & Mervis, 1997).

Overall, the average co-occurrence probability of synonyms was .033 in the Co-occurring condition and .000 in the Non-co-occurring condition, independent-samples $t(6) = 2.26$, $p = .03$. Unrelated test items were also labels that referred to natural kind objects. Unrelated test items

were matched in syllable length to the related items for all triads except one¹.

A separate calibration study was conducted with an independent group of 22 adults to establish semantic similarity of labels within each triad. Adults were asked to rate semantic similarity of the Target items to the Related and Unrelated test items (e.g., *rock-stone*, *rock-cloud*, and *stone-cloud*) on a scale of 1 – 7, with 7 indicating that the labels could be used interchangeably, and 1 indicating that the labels had no overlap in meaning. Results of this calibration confirmed that targets and related test items (i.e. synonyms) were more semantically similar ($M = 6.3$) than targets and unrelated test items ($M = 2.8$), $t(14) = 11.43$, $p < .001$. There were no differences found when the analysis was separated by co-occurrence condition, $F(1, 15) < 1$, *ns*.

Table 1: List of stimuli and co-occurrence probabilities of semantically similar labels.

Target Items	Related Test Items	Unrelated Test Items	Blank Predicates	Co-Occ Prob
Rock	Stone	Cloud	Higa	.000
Dolphin	Whale	Seal	Omat	.000
Alligator	Crocodile	Hippo	Matlen	.000
Toad	Frog	Bird	Koski	.000
Mouse	Rat	Duck	Lignin	.000
Puppy	Dog	Cow	Erwin	.010
Kitty	Cat	Pig	Manchin	.040
Bunny	Rabbit	Squirrel	Creighan	.070
Pony	Horse	Fox	Troxel	.01

Procedure

Children were tested individually at their daycares in a quiet room or hallway. Adults were tested individually in a laboratory on campus. Visual stimuli were presented on a computer and labels were provided verbally by experimenters.

Labels used in the Synonyms condition are displayed in Table 1. The same set of labels was used in the Identical condition with the exception that the Target items and Related Test items were referred by identical labels (e.g., *rock-rock* for half of the participants and *stone-stone* for the other half of the participants). Half of the participants participated in the Co-occurring condition first, and the other half participated in the Non-co-occurring condition first. Within each co-occurrence condition trials were presented in one of two random orders. The *rock-stone-cloud* triad always appeared first as served as an instructional trial for all participants; the data from this trial were not included in the analyses reported below.

Participants were told that they would be playing a game about objects that were hiding behind doors (see Figure 1). The experimenter told participants what object was hiding

¹ Due to 4-year-old parlance, hippo was included as a lure for alligator-crocodile, despite it not matching the number of syllables of the related test item.

behind each door. The Target objects were always hidden behind the topmost door, and the location of the Related and Unrelated Test objects (to the left or to the right of the Target) was randomized across trials. The experimenter first introduced the Target item (e.g., *There is a rock hiding behind this door*) and then introduced the Test items in random order (e.g., *There is a cloud hiding behind this door*, *There is a stone hiding behind this door*). Then participants were told about the property of the Target item (e.g., *The rock behind this door has higa inside*) and asked to generalize this property to one of the Test items (e.g., *Do you think that the cloud behind this door or the stone behind this door also has higa inside?*).

Additionally, participants were asked to remember where each object was hiding. The memory check was included to ensure that possible differences in induction performance could not be attributed to children's better memory for co-occurring than for non-co-occurring synonyms. After the induction response was recorded, a memory check was performed: the experimenter asked the participant if (s)he remembered what was hiding behind each door, pointing to the doors in random order.

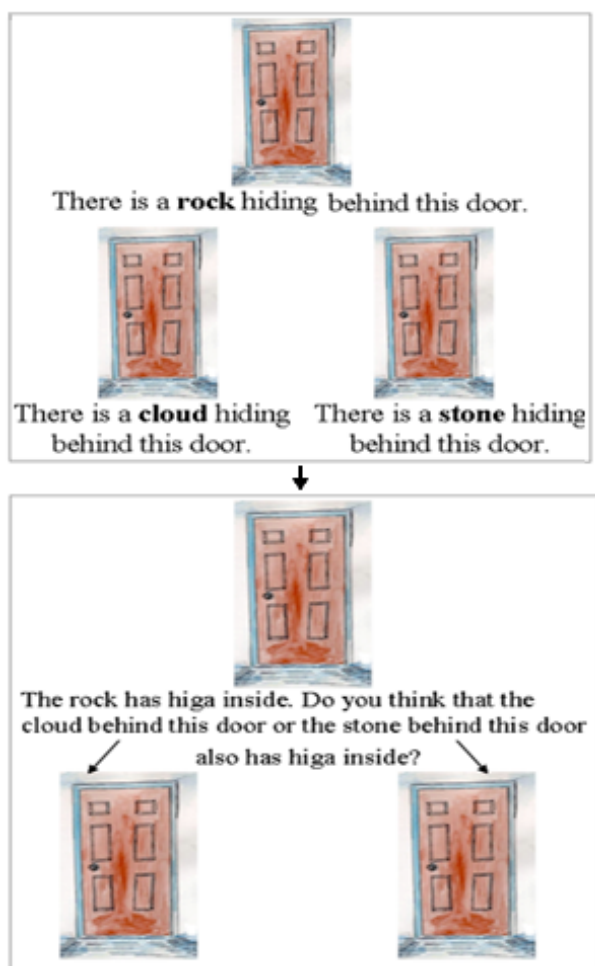

Figure 1: Schematic depiction of door task.

After the induction task children (but not adults) participated in a Picture Identification task similar to the Peabody Picture Vocabulary Test (Dunn & Dunn, 1997). The goal of this task was to confirm that children were familiar with each of the labels used in the induction task. In each trial children were presented with four different pictures, and asked to point to the target picture that was verbally indicated by the experimenter (e.g., *“can you find the rock?”*). Target items in the Picture Identification consisted of all Target, Related, and Unrelated labels that were included in the induction task. Importantly, knowledge of synonymous labels was always tested using *identical* pictures on separate trials (with location of the correct response counterbalanced across trials). There were 18 unique pictures of interest (for the two labels in eight experimental and one instructional trial in the induction task). Pictures testing knowledge of synonyms were presented twice and pictures testing knowledge of the unrelated items were presented once, resulting in a total of 27 trials in the picture identification task.

Results

Preliminary analyses revealed no effects of block order (all p 's $> .20$). In the Picture Identification task, children's accuracy was .99 in each Label condition, indicating that 1) children were familiar with the words used in the experiment proper, and that 2) children could readily apply synonymous labels to the *same* objects.

Induction Accuracy

Proportions of category-based responses (i.e., choices of identical or synonymous labels) were analyzed in a 3-way mixed ANOVA, with Label condition and Age group as between-subject factors and Co-occurrence condition as a within-subject factor. The analysis revealed a significant effect of Age, $F(1, 58)=29.57$, $p<.001$; a significant interaction between Co-occurrence and Age $F(1, 59)=5.58$, $p<.05$; and a significant three-way interaction $F(1, 59)=4.41$, $p<.05$. Follow-up analyses revealed no differences among conditions for adults (all p 's $>.63$). Adults' category-based responding was above chance in all conditions (all p 's $<.001$) (means in all conditions were $\geq .97$, SD's $\leq .09$).

Proportions of children's category-based responses are presented in Figure 2. For children there was a reliable difference in performance between the Non-Co-Occurring Synonyms and the Co-occurring Synonyms conditions, paired-sample $t(16) = 3.45$, $p <.005$ ($M = .52$ and $.74$, respectively). Within the Non-co-occurring condition, there was also a reliable difference between the Synonymous and Identical Label conditions, independent-sample $t(31) = 2.41$, $p <.05$ ($M = .52$ and $.75$, respectively). Furthermore, children's performance in the Non-co-occurring Synonyms condition did not exceed chance, one-sample $t(17) = .20$, $ns.$, whereas performance in all other conditions was above chance (all one-sample t 's > 2.54 , p 's $<.05$). There were no differences in children's performance with Identical Co-occurring and Identical Non-co-occurring labels, paired-samples $t(15) = .53$, $ns.$ ($M=.75$ and $.70$, respectively).

Figure 2. Proportion of category-based responses in children.

To investigate performance at an individual level, we classified participants into category-based and non-category-based responders. A category-based responder was defined as a participant who provided at least 3 of 4 category-based responses within each condition (see Figure 3). Individual response patterns mirrored the group data summarized above. In particular, all adult participants in all conditions were classified as category-based responders. In the Co-Occurring labels condition the majority of 4-year-olds were also classified as category-based responders: 11 out of 17 (65%) in the Identical labels condition and 10 out of 16 (63%) in the Synonyms condition (this association was not significant, Fisher's exact $p > .99$). Similarly, in the Non-Co-Occurring/Identical labels condition the majority of children were classified as category-based responders: 12 out of 16 (75%). However, in the Non-Co-Occurring/Synonyms condition only 6 out of 17 children (35%) were classified as category-based responders. The association between condition and response type in the Non-Co-Occurring/Synonyms and Non-Co-Occurring/Identical labels condition was significant, Fisher's exact $p < .05$.

Figure 3. Number of children classified as category-based and non-category-based responders.

Memory Accuracy

Adults' overall memory scores were 99% in each label condition. Children's overall memory scores were 86% and 84% in the Synonymous and Identical Label conditions, respectively. Children's memory was well above chance level of 33% in both conditions, both one-sample p 's $< .001$, indicating that children had little difficulty with the memory demands of the task. Most importantly, there was no difference in children's memory performance when separated by co-occurrence condition (86% and 85% correct in the Co-occurring and Non Co-occurring Synonyms conditions, respectively), paired-sample $t(32) < 1$, ns . A linear regression performed on children's memory scores and their induction performance revealed no significant relationship in the Synonyms condition, $r^2(134) = .055$, $p > .50$, or the Identical condition, $r^2(126) = .019$, $p > .95$.

Discussion

Contrary to the notion that the ability to perform synonym-based induction is well established by four years of age, the results of the present study suggest that this ability still undergoes development during the preschool years. In particular, 4-year-old children performed at chance in the triad induction task when semantically similar label-pairs did not co-occur in child-directed speech (e.g., *alligator-crocodile*). However, we observed a significant improvement in performance when children were presented with semantically similar labels that co-occurred in child-directed speech (e.g., *bunny-rabbit*) and with identical labels (e.g., *bunny-bunny* and *alligator-alligator*).

These findings are not easily explained by children's unfamiliarity with some of the words used in this research as our participants exhibited near ceiling accuracy on the picture identification task. Importantly, children readily applied different words with shared meaning (e.g., *alligator-crocodile*) to the *same* items in the picture identification task. Therefore, children clearly possessed the requisite knowledge to perform synonym-based induction. Yet, few 4-year-old children spontaneously relied on this knowledge in the induction task, unless the labels not only shared meaning but also co-occurred in child-directed speech.

Results reported in this paper suggest that poor understanding of class-inclusion relations is not the sole reason why preschool-age children fail to utilize taxonomic labels (e.g., *animal-cat*) in the course of induction tasks. The present findings add to the growing body of evidence suggesting that the understanding that labels refer to categories matures gradually between four and seven years of age (Fisher, 2010; Fisher & Sloutsky, 2005; Matlen & Fisher, 2008). In particular, consistent with the results reported in this paper, Matlen and Fisher (2008) found that only 15% of 4-year-old children spontaneously performed synonym-based induction with labels that did not co-occur in child-directed speech; this number increased to 51% of 5-year-olds. By 6 years of age the majority of children (86%) readily relied on synonymous labels to perform induction.

The present study is the first to demonstrate the effect of label co-occurrence on induction using a within-subject design. Therefore, this study provides direct evidence that results of earlier research on the development of synonym-based induction could stem from the fact that responses were averaged across items that were likely to result in above-chance performance (e.g., *bunny-rabbit*, *puppy-dog*) and items that were unlikely to result in above-chance performance (e.g., *rock-stone*, *cobra-snake*). It is conceivable that overall results aggregated over a bimodal distribution of responses could result in a mean proportion of synonym-based responses that exceeded chance level (i.e., 63%; Gelman & Markman, 1986; Experiment 2). Indeed, when children's responses in the Synonym condition of the present study were aggregated across both co-occurrence conditions, the average proportion of category-based responses was .63, above chance, paired-sample $t(16) = 2.17, p < .05$.

In sum, the results presented in this paper provide evidence that preschoolers' willingness to rely on semantically similar labels in the course of induction is influenced by co-occurrence probability of these labels in child-directed speech. This finding poses a challenge to the theoretical approach that assumes children's induction to be category-based from very early in development. At the same time, these results are consistent with the approach suggesting that the development of category-based induction follows a protracted developmental course.

Acknowledgments

We thank Malika Sinha, Sarah Shade, Janelle Higa, Tina Li, Stephanie Brown, and Kimberly Dye for help in data collection and the CHILDES analysis. We also thank the children, parents, teachers, and administrators for their participation. Abstract

The present study explored children's ability to utilize synonymous labels during relational reasoning. In Experiment 1, 4- to 5-year-old children and adults were presented with a base pair of related words (e.g., Castle:Rock) and then were given a partially completed target word-pair (Castle:?) that they could complete with a label that made the target word-pair relationally identical to the base word-pair (e.g., Stone). Additional response options included a label thematically related to the first word in the target pair (e.g., King) or an unrelated word (e.g., Milk). Results indicated that adults and 5-year-olds successfully completed the task, whereas 4-year-olds exhibited difficulty. In Experiment 2, 4-year-old children were presented with the same task, however relations were conveyed by identical rather than synonymous labels. Under these conditions, 4-year-old children exhibited no difficulty in either lure condition. These findings are discussed with regards to the theories of learning early in development.

Keywords: Synonyms; Language Acquisition; Word Learning; Relational Reasoning; Cognitive Development.

Introduction

Many objects in the world can be referred to by more than one label, a phenomenon called polyonymy. For example, one could accurately refer to a pet as *Fluffy*, *kitty*, *cat*, and *animal*. It is well-documented that in the beginning stages of language acquisition children struggle with this phenomenon; however by three years of age children are able to learn multiple labels in reference to the same object, both in the form of taxonomically-related labels (such as *cat-animal*) and semantically similar labels at the same level of taxonomic hierarchy (i.e. synonyms, such as *kitty-cat*) (Banigan & Mervis, 1988; Blewitt, 1994; Deák & Maratsos, 1998; Haryu & Imai, 1999; Johnson, Scott, & Mervis, 1997; Liitschwager & Markman, 1994; Mervis et al., 1994). Learning to refer to an object by more than one label may signify development of understanding that labels denote categories rather than individual objects. However, mature understanding of labels as category markers requires that one not only can use multiple labels in reference to the same object, but is also able to rely on related labels to perform a variety of reasoning tasks, such as categorization, inductive reasoning, and analogical reasoning.

Research investigating development of the ability to use hierarchically-related labels in reasoning tasks indicates that this ability does not mature until 7- to 8-years of age (Gelman & O'Reilly, 1988; Johnson, et. al., 1997). However, research into children's ability to use semantically similar labels at the same hierarchical level – or synonyms – in reasoning tasks has produced mixed results. In particular, Gelman and Markman (1986) observed that 4-year-old children can perform inductive reasoning tasks at above chance level with identical labels (e.g., generalizing a property from one rabbit to another rabbit, rather than from a squirrel to a rabbit) as well as semantically similar labels (e.g., generalizing a property from a bunny to a rabbit, rather than from a squirrel to a rabbit).

However, while Gelman and Markman's study provides valuable insight into children's reasoning with semantically similar labels, several factors warrant further investigation of this phenomenon. First, some stimuli used in this study included taxonomically-related labels (e.g. *rose-flower* and *cobra-snake*) rather than synonyms. Second, some of the semantically similar labels used in this study are likely to co-occur in the speech of children and their caregivers as compound noun-phrases (e.g., *bunny-rabbit* and *puppy-dog*) according to the CHILDES database (MacWhinney, 2000). For example, the word "bunny" occurred in CHILDES 803 times, the word "rabbit" occurred 579 times, and these words co-occurred 103 times. At the same time, other semantically similar labels used in the Gelman and Markman (1986) study (e.g., *rock-stone*) never co-occurred in the CHILDES database. It is possible that effects of semantic similarity of labels on inductive reasoning in 4-year-old children were amplified by co-occurrence probability of some of the label pairs used in this research. In support of this hypothesis, Matlen and Fisher (2008) found that 4-year-old children successfully relied on semantically similar labels in a property induction task only if these labels were likely to co-occur in child-directed speech, whereas children's performance with non-co-occurring semantically similar labels was not different from chance. Therefore, the extent to which young children can rely on semantically similar labels in the course of reasoning tasks remains unclear.

The goals of the research reported below were two-fold. The first goal was to explore to what extent young children are capable of using semantically similar labels that span the same level of taxonomic hierarchy as a basis for reasoning. Prior research on this topic has primarily been concerned with children's reasoning within property induction tasks (Gelman & Markman, 1986; Matlen & Fisher, 2008). To assess the robustness of children's reasoning with semantically similar labels, we employed a relational reasoning task where relations were conveyed by synonyms. In contrast to property induction tasks, relational reasoning tasks have typically been utilized in research aimed at assessing children's analogical thinking (see Goswami 1991 for review). These tasks tend to follow the format of A:B::C:?. For example, Goswami and Brown (1990) assessed 4- and 5-year-olds' ability to perform analogical reasoning tasks with familiar relations by presenting them with a base word-pair (e.g., Spider-Web) and an incomplete target word-pair (e.g., Bee-?). Children could complete the target word-pair with a relational choice (e.g., Hive), or with a word that did not preserve the relation specified in the base word-pair: a thematic lure (e.g., Honey). Goswami and Brown found that by four years of age children could correctly complete these analogies based on the relational choice, even in the presence of a thematic lure. It follows then that if young children possess the ability to reason with semantically similar labels, then they should be able to correctly complete relational reasoning tasks when semantically similar labels convey the relations.

The second goal of the present research was to examine children's understanding of linguistic labels as markers of category membership. It has been suggested that understanding of labels as category markers develops as early as two years of age (Gelman & Coley, 1991; Welder & Graham, 2001). Therefore, children realize that objects referred to by the same label – or by semantically similar labels – refer to objects of the same kind, and that objects of the same kind are likely to have many properties in common. However, it has recently been argued that understanding of labels as referents to categories may have a more protracted developmental course than previously believed (Sloutsky, Lo, & Fisher, 2001; Sloutsky & Fisher, 2004). In particular, children may rely on identical labels in reasoning tasks because labels are features contributing to the overall similarity of presented entities, and identical labels increase the *perceived* similarity of compared objects. At the same time, children may not rely on semantically similar labels in the course of reasoning tasks, unless there are factors other than shared meaning (such as co-occurrence probability) that promote label-based inference.

To achieve the goals outlined above, the present study utilized a modified analogical reasoning task of the type employed by Goswami and Brown (1990). Specifically, participants were presented with a base word-pair relation (e.g. Castle:Rock), and a partially completed target word-pair relation (Castle: ?). Participants could complete the target word-pair with a label that preserved the relationship

specified in the base word-pair (i.e., a label semantically similar to the second term in the base word-pair, such as “Stone”) or with a word that did not preserve the relation specified in the base word-pair: a word thematically related to the first term in the target word-pair (e.g., King; in the Thematic Lure condition) or an unrelated word (e.g., Milk; in the Unrelated Lure condition). Thus, this task followed an A:B::A:B' format (where B'-term was semantically similar to the B-term). Children's ability to perform the relational reasoning A:B::A:B' task using semantically similar labels was compared to their ability to perform this task using identical labels.

If children have acquired mature understanding that identical as well as semantically similar labels refer to objects of the same kind (Gelman & Markman, 1986; Gleman & Coley, 1991; Jaswal, 2004), then children should have little difficulty in completing the relational reasoning A:B::A:B' task using identical as well as semantically similar labels. However, if understanding that labels refer to categories has a protracted developmental course and is not yet complete by four years of age (Fisher, in press; Matlen & Fisher, 2008; Sloutsky & Fisher, 2004) then 4-year-old children, unlike adults, may have difficulty in completing relational reasoning tasks using semantically similar labels. At the same time, children should succeed in completing relational reasoning tasks using identical labels.

Experiment 1

Method

Participants

Participants were 35 four-year-old children ($M = 4.43$ years, $SD = .30$ years; 19 females and 16 males), 30 five-year-old children ($M = 5.5$ years, $SD = .32$ years; 12 females and 18 males), and 45 adults ($M = 19.94$ years, $SD = 1.14$ years; 26 females and 19 males).

Design

For the purpose of brevity, semantically similar labels will be referred to as “synonyms” henceforth. Experiment 1 had a two (Lure type: Thematic vs. Unrelated) by four (Age: 4-year-old, 5-year-olds, and adults) between-subjects design. Participants were randomly assigned to one of the two experimental conditions: the Thematic Lure or the Unrelated Lure condition.

Materials

Materials consisted of 12 picture sets presented on a computer screen, accompanied by 12 label sets provided by the experimenter (see Table 1 for the list of labels used in the experiment). Each picture set consisted of a series of four pictures: the first picture contained four doors in two rows of two. One by one, the first three doors disappeared to reveal objects hidden behind them (see Figure 1 for a schematic depiction of the task). As the doors disappeared to reveal hidden objects, the experimenter labeled each object. The objects behind the first and second doors had a

clear relationship, and the object behind the third door was identical in picture and label to the object behind the first door. The fourth door revealed no hidden object, but instead the experimenter provided two response options for the participant to guess the final object.

Table 1: Labels provided during task.

A-term	B-term	B'-term: Synonym Choice	Thematic Lure	Unrelated Lure
Bread	Jam	Jelly	Crumbs	Foot
Hand	Mitten	Glove	Foot	Ant
Castle	Stone	Rock	King	Milk
Cat	Couch	Sofa	Milk	Banana
Fly	Toad	Frog	Ant	Phone
Cheese	Rat	Mouse	Cracker	Dress
Apple	Belly	Tummy	Banana	Puppy
Duck	Lake	Pond	Feathers	TV
Vacuum	Carpet	Rug	Mop	Lion
Water	Ship	Boat	Fish	Cookie
Beach	Ocean	Sea	Sand	Chair
Car	Road	Street	Steering Wheel	Clock

In both the Unrelated Lure and the Thematic Lure conditions the relational choice was communicated by a label that was synonymous to the B-term of the base word-pair. For example, in the trial where the base word-pair consisted of the words “Castle:Rock”, the relational choice consisted of the word “Stone”. Note that half of the participants received the base word-pair of “Castle-Rock” with the word “Stone” being the relational response option, whereas the other half of the participants received the base word-pair of “Castle-Stone” with the word “Rock” being the relational choice (the B- and B'-terms alternated in this manner for all of the trials in this and other experiments described in this paper). To avoid the potential confound of co-occurrence probability influencing children's responses, only synonyms that never co-occurred in child-directed speech according to the CHILDES database (MacWhinney, 2000) were chosen for this study. Thus, common synonym pairs used in prior research, such as puppy-dog and bunny-rabbit, were not utilized. The outcome measure was the proportion of relational responses (i.e. choosing synonymous labels over thematic and unrelated lures) across the 11 experimental trials.

Calibration of Experimental Materials Experimental materials used in this research were calibrated in several separate studies to establish that (1) 4-year-old children were familiar with all of the labels used in this research and were willing to apply synonymous labels to the same object, (2) 4-year-old children were familiar and could identify the relationship specified by the A-term and the B-term labels, and (3) 4-year-olds children perceived labels chosen as thematic lures to be thematically related to the A-term labels.

Figure 1: Schematic depiction of the A:B::A:B' task.

Label Calibration A group of four-year-old children, none of whom participated in the experiment proper ($N = 12$, $M = 4.28$ years) was presented with a picture-naming task analogous to the Peabody Picture Vocabulary Test (Dunn & Dunn, 1997). Participants were presented with a series of pictures on a computer screen, four pictures at a time, with one target picture for children to identify (location of all target pictures was counterbalanced across multiple presentation of the same picture) and three distracters. Children were asked to select the target picture according to the label spoken by the experimenter (e.g., “Can you point to the *rock*?”). Each of the 12 target pictures was presented to children in two separate picture sets, resulting in a total of 24 trials. The target pictures were identified by different synonymous labels during the first and second presentation of each target picture. Children correctly identified pictures referred to by the B- and B'-terms used in Experiment 1 (see Table 1) with the overall accuracy of 97%. Therefore, the synonym labels used in Experiment 1 were familiar to four-year-old children. Importantly, four-year-old children were willing to accept the synonymous labels used in Experiment 1 as referents to the *same* objects.

A:B Relationship Calibration The same group of 4-year-old children who participated in the Label Calibration were presented with the relation familiarity check (the order of these tasks was counterbalanced across participants). Children were presented with a series of triads depicting objects that can be referred to by an A-term, an unrelated lure, and a B-term or a synonymous B'-term (see Table 1). Children were provided verbal labels for all three objects and asked to select the two objects that “go together.” Half of the participants were asked about a B-term (e.g., a *rock*) and the other half about the synonymous B'-term (e.g., a *stone*). For instance, participants could be shown a triad consisting of pictures of a ‘rock’, a ‘castle’, and ‘milk’, and asked which objects go together. Additionally, children were asked to explain why the two pictures they had chosen “go together,” and their explanations were recorded. All of the B- and B'- presented in Table 1 were judged to be identifiably related to the A-terms by 4-year-old children: children selected the B- or the B'-term over the unrelated lure and correctly specified the nature of the A:B

relationship with the average accuracy of 95% (all individual item M s were above 83%, above chance, all one-sample t s > 4.4 , p s $< .001$).

Calibration of Thematic Lures A separate group of 4-year-old children ($N = 12$, $M = 4.77$ years) was presented with a series of triads depicting objects referred to by the A-term, thematic lures, and unrelated lures (see Table 1) and asked to select the two objects that “go together.” For instance, participants could be shown a triad depicting a ‘castle’, a ‘king’, and ‘milk’, and asked which objects go together. Children selected the thematically related lure as the objects that “goes with the target” over the unrelated lure with the mean accuracy of 94% (all individual item M s were above 91%, above chance, all one-sample t s > 7.0 , p s $< .001$).

Procedure

Children were tested individually in a quiet room in their preschools and adults were tested in a laboratory on campus. Participants were presented with pictures of four doors in two rows of two on a computer screen. The experimenter explained that there were objects hiding behind all of the doors, and that after showing the objects behind the first three doors, the participant would have to guess what was hiding behind the last door. The word-pair “Bread:Jam” served as a practice trial (see Table 1) and thus was always presented first. The order of the rest of the trials was randomized for each participant. When pictures of bread and jam were revealed during the practice trial, participants were told, “*bread and jam go together because jam goes on bread to make a sandwich.*” Participants were then asked to guess what object was hiding behind the fourth door and presented with two response options; participants were asked to choose the option that “*goes with the bread the same way that jam goes with the bread*”. Upon completing the practice trial children were provided with corrective feedback. No feedback was provided after the experimental trials. At the conclusion of the practice trial children were told that they would keep playing the game, and that to solve the task they needed to think how the objects behind the first two doors go together.

Results

Proportions of relational responses in each condition are presented in Figure 2. A 2 x 2 Analysis of Variance was performed on the proportions of relational responses with experimental condition (Thematic Lure vs. Unrelated Lure) and age (4-year-olds, 5-year-olds, and adults) as between-subject factors. The results indicated the main effect of condition, $F(1, 104) = 10.9$, $p = .001$, and age, $F(2, 104) = 50.7$, $p < .001$. Performance was significantly higher in the Unrelated Lure condition ($M = 89.8\%$) than in the Thematic Lure condition ($M = 80.1\%$), $F(1, 104) = 10.9$, $p = .001$. These main effects were qualified by a condition by age interaction, $F(2, 104) = 3.4$, $p < .05$.

Post hoc Tukey tests indicated that performance increased significantly from 4- to 5- years of age ($p < .001$), and again from 5-years of age to adulthood ($p < .05$). Planned

comparisons revealed that performance of adults was equivalent in the Thematic Lure and Unrelated Lure conditions (both means over 99%). However, 5-year-old children exhibited a higher level of performance in the Unrelated Lure condition compared to the Thematic Lure condition (97% and 83% of relational responses, respectively), independent samples $t(28) = 2.98$, $p < .01$. This difference in performance between the lure conditions was marginally significant in 4-year-old children (73% and 58% of relational responses, respectively), independent-samples $t(33) = 1.9$, $p = .07$.

Follow-up comparisons to chance indicated that in the Unrelated Lure condition participants in all age groups responded at a level above chance (chance = 50%), all one-sample t 's > 4.5 , p 's $< .001$. However, in the Thematic Lure condition only 5-year-olds and adults responded at above chance level, both one-sample t 's > 7.6 , p 's $< .0001$, whereas responses of 4-year-old children were not different from chance, one-sample $t(16) = 1.2$, $p = .25$.

Figure 2: Proportions of relational responses in Experiment 1. Error bars represent standard errors of the mean.

To further understand the source of differences among conditions, we conducted analysis of the individual patterns of responses. Participants were judged to be relational responders if they selected the synonymous choice on at least 8 out of 11 trials (binomial $p < .05$). Proportion of relational responders in each condition is presented in Figure 3. All adult participants in both lure conditions were deemed to be relational responders. Among 5-year-old children, all participants in the Unrelated Lure condition were deemed to be relational responders, and 12 out of 15 (or 80%) participants in the Thematic Lure condition were classified as relational responders (marginally different from the pattern observed in adults, Fisher's exact $p = .058$). Among 4-year-old children, 10 out of 18 (56%) participants exhibited the relational pattern of responding in the Unrelated Lure condition, and only 5 out of 17 (29%) participants exhibited the relational pattern of responding in the Thematic Lure Condition. Proportion of relational responders in the 4-year-old group was significantly lower than that of participants in both older age groups in both experimental conditions, all Fisher's exact p s $< .006$).

Figure 3: Individual patterns of responses in Experiment 1.

Overall, results of Experiment 1 suggest that the ability to utilize synonymous labels in the course of reasoning may follow a more protracted developmental course than it has been previously believed. Experiment 2 was designed to investigate 4-year-olds' performance in the A:B::A:B' task when identical labels were used. If by 4 years of age children realize that labels refer to kinds, then children's performance with identical labels should be similar to that with synonymous labels in Experiment 1 (Gelman & Markman, 1986). However, if 4-year-old children do not yet treat labels as category markers, their performance with identical labels may be superior to that with synonymous labels.

Experiment 2

Method

Participants

Participants in Experiment 2 were 27 four-year-old children ($M = 4.48$ years, $SD = .27$; years; 9 females and 18 males).

Design, Materials, and Procedure

Similar to Experiment 1, there were two between-subject conditions in Experiment 2: a Thematic Lure condition and an Unrelated Lure condition. Children were randomly assigned to one of the two experimental conditions. The order of trials was randomized for each participant.

Materials used in Experiment 2 were identical to those in Experiment 1, with the exception that relational choices were communicated by a label identical to the B-term, rather than by a synonymous label. The B- and B'-terms in Table 1 were counterbalanced across participants, such that half of the participants received the "Castle:Rock" base word-pair, whereas the other half of the participants received the "Castle:Stone" base word-pair.

Results

In both the Thematic Lure condition and the Unrelated Lure condition children averaged 94% of relational choices, above chance (chance = 50%), both one-sample t s > 16.7 , p s $< .0001$. Analysis of the individual patterns of responses

revealed that in both experimental conditions, 100% of participants successfully chose identical labels over unrelated as well as thematic lures.

Responses of 4-year-old children in Experiment 2 were compared to those in Experiment 1 in a 2 (Label condition: Identical vs. Synonymous labels) by 2 (Lure Type: Unrelated vs. Thematic Lures) ANOVA. This analysis revealed a main effect of the Label condition, $F(1, 58) = 34.17$, $p < .001$. The labeling condition by lure type interaction did not reach significance, $F(1, 58) = 2.55$, $p = .11$, possibly due to unequal variances in the Synonymous and Identical labels condition, Levene's test of equality of error variances: $F(3, 58) = 8.98$, $p < .0001$.

Overall, children performed significantly better when they could rely on identical labels rather than synonymous labels in both the Thematic Lure condition (94% and 73% of relational responses, respectively) and the Random Lure condition (94% and 58% of relational responses, respectively), both independent-sample t s > 3.2 , p s $< .005$. This conclusion was supported by the analysis of the individual patterns of responses. In the Thematic Lure condition all 13 4-year-old children were classified as relational responders when children could rely on identical labels (Experiment 2), whereas only 5 out of 17 4-year-olds (29%) in the Thematic Lure condition exhibited this pattern of responding with synonymous labels (Experiment 1), Fisher's exact $p < .001$. Similarly, in the Unrelated Lure condition 13 out of 14 4-year-olds (93%) exhibited the relational pattern of responding with identical labels, whereas only 10 out of 18 4-year-olds (56%) exhibited this pattern Unrelated Lure condition with synonymous labels, Fisher's exact $p < .05$.

Discussion

The primary goal of the present study was to examine development of the ability to utilize semantic similarity of labels in a relational reasoning task. Results of the two experiments reported above point to several novel findings. First, adult participants successfully utilized semantic similarity of labels in the Semantic Completion (A:B::A:B') task and their performance was not affected by the type of lure. Importantly, all adult participants exhibited the same pattern of responding on this task. Second, 5-year-old children exhibited a decrease in performance in the Semantic Completion task in the presence of thematic lures compared to unrelated lures. At the same time, proportion of relational responses was well above chance level in 5-year-old children with both types of lures. Furthermore, the majority of 5-year-old children, similar to adults, were classified as relational responders in both lure type conditions. Third, 4-year-old children reliably made relational choices in the Semantic Completion task regardless of the type of lure when relational responses were communicated by identical labels; when relational choices were communicated by synonymous labels, 4-year-old children performed above chance only if correct responses were pitted against unrelated lures, but not thematic lures.

Finally, less than a third of 4-year-old children were classified as relational responders when response competition was strong (in the Thematic Lure condition) and only half of 4-year-olds reliably provided relational responses in the absence of response competition (in the Unrelated Lure condition).

Great care was taken to calibrate stimulus materials used in this research, therefore the reported results cannot be explained by children's unfamiliarity with the words or the relations used in the Semantic Completion and Semantic Substitution tasks. Instead, it appears that less than half of 4-year-old children spontaneously realize that synonymous labels refer to objects of the same kind and can use this knowledge in a reasoning task. This finding has important implications for different theoretical approaches to development of induction. In particular, successful performance on the Semantic Completion task with identical labels does not require that children realize that identical labels refer to objects of the same kind – children could have successfully performed the task based on simple matching of identical labels. However, successful performance on the task with synonymous labels (that do not co-occur in child-directed speech) can only be achieved if children understand that semantically similar labels refer to objects of similar kind. A large decrease in performance on the Semantic Completion task with synonymous labels compared to near ceiling performance with identical labels suggests that at four years of age many children do not yet treat labels as referents to object kind. Therefore, these results pose a challenge to the theoretical accounts of early induction that assume such understanding in very young children (Gelman & Coley, 1991; Welder & Graham, 2001) and suggest that children's understanding that labels refer to kinds continues to develop beyond toddlerhood.

Acknowledgments

We thank children, parents, and teachers for their participation in this research. This project was funded by a Small Undergraduate Research Grant at Carnegie Mellon University awarded to Sheela Ramesh.

Abstract

The current experiment examined whether successful solution on one type of problem, indicating the relaxation of a constraint, had a negative impact on subsequent problems that did not involve the same constraints. One hundred and forty-five participants solved a series of matchstick arithmetic problems. In one group, participants were given three relatively simple “chunk decomposition” problems (CD). A second group solved one “operator decomposition” (OD) problem, involving more constraints, between the baseline CD problem and two later problems. The third group solved three OD problems, similarly placed. Results indicated that successful solution of an OD problem produced negative transfer to subsequent CD problems in the form of longer solution times. Participants who did not successfully solve OD problems did not slow down on subsequent problems; they displayed evidence of positive transfer. The findings were interpreted with reference to theories of constraint relaxation and its relationship to problem solving performance.

Keywords: mental set; insight problem solving; negative transfer

Procedures in Problem Solving

Whenever new problems are encountered in everyday life, our general approach is to apply procedures or solutions that produced successful outcomes in the past. For example, in the event that you are moving a couch to a new apartment, it is possible that the couch will not fit through a particular doorway or up a particular flight of stairs. Solutions that worked in the past were to unscrew the feet on the couch, or to try the other stairway/doorway into the apartment. If we try one of these solutions and it works again, we will likely bring them to bear when similar situations arise in the future.

Similarly, procedures or solutions that have worked in one context are often evoked and applied to another context. In the first author's most recent move, her bookcase was too large to fit up the front staircase, but could be brought up the back staircase with little trouble. Because the try-the-other-staircase procedure worked in a different situation, it may be

that the procedure becomes generalized, thus making it more likely to be employed in a variety of situations.

However, known procedures do not always apply to new situations, and, in fact, may lead to situations of impasse. To use one final example, again from the first author's most recent move, her box spring would not fit up the front staircase. The back staircase was next attempted with no success. She and her movers tried rotating the box spring in multiple orientations on each staircase to no avail. Over an hour was spent attempting to apply a known procedure that was not leading to any progress. Eventually, a neighbor suggested using a chainsaw to split the box spring and fold it in half. The chainsaw procedure was used and the box spring entered the apartment. Thus, a successful procedure was applied, but only after lengthy misapplications of known, and previously useful, procedures.

The preceding everyday example of misapplying previously successful procedures to the moving of furniture is analogous to the sequence that occurs when solving insight problems. An individual's initial representation of an insight problem is often faulty because unhelpful prior knowledge and experiences are activated by the problem (Kershaw & Ohlsson, 2004; Knoblich, Ohlsson, Haider, & Rhenius, 1999; Ohlsson, 1992). The individual's initial problem-solving attempts are guided by this unsuitable knowledge. These initial attempts are usually unsuccessful and the individual then enters a period of impasse, in which no overt problem-solving behavior occurs. In order to exit the impasse, the individual must relax constraints (Knoblich et al., 1999; Ohlsson, 1992) or overcome mental sets caused by incorrect application of procedures (Luchins, 1942). The likelihood of relaxing constraints or breaking mental set depends on the number and strength of the constraints or procedures.

Constraint Relaxation and Breaking Mental Set

The difficulty of a particular insight problem is dependent upon several factors. For many insight problems, including famous examples such as the nine-dot problem, the necklace

problem, and the four tree problem, multiple types of constraints interact to make the achievement of solution difficult (Kershaw & Ohlsson, 2004). For example, Kershaw and Ohlsson identified perceptual (figural integrity and other Gestalt laws), knowledge (prior experiences and knowledge), and process (size and variability of search space) constraints that prevent solution of the nine-dot problem. Likewise, Flynn, Gordon, and Kershaw (2010) identified perceptual and knowledge constraints in the four tree problem.

Several researchers state that the difficulty of a particular problem can be found in the strength of constraints present in a particular problem. For example, Knoblich et al. (1999) identified three types of constraints in matchstick arithmetic problems: value, operator, and tautology. The value constraint, the weakest of the three, suggests that numerical values on one side of an equation cannot be changed without compensatory changes on the other. The operator constraint, which is described as having a moderate level of strength, signifies that arithmetic functions (operators) cannot be arbitrarily changed. The tautology constraint, which is the strongest of the three, signifies that arithmetic equations should follow a particular format in which a calculation is specified. That is, an arithmetic operation on one side of the equation should indicate a value on the other side of an equation, such as $V + I = VI$. While statements like $II = II = II$ are valid, they are not common in arithmetic and therefore violate the tautology constraint.

Knoblich et al. (1999) also classified the difficulty of matchstick arithmetic insight problems by the strength of the chunks that had to be decomposed in order to solve the problem. People tend to view Roman numerals as perceptual chunks, but the strength of these particular chunks depends on the numeral or other element of the equation. Tight chunks, such as V and I, are composed of single units. Loose chunks, such as VII and III, are composed of other chunks. For example, VII is composed of three tight chunks, V, I, and I. Knoblich et al. also suggest there are intermediate chunks, such as operators like the plus sign (+) and the equal sign (=). Although these symbols are composed of other chunks, people are unlikely to have experience decomposing a + into its horizontal and vertical components, for example.

A different explanation of the difficulty of a particular problem is the success of the procedures applied to the problems that preceded it. In a classic demonstration of mental set, Luchins (1942) gave participants a series of water jug problems. The first five problems could all be solved successfully using a particular procedure, but the last five problems either could not be solved using the known procedure or could be solved using a simpler procedure. Luchins (1942) found that participants continued to apply the known procedure to the last five problems, and that over half of the participants were unable to solve problems for which the known procedure could not be applied. That is, participants experienced impasse on some problems and were unable to break impasse to reach solution.

Thus, the difficulty of particular insight problems may be due to the number and strength of constraints or procedures present. Likewise, the likelihood of relaxing these constraints or procedures should also be affected by number and strength. Knoblich et al.'s (1999) theory presupposes that relaxing one weak constraint will be much easier than relaxing multiple strong constraints. Researchers have implemented experimental interventions to increase the likelihood of constraint and procedure relaxation. For example, Kershaw and Ohlsson (2004) and Flynn et al. (2010) developed training procedures that targeted particular constraints, such as practicing non-dot turns for the nine-dot problem (Kershaw & Ohlsson) or comparing solved analogs of the four tree problem (Flynn et al.). Luchins and Luchins (1950) tried to prevent mental set by limiting the amount of liquid available, adding a fourth jar to the problems, and giving participants physical objects (actual jars and water) instead of using paper-and-pencil forms of the problems. Of these three manipulations, only adding a fourth jar was successful, because participants needed to figure out the amount that each jar could hold for each problem. Luchins and Luchins' other two manipulations did not work because participants were poor at keeping track of how much liquid they had used or they persisted in doing paper-and-pencil calculations prior to using the physical materials.

The Current Experiment

In the current experiment, we examine the connection between the strength of constraints and the effect of mental set by using matchstick arithmetic insight problems of two types. One type of problem we used required the decomposition of loose chunks. For example, to solve $VI = VII + I$, a participant needs to move a single matchstick (I) from VII to VI, thus making the solution of the problem $VII = VI + I$. Knoblich et al. (1999) states that these types of problems require the relaxation of the value constraint and the decomposition of loose chunks. For simplicity sake, we refer to these problems as chunk decomposition (CD) problems.

The second type of problem we used required the decomposition of the operator in the problem, in this case the plus sign (+). For example, to solve $VII = VII + I$, a participant needs to move the vertical matchstick from the + to the second VII, thus making the solution of the problem $VII = VIII - I$. Knoblich et al. (1999) note that these type of problems require the relaxation of the value and operator constraints as well as the decomposition of loose and intermediate chunks. We refer to these problems as operator decomposition (OD) problems. Although Knoblich et al. make a conceptual distinction between constraint relaxation and chunk decomposition mechanisms, we group both into the general category of constraints in the current work. Thus, CD problems contain two constraints and OD problems contain four. Because OD problems contain a greater number of constraints, as well as stronger constraints, they should be harder to solve than CD

problems as well as require longer solution times, predictions that are supported by Knoblich et al.'s findings.

In this experiment, all participants solve three CD problems. Participants differed in the number of OD problems that they received. A baseline group of participants did not receive any OD problems, a second group received one OD problem, and a third group received three OD problems. The groups that received the OD problem(s) solved one CD problem, the OD problem(s), followed by two additional CD problems, which functioned as transfer problems.

Our first research goal was to examine how the sequencing of constraint relaxation types affected solution time. In the group that did not receive any OD problems, we expected a general decrease in solution time across the CD problems because, as stated by Knoblich et al. (1999), once constraints are relaxed they will remain relaxed. In the groups that receive the OD problem(s), we explored the possibility that solving the OD problem(s) would make it more difficult to solve the subsequent CD problems. Knoblich et al. (1999, cf. Ohlsson, 1992) posit that constraint relaxation occurs through the natural spreading of activation after persistent failure is experienced via impasse. Because activation to memory nodes decays, it is possible that the CD solution space might become reconstrained after participants spend some time exploring the OD solution space. Therefore, successful solution of OD problems may make solving subsequent CD problems difficult because the constraint would need to be re-relaxed, thus leading to longer solution times for the CD problems received after the OD problem(s) relative to the CD problem received prior to the OD problem(s).

Our second research goal involved the amount of time that participants spent using the procedure needed to solve the OD problems. Thus, we manipulated the mental set that participants experienced due to the OD problems. Some participants only received one OD problem, while others received three. We expected that participants who received three OD problems would show longer solution times on subsequent CD problems than the participants who only received one OD problem relative to the CD problem solved prior to the OD problem(s). We will refer to these post-OD problems as return-to-chunk-decomposition problems and therefore they will be labeled RCD1 and RCD2.

Öllinger, Jones, and Knoblich (2008) explored similar questions using matchstick arithmetic problems. In Experiment 2 they found that solving a series of CD problems did not affect the solution rate for one OD problem (type CR1 in their experiment), although they did affect the solution rate for other constraint relaxation problem types. In Experiment 3 they found that solving a series of constraint relaxation problems negatively impacted CD problems, but the constraint relaxation problems were of a different type than the OD problems used in the current experiment. Thus, while Öllinger et al. (2008) explored similar questions to the current experiment, the current work builds on these findings in terms of providing solvers with

different problem types and in varying the number of OD problems between participants.

Overall, we made the following predictions for the experiment:

- 1) Participants who receive OD problems will have slower solution times than participants who do not receive OD problems on RCD1 compared to the baseline CD problem (B).
- 2) Participants who receive three OD problems will have slower solution times than participants who receive one OD problem on RCD1 compared to B.
- 3) Participants who do not receive OD problems will show faster solution times from B to RCD1 and from RCD1 to RCD2. Participants who receive OD problems will not show this pattern.

Method

Participants

Participants were 145 introductory psychology students who received research credit for their participation. Sixty of the participants were from the University of Illinois at Chicago and 85 of the participants were from the University of Massachusetts Dartmouth. No demographic data were collected about the participants.

Materials

A series of matchstick arithmetic insight problems were developed for the study. The problems were of two types, chunk decomposition (CD) and operator decomposition (OD). Following the terminology of Knoblich et al. (1999), the CD problems required the decomposition of loose chunks, which are composite Roman numerals (such as IV, VII, etc.). In each problem, one matchstick is moved from one numeral to another. For example, the problem $V = VI + I$ is solved by moving one matchstick from VI to V, thus making the answer $VI = V + I$ (an acceptable alternate solution is $V = IV + I$). The CD problems and their solutions are in Table 1.

Table 1: CD problems and solutions.

Problem	Solution(s)
$XI = XII + I$	$XII = XI + I$
$V = VI + I$	$VI = V + I, V = IV + I$
$VI = VII + I$	$VII = VI + I$
$VII = VIII + I$	$VIII = VI + I$

The OD problems were akin to Knoblich et al.'s (1999) constraint relaxation (Type B) problems, and specifically required the relaxation of the operator constraint by decomposing the plus sign (+) into two matches and moving the vertical match elsewhere in the location, thus turning the operator into a minus sign (-). For example, the problem $II = VIII + V$ is solved by moving the vertical matchstick from the + to the II, thus making the answer $III = VIII - V$ (an

acceptable alternate solution is $II = VIII - VI$). The OD problems and their solutions are in Table 2.

Table 2: OD problems and solutions.

Problem	Solution(s)
$VII = VII + I$	$VII = VIII - I$
$II = VIII + V$	$III = VIII - V$, $II = VIII - VI$
$V = VII + I$	$VI = VII - I$, $V = VII - II$
$I = V + III$	$II = V - III$, $I = IV - III$

Procedure

Participants were run individually. After completing the consent process, participants were given a packet containing the experimental materials. Rules for solving matchstick arithmetic problems were provided on each problem page in the packet. The rules were:

- A) Only one matchstick is to be moved.
 - B) A matchstick cannot be discarded; that is, it can only be moved from one position in the equation to another.
 - C) A slanted stick cannot be interpreted as a vertical matchstick.
 - D) The result must be a correct arithmetic equation.
- In addition to these rules, participants were given a list of Roman numerals and their Arabic numeral equivalents (e.g., $X = 10$).

The first problem for all participants was $XI = XII + I$, which served as a practice problem. Participants were given five minutes to work on the problem and were instructed to alert the experimenter when they came up with a solution. If the participant correctly solved the problem, the experimenter summarized the participant's actions and stated that the solution was correct. The experimenter emphasized that one matchstick had been moved to create a correct equation. If the participant came up with an incorrect solution, the experimenter referred back to the rules to explain why the solution was incorrect. For example, the participant might be reminded that only one matchstick could be moved. If the participant did not solve the practice problem correctly within the time limit, the experimenter first checked to see if he/she had any questions and then gave him/her two more minutes to work on the problem. If, after this additional time, no solution was offered, then the experimenter explained how to move one matchstick to achieve the correct solution, $XII = XI + I$.

The second problem in the packet was the baseline chunk decomposition problem (B), $V = VI + I$. Participants had four minutes to work on this problem (and all subsequent problems). Participants wrote down their start time, worked on the problem, and wrote down the end time if they came up with a solution. The accuracy of the solution was checked by the experimenter. If the solution was incorrect, the experimenter used the rules to point out the inaccuracies of the solution.

The penultimate and final problems in the packet were also CD problems. As stated previously, the penultimate problem, $VI = VII + I$, will be referred to as the first return-

to-chunk-decomposition problem (RCD1), and the last problem, $VII = VIII + I$, will be referred to as the second return-to-chunk-decomposition problem (RCD2). Participants received the same instructions and same amount of time to solve the B, RCD1, and RCD2 problems.

The problems in between B and the RCD1, RCD2 sequence differed by condition. One group of participants did not receive any OD problems. A second group of participants received one OD problem between B and the RCDs. A third group of participants received three OD problems between B and RCDs. On all OD problems, participants followed the same procedure as used for the CD problems by writing down their start and end times and checking their solutions with the experimenter.

After completing RCD2, participants filled out a problem familiarity survey, which asked participants if they had seen and solved any of the matchstick arithmetic problems prior to the experimental session. No participants had any familiarity with the matchstick arithmetic insight problems. At the end of the session, participants were debriefed and thanked for their participation.

Analysis

Participants were originally grouped by the number of OD problems they received. There were 46 participants who received no OD problems, 50 who received one OD problem, and 49 who received three OD problems. However, initial examination of the data revealed that not all participants in the OD conditions solved the OD problems. Therefore, participants were regrouped by the number of OD problems they solved. If participants did not solve the OD problems, we could not expect that they also relaxed this constraints associated with these problems. Thus, in the final analyses, there were 64 participants who solved no OD problems, 35 participants who solved one OD problem, and 46 participants who solved three OD problems.¹

Time to solve the B, RCD1, and RCD2 problems was calculated by subtracting the end time from the start time for each problem. If a participant did not solve one of these problems, then his/her time data were not included. The number of non-solvers was low for each problem: one participant did not solve B, five participants did not solve RCD1, and three participants did not solve RCD2. The time-to-solve data were then screened for outliers, which were defined as time to solve values that were greater than three standard deviations above the mean. Rather than deleting data list-wise, data points were removed case-wise. Three time-to-solve values were removed from the B and RCD1 values, and four time-to-solve values were removed from the RCD2 values.

Three variables were computed for the planned comparisons between the solution times. First, a value was

¹ Removing participants who did not conform to their groups rather than regrouping participants led to the same pattern of results.

calculated for RCD1 – B, that is, the difference between the time needed to solve the baseline and first return to chunk decomposition problems. Next, a value was calculated for RCD1 – RCD2, that is, the difference between the time needed to solve the first and second return to chunk decomposition problems. Third, a value was calculated for B – RCD2, that is, the difference between the time needed to solve the baseline and second return to chunk decomposition problems.

Results

A one-way analysis of variance (ANOVA) compared participants on the difference between the time needed to solve the baseline chunk decomposition problem (B) and the time needed to solve the first return-to-chunk-decomposition problem (RCD1). The ANOVA was significant, $F(2, 135) = 4.44$, $p < .05$, $\eta^2 = .06$. Tukey post-hoc tests indicated that participants who solved three OD problems showed a significant increase in solution time from the B to the RCD1 problems ($M = 19.26$ seconds, $SD = 43.44$) compared to participants who did not solve any OD problems ($M = -4.18$ seconds, $SD = 40.99$), $p < .05$. Participants who did not solve any OD problems showed a decrease in time-to-solve between B and RCD1. There was also a marginal difference between participants who did not solve any OD problems and those who solved one OD problem ($M = 15.41$ seconds, $SD = 45.74$), $p = .09$. Importantly, there was no difference between participants who solved one OD problem and those who solved three.

A second analysis compared participants on the difference between the time needed to solve RCD1 and RCD2 (RCD1 – RCD2). A one-way ANOVA did not show any inter-group differences, $F(2, 129) = .86$, $p > .05$, $\eta^2 = .01$.

A third analysis compared participants on the difference between the time needed to solve B and RCD2 (B – RCD2). A one-way ANOVA showed an overall difference between the conditions, $F(2, 131) = 4.64$, $p < .05$, $\eta^2 = .07$. Tukey post-hoc tests indicated that participants who did not solve any OD problems needed significantly less time to solve RCD2 than to solve B ($M = 15.14$ seconds, $SD = 23.08$) compared to participants who solved three OD problems ($M = 2.35$ seconds, $SD = 22.25$), $p < .05$. There was also a marginal difference between participants who did not solve any OD problems and those who solved one OD problem ($M = 3.69$ seconds, $SD = 24.30$), $p = .07$. There was no difference between participants who solved one OD problem and those who solved three.

Discussion

The current work produced four main important findings. First, in the absence of successful OD performance, participants got progressively faster when solving CD problems. This finding suggests that relaxation of the value constraint made it easier to solve subsequent value constraint problems. In this sense, we found some evidence of positive transfer on problems that presumably required relaxation of the same constraint. This finding supported our

third prediction, that participants who did not receive OD problems would show faster solution times from B to RCD1, while participants who received OD problems would not show this pattern. This finding also supports Knoblich et al.'s (1999) theory – once a constraint is relaxed, it will remain relaxed and affect subsequent performance on similar problems.

Second, the current results provide greater confidence that constraint relaxation can also negatively impact subsequent problem solving performance, particularly in the event that a different, more complex constraint was relaxed. Generally, successful solution of OD problems resulted in longer subsequent solution of CD problems compared to those who did not solve or were not presented with OD problems. Thus, the longer solution times indicate that there was at least some negative transfer associated with the relaxation of the operator constraint. Solution of an OD problem appeared to make it more difficult to solve the simple CD problems; this difficulty was absent for those who did not solve OD problems. This finding supports our first prediction, that participants who received OD problems would have slower solution times than participants who did not receive OD problems on RCD1 compared to B. Additionally, this finding replicates and extends the findings of Öllinger et al. (2008), who also found successful solution of constraint relaxation problems (of a different type) affected later problem solving performance.

Third, as stated previously, we varied the number of OD problems that were presented to participants and were solved in between the CD problems. Participants who solved one and three OD problems displayed similar indications of negative transfer on subsequent RCDs, as evidenced by longer solution times. This finding did not support our second prediction, in which we predicted relatively slower solution times for participants who received three OD problems than participants who received one OD problem. Our finding suggests that, indeed, after one successful solution of an OD problem, the operator constraint was relaxed. Moreover, there did not seem to be an additional slowing associated with solving multiple OD trials.

The final important point is that the negative transfer effects associated with the relaxation of the operator constraint were relatively lasting. That is to say that successful solution not only affected the immediate CD problem, but also the problem that followed. Although the current data does not provide an indication of how long-lasting this kind of negative transfer would be, there did seem to be a “downstreaming” effect into subsequent problem solving performance, beyond the problem situation that immediately followed the constraint relaxation.

Overall, the findings of this experiment point to the manner in which previously appropriate procedures can be persistently misapplied to a new situation. As demonstrated by Luchins (1942; Luchins & Luchins, 1950), mental set can hinder future problem solving. Mental set and other interference effects fit within the larger concept of negative

transfer, in which prior knowledge and experiences hinder learning in new situations that are similar to known situations. The type of negative transfer effects shown in this experiment are similar to those proposed by Singley and Anderson (1989): participants show behavioral slowing due to the misapplication of a procedure. However, the misapplication is an incorrect method, not a non-optimal method, and this misapplication of procedure lasts for more than one trial, thus lending some support to Woltz, Gardner, and Bell's (2000) theory of negative transfer.

Further work is needed to address the direction and duration of negative transfer effects. It is possible that completing a series of CD problems could lead to negative transfer on the OD problems. Likewise, it would be interesting to determine if increases in solution time on the RCD problems lasts more than two iterations. The negative transfer literature is divided on whether negative transfer effects are fleeting (e.g., Singley & Anderson, 1989) or lingering (e.g., Woltz et al., 2000). Additional studies extending the number of to-be-solved CD problems may inform on this issue.

Another future direction for this research would be to examine the processes that underlie the interaction between constraint relaxation mechanisms. Our findings, as well as the findings of Öllinger et al. (2008), show that relaxing some constraints hinders the relaxing of other constraints. One explanation for these findings is that successful solution of OD problems may make solving subsequent CD problems difficult because the constraint would need to be re-relaxed. Thus, there would be longer solution times for the CD problems received after the OD problems relative to the CD problem received prior to the OD problems. Alternatively, relaxing a stronger constraint, such as the operator constraint present in the OD problems, may cancel out a weaker constraint, such as the value constraint present in the CD problems. Although this a different explanation the same effect would be expected, in which solution times are longer for the CD problems received after the OD problem(s) than for the CD problem received prior to the OD problem(s). A third possibility is that the relaxing of multiple constraints opens up the problem space too much, thus leading to a difficulty in finding a correct solution path (c.f. Ohlsson, 1996; Ormerod, MacGregor, & Chronicle, 2002). This third explanation would also lead to the same pattern of results. Future research should address the mechanisms that underlie constraint relaxation interactions and, if possible, attempt to tease apart which of these three possibilities best explains negative transfer in problem solving performance.

Acknowledgments

We thank Valentina Pacheco and Justin Faria for their assistance with data collection. We also thank three anonymous CogSci reviewers for their comments and suggestions for future research.

Abstract

Multi-voxel pattern analysis (MVPA) is a popular analytical technique in neuroscience that involves identifying patterns in fMRI BOLD signal data that are predictive of task conditions. But the technique is also frequently used to make inferences about the regions of the brain that are most important to the tasks in question, and our analysis shows that this is a mistake. MVPA does not provide a reliable guide to what information is being used by the brain during cognitive tasks, nor where that information is. This is due in part to inherent run to run variability in the decision space generated by the classifier, but there are also several other issues, discussed here, that make inference from the characteristics of the learned models to relevant brain activity deeply problematic. These issues have significant implications both for many papers already published, and for how the field uses this technique in the future.

Keywords: neuroscience, machine learning, inference, philosophical issues.

Introduction

Multi-voxel pattern analysis (MVPA) is an increasingly popular analytical technique in neuroscience. MVPA involves searching through the Blood Oxygenation Level Dependent (BOLD) signal data produced in fMRI experiments to identify patterns that are highly predictive of task conditions. To illustrate, consider a simple experiment in which participants are asked to view pictures representing various object categories (e.g. faces, houses, chairs, shoes, etc.). One early MVPA study showed it was possible to determine, by looking only at BOLD data, which class of object an experimental participant was viewing when that data was collected (Haxby et al., 2001). The technique has since been used to predict the orientation of lines being viewed by a participant (Haynes & Rees, 2005), to differentiate between lying and truth-telling (Davatzikos et al., 2005), and to predict which action a participant was about to take (Haynes et al., 2007), among many other things (see Pereira, Mitchell & Botvinick, 2009; Norman et al., 2006; Haynes & Rees, 2006 for reviews of the technique and its applications).

This is indeed impressive, and we expect that MVPA will have many important experimental and diagnostic applications (Lao et al., 2004). It has become commonplace to make certain inferences about the way differences in BOLD signal patterns correspond to differences in mental states. For instance, by finding the set of voxels that are most predictive of a certain task outcome, studies have claimed to discover the “cognitive states associated with perception of tools and dwellings” (Shinkareva et al., 2008),

“localizable task-specific representations of freely chosen intentions” (Haynes et al., 2007), and the regions of the brain that “contain information” (Preston et al., 2008) relevant to the cognitive or perceptual task under investigation.

To put it bluntly, however, such inferences are at best misleading and at worst entirely unwarranted. The issues dovetail with, but are distinct from, the more general concerns about the unreliability of “reverse inference” from neuroimaging data (Poldrack, 2006), and have significant implications both for how we ought to interpret some of the many papers already published, and for how the field applies this technique in the future.

Of course, not every MVPA study is governed by the logic that we will criticize here. For instance, Mitchell et al. (2008) take something like the opposite approach, and see if they can predict the pattern of brain activity that will be caused by listening to novel words. Here the point of the study is not to discover which brain regions are responsible for understanding; rather, they are testing the hypothesis that meanings of words are based on sets of “semantic features” that can be inferred from word co-occurrence in language corpora. McDuff, Frankel & Norman (2009) are likewise focused on hypothesis testing, in their case about the characteristics of targeted memory retrieval. We think that MVPA has a very promising future both as a diagnostic tool, and as a useful dependent variable—in part because the technique is sensitive to contingencies beyond classical single-voxel effects—but that for the reasons outlined in this paper it is a very poor tool for reliably localizing information or identifying cognitive states.

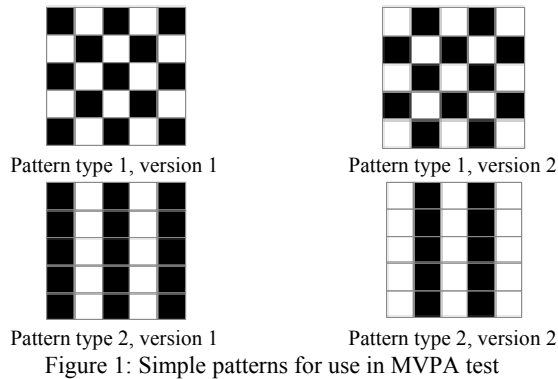

Information and the brain

There are three general ways in which information could inhere in the BOLD signal. First, the information could be non-local, that is, carried by irreducibly relational features of the signal like regional co-variance. We might expect this to occur when large-scale neural synchrony is the relevant aspect of brain activity (Varela, et al., 2001; Gross et al., 2004). Second, it could be local and distributed, that is, the information could be carried by the activity of individual voxels, and the information-carrying voxels could be spread throughout the brain. We might expect this for cognitive processes that require the cooperation of many different brain regions. Third, the information could be local and concentrated, that is, carried by individual voxels that are grouped together in one or a few clumps. This might happen when the work done by local neural circuits is most important to the cognitive task(s) in question. In this essay, we will consider the performance of MVPA in all three

situations, and discuss what can, and cannot, be inferred from features of the learned model in each case.

Local, distributed information

Consider the problem of differentiating between the following two patterns of hypothetical voxel-level activation data, each presented with two *versions* of the same pattern *type* (see Figure 1). In this simple example each of the 25 “voxels” can be in one of two states (active or inactive, if you like). Suppose “brain scans” like these had been observed during an experiment in which participants were asked to classify pictures as “living” or “non-living”. If these judgments reliably corresponded to the two patterns, respectively, could we use MVPA to read the mind of the participants?

Now, when the ratio of pattern versions within each pattern type is 1:1, every voxel is in both of its possible states in every task condition. That is: no voxel is by itself predictive of any cognitive state, and thus in this condition all information is non-local. In this condition *linear* MVPA cannot distinguish between these two patterns; it is blind to non-local information (Kamitani & Tong, 2005; Norman et al. 2006). For linear classifiers, since the evidence provided by each voxel is integrated separately, linear MVPA is successful only when there are individual voxels that are sensitive to the difference between classes. In general, a (binary) linear classifier over an input space of dimension n looks like this:

$$\text{prediction} = \text{sign} \left(b + \sum_{i=1}^n w_i * x_i \right)$$

where the i^{th} weight is w_i and the i^{th} component of the input vector (the list of numbers that describe the patterns to be classified) is x_i and the bias value is b . If the sum above is positive, the instance is classified one way; if it is negative, the instance is classified the other way.

However, manipulating the version ratio changes the situation from one in which no voxel is more informative than any other—a situation in which linear classifiers fail—to one in which there is indeed a set of voxels, scattered through the patterns, that are informative about class membership. That is to say, although there is still non-local information in the patterns—and it is arguable that the non-local co-variance structure is the crucial, relevant distinction between these patterns—the initial test situation is one in

which there nevertheless is also relevant local information, distributed across many voxels.

For our analysis of the performance of MVPA with local, distributed information, we generated 20 sets of 80 “scans”—that is, 20 datasets, each containing 40 instances of each pattern type. Patterns were corrupted with 5% noise—a 5% chance for each voxel that it will be in a state inconsistent with the pattern. For each dataset, we used 40 of the 80 scans for training and 40 for test, and classified them using a Support Vector Machine. Because classification accuracy roughly tracks the relative proportion of pattern versions, our scans contained a 4:1 ratio of pattern versions within each type, and classification accuracy averaged 80%.

Thus, our hypothetical experiment would have produced a solid predictive success; we would be able to tell, 80% of the time, which task condition the participant was in just by looking at the fMRI data. But what, if anything, would we be permitted to conclude about the local neural conditions—representations, information content, activity, etc.—contributing to the differences in cognitive tasks (thinking about or judging the difference between living vs. non-living things)?

Although any of the input components could contribute to the prediction breaking one way or the other in a given case (and it needn’t be the same components for each instance), in practice there can be a small number of voxels that contribute most to the classifier performance because they (literally) carry the most weight—that is, they have the highest values of w_i . In linear MVPA, this set of highly weighted voxels is considered the “most informative”.

Figure 2 shows a map of the voxels that were most informative for distinguishing between pattern types 1 and 2 in dataset 1.

Figure 2: Most informative voxels for an MVPA classification

What is the proper interpretation of these results in the context of MVPA? These are the voxels that, had they been in a different state, would have been most likely to cause the classifier to place the pattern in the other class. But consider the following inference, an inference of similar structure to those being made in the MVPA literature: if the state of these voxels had been different in the right way—and note this picture provides no information about what the right way is—the brain would have been in the relevantly different state (or the participant would have been in the different cognitive state). This inference does not follow, because if covariance is the crucial cognitively relevant property of the activity here, then all the other voxels would also be different when the brain/participant is in the other state: they will be covarying with a different set of partners. And, even if covariance is not the crucial property—if the relevant information is the local information—it seems pretty clear that it isn’t all or only the voxels in the “most

informative” set that would need to be in a different state to turn one pattern into the other.

Likewise, consider a similar inference (versions of which can also easily be found in the literature): the information contained in these voxels is the information crucial to the difference between the cognitive states under investigation (judging living vs. non-living things). This inference is also unwarranted, for similar reasons. For one strong possibility is that the relevant information is carried by the covariance structure of the patterns, and this non-local information is not contained in the set of “most informative” voxels. And even if the local information is what is relevant here, we can see from the results above that the set of most informative voxels does not consist of all or only the voxels carrying the relevant information.

The uncertainty of inferences about brain or cognitive states based on which voxels are most highly weighted is driven home even more strongly when one looks at the stability of the set of highly weighted voxels over multiple trials of the same task. Figure 3 shows the most highly weighted voxels from the first three datasets.

Figure 3: Most informative voxels for three different classification runs

Obviously, the highly weighted voxels vary from run to run. To get a better quantitative handle on the stability of the highly weighted voxel set, we counted the number of times each voxel was among the top 10 most highly weighted. Overall, every voxel was in this set at least twice, and none more than 12 times. 24 voxels were in the set between 6 and 12 times, and 22 between 6 and 10 times. The characteristics of the classification model can vary considerably, driven in part by noise in the training instances, but also by the fact that the algorithm needs only find *some* of the features that discriminate between *some* instances of the patterns *some* of the time. It is not guaranteed to find all of the relevant differentiating features, nor the best. The conclusion seems obvious, but is worth stating clearly: when any voxel can make it into the “most informative” set, and many voxels are more or less equally likely to end up there, this should make us a bit uneasy about their actual informativeness. If there is something stable to the cognitive states differentiating the task conditions, the set of most informative voxels is certainly not tracking it, nor can it therefore be a reliable indicator of the location of the cognitively relevant information.

It should be noted that cross-validation does not alleviate this issue. Cross-validation consists of a family of methods designed to prevent over-fitting of the model to what could be an unusually biased sample. Typically, it involves building multiple models based on multiple partitions of the sample, and averaging results over the range of different partitions (Pereira et al., 2009). For instance, K-fold cross-validation involves splitting the training data into K parts,

and training K times on a rotating K-1 of the partitions. We performed 10-fold cross validation on our 20 training sets, and found similar variability in the set of most informative voxels in each fold. The mean number of inclusions among the top 10 most highly weighted voxels was 4 (SD 2.83). 23 of the voxels were among the 10 most highly weighted voxels in at least one fold.

Non-local information

So, that seems to be the situation when information is local and distributed. What about when the only information is non-local, that is, when the ratio of pattern versions is 1:1? It turns out it is possible to classify these patterns with 100% accuracy, applying MVPA using a support-vector machine with a polynomial kernel of degree two. Can we conclude anything in this case about the neural conditions—representations, information, activity, etc.—contributing to the differences in cognitive tasks?

One is of course tempted to simply dismiss the possibility. In our examples every voxel is in both of its possible states in every task condition. That is: no voxel is by itself predictive of any cognitive state, and thus no inference to the special status of activity in any voxel could possibly be supported by the predictive success of MVPA. Yet researchers do extract “most informative” voxel sets even when using polynomial kernels (e.g. Davatzikos et al., 2005), so it is wise to consider the matter more carefully.

In linear classifiers identifying most important voxels for the classifier is easy—the features in the decision space that have the highest weights are the most important, and these features have a 1:1 correspondence with components of the input vector, that is, with the voxel values fed into the classifier. But non-linear SVMs use “kernel functions”, whereby a vector input is projected into a kernel-specific high-dimensional space, and the importance of each feature is determined in that space. The original space for a given vector x has one dimension for each component of the input vector, and the value of that feature—its position on dimension i —is just x_i . In contrast, a polynomial kernel of degree 2 (K_2) projects the input vector into a space having a dimension for each unique (unordered) pair of features in the vector, and the value of each of those features—its position on dimensions (i,j) —is $x_i * x_j$.

Thus, the K_2 classifier over an input space of dimension n looks more like this:

$$\text{prediction} = \text{sign} \left(b + \sum_{i,j=1}^n w_{i,j} * x_i * x_j \right)$$

In fact, we can get exactly this situation by manually projecting our input vectors into the polynomial space—turning them in this case from n -dimensional vectors into $n+(n^2-n)/2$ dimensional vectors—and using linear SVMs to classify them. This procedure will produce the same decision surface as using K_2 in the original space, but will allow us to directly inspect the resulting weights to determine which features were most important.

However, given the nature of non-linear SVMs, relating features to individual components of the input vectors is inherently problematic. For note that what gets weighted in the decision function is the product of each pair of

components. So, if a given product turns out to be important to the classifier, shall we attribute this importance to just one of the components, or to both? Either decision seems likely to give misleading results. Nevertheless, for the sake of the discussion, let's adopt the simple rule that when a given feature is highly weighted, both components (voxels) will be counted as "informative". Given this, we can examine the frequency with which voxels are informative, and track the voxels that are frequently informative.

To test this procedure when using K_2 , we generated 40, 10x10 versions of the standard patterns from Figure 1, 20 of each pattern type, with a 1:1 ratio of versions, and a noise level of 5%. We projected each of these patterns into the 5,050-dimensional feature space of K_2 , and trained a linear SVM on the set. Then we found the top 500 highest weighted features, and projected these back onto the 10x10 pattern following the rule above. Now, it is perfectly legitimate to make the following inference from this procedure: the highly weighted voxels are the ones that, had they been in a different state, would have been most likely to cause the classifier to place the pattern in the other class. The trouble is, the weighting is often taken to tell us something about the relative importance of each voxel to the intrinsic difference between the patterns (and to the underlying cognitive states), and no such inference is warranted in this case.

First, there is a basic problem of interpretation given that the important features are in fact products of two voxels—so, every time a voxel is deemed informative, it has a partner with which it was important, and the set itself gives no information about the distribution of these partners. Second, it is clear in this case (because there is no local information) that the relevant information differentiating between the patterns is non-local, carried in the covariance structure of the pattern, and this information is not contained in the set of frequently informative voxels. Third, the most highly-weighted features are not those that contain the most information. As in the linear case, they are the features that contained sufficient information to drive the classifier on a given set of training examples. Fourth and finally, as should not be surprising, the set of informative features and informative voxels is highly unstable in this case, as well.

To explore the stability of the set of important features when using K_2 , we generated 10x10 versions of the standard patterns above, creating 100 sets of 40 (20 of each pattern) with a noise level of 5%. We projected each of these patterns into the 5,050-dimensional feature space of K_2 , and trained a linear SVM on each of the 100 sets. From each of these 100 sets, we extracted the top 500 most important features. Doing a pair-wise comparison of the most important features from each set revealed that, on average, only 101.08 (SD 16.94) of these features (20.21%) were common between each pair. Moreover, the common features varied from pair to pair. Doing a 5-wise comparison of the most important features sets reveals an average of just 0.81 (SD 1.09) of the features (0.16%) are shared across all five sets. Note that despite the instability of the "most informative" feature sets, classification accuracy in all cases was 100%.

Given the high degree of variability in the features considered most important, it seems certain that the set of frequently informative components (voxels) is likewise unstable. To confirm this, we generated 500 training sets of the 10x10 patterns, and, following the procedure above, found the top 500 most important features for each set. Then, we counted the number of times each individual component of the input vector was included in a pair that was in this important feature set. On average, each component was included in the set 10.00 times (SD 0.39). No component averaged fewer than 9 inclusions, or more than 11.00. Once again, if there is some stable difference between the cognitive states in the two task conditions, the set of most informative voxels is certainly not tracking it, nor can it therefore be a reliable indicator of the location of the cognitively relevant information.

Admittedly, this example was based on a very simple rule for mapping features in the multi-dimensional space to components of the original vector, and it is true that more sophisticated procedures for uncovering the most informative components have been developed (Davatzikos et al., 2005; Lao et al., 2004). But insofar as these techniques still depend in one way or another on identifying the most highly weighted features in a multi-dimensional space, and insofar as this set is not determinate for a given classification task, then the results of such analyses need to be interpreted with extreme caution.

Before moving on with the remainder of the analysis, it is worth pausing to summarize the findings. In the case where there is local information relevant to distinguishing patterns, linear MVPA does not reliably find it; and in the case where there is relevant non-local information, carried for instance by covariance patterns, linear MVPA cannot find it, and non-linear MVPA models can make it look as if they were using local information. More importantly, having discovered some features whose state matters most to the classification decision is not the same as having discovered the brain regions whose activity matters most (or even relatively more) to the participant (or her brain). Indeed, these two sorts of information need have no regular correspondence to one another; one need not track, be a reliable indicator of, or be otherwise instructive about the nature, scope or location of the other.

Local, concentrated information

How is this disconnect possible? Consider first an example from the MVPA literature meant to showcase the power of the technique. Haynes and Rees (2005) were able to use MVPA to correctly identify the orientation of visually-presented lines, even when the stimuli were presented briefly and masked so that the participant did not consciously perceive them. That is an intriguing result, and may tell us something interesting about the operation of V1 (the ROI they used to make the predictions). But note the broader implication for the method: since the participants cannot judge the orientation of the lines, they cannot be in whatever cognitive state gives the ability to judge the orientation of the lines. Thus, MVPA can be used to infer features of the task environment from characteristics of the

BOLD signal, without being a reliable indicator of the cognitive state of the participant.

Now consider extending the experiment in the following straightforward way: while the visual stimulus is being shown (and masked), experimenters play an auditory tone from which the participant could reliably infer the orientation of the line. If, as seems likely in this particular case, the most informative voxels for the pattern classifier would remain in V1, this outcome would provide a clear instance in which the information used by the participant and the information used by the classifier would not have the expected relation.

But is such an outcome really possible? In fact, this hypothetical example points in the direction of a well-known fact about the way classification algorithms perform. Numerous theoretical results and a tremendous amount of empirical evidence in machine learning demonstrate that there is no universally best learning algorithm (Wolpert, 1996). Every algorithm has a bias that is appropriate for some problems and inappropriate for others. This is true for the brain, and the same is true of kernels. There is no universally best kernel, and changing from one kernel to another can lead to large changes in the learned decision surface and thus to changes in what features in the data set seem to be important.

The relevance of this problem for MVPA is that a particular set of stimuli may elicit different patterns of activity, call them pattern A and pattern B, in different parts of the brain, and one kernel may be able to detect pattern A but not pattern B, whereas another kernel may be able to detect pattern B but not pattern A. Thus, when relating “most informative features” to “most important activity”, the area of the brain implicated in the experiment will change depending on which kernel is used.

To make this concrete, consider two patterns with 20 binary features ($f_1 - f_{20}$) in which for every instance of the first (positive) pattern the following two conditions hold:

- (a) Either $f_{19} = 1$ and $f_{20} = -1$, or $f_{19} = -1$ and $f_{20} = 1$
- (b) The sum of the first 5 bits is less than or equal to zero

For every instance of the second (negative) pattern, the following two conditions hold:

- (a) Either $f_{19} = 1$ and $f_{20} = 1$, or $f_{19} = -1$ and $f_{20} = -1$
- (b) The sum of the first 5 bits is greater than zero

The values of the other bits are chosen uniformly at random from $\{-1, 1\}$. Condition (a) is the logical exclusive or (XOR) function on bits 19 and 20 and is easily learned by the polynomial kernel of degree two (the class label is $-\text{sign}(f_{19} * f_{20})$) but is impossible to learn with a linear kernel. Condition (b) is easily learned with a linear kernel (the class label is 1 if $f_1 + f_2 + f_3 + f_4 + f_5 \leq 0$ and is -1 otherwise), but is extremely difficult for the polynomial kernel of degree two because it has access to individual feature f_i only as $f_i * f_i$ which is 1 regardless of the value of f_i .

We created 100 datasets based on the above rules and trained an SVM with a linear kernel on both the original feature space and the feature space constructed for the

polynomial kernel of degree two. In the latter space, the feature corresponding to $f_{19} * f_{20}$ had an average weight of 3.64. The remaining 209 features had average weights in the range (0.05, 0.10). In the former case, the average weights for features f_1 through f_5 were 1.92, 1.94, 1.94, 1.93, and 1.94. The remaining 15 features had average weights in the range (0.03, 0.10). Clearly, the choice of kernel can have a dramatic impact on which features are deemed important and, in the case of MVPA, which voxels are implicated in various cognitive tasks.

Thus, although much of this paper was spent detailing the worrying instability and potential deceptiveness of the most informative voxel set when information is non-local or distributed, the fact is that even if MVPA were perfectly reliable at the task of finding the most informative features in a data set, the inference from this to the brain activity most important determining the outcome in given task would remain fairly weak. This is because inference from most informative features to most important activity apparently relies on the unwarranted additional assumption that the pattern classification algorithm and the brain are classifying on a relevantly similar basis. While of course no one claims that the success of MVPA shows that the brain is implementing an identical classifier, the issue is that the hypothesis space is different for different classifiers, and so different information will be relevant to each. What is relevant in the brain, and what is relevant to classifying an image of the brain, need not bear much relation.

Conclusion

There are very many challenges to the task of reliably relating the features (of the BOLD signal) most important to classification success to the features (of brain activity) most important to cognitive states/outcomes. By way of summation, consider this general list of possible ways in which these features might fail to relate as expected.

(1) The highly informative elements of the pattern as discerned by MVPA are distributed in the brain in such a way that the brain is anatomically or functionally incapable of integrating the information. If people are nevertheless capable of making the relevant discrimination, it must have been on the basis of different information.

(2) There may well be classes of stimuli that differ in ways undetectable to subjects (under any presentation condition, conscious or otherwise), but which nevertheless create patterns in the BOLD signal allowing for successful classification by MVPA. Consider in this regard an experiment run by Hung et al. (2005). Macaques passively viewed picture stimuli in eight different categories while undergoing direct recording of neural activity using microelectrode arrays. Hung et al. were able to successfully classify the stimuli with a linear SVM taking the multi-unit activity as input. But here the macaques did not—indeed, in all likelihood could not—classify the stimuli, because they had not been trained to do so. In this case, the SVM might have been making distinctions that the (untrained) macaques were not.

(3) Stimuli may differ along more than one dimension, both of which lead to differences in the BOLD signal. MVPA classification could rely on patterns relating to one

dimension, while participants use information relating to the other. That is, even when there is information in the BOLD signal that is theoretically accessible by (or that is tracking information accessible by) the participant, this may not be the information that is being used by the participant.

(4) The MVPA classifier may be using a kernel that is significantly different from what is implemented in the brain. As we saw, classifiers with different kernels trained on the very same data will extract different features, and thus come to different decisions about which features (and which elements of the input vectors) are most important.

(5) Since there will always be a set of highly informative voxels produced by the MVPA classifier, the existence of such a set won't tell us whether the relevant information in the brain is local and concentrated, local and distributed, non-local, or some combination of these.

The discussion also raises a much more general issue. As we noted at the outset, MVPA offers an exciting new way to investigate the operation of the brain, by looking at the predictive value of (typically widely) distributed patterns of activity. The problematic inferences generally come in the attempt to reduce such patterns to local features of brain activity. But if the best predictor of cognitive states is not the location of an activated region, but rather the patterns of cooperation and coactivation between them—as the success of MVPA might be said to indicate, and as has been argued for independent reasons (Anderson, 2008; Sporns, et al., 2004; Uttal, 2001)—then perhaps it is time to pay more heed to the patterns than to the partners. We are just beginning to develop the tools to make such an investigation fruitful and rigorous—including not only MVPA but other forms of statistical pattern analysis, machine learning, graph theory, etc.—and it seems a shame instead to use these tools in the service of localization projects for which they are ultimately ill-suited. New tools often come with the opportunity to re-consider the strengths of theoretical perspectives and paradigms, and these are offering a chance to look beyond localization, to what other perspectives on brain organization might have to offer.

The Origins of Collective Overvaluation: Irrational exuberance emerges from simple, honest and rational individual behavior

Abstract

The generation of value bubbles is an inherently psychological and social process, where information sharing and individual decisions can affect representations of value. Bubbles occur in many domains, from the stock market, to the runway, to the laboratories of science. Here we seek to understand how psychological and social processes lead representations (i.e., expectations) of value to become divorced from the inherent value, using asset bubbles as an example. Using an agent-based model we explore whether a simple switching rule can generate irrational exuberance, and systematically explore how communication between decision makers influences the speed and intensity of overvaluation. We show that rational and simple individual level rules combined with honest information sharing are sufficient to generate the collective overvaluation characteristic of irrational exuberance. Further, our results demonstrate that simple noise in the exchange of value information leads to rapidly increasing expectations about value, even when no one is engaged in exaggerating their expectations for the assets they own.

Keywords: decision making; valuation; agent-based modeling; rationality; emergence.

Introduction

Chances are, your savings are invested in one or more kinds of assets—stocks, bonds, real estate, etc. Moreover, if you are an individual investor, or are planning on becoming one soon, you probably discuss the markets with various other investors, including friends, family, colleagues and investment professionals. You might also listen to one of the many market watch programs, or read the business section of your daily newspaper. In short, you are probably engaged in both soliciting and offering opinions on how various market sectors will perform in the future. Once in a while, this information will cause you to make a change in your portfolio. Imagine, for instance, that someone you trust shares with you their expectation for the performance of one of their investments. Imagine further that this expectation exceeds the expectation that you yourself have for your own investments. Surely there is some chance that you would sell (some of) your own portfolio, and invest in the asset with the higher expected return. Whether you would do this naturally depends on myriad other factors—your tolerance for risk, the perceived balance of your

current investments, the liquidity of this new asset class, etc. But there remains some chance that you will make the switch. This is natural, and even—assuming that one of your financial goals is to maximize return consistent with other priorities—rational. But if we are right, this natural, rational behavior is sufficient to spark irrational exuberance.

Asset bubbles are among the most fascinating and puzzling phenomena in economic markets. Decision makers frequently drive up prices and demand to levels that seem completely divorced from the underlying value. Bubbles are common, and far from innocuous. Post-bubble market “corrections” have led to financial ruin for many, as occurred in the great depression and in the current real estate and financial crises. And there seem to be some important similarities between asset bubbles and other sorts of collective behavior, including clothing fashions, popular music trends and perhaps even the trajectory of science (with processes such as paper acceptances and grant funding being based on the expectations of reviewers about the future value of the work). Thus, bubbles are important to understand, to say the least. In the current paper, rather than seeking to understand these events through analyzing or modeling the complex historical and economic factors that lead to a specific instance of collective overvaluation, we have instead focused on formulating some simple and general individual rules that we hypothesize are sufficient to generate the phenomenon of irrational exuberance. We have isolated what we believe to be a key underlying cause of collective overvaluation / irrational exuberance across many contexts, and have constructed a simple model to explore whether it generates the predicted outcomes.

Here we model the genesis of collective overvaluation as a general phenomenon, using decision making about asset classes as an example. We aim to make this model as general as possible, making it potentially applicable to other domains.

Model Description

The model description offered below follows the standardized ODD protocol for describing individual and agent based models (Grimm and Railsback 2005; Grimm et al. 2006). This protocol for describing agent based models has been developed with input from modelers across the disciplines and is in wide use.

Purpose

A commonly observed behavior in markets of many kinds is continually increasing expectations about the future value of certain commodities/asset groups. Here we used agent based techniques to model a simple decision rule that we predict to be sufficient to generate both increasing expectations and overexploitation of certain assets (absorption of all individuals into a small number of asset groups). We also explore the impact of communication fidelity on the outcomes.

State variables and scales

In this model, time and space are both represented discretely. During each time period, all agents execute the commands described in the schedule. The simulation is constructed in a spatial environment for the purposes of visualizing interactions between asset groups.

Process overview and scheduling

This model proceeds in discrete time steps, and entities execute procedures according to the following ordering:

1. Individual A identifies random partner B to be recipient of information about asset value expectations.
2. Individual A communicates current expectation of value for A's current asset class to individual B with some fidelity
3. Individual B adopts expectation of individual A with some probability (opportunism) if A and B come from different groups, and A's expectation is higher than B's.
4. If B has adopted A's expectation then B switches to A's group.

Figure 1: Two screen shots showing the initial conditions and the state of the simulation after 150 time steps under the default parameters (see Table 2). *Left:* The run begins with 10 groups of uniform size with an average expectation of 100. *Right:* After 150 time steps, there is one large group and the expectations of agents have increased to 131.5 (as indicated by the darker red shade of the agents).

Table 1. Overview of state variables associated with each type of entity in the simulation. Bold indicates manipulated independent variables and arrows indicate dependent variables.

Entity	State variable	Description
<i>Global</i>	• Transmission fidelity	Accuracy of communication of expectation. This is modeled by communicating to the partner not the agent's actual expectation, but an expectation taken randomly from a normal distribution with the transmission fidelity as its standard deviation and the agent's actual expectation as its average.
	• Expectation distribution	Initial variability (expressed as Standard Deviation) of expectations among individuals in the population
	• Opportunism	Probability of changing groups given a higher expectation communicated from partner
	➤ Number of groups	The number of groups (asset classes)
	• Number of agents	The number of individuals included in the model
	• Communication target	Binary, either random individual or individual in another group
	➤ Switches per step	The number of agents that change groups each step
	➤ SD switches per step	The standard deviation in the number of switches per step
	➤ Average expectation	The average expectation of all individuals regarding the future value of their investment
	➤ Change in expectation per step	The average change in the average expectation each step
<i>Groups (Asset classes)</i>	• Location	Coordinates of the group
	• Group size	Number of individuals in asset class
<i>Agents</i>	• Expectation	The future value the individual assigns to the current asset
	• Partner expectation	The information the individual has about their current partner's expectation in their asset class
	• ID number	The identification number of the individual
	• Partner ID number	The identification number of the current partner

Design Concepts

Emergence Irrational aggregate behavior emerged from individual-level rational decision making processes.

Prediction Agents did not have a complex function for predicting the future value of asset classes. They simply adopted information from partners if the information met the conditions described above.

Sensing Individuals have an initial expectation of the value of their asset class based on the expectation distribution. From this point forward, individuals' expectations change only from information transmission from other agents.

Interaction Individuals can transfer information about their expectation of the value of their asset class to partners (with some fidelity). Individuals can move to a new group (asset class), if the partners communicated expectation is higher than the current expectation.

Stochasticity Initial distribution of expectations is randomly distributed around the inherent value of a particular asset class. Opportunistic switching is implemented probabilistically and so has a stochastic element.

Collectives Agents were parts of groups (asset classes) and could transfer information to a 'partner' (from the same or other group). Partners were reset each time period and information transfers were unidirectional (i.e., A might transfer information to B, and B to C)

Observation Simulations were run for 2000 time steps or until only a single group remained. Each combination of independent variables (see Experiments, below) was run 10 times. The dependent variables were measured at the end of each run. Reported results are averages over 10 runs.

Initialization

Table 2 lists the variables associated with various entities in the simulation. All runs were initialized according to default parameters in the table.

Table 2. Initial and default values for all instance variables and independent variables (bold).

Entity	State variable	Initial/Default Value	Units
<i>Global</i>	• Transmission fidelity	Perfect (SD of 0)	
	• Expectation distribution	SD of 10	
	• Opportunism	5%	
	• Number of groups	10	count
	• Number of agents	1,000	count
<i>Groups (Asset classes)</i>	• Group size	100	count
	• Average expectation	100	Expected future value

<i>Agents</i>	• Expectation	Assigned from expectation distribution
	• Partner expectation	
	• ID number	
	• Partner ID number	

Input

This model is designed as a general model of irrational exuberance and collective overvaluation. We did not initialize this model with real world data.

Experiments

We ran three simple and three complex experiments. In the three simple experiments, we used only a single independent variable, while in the three complex we used two, to look for interactions between the effects.

As noted above, all runs were initialized with 10 groups, each containing 100 agents, with an overall average expectation of 100. The three independent variables of interest were: initial expectation distribution, opportunism, and transmission fidelity.

Experiment 1, expectation

This experiment varied only the initial expectation distribution, setting it so the initial distribution of expectations had a standard deviation of 10, 20 and 30. Opportunism was fixed at 5%, and transmission fidelity was perfect.

Experiment 2, fidelity

This experiment varied only transmission fidelity, setting it at 0, 5 and 10. Recall that transmission fidelity is modeled by communicating to the partner not the agent's actual expectation, but an expectation taken randomly from a normal distribution with the transmission fidelity as its standard deviation and the agent's actual expectation as its average. Thus 0 equals perfect fidelity. Opportunism was fixed at 5% and the initial expectation distribution was fixed at 10.

Experiment 3, opportunism

This experiment varied only opportunism, setting it at 5%, 10%, and 15%. The initial expectation distribution was fixed at 10 and transmission fidelity was perfect.

Experiment 4, expectation x fidelity

This experiment varied both expectation distribution (10, 20, 30) and fidelity (0, 5, 10). Opportunism was fixed at 5%.

Experiment 5, fidelity x opportunism

This experiment varied both fidelity (0, 5, 10) and opportunism (5%, 10%, 15%). The initial expectation distribution was fixed at 10.

Experiment 6, expectation x opportunism

This experiment varied both expectation distribution (10, 20, 30) and opportunism (5%, 10%, 15%). Fidelity was perfect.

Dependent variables

The dependent variables measured in these experiments were:

- The average expectation at the end of the run, representing the average agent expectation of the value of the asset class(es).
- The number of groups remaining at the end of the run, representing the number of asset classes with investors
- The number of switches per step, corresponding to the number of agents that switched groups each time step
- The average change in expectation per step, corresponding to the change in expectation that occurs as agents switch and adopt the expectations of others
- The volatility of the system, measured as the summed standard deviations of the number of moves per step and the average change in expectation per step.

Results

Descriptive statistics for experiment 1, expectation, are listed in Table 3. Increasing the distribution of expectations lead to a higher average expectation at the end of the run (ANOVA, $F(2, 27) = 112.45$, $p < .01$, see Figure 2) a larger change in expectation each time period (ANOVA, $F(2, 27) = 58.31$, $p < .01$), and higher overall volatility (ANOVA, $F(2, 27) = 34.34$, $p < .01$).

Table 3. Descriptive statistics for experiment 1, expectation.

Expectation distribution:	10	20	30
Groups at end	1.0 (0.0)	1.0 (0.0)	1.0(0.0)
Average expectation at end	131.55 (4.34)	165.99 (10.44)	199.95 (13.57)
Number moves per step	11.65 (2.25)	12.18 (0.92)	12.13 (1.31)
Δ-expectation per step	0.09 (0.02)	0.21 (0.04)	0.29 (0.6)
Volatility	10.81 (0.52)	12.21 (0.47)	12.85 (0.68)

Descriptive statistics for experiment 2, fidelity, are listed in Table 4. Greater noise (low transmission fidelity) led to much higher average expectations at the end of the runs $F(2, 27) = 68.66$, $p < .01$ (see Figure 3); to more groups at the end of the simulation $F(2, 27) = 91.5$, $p < .01$; and to less overall volatility $F(2, 27) = 521.56$, $p < .01$.

Figure 2: Increase in average expectation as a function of initial expectation distribution. Error bars represent ± 1 S.E.

Table 4. Descriptive statistics for experiment 2, fidelity.

Transmission fidelity:	0	5	10
Groups at end	1.0 (0.0)	3.3 (0.48)	2.7(0.48)
Average expectation at end	133.84 (2.86)	375.31 (107.04)	682.72 (146.98)
Number of moves per step	12.67 (1.23)	17.88 (0.68)	17.90 (1.30)
Δ-expectation per step	0.11 (0.02)	0.25 (0.01)	0.49 (0.02)
Volatility	10.94 (0.51)	5.68 (0.17)	6.57 (0.40)

Figure 3: Increase in average expectation as a function of transmission fidelity. Error bars represent ± 1 S.E.

Note the increase in expectation is driven in part by the fact that with high noise, the number of groups never drops to one, as it always does when fidelity is perfect. Thus the

simulations when fidelity was > 0 lasted for all 2,000 steps, rather than stopping after around 300 steps, as is typical when fidelity is perfect. Even so, there was also a significant increase in the average change in expectation per step, indicating that the effect is not simply a matter of running the simulation for longer.

Descriptive statistics for experiment 3, opportunism, are listed in table 5. Greater opportunism increases the number of moves per step $F(2, 27) = 657.16$, $p < 0.01$; increases the amount by which expectations change each step $F(2, 27) = 657.16$, $p < 0.01$; and increases volatility $F(2, 27) = 1531.22$, $p < 0.01$. In addition, there was a decrease in the number of steps it took to achieve one group, and thus for the simulation to end $F(2, 27) = 260.41$, $p < 0.01$. That is, the more opportunistic the agents are, the faster the collective converges on a single asset. This explains why, despite a significant increase in the change in expectation each step, there was no main effect on average expectation at the end.

Table 5. Descriptive statistics for experiment 3, opportunism.

Opportunism:	5%	10%	15%
Groups at end	1.0 (0.0)	1.0 (0.0)	1.0(0.0)
Step when one group reached	298.80 (30.68)	162.30 (14.86)	98.70 (6.46)
Average expectation at end	133.45 (4.71)	132.21 (2.49)	133.76 (3.35)
Number of moves per step	12.71 (1.07)	25.33 (1.83)	38.73 (1.80)
Δ-expectation per step	0.11 (0.02)	0.20 (0.01)	0.34 (0.04)
Volatility	11.09 (0.41)	21.02 (1.22)	31.95 (0.69)

Interactions

The three complex experiments revealed the same main effects, which won't be repeated here. Instead we'll simply summarize some of the significant interactions.

Experiment 4, Expectation x Fidelity reveals a significant interaction between expectation distribution and fidelity on volatility $F(4,81) = 3.42$ $p = 0.012$. Whereas the general effect of fidelity on volatility is to decrease it when going from 0 to 5, and increase it slightly when going from 5 to 10, this latter effect disappears at higher levels of expectation distribution.

Experiment 5, Fidelity x Opportunism reveals an interaction between fidelity and opportunism on the number of moves per step $F(4,81) = 21.66$, $p < 0.01$; the change in expectation per step $F(4,81) = 341.86$, $p < 0.01$; and volatility $F(4,81) = 256.84$, $p < 0.01$. Both fidelity and opportunism increase the number of moves per step, and increase the change in expectation per step, and together the higher values increase the magnitude of the effect. As noted above, the change in fidelity tends to decrease volatility

initially, then increase it slightly. These effects are greater as opportunism increases.

Experiment 6, Expectation x Opportunism reveals an interaction between expectation distribution and opportunism on the change in expectation per step $F(4,81) = 15.40$, $p < 0.01$ and on volatility $F(4,81) = 10.71$, $p < 0.01$. In each case the tendency of the independent variables to increase volatility and change in expectation per step is enhanced at higher levels of the other variable.

Discussion

On December 5, 1996, after nearly fifteen years of steady growth in the S&P 500 and Dow Jones Industrial Average (and just before the record-breaking bull market to follow), Federal Reserve chairman Alan Greenspan expressed his concern that the behavior of the stock market was characterized by "irrational exuberance". Whether he was right or not, it is certainly true that the price to earnings ratio had by then surpassed 27, a level that hadn't been seen since 1929, and was on its way to the record high of 47 it achieved in March of 2000. What leads to this sort of (apparent) disregard for underlying real value? There are several possible explanations. Some favor accounts based on individual irrationality—e.g. "animal spirits" like (over-) confidence and our tendency to be influenced by nominal amounts of money—that can be amplified under certain market and social conditions (Akerloff, 2005; Akerloff & Shiller, 2009). Others favor "herd behavior" models in which individuals allow their choices to be guided by other people's choices, on the (reasonable, but by no means certain) assumption that there is wisdom in crowds (Surowiecki, 2004). On these models, observations of early choices create an information cascade that causes late choosers to follow early ones, rather than following their own signal (Banerjee, 1992; Bikchandri, Hirshleifer & Welch, 1992). Finally, there is currently a great deal of discussion of the role of deception in the recent real-estate bubble (Bitner, 2008).

Here we consider the alternate possibility that irrational exuberance is driven by neither irrationality nor deception, nor requires individuals to ignore their own information and preferences, but instead emerges from simple, honest and rational individual-level behavior. To explore this possibility we created an agent-based model where agents have simple and seemingly rational individual-level rules for switching between asset classes and updating their representations of asset value based on information from others. Our results show that a simple rule—when another agent's expectation for the performance of their investment exceeds your own expectation for your own investment, consider switching investments—can generate collective behavior resembling irrational exuberance.¹ In particular,

¹ Although communication partners were chosen at random, agents adopted new expectations *only* when the partners represented different asset classes. Restricting communication to partners from other groups greatly speeds the dynamics outlined here, because members of smaller groups are bombarded with

we see rapidly increasing expectations for the value of commodities and the overexploitation of a single asset class. Further, our model shows that this collective overvaluation can occur even when there is no individual deception or bias in favor of exaggerating value when communicating to others about it. This suggests that surprisingly simple and rational individual level rules can generate some of the complex and irrational aggregate outcomes associated with market bubbles.

One especially interesting finding was the massive effect that transmission fidelity had on overvaluation. Here is a system in which increasing noise increases the rapidity and magnitude of overvaluation, and the interactions demonstrate that this effect can be magnified by other factors. Ironically, then, Alan Greenspan's infamous opacity could itself have been a contributor to the irrational exuberance he warned against. Although we do not explore this possibility explicitly here, it is clear that combining noise with even a few agents intent on deception would cause even greater overvaluation than we demonstrated in these experiments. This is perhaps part of the combination that led to the recent real-estate bubble.

This model has both specific implications for the phenomenon of market bubbles as well as general implications for the phenomenon of collective overvaluation across domains. Because this model simulates individual decision making processes (as is typical of agent based models) rather than simply aggregate dynamics, it is able to capture important effects of interactions among individuals (in terms of information sharing and switching). Models such as this can be used to improve our understanding of the psychological and social components of decision making behavior by allowing us to explore the generative sufficiency of individual rules as well as the sensitivity of the system to alterations in parameters such as those explored here (i.e., transmission fidelity, initial expectation, opportunism in switching). The model presented here demonstrates that representations/expectations of value can become dissociated from inherent value when individuals use simple and rational decision rules combined with well-intentioned communication. The emergence of increasing expectation from these simple and general decision making and communication processes may be the fundamental principle that gives rise to irrational exuberance, not just in the market place, but in any domain in which individuals switch from their current option when they hear about better opportunities elsewhere.

Thus, in addition to the potential relevance of this model for market phenomena, there are more general implications that can be drawn as well. The emergence of collective overvaluation from a simple switching rule could occur in a wide range of domains, making this model applicable to a wide range of phenomena. In fact, this model is sufficiently abstract that it can be applied to a variety of other situations in which individuals' assessments of value are based on

social information. For example, clothing fashions, popular music, and even current trends in areas of scientific study might be subject to similar processes. These may be fruitful avenues for future research.

Future work will also explore market dynamics in greater depth and detail. For instance, we will explore the effect that broadcast information (e.g. announcements from the Fed, ratings agencies, etc) might have on the creation of asset bubbles. We will also allow for the dynamic creation of new asset classes, and allow agents to decide to temporarily opt out of the market. Finally, we will explore what can be done to reverse such overvaluation in a more controlled fashion than is typical in a market crash, or prevent high degrees of overvaluation from occurring in the first place.

Keywords: systematicity; classicism; connectionism; compositionality; category theory; product; functor; adjunction

Abstract

Classical and Connectionist theories of cognitive architecture “explain” systematicity, whereby the capacity for some cognitive behaviors is intrinsically linked to the capacity for others, as a consequence of syntactically and functionally combinatorial representations, respectively. However, both theories depend on *ad hoc* assumptions to exclude specific architectures—grammars, or Connectionist networks—that do not account for systematicity. By analogy with the Ptolemaic (i.e., geocentric) theory of planetary motion, although either theory can be made to be consistent with the data, both nonetheless fail to explain it (Aizawa, 2003b). Category theory provides an alternative explanation based on the formal concept of adjunction, which consists of a pair of structure preserving maps, called functors. A functor generalizes the notion of a map between representational states to include a map between state transformations (processes). In a formal sense, systematicity is a necessary consequence of a “higher-order” theory of cognitive architecture, in contrast to the “first-order” theories derived from Classicism or Connectionism. Category theory offers a re-conceptualization for cognitive science, analogous to the one that Copernicus provided for astronomy, where representational states are no longer the center of the cognitive universe—replaced by the relationships between the maps that transform them.

Introduction

For more than two decades since Fodor and Pylyshyn’s seminal paper on the foundations of a theory of cognitive architecture (Fodor & Pylyshyn, 1988), the problem of explaining systematicity remains unresolved (Aizawa, 2003b) despite numerous Classicist and Connectionist claims to the contrary (Fodor & McLaughlin, 1990; van Gelder, 1990; Smolensky, 1987).

The problem of systematicity for a theory of cognition is to explain why the capacity for some cognitive behaviours is intrinsically linked to some other cognitive capacities. The systematicity problem is actually three problems:

1. *Systematicity of representation*—why is it the case that the capacity to generate some representations (e.g., the representation John loves Mary) is intrinsically linked to the

capacity to generate some other representations (e.g., the representation Mary loves John)?

2. *Systematicity of inference*—why is it the case that the capacity to make some inferences (e.g., that John is the lover in the proposition John loves Mary) is intrinsically linked to the capacity to make some other inferences (e.g., that Mary is the lover in the proposition Mary loves John)?
3. *Compositionality of representation*—why is it the case that the capacity for some semantic content (e.g., the thought that John loves Mary, however that thought may be represented) is intrinsically linked to the capacity for some other semantic context (e.g., the thought that Mary loves John, however that thought may also be represented)?

These problems are logically independent—one does not necessarily follow from another (Aizawa, 2003a), and so a theory is required it explain all three.

Classicists and Connectionists employ some form of combinatorial representations to explain systematicity. For Classicists, representations are combined in such a way that tokening of representations of complex entities entails tokening of representations of their constituent entities, so that the syntactic relationships between the constituent representations mirror the semantics ones—systematicity is a result of a combinatorial syntax and semantics (Fodor & Pylyshyn, 1988). For Connectionists, representations of complex entities are constructed more generally so that their tokening does not necessarily imply tokening constituent entity representations (van Gelder, 1990; Smolensky, 1987). We refer to the former as *classical compositionality*, and the latter as *functional compositionality*.

In general, a Classical or Connectionist architecture can demonstrate systematicity by having the “right” collection of grammatical rules, or functions such that one capacity is indivisibly linked to another. Suppose, for example, a Classical system with the following three production rules:

G1: P → Agent loves Patient
Agent → John | Mary
Patient → John | Mary.

The capacities to generate all four representations (i.e., John loves John, John loves Mary, etc.) are indivisibly linked, because the presence of all three, or absence of any one of those rules means the system is only capable of generating either all or none of those representations. In no case can the

system generate one without being able to generate the other. So, this Classical architecture has the systematicity of representation property with respect to this group of four propositions. Tensor products (Smolensky, 1990), or Godel numbers (van Gelder, 1990) are functionally compositional analogues to this explanation. Systematicity of inference follows from having additional processes that are sensitive to the structure of these representations. For Classical architectures, compositionality of representation also follows, because the semantic content of a complex representation is built up from the semantic contents of the constituents and their syntactic relationships (Aizawa, 2003a). Aizawa (2003a, 2003b) disputes whether a Connectionist architecture can also demonstrate compositionality of representation. Regardless, though, neither Classicism, nor Connectionism can derive theories that provide a full account of systematicity (Aizawa, 2003b).

A demonstration of systematicity is not an explanation for it. In particular, although grammar G1 has the systematicity of representation property, the following grammar:

G2: P → John loves Patient |
 Agent loves Mary
Agent → John | Mary
Patient → John | Mary

does not. This architecture cannot generate a representation of the proposition Mary loves John even though it can generate representations of both John and Mary as agents and patients, and the John loves Mary proposition. The essential problem for Classical theory—likewise Connectionist theory—is that syntactic compositionality by itself is not sufficient without some additional assumptions that admit grammars such as G1 that have the systematicity property, but exclude grammars such as G2 that do not. An explanation for systematicity in these cases turns on the nature of those additional, possibly *ad hoc* assumptions.

Ad hoc assumptions

Aizawa (2003b) presents an explanatory standard for systematicity and the problem of *ad hoc* assumptions by analogy with the Ptolemaean (geocentric) versus Copernican (heliocentric) explanations for the motions of the planets (see Phillips, 2007, for a review). The geocentric explanation for planetary motion places the Earth at the center of the other planets' circular orbits. Although this theory can roughly predict planetary position, it fails to predict periods of apparent retrograde motion for the superior planets (i.e. Mars, Jupiter, etc.) across the night sky. To accommodate this data, the geocentric theory was augmented with the assumption that the other planets revolve around points that revolve around the Earth. This additional assumption is *ad hoc* in that it is unconnected with the rest of the theory and motivated only by the need to fit the data—the assumption could not be confirmed independently of confirming the theory. The heliocentric explanation, having all planets move around the Sun, eschews this *ad hoc* assumption. Retrograde motion falls out as a natural consequence of the positions of the Earth and other planets relative to the Sun. Tellingly, as more accurate data

became available, the geocentric theory had to be further augmented with epicycles on epicycles to account for planetary motion; not so for the heliocentric theory.

The problem for Classical and Connectionist theories is that they cannot explain systematicity without recourse to their own *ad hoc* assumptions (Aizawa, 2003b). For Classicism, having a combinatorial syntax and semantics does not differentiate between grammars such as G1 and G2. For Connectionism, a common recourse to learning also does not work, whereby systematicity is acquired by adjusting network parameters (e.g., connection weights) to realize some behaviours—training set—while generalizing to others—test set. Learning also requires *ad hoc* assumptions, because even widely used learning models, such as feedforward (Rumelhart, Hinton, & Williams, 1986) and simple recurrent networks (Elman, 1990), fail to achieve systematicity (Marcus, 1998; Phillips, 2000) when construed as a degree of generalization (Hadley, 1994; Niklasson & Gelder, 1994). Hence, neither Classical nor Connectionist proposals satisfy the explanatory standard laid out by Aizawa, or Fodor and Pylyshyn for that matter.

Our category-theory based approach addresses the problem of *ad hoc* assumptions because the concept of an adjunction, which is central to our argument, ensures that the construct we seek (a) exists, and (b) is unique. That is to say, from this core assumption and category theory principles, the systematicity property necessarily follows for the particular cognitive domains of interest, because in each case the one and only collection of cognitive capacities derived from our theory is the systematic collection, without further restriction by additional (*ad hoc*) assumptions.

Basic category theory

Category theory is a theory of structure *par excellence* (see Awodey, 2006; Mac Lane, 2000, for introductions). It was developed out of a need to formalize commonalities between various mathematical structures (Eilenberg & Mac Lane, 1945), and has been used extensively in computer science for the analysis of computation (see, e.g., Pierce, 1991; Walters, 1991). Yet, applications to cognitive psychology have been almost non-existent (but, see Halford & Wilson, 1980; Phillips, Wilson, & Halford, 2009, for two examples). Our explanation of systematicity with respect to binary relational propositions is based on the concept of an *adjunction*. In this section, we provide definitions of this and other formal concepts that it depends.

Category

A *category* \mathbf{C} consists of a class of objects $|\mathbf{C}| = (A, B, \dots)$; a set $\mathbf{C}(A, B)$ of morphisms (also called arrows, or maps) from A to B where each morphism $f : A \rightarrow B$ has A as its domain and B as its codomain, including the *identity* morphism $1_A : A \rightarrow A$ for each object A ; and a composition operation, denoted “ \circ ”, of morphisms $f : A \rightarrow B$ and $g : B \rightarrow C$, written $g \circ f : A \rightarrow C$ that satisfy the laws of:

- *unity*, where $f \circ 1_A = f = 1_B \circ f$, for all $f : A \rightarrow B$; and
- *associativity*, where $h \circ (g \circ f) = (h \circ g) \circ f$, for all $f : A \rightarrow B$, $g : B \rightarrow C$ and $h : C \rightarrow D$.

The most familiar example of a category is **Set**, which has sets for objects and functions for morphisms, where the identity morphism 1_A is the identity function and the composition operation is the usual function composition operator “ \circ ”.

A morphism $f : A \rightarrow B$ is an *isomorphism* if there exists a $g : B \rightarrow A$, such that $g \circ f = 1_A$ and $f \circ g = 1_B$. In this case, A is said to be isomorphic to B , written $A \cong B$.

Product

A *product* of two objects A and B in a category \mathbf{C} is an object P together with two morphisms $p_1 : P \rightarrow A$ and $p_2 : P \rightarrow B$, such that for any pair of morphisms $z_1 : Z \rightarrow A$ and $z_2 : Z \rightarrow B$, there is a unique morphism $u : Z \rightarrow P$, such that the following diagram commutes:

$$\begin{array}{ccc} & Z & \\ z_1 \swarrow & | & \searrow z_2 \\ A & \xleftarrow{p_1} P \xrightarrow{p_2} & B \end{array} \quad (1)$$

where a broken arrow indicates that there exists exactly one morphism making the diagram commute. That is, the compositions along any two paths with the same start object and the same finish object are the same. So, in this diagram, $z_1 = p_1 \circ u$ and $z_2 = p_2 \circ u$, where p_1 and p_2 are sometimes called projection morphisms. A product object P is *unique up to a unique isomorphism*. That is, for any other product object P' with morphisms $p'_1 : P' \rightarrow A$ and $p'_2 : P' \rightarrow B$ there is one and only one isomorphism between P and P' that makes a diagram like this one commute. Hence, P is not unique, only unique with respect to another product object via isomorphism. In **Set**, P is (up to isomorphism) the Cartesian product $A \times B$, $p_1 : A \times B \rightarrow A$, $p_2 : A \times B \rightarrow B$, where p_1 and p_2 are the projection maps to A and B , i.e., $p_1 : (a, b) \mapsto a$, and $p_2 : (a, b) \mapsto b$, and u is the function $\langle z_1, z_2 \rangle : Z \rightarrow A \times B$, sending x to tuple $(z_1(x), z_2(x))$, so that $p_1 \circ u = z_1$ and $p_2 \circ u = z_2$. (The \mapsto arrow, often read as “maps to”, indicates the action of a function on a domain element. Thus $f(a) = b$ is equivalent to $f : a \mapsto b$.) Since u is uniquely determined by z_1 and z_2 , u is often written as $\langle z_1, z_2 \rangle$, and the diagram used in defining a product then becomes

$$\begin{array}{ccc} & Z & \\ z_1 \swarrow & | & \searrow z_2 \\ A & \xleftarrow{p_1} A \times B \xrightarrow{p_2} & B \end{array} \quad (2)$$

Functor

A functor $F : \mathbf{C} \rightarrow \mathbf{D}$ is a structure-preserving map between categories \mathbf{C} and \mathbf{D} that associates each object A in \mathbf{C} to an object $F(A)$ in \mathbf{D} ; and each map $f : A \rightarrow B$ in \mathbf{C} to a map

$F(f) : F(A) \rightarrow F(B)$ in \mathbf{D} , such that $F(1_A) = 1_{F(A)}$ for each object A in \mathbf{C} ; and $F(g \circ_C f) = F(g) \circ_D F(f)$ for all maps $f : A \rightarrow B$ and $g : B \rightarrow C$ for which compositions \circ_C and \circ_D are defined in categories \mathbf{C} and \mathbf{D} , respectively. The object and arrow components of a functor are sometimes explicitly distinguished as F_0 and F_1 , respectively. Otherwise, the functor component is implicitly identified by its argument.

Functor composition and isomorphism are defined analogously to maps (above). That is, the composition of functors $F : \mathbf{C} \rightarrow \mathbf{D}$ and $G : \mathbf{D} \rightarrow \mathbf{E}$ is the functor $G \circ F : \mathbf{C} \rightarrow \mathbf{E}$, sending all objects A in \mathbf{C} to objects $G \circ F(A)$ in \mathbf{E} ; and maps $f : A \rightarrow B$ in \mathbf{C} to maps $G \circ F(f) : G \circ F(A) \rightarrow G \circ F(B)$, such that identity and composition are respected. That is, $G \circ F(1_A) = 1_{G \circ F(A)}$; and $G \circ F(g \circ_C f) = (G \circ F(g)) \circ_E (G \circ F(f))$. A functor $F : \mathbf{C} \rightarrow \mathbf{D}$ is an *isomorphic functor*, if and only if there exists a functor $G : \mathbf{D} \rightarrow \mathbf{C}$ such that $G \circ F = 1_{\mathbf{C}}$ and $F \circ G = 1_{\mathbf{D}}$, where $1_{\mathbf{C}}$ and $1_{\mathbf{D}}$ are the identity functors sending objects and maps to themselves in the respective categories.

Natural transformation

A *natural transformation* $\tau : F \rightarrow G$ is a structure-preserving map from domain functor $F : \mathbf{C} \rightarrow \mathbf{D}$ to codomain functor $G : \mathbf{C} \rightarrow \mathbf{D}$ that consists of \mathbf{D} -maps τ_A for each object A in \mathbf{C} , such that $G(f) \circ \tau_A = \tau_B \circ F(f)$, as indicated by the following commutative diagram in the category \mathbf{D} :

$$\begin{array}{ccc} F(A) & \xrightarrow{\tau_A} & G(A) \\ F(f) \downarrow & & \downarrow G(f) \\ F(B) & \xrightarrow{\tau_B} & G(B) \end{array} \quad (3)$$

A natural transformation is a *natural isomorphism*, or *natural equivalence* if and only if each τ_A is an isomorphism. That is, for each $\tau_A : F(A) \rightarrow G(A)$ there exists a $\tau_A^{-1} : G(A) \rightarrow F(A)$ such that $\tau_A^{-1} \circ \tau_A = 1_{F(A)}$ and $\tau_A \circ \tau_A^{-1} = 1_{G(A)}$. Natural transformations also compose, and the composition of two natural transformations is also a natural transformation.

Adjunction

An *adjunction* consists of a pair of functors $F : \mathbf{C} \rightarrow \mathbf{D}$, $G : \mathbf{D} \rightarrow \mathbf{C}$ and a natural transformation $\tau : 1_{\mathbf{C}} \rightarrow (G \circ F)$, such that for every \mathbf{C} -object X and every \mathbf{C} -map $f : X \rightarrow G(Y)$ there exists a unique \mathbf{D} -map $g : F(X) \rightarrow Y$, such that the following diagram commutes:

$$\begin{array}{ccc} X & \xrightarrow{\tau_X} & G(F(X)) \\ f \searrow & & \downarrow G(g) \\ & & G(Y) \end{array} \quad \begin{array}{ccc} F(X) & & \\ \downarrow g & & \\ Y & & \end{array} \quad (4)$$

where the functors are implicitly identified by (co)domain categories \mathbf{C} (left subdiagram) and \mathbf{D} (right subdiagram). The two functors are called an *adjoint pair*, (F, G) , where F is the *left adjoint* of G , and G is the *right adjoint* of F ; and natural transformation τ is called the *unit* of the adjunction.

Category theory explanation: Adjoint functors

We develop our adjoint functors explanation of systematicity in three movements. First, we show that a categorical product provides an account of systematicity of representation and systematicity of inference. However, a product of two objects may afford many isomorphic product objects that do not also account for compositionality of representation. Second, we show that the product functor provides the principled means for constructing only those products that also have the compositionality of representation property. However, there may be more than one product that has the compositionality property, but differs in semantic content by having different syntactic relationships between identical sets of constituents. So, a principled choice is needed to determine *the* product. Third, we show that the diagonal functor, which is left adjoint to the product functor, provides that principled choice. For concreteness, we refer to the category **Set**, but our explanation does not depend on this category.

First, suppose objects A (say, agents) and B (patients) are sets containing representations of John and Mary, denoted as $\{J, M\}$. Although A and B are the same set in this example they may not be in the general case. Since our argument does not depend on equality, we maintain distinct names for generality, and for conceptual clarity. A categorical product of these two sets is the Cartesian product of A and B , which is the set of all pairwise combinations of elements from A and B , together with maps p_1 and p_2 for retrieving the first and second constituent in each case. That is, $A \times B = \{(J, J), (J, M), (M, J), (M, M)\}$, $p_1 : (a, b) \mapsto a$, and $p_2 : (a, b) \mapsto b$. By definition, the Cartesian product, $A \times B$, generates all pairwise combinations of elements from A and B , therefore the Cartesian product has the systematicity of representation property. Moreover, by definition, the categorical product, $(A \times B, p_1, p_2)$, affords the retrieval of each constituent from each representation (otherwise it is not a product), therefore the categorical product also has the systematicity of inference property. In this case, Z from the categorical product definition takes the role of input, so inferring John as the lover from John loves Mary is just $z_1(JM) = p_1 \circ u(JM)$, where JM is the input and u is the input-to-product object map, whose unique existence is guaranteed.

The Cartesian product, however, is not the only product object that satisfies the definition of a categorical product of A and B . An alternative product has $P = \{1, 2, 3, 4\}$ as the product object, and $p'_1 : 1 \mapsto J, 2 \mapsto J, 3 \mapsto M, 4 \mapsto M$ and $p'_2 : 1 \mapsto J, 2 \mapsto M, 3 \mapsto J, 4 \mapsto M$ as the projections. However, this alternative does not have the compositionality of representation property: the semantic contents of these representations, whatever they may be, are not systematically related to each other, or the semantic content of John, or Mary. Hence, categorical products, in themselves, are not sufficient for an explanation of systematicity.

Second, for any category \mathbf{C} that has products (i.e. every pair of objects in \mathbf{C} has a product), one can define a product functor $\Pi : \mathbf{C} \times \mathbf{C} \rightarrow \mathbf{C}$, that is from the Cartesian

product of categories, $\mathbf{C} \times \mathbf{C}$, itself a category, to \mathbf{C} , where $\Pi_0 : (A, B) \mapsto A \times B$, $\Pi_1 : (f, g) \mapsto f \times g$, as indicated by the following diagram:

$$\begin{array}{ccc} (A, B) & \xrightarrow{\Pi_0} & A \times B \\ (f, g) \downarrow & & \downarrow f \times g \\ (C, D) & \xrightarrow{\Pi_0} & C \times D \end{array} \quad (5)$$

omitting $\Pi_1 : (f, g) \mapsto f \times g$ for clarity. In this case, the semantic contents of these elements are systematically related to each other and their constituents John and Mary. This categorical construction is an instance of Classical compositionality, whereby the constituents $a_i \in A, b_j \in B$ are tokened whenever the compositions $(a_i, b_j) \in A \times B$ are tokened. As such, it has the compositionality of representation property.

Although the product functor explanation accounts for compositionality of representation, it introduces a new problem: $(B \times A, p'_2, p'_1)$, where $p'_2 : (b, a) \mapsto a$ and $p'_1 : (b, a) \mapsto b$ is also a valid product, but the semantic content of (a, b) is not the same as (b, a) . That is because they have different order relationships between their constituents even though the corresponding constituents are identical. Thus, a principled choice is required to determine whether, for example, John loves Mary should map to $(\text{John}, \text{Mary})$, or $(\text{Mary}, \text{John})$. Otherwise, one can define an architecture that does not have the systematicity of inference property by employing both products to correctly infer John as the lover in John loves Mary via $(A \times B, p_1, p_2)$, yet incorrectly infer John as the lover in Mary loves John via $(B \times A, p'_2, p'_1)$, where position within the product triple identifies the relevant projection. The assumption that architectures employ only the first product is *ad hoc* just like the assumption that Classical architectures employ grammars such as G1, but not G2. So, a principled choice is needed to determine *the* product.

Third, and finally, the left adjoint to the product functor is the *diagonal* functor $\Delta : \mathbf{C} \rightarrow \mathbf{C} \times \mathbf{C}$, where $\Delta_0 : A \mapsto (A, A)$, $\Delta_1 : f \mapsto (f, f)$ as indicated by the following diagram:

$$\begin{array}{ccc} A & \xrightarrow{\Delta_0} & (A, A) \\ f \downarrow & & \downarrow (f, f) \\ B & \xrightarrow{\Delta_0} & (B, B) \end{array} \quad (6)$$

The (diagonal, product) adjoint pair is indicated by the following commutative diagram:

$$\begin{array}{ccc} C & \xrightarrow{\tau_C = \langle 1_C, 1_C \rangle} & C \times C \\ & \searrow \langle s, t \rangle & \downarrow s \times t \\ & & M \times N \end{array} \quad \begin{array}{ccc} (C, C) & & \\ \downarrow (s, t) & & \\ (M, N) & & \end{array} \quad (7)$$

(see Pierce, 1991, Example 2.4.6). In this manner, the John loves Mary family of cognitive capacities is specified by the

commutative diagram

$$\begin{array}{ccc}
 Pr & \xrightarrow{\langle 1_{Pr}, 1_{Pr} \rangle} & Pr \times Pr & (Pr, Pr) \\
 & \searrow \langle ag, pt \rangle & \downarrow ag \times pt & \downarrow (ag, pt) \\
 & & S \times S & (S, S)
 \end{array} \quad (8)$$

where ag and pt are the *agent* and *patient* maps from the set of proposition inputs Pr into the set $S \supseteq A \cup B$ containing all the possible constituent representations. Given $\langle ag, pt \rangle$ as the morphism used by the architecture to map proposition inputs to their corresponding internal representations, then as mentioned (Introduction) the definition of an adjunction guarantees that $ag \times pt$ is unique with respect to making Diagram 8 commute. That is, $ag \times pt \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{JM}) = ag \times pt(\mathcal{JM}, \mathcal{JM}) = (\text{John}, \text{Mary}) = \langle ag, pt \rangle(\mathcal{JM})$, where \mathcal{JM} is the input for proposition John loves Mary. The alternative construction $pt \times ag$ is excluded because $pt \times ag \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{JM}) = pt \times ag(\mathcal{JM}, \mathcal{JM}) = (\text{Mary}, \text{John}) \neq (\text{John}, \text{Mary}) = \langle ag, pt \rangle(\mathcal{JM})$. Having excluded $pt \times ag$ by the commutativity property of the adjunction, the only two remaining ways to map the other inputs (i.e., $\langle ag, pt \rangle$ and $ag \times pt \circ \langle 1_{Pr}, 1_{Pr} \rangle$) are equal. So, given that the architecture can represent John loves Mary as $(\text{John}, \text{Mary})$ via $\langle ag, pt \rangle$ and infer John as the lover via p_1 from the product $(A \times B, p_1, p_2)$, then necessarily it can represent Mary loves John and infer Mary as the lover using the same maps. That is, $p_1 \circ \langle ag, pt \rangle(\mathcal{MJ}) = p_1(\text{Mary}, \text{John}) = \text{Mary}$, or $p_1 \circ ag \times pt \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{MJ}) = p_1 \circ ag \times pt(\mathcal{MJ}, \mathcal{MJ}) = p_1(\text{Mary}, \text{John}) = \text{Mary}$.

This explanation works regardless of whether proposition John loves Mary is represented as $(\text{John}, \text{Mary})$ via $\langle ag, pt \rangle$, or $(\text{Mary}, \text{John})$ via $\langle pt, ag \rangle$. In the latter case, the adjunction picks out the construction $pt \times ag$, because it is the one and only one that makes the following diagram commute:

$$\begin{array}{ccc}
 Pr & \xrightarrow{\langle 1_{Pr}, 1_{Pr} \rangle} & Pr \times Pr & (Pr, Pr) \\
 & \searrow \langle pt, ag \rangle & \downarrow pt \times ag & \downarrow (pt, ag) \\
 & & S \times S & (S, S)
 \end{array} \quad (9)$$

$pt \times ag \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{JM}) = pt \times ag(\mathcal{JM}, \mathcal{JM}) = (\text{Mary}, \text{John}) = \langle pt, ag \rangle(\mathcal{JM})$, but $ag \times pt \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{JM}) = ag \times pt(\mathcal{JM}, \mathcal{JM}) = (\text{John}, \text{Mary}) \neq (\text{Mary}, \text{John}) = \langle pt, ag \rangle(\mathcal{JM})$. Given that the architecture can represent John loves Mary as $(\text{Mary}, \text{John})$ via $\langle pt, ag \rangle$ and infer John as the lover via p'_2 from the product $(B \times A, p'_2, p'_1)$, then necessarily it can do so for Mary loves John using the same maps. That is, $p'_2 \circ \langle pt, ag \rangle(\mathcal{MJ}) = p'_2(\text{John}, \text{Mary}) = \text{Mary}$, or $p'_2 \circ pt \times ag \circ \langle 1_{Pr}, 1_{Pr} \rangle(\mathcal{MJ}) = p'_2 \circ pt \times ag(\mathcal{MJ}, \mathcal{MJ}) = p'_2(\text{John}, \text{Mary}) = \text{Mary}$.

Importantly, the unit of the adjunction, $\langle 1_{Pr}, 1_{Pr} \rangle$, is not a *free parameter* of the explanation; it defines the adjunction. Also, there is no choice in representational format (i.e. left-right, or right-left constituent order)—the given capacity to represent a proposition fixes the same order for all the

other propositions. Hence, systematicity is a necessary consequence of this adjoint pair without recourse to additional (*ad hoc*) assumptions, and so meets the explanatory standard set by Aizawa, and Fodor and Pylyshyn.

Explanatory levels: n -category theory

A generalization of category theory, called n -category theory (see Leinster, 2003) is used to formally contrast our category theory explanation against Classical and Connectionist approaches. Notice that the definitions of functor and natural transformation are very similar. In fact, they are morphisms at different levels of analysis. For n -category theory, a category such as **Set** is a 1-category, with 0-objects (i.e. sets) for objects and 1-morphisms (i.e. functions) for arrows. A functor is a morphism between categories. The category of categories, **Cat**, has categories for objects and functors for arrows. Thus, a functor is a 2-morphism between 1-objects (i.e. 1-categories) in a 2-category. A natural transformation is a morphism between functors. The functor category, **Fun**, has functors for objects and natural transformations for arrows. Thus, a natural transformation is a 3-morphism between 2-objects (i.e. functors) in a 3-category. (A 0-category is just a *discrete* category, where the only arrows are identities, which are 0-morphisms.) In this way, the order n of the category provides a formal notion of explanatory level.

Classical or Connectionist compositionality is essentially a lower levels attempt to account for systematicity. For the examples we used that level is perhaps best described in terms of a 1-category. Indeed, a context-free grammar defined by a graph is modeled as the *free* category on that graph containing sets of terminal and non-terminal symbols for objects and productions for morphisms (Walters, 1991). By contrast, our category theory explanation involves higher levels of analysis, specifically functors and natural transformations, which live in 2-categories and 3-categories, respectively. Of course, one can also develop higher-order grammars that take as input or return as output other grammars. Similarly, one can develop higher-order networks that take as input or return as output other networks. However, the problem is that neither Classical nor Connectionist compositionality delineates those (higher-order) grammars or networks that have the systematicity property from those that do not.

Discussion

In addition to explaining systematicity, our category theory approach has further implications. According to our explanation, systematicity with respect to binary relational propositions requires a category with products. Phillips et al. (2009) also provided a category theory account of the strikingly similar profiles of development for a suite of reasoning abilities that included *Transitive Inference* and *Class Inclusion*, among others—all abilities are acquired around the age of five years. The difference between the failures of younger children and the successes of older children (relative to age five) across all these reasoning tasks was explained as their capacity to compute (co)products. (A *coproduct* is related to a product

by arrow reversal—see, e.g., Pierce, 1991, for a formal definition.) Therefore, our explanation implies that systematicity is not a property of younger children's cognition. Some support for this implication is found on memory tasks that require binding the background context of memorized items (Lloyd, Doydum, & Newcombe, 2009), though further work is needed to test this implication directly.

Our explanation does not depend on **Set**, it only requires a category with products. For example, the categories **Top** of topological spaces and continuous mappings, and **Vec** of vector spaces and linear mappings (see, e.g., Awodey, 2006) could also be used. These possibilities imply that an explanation of systematicity does not depend on a particular (discrete symbolic, or continuous subsymbolic) representational format. Thus, a further benefit is that our approach opens the way for integration of other (sub/symbolic) levels of analysis.

For reasons of space, we have only sketched our category theory approach to systematicity. More detailed explanation and justification are given in Phillips and Wilson (in prep.), where we also address other examples of systematicity, such as multiple relations, and relational schemas. In our approach, we have not dealt with domains that are quasi-systematic, which appear to be particularly prevalent in language (see Johnson, 2004). For these cases, we would also need category theory-derived principled restrictions to products. *Pullbacks* (see Phillips, Wilson, & Halford, 2009, for an application to cognitive development) are one way to restrict product objects, in the same arrow-theoretic style.

From a category theory perspective, we now see why cognitive science lacked a satisfactory explanation for systematicity—cognitive scientists were working with lower-order theories in attempting to explain an essentially higher-order property. Category theory offers a re-conceptualization for cognitive science, analogous to the one that Copernicus provided for astronomy, where representational states are no longer the center of the cognitive universe—replaced by the relationships between the maps that transform them.

The Effect of Word-internal Properties on Syntactic Categorization: A Computational Modeling Approach

Abstract

We study the acquisition of abstract syntactic categories of words in children by using a computational model of categorization. Especially, we examine the effect of word-internal properties, such as morphological and phonological cues, on the identification of different categories, such as nouns, verbs, and determiners. To evaluate our model, we use it to determine the syntactic category of actual novel words selected from naturalistic child-directed utterances. We argue that such an evaluation is necessary for a better understanding of the effect of different cues (including word-internal properties and contextual cues) on category acquisition.

Keywords: Computational modeling, Syntactic category learning.

Introduction

Infants have a good understanding of the syntactic categories of words long before attending school. Psychological observations at different stages of child language development have shown the ability of children to recognize abstract (syntactic or semantic) categories, such as verb and noun, countable and uncountable (Brown, 1957; Gelman & Taylor, 1984; Samuelson & Smith, 1999). A variety of proposals exist in the psycholinguistics literature regarding the types of cues that are informative about such word categories, and the way children may use them to learn the categories. Computational modeling has often been used as a powerful tool to shed light on many aspects of language acquisition, including word categorization (Pearl, 2009). In this study, we draw on an existing categorization model in order to achieve a better understanding of the mechanisms and the information sources children use during the acquisition of syntactic categories, such as verbs and nouns.

Syntactic category learning in children has been suggested to be based on several information sources, such as word-external properties including distributional information about neighboring (co-occurring) words, as well as word-internal properties such as phonological and morphological cues (e.g., Brown, 1957; Gerken et al., 2005; Monaghan et al., 2007). Many of the computational studies on syntactic category acquisition focus on showing the relevance of the above properties to the acquisition of adult-like, linguistically-salient categories, such as verbs, nouns, and adjectives. For example, Mintz (2003), Monaghan et al. (2007) and Onnis and Christiansen (2008) present analyses of child-directed data to determine whether there are correspondences between particular syntactic categories and certain types of cues. Moreover, most of the existing computational models of child category

learning lack cognitive plausibility in some respects: The categorization models proposed by Schütze (1993), Redington et al. (1998), and Clark (2003) incorporate a batch (non-incremental) clustering algorithm; The connectionist model of Onnis and Christiansen (2008) is minimally supervised, assumes a fixed number of categories, and can only be used to study words in isolation.

A few studies have introduced cognitively-plausible models for syntactic category learning (Cartwright & Brent, 1997; Parisien et al., 2008; Alishahi & Chrupała, 2009). These incorporate fully-unsupervised incremental algorithms for clustering words as they appear in naturally-occurring utterances. However, these studies have focused solely on the role of context (co-occurring words) for inferring the syntactic category of a target word, and have overlooked the importance of other sources of information, such as phonology and morphology.

In our modeling of syntactic category acquisition, we address some of the aforementioned shortcomings. Specifically, we choose a simple incremental clustering algorithm (one proposed by Alishahi & Chrupała, 2009), which we further modify to increase simplicity. In addition, we examine the role of word-external information sources (namely, word co-occurrence), as well as that of word-internal sources (namely, phonology, and morphology) in order to better understand the interactions among these types of cues on the acquisition of syntactic categories. We use only very simple cues that are known to be accessible by children early in their language development. Finally, we propose and use a novel evaluation framework to examine the role of each type of information in the acquisition of syntactic categories.

Results of our experiments on naturally-occurring English child-directed utterances indicate that different cues are useful for the identification of different classes of words. In particular, we find that the identity of the word is essential to the identification of closed-class words. Open-class words, however, share similarities with respect to other types of cues, both word-external and word-internal. Nonetheless, even among these classes, different categories seem to be identified based on different properties: whereas verbs are better categorized with the help of morphological and phonological properties, co-occurrence information alone is reliable for categorizing nouns.

Algorithm 1: Incremental word clustering

```

1: initialize set of clusters  $\mathcal{K} = \emptyset$ 
2: for every frame  $f$  do
3:    $C_M = \operatorname{argmax}_{C \in \mathcal{K}} \operatorname{Sim}(f, C)$ 
4:   if  $\operatorname{Sim}(f, C_M) \geq \theta$  then
5:     Add frame  $f$  to cluster  $C_M$ 
6:   else
7:     Construct a new cluster for frame  $f$ 
8:   end if
9: end for

```

(This algorithm is a modification of the one proposed by Alishahi & Chrupała, 2009).

Modeling the acquisition of syntactic categories

Our goal is to build a computational model of syntactic categorization that is cognitively plausible, i.e., we make as few assumptions as possible about the type of cues accessible to young children, and about the mechanisms children might use for categorization. We thus use an adaptation of a simple incremental algorithm proposed by Alishahi and Chrupała (2009), which forms categories simply by drawing on the similarity among words to be categorized. Here, we present an overview of our adaptation of the algorithm, and a description of three types of cues we use for categorization.

The categorization algorithm

The unsupervised clustering algorithm proposed by Alishahi and Chrupała (2009) works based on contextual similarities among words. The algorithm is incremental in that it processes words one by one, discarding each word after clustering. For each newly-observed *frame* (a target *head-word* along with its neighboring words from left and right), if the similarity to all of the already-shaped clusters is less than a predefined threshold, a new cluster is constructed. Otherwise, the word is assigned to the most similar cluster. We modify this algorithm in two ways: (i) the original algorithm of Alishahi and Chrupała includes a phase in which clusters are merged if they are sufficiently similar. To keep the algorithm simple, we removed this step; (ii) our frames are composed of three different types of *features* (five features in total besides the head-word content; see next subsection for details). We thus need to slightly modify the similarity score calculation in order to accommodate for more than one set of features. The similarity between a frame and a cluster (a group of frames) is calculated as in:

$$\operatorname{Sim}(f, C) = \sum_{i \in \mathcal{F}} \omega_i * \operatorname{Sim}_i(f, C) \in \mathcal{F} \quad (1)$$

where f is a frame, C is a cluster, i is a feature, \mathcal{F} is the set of all features, $\operatorname{Sim}_i(f, C)$ is the similarity of frame f to cluster C with respect to the i^{th} feature, and ω_i determines the weight of the contribution of feature i in determining the overall similarity. Weights for all features need to sum to 1, i.e., $\sum_i \omega_i = 1$. The modified version of the algorithm is shown in Algorithm 1.

Cues used for categorization

As previously mentioned, children are known to group words into syntactic categories by drawing on a number of different information sources. In our work, we include three different sources of information, and five types of cues (features) in total, as explained below:¹

- **Distributional information about word co-occurrences:** This kind of information has been reported to be reliable and very important in syntactic categorization (Schütze, 1993; Redington et al., 1998; Mintz, 2003; Clark, 2000; Parisien et al., 2008; Alishahi & Chrupała, 2009). We take one word from each side of a target head-word as its co-occurrence features, because in many of the above studies words closer to a word have been shown to be more informative about its category. For example, considering sentences, such as “There is a cat in the basket”, and “We need a table in our kitchen”, “A cat is in the basket”, and “A table is in the kitchen.” provides a clue to the model to group *cat* and *table* together since they share similar co-occurrence features. In our framework, each co-occurring word is considered as an independent feature when determining similarity between a word (frame) and a cluster (as in many previous studies, and in contrast to representations such as “frequent frames” of Mintz, 2003). For example, even if the two tokens *cat* and *table* did not share the preposition *in*, they would still be considered as similar because of the preceding determiner *a* they have in common.
- **Phonological information:** Words belonging to the same syntactic category tend to have common phonological properties. For example, looking at child-directed utterances, (Monaghan et al., 2007) show that verbs and nouns are different with respect to several phonological features, including the number of syllables. The study of Monaghan et al. focuses on the relevance of syntactic categories and a large number of word-level, syllable-level, and phoneme-level phonological properties. We focus here on two of the simplest word-level phonological properties that we assume are readily accessible by young children, namely the length of a word in terms of number of syllables and phonemes (we use the number of letters to approximate the number of phonemes in a word).
- **Morphological information:** It has been shown that English affixes, such as *-ing* in verbs, can provide strong clues to the identification of syntactic categories, and that such information is abundant in child-directed speech (Onnis & Christiansen, 2008). Nonetheless, it is not clear whether we can assume that children have access to such accurate morphological knowledge about words and categories prior to syntactic category learning. Inspired by the work

¹In this study, we do not consider one other important source of information for learning of syntactic categories, namely, semantic information about words. This type of information requires making assumptions about what *meaning* is and how children may represent it, and hence is outside the scope of this study.

of Onnis and Christiansen (2008), here we use the last phoneme (ending) of the words as an approximation of the morphological affixes.²

Overall, we include six different features (cues) in our categorization: two Cooc features, Head word, two Phon features, and one Morph feature. The Cooc cues are considered as properties external to the word (properties of the context the word appears in), whereas the rest are related to the word itself and hence are considered as word-internal cues. In our experiments, we examine the effect of each different type of cue on categorization, and also consider the role of word-internal cues versus external ones.

Experimental Setup

Corpus

We extract our input data (both for training and testing) from the Manchester corpus (Theakston et al., 2001), one of the English subsets in the CHILDES database (MacWhinney, 2000). The Manchester corpus contains conversations of parents/caregivers with 12 British children between the ages of 1;8 (years;months) and 3;0.³ For training, we choose around 10000 child-directed utterances from the conversations of all 12 children, such that the chronological order of the utterances is maintained, and the utterances contain only words selected from a limited vocabulary of 500 words. When selecting the 500 words, we make sure that their distribution in the corpus matches a Zipfian distribution, so that our results are not biased towards words from certain frequency ranges. We limit the size of vocabulary because some feature values need to be determined manually. In addition, in one experimental task, we need access to actual novel words not previously seen in the training corpus, as opposed to made-up novel words used in many psychological experiments.

We use two different test corpora, one for each experimental task (as explained in the Evaluation subsection below). The first set of test data (used in the Word Category Prediction Task) is selected exactly as the training data, though from a non-overlapping portion of the original (Manchester) corpus. The other test data (used in the Novel Word Categorization Task) is selected such that the target words to be categorized are a novel word not in the vocabulary of 500 words. This second test set is similar to the training data in all other aspects. Each test corpus contains 2000 word usages (tokens to be categorized).

Feature Extraction

From each utterance (in the training or test data), we extract a number of frames to be clustered. As explained previously,

²We also included the first phoneme (beginning) of a word as also done by Onnis and Christiansen (2008). However, in our initial evaluations we found that the inclusion of this feature did not affect the results, and hence removed it from our set of features.

³Thanks to Chris Parisien for providing us with a preprocessed version of this corpus.

Head:	<i>table</i>	Cooc:	<i>a, in</i>
Phon:	2, 5	Morph:	<i>l</i>

Figure 1: Sample frame extracted for the target word *table* from the utterance “We need a *table* in the kitchen”.

each frame contains a head word (the target word to be categorized), as well as several other features (two Cooc, two Phon, and one Morph features). A sample frame is shown in Figure 1. The head word and the Cooc features can be directly extracted from the utterance. If any of the Cooc features are missing (i.e., the target word is the first or the last word of the utterance), that feature is set to “Unknown”. For the two other types of features (Phon and Morph) we need to have access to a phonemic representation of words and other phonological features. We extract two of these features (the ending phoneme, and the number of syllables) from the MRC Psycholinguistic Database, a publicly available resource built for use in studies on child language (Wilson, 1988).⁴ If a word is not found in MRC, we set the values of the above features manually. For the third feature, the number of phonemes in a word, we use the number of letters as an approximation.

Evaluation

To examine the contribution of different types of cues on syntactic categorization, we evaluate the effectiveness of clusters resulting from one or a combination of features in two tasks. Specifically, we train our model (on the training corpus) in three different conditions, that is, using one of the following feature combinations: Head+Cooc, Head+Cooc+Morph, Head+Cooc+Phon. We then determine the effectiveness of the resulting clusters in each condition by examining the performance of the model on inferring the category of a number of test words. Note that the model does not create any new clusters during the test phase, but assigns each word to one of the clusters formed in the training phase.

We evaluate our model using two experimental tasks: one is to predict the syntactic category of a word whose identity is known to the model/learner; the other one is to infer the syntactic category of a novel (previously-unseen) word. In the word category prediction task (Experiment 1) the Head of a frame is considered as a feature, whereas it is not included in the task of novel word categorization (Experiment 2). More details on each of these tasks is given in the following section.

Note that the resulting categories do not necessarily need to match the conventional adult-like categories put forth by linguists. Nonetheless, as a first-line evaluation, here we compare the categories learned by our model to a gold-standard set of syntactic categories. To measure test performance, we must compare the ‘true’ syntactic category of each test word (according to the gold-standard) to the label of its associated cluster. We thus need to label each cluster with a syntactic category. Words in the Manchester corpus are tagged with their parts of speech according to a fine-grained tag set. For

⁴<http://www.psych.rl.ac.uk/>

our evaluation, we use a coarse-grained version of this original tagging (also used by Parisien et al., 2008), including 11 tags, namely: Noun, Verb, Adjective, Adverb, Determiner, Negation, Infinitive, Auxiliary, Conjunction, Preposition, and Others. Each cluster is assigned the majority label among all its members. E.g., a cluster containing 30 nouns, 90 verbs, and 20 adjectives is labeled as Verb.

Test performance is measured using *Accuracy*: the proportion of test words assigned to their correct category. We also look into the accuracy for different groups of words, such as Verbs and Nouns, as well as open-class and closed-class words.

Model Parameters

Our model contains two sets of parameters: the weights ω_i used for measuring the similarity of a frame to a cluster (in Eqn 1), and a similarity threshold θ used for deciding whether to create a new cluster for a given frame. We set the weights ω_i uniformly, giving equal weights to all features. The value of θ affects the number of generated clusters: a low value increases the likelihood of grouping words, hence decreasing the total number of clusters. We set this parameter to different values for different experimental conditions (i.e., different combinations of features), so that we maintain the total number of clusters generated in each condition within a desired range.

We use two different ways of measuring $Sim_i(f, C)$ in Eqn 1 depending on feature i . For categorical features (Head, Cooc, Morph) we use the cosine of the vectors (widely used for similar clustering algorithms). A vector representing a categorical feature such as Head is of the size of word types in the corpus. E.g., for a sample frame f this vector includes 0 in all elements except where the value of Head in that frame is presented. For numerical features (Phon) we use the Euclidean distance.

Experimental Results

Experiment 1: Word Category Prediction

Recall that to determine the effect of different types of cues (Head, Cooc, Phon, Morph) in the acquisition of syntactic categories, we train our model in three conditions (i.e., using three combinations of features, namely Head+Cooc, Head+Cooc+Phon, and Head+Cooc+Morph). In Experiment 1, we measure the accuracy of category prediction over a test data containing 2000 known words. Comparing the accuracy of the categorization model across these conditions is fair and meaningful only if the number of clusters are relatively close for all conditions. Generally, allowing a larger number of clusters makes the categorization more conservative (i.e., by forming too many small clusters each containing one or a few word types that are highly similar). Based on our observation, this implicitly affects the test accuracy. Hence, in the training phase for each of the three above-mentioned conditions, we use different values for the similarity threshold θ to obtain approximately similar number of final clusters (i.e.,

Figure 2: %Accuracy of known-word category prediction in three conditions; the total number of clusters constructed during training phase is in the range 258–288.

between 258–288).⁵ This way we maintain one factor (number of clusters) constant, allowing us to focus on the effect of different features involved in categorization.

Results are presented in Figure 2. In each condition, we measure accuracy on all 2000 words (displayed in the figure as the Overall accuracy), as well as for open-class and for closed-class words separately. Since Head is used as a feature in all conditions, for the ease of exposition, the figure refers to the conditions as Cooc, Cooc+Phon, and Cooc+Morph.

Figure 2 shows that the overall categorization accuracy of the model is improved by adding morphological or phonological information, reinforcing that word-internal features are indeed informative about a word’s syntactic category. The best performance is achieved by combining Cooc and Morph features, suggesting that our morphological feature might be more indicative of syntactic category than the phonological features.

Comparing the accuracy on open-class words and on Closed-class words, we can see that in two out of the three conditions (i.e., Cooc and Cooc+Phon), open-class words are better categorized in comparison to closed-class words. This is expected because it is more likely that the word co-occurrence information (which is the main source of information in all conditions) reveals the similarity among open-class (content) words more easily than for closed-class (function) words. As an example, we expect nouns to often appear after a small set of determiner types (e.g., *a*, *an*, *the*), whereas determiners may precede many different nouns, sharing fewer context features.

Previous studies have shown a strong effect for the Head feature in determining a word’s syntactic category (e.g., Chang et al., 2006). It is thus reasonable to compare the over-

⁵We have performed experiments with different ranges of cluster numbers, and found that the general patterns in results are similar. As noted before, we prefer fewer clusters (fewer than our vocabulary size) to allow for generalization. Indeed, we observe that even with 258–288 clusters, the generalization of the model is reasonably good. Since more than 55% of the clusters contain three or more word types.

all performance of our model in the three conditions with that of a simple category learner that uses only the Head feature, which we refer to as the *lex-stat* learner following Chang et al. (2006). For the performance of our model and that of the *lex-stat* learner to be comparable, we must set the similarity threshold so that we end up with around 500 clusters for all conditions (since the *lex-stat* learner constructs a separate cluster for each word type in the vocabulary). Indeed, we find that the overall performance of *lex-stat* (92%; not shown in Figure 2) is better than for Cooc (89%), and is comparable to the other two categorization conditions, Cooc+Phon (92%), and Cooc+Morph (92%). This raises an important question: whether the positive effect we observe here for the addition of Phon and Morph features is a true effect. In other words, since both Phon and Morph features are word-internal, it is possible that their inclusion in categorization increases the contribution of the Head feature in calculating similarity, implicitly giving more weight to the Head feature.

Note that the *lex-stat* learner is a very conservative model with no generalization abilities (since each word type is in its own cluster). Such a model thus fails to properly categorize novel (previously unseen) words. In contrast to such a learner, children have the ability to categorize novel words (even meaningless artificial words made up for experimental purposes), by the help of the context, or based on their morphological properties (Brown, 1957). We thus argue that for a categorization model to reveal the true effect of features such as morphology or phonology, it should be able to generalize well on unseen words. In the second Experiment, we use our three categorization models to determine the category of novel words. We consider actual novel words in this task because we want to draw on word-internal features, e.g., phonological and morphological properties of words.

Experiment 2: Novel Word Categorization

In this task, we use our model (in the three conditions) to categorize 2000 novel words. In such cases, the Head feature is not informative (since test words have not been seen during training), and hence the model has to utilize other sources of information to determine the category of a word. Results are presented in Figure 3. Comparing performance on this Experiment with those on Experiment 1 (Figure 2) shows a substantial decrease in the overall categorization accuracy (note that here Head feature is taken out of consideration). We especially observe a significant drop in performance for closed-class words. This decrease in performance emphasizes the importance of the Head feature for word categorization, particularly in determining the category of closed-class words. This is again an expected result, given our discussion presented in the previous subsection about the weakness of co-occurrence features in categorizing closed-class words.

Comparing results for the conditions shown in Figure 3 reveals that, as in Experiment 1, the use of Morph features does not improve the overall accuracy of categorization. These results are in contrast to the findings of Onnis and Christiansen (2008), who claim that featuring words solely based on their

Figure 3: %Accuracy of novel word categorization in three conditions; the total number of clusters constructed during training phase is in the range 258–288.

(beginning and) ending phonemes results in good categorization. Their approach differs from ours in that they perform a batch processing over child-directed utterances, which allows their model to more easily learn the correspondences between a certain category, e.g., verbs, and endings shared by words from this category, such as *-ing* in *finishing*, *playing*, *reading*. Our model has to learn such correspondences incrementally, and hence is prone to making errors when calculating similarity between a word form such as “finishing” (a verb ending in the suffix *-ing*) and one such as “string” (a noun with a similar ending which is not a suffix but part of the word itself). Such errors in early stages may cause the algorithm to form incoherent clusters in later stages.

Figure 3 also includes the performance of our model (in all three conditions) separately shown for Nouns and Verbs. Although the use of Morph features does not help the overall categorization accuracy, it does seem to be particularly helpful in identifying Verbs. Interestingly, using Cooc features alone results in a better detection of novel nouns, whereas for verbs, other types of information (Morph and Phon) are helpful. Hence, even among open-class words, discovering different categories seems to rely on different types of information. This is supported by the observation that, typically, context words such as determiners mark the appearance of nouns; in contrast, verbs particularly share morphological and phonological properties. Related statistical analysis, such as that of (Monaghan et al., 2007; Clark, 2003) suggest such a complementary contribution of different cues; and moreover, some psychological studies implicitly take this into account when designing their experiments on children (Brown, 1957).

Conclusions

We have used an adaptation of a categorization algorithm proposed by Alishahi and Chrupala (2009) to model the acquisition of syntactic categories (e.g., verbs and nouns) in children, and to examine the effect of different types of cues on this task.

Our novel word categorization task provides a suitable

framework to evaluate the helpfulness of word-external (e.g., context) as well as word-internal features (e.g., morphological and phonological properties), independently from the identity of the word being categorized (head word). For example, our results indicate that categorizing closed-class words strongly relies on the head word. Specifically, these classes of words do not share intra-category similarities (neither contextual nor morpho/phonological similarities), and hence cannot be categorized well only by drawing on such properties. In contrast, open-class words can be successfully categorized based on a combination of word-internal and word-external properties, even without considering the head word.

In a more detailed investigation of the roles of word-external versus word-internal features, we find that verbs are better recognized when phonological and morphological properties are taken into account in addition to the context (co-occurring words). Note that we do not assume a full knowledge of morphology, but instead use word endings as an approximation to word suffixes (as suggested by Onnis & Christiansen, 2008). Interestingly, for nouns, considering only the information about the co-occurring words results in a more accurate categorization. This finding is in contrast to that of Onnis and Christiansen (2008). We argue this difference to be due to the incremental nature of our model.

Evaluating the effect of different cues in word categorization models needs much care. Studies such as those of Parisien et al. (2008) and Alishahi and Chrupała (2009) have reported the capability of co-occurrence information in categorizing words. They include, however, the head word itself as part of their features used for categorization. These studies evaluated the performance of their models on various tasks, such as noun/verb disambiguation, and semantic feature prediction. But they did not provide a comparison between their models and a categorization model that only uses the head word. As shown in our experiments, it is possible to achieve a high accuracy on a task by using such a simple conservative model. The task of novel word categorization that we propose is appropriate for evaluating the ability of a set of categories generated by a model to make generalizations.

In this study, we have shown that different types of cues, e.g., contextual or word-internal properties, provide children with complementary information, each helping with the categorization of a particular group of words. However, our framework is general and can be extended to incorporate other similar features (e.g., other morphological or phonological cues), as well as information about the semantic properties of words.

Abstract

Taking an initial test leads to improved performance on later tests for those previously tested questions. Whether prior testing improves one's ability to answer related questions, however, is less clear, with some results showing impairment for related information, an effect called retrieval-induced forgetting (RIF; e.g., Anderson, Bjork, & Bjork, 1994). Two experiments investigated the use of initial multiple-choice tests on the retention of previously studied prose passages, specifically on the retention of related, but initially nontested information. In both experiments, an incorrect alternative on the initial test served as the correct answer to a related question on the final test. Results demonstrated that the retention of related information can, indeed, be facilitated by initial multiple-choice tests (Experiment 1) and that this benefit is dependant upon using competitive incorrect alternatives (Experiment 2). We discuss how and why our results differ from previous work (e.g., RIF) and address possible educational applications.

Keywords: memory; testing effects; prose passages; RIF

Introduction

Testing is ubiquitous in education. In most cases, teachers use tests to assess how much a student has learned. Similarly, when students self-test (e.g., with flashcards or practice tests), they typically do so in order to assess their current mastery of the to-be-learned materials. Testing, however, can have other benefits that extend beyond evaluation because retrieval modifies memory so as to improve future recall (see Bjork, 1975).

Multiple-Choice Tests in Educational Contexts

Nowhere is the implementation of testing more widespread than in educational contexts, and in such contexts, the use of multiple-choice (MC) tests is very popular. Some concerns exist regarding their use, however. One concern is that MC tests might provide less opportunity for learning than do cued-recall (e.g., short answer) or free-recall (e.g., essay) tests. Indeed, some studies have shown that although initial MC, cued-recall, and free-recall tests all lead to better retention of the tested information, as compared to nontested information, retention of tested information is better after cued-recall or free-recall tests (e.g., Gay, 1980; Kang, McDermott, & Roediger, 2007; McDaniel, Anderson, Morrisette, & Derbish, 2007).

Perhaps the increased difficulty of answering a recall question correctly (versus a similar MC question) accounts for this difference; that is, retrieval, but not necessarily the recognition and selection of a correct answer, modifies memory (e.g., Bjork, 1975; McDaniel & Masson, 1985). We argue, however, that answering an MC question need not be just a matter of recognizing the correct alternative. In a well-constructed MC test, the test-taker likely recognizes most or all of the alternatives from previous study, but must decide whether or not that alternative is an appropriate answer to the question at hand (Sax & Collet, 1968; Whitten & Leonard, 1980). Often processes of discrimination and memory search are utilized as one thinks not only of which alternative is correct and why, but also of which alternatives are incorrect and why. Certain MC tests could, therefore, invoke a type of processing comparable to that invoked by recall tests (Whitten & Leonard, 1980).

Related Information

Although previous testing is clearly beneficial for retention of identical information, it is less clear whether testing might also benefit the retention of related, but initially nontested information. For example, if one reads a chapter about several U.S. presidents and then answers questions about some of those presidents, will information about the other presidents be strengthened as well? This issue seems particularly germane to the educational context where instructors would rarely ask the same questions on both a quiz and a later exam. In addition, instructors often give practice tests to students, with the intention of providing them with an idea of what the later exam will be like, while not providing them with the actual questions.

On the basis of previous research examining the effects of initial testing on the later recall of related information, one might expect the retention of such information to be impaired. To illustrate, using a retrieval-practice paradigm, Anderson, Bjork, and Bjork (1994) found that—after an initial study phase—testing or giving retrieval practice to some items from a given category improved their later recall, but impaired the recall of other items in that category that were not themselves tested, as compared to the recall of items from another category, none of which were tested—a phenomenon now known as retrieval-induced forgetting. Thus, it seems possible that by giving initial tests or practice

questions, instructors could be inadvertently impairing their students' performance for related nontested questions that may appear on later exams.

Such retrieval-induced forgetting has been demonstrated for educational materials, including facts (Chan, 2009; Macrae & MacLeod, 1999); prose materials (Carroll, Cambell-Ratcliffe, Murnane, & Perfect, 2007); and even one's native language when words from a second language were practiced (Levy, McVeigh, Marful, & Anderson, 2007). Retrieval-induced forgetting has been argued to occur as the consequence of inhibitory processes needed to resolve competition among alternative responses to the same or similar cues (Anderson et al., 1994). Interestingly, it is argued that the processes that lead to forgetting are largely unconscious, as competitive alternatives need not be explicitly brought to mind for them to be suppressed. To the extent that related concepts are brought to mind, however, and can then be used to access the correct answer to a given question, related information might be facilitated.

Indeed, in recent work, Chan, McDermott, and Roediger (2006) developed question pairs such that answering one question on an initial test would encourage the spontaneous recall of information related to the second question that was then to be asked on the later test. Using these question pairs, Chan et al. found facilitation for related, but initially nontested information, although this result likely depended upon specific aspects of the procedure and materials in addition to the facilitative nature of the pairs (i.e., a 24-hr delay between the initial and final tests and integrated encoding of the to-be-learned information). In subsequent research, Chan (2009) demonstrated that although facilitation for these initially nontested, related items occurred at a 24-hr delay when the information had been learned in a prose context, forgetting occurred at a shorter delay when the information had been learned as an unordered series of facts. Importantly, in all of these studies that used short delays to final test, no facilitation was found for related information, even though the time spent on the initial test led to a greater amount of time-on-task—that is, time that the participant spent thinking about information from the tested passage.

In the present research, we tested whether MC tests might afford a benefit for related information that is not as easily afforded by cued-recall tests. Multiple-choice tests differ from free- and cued-recall tests in that they provide students with a set of related (and often competitive) concepts through which they can consciously search in selecting the correct answer, whereas cued-recall tests do not. For example, if given a cued-recall question about who served as the fourth president of the United States, although one may eventually recall the answer (i.e., *Madison*), in the process of doing so, other alternatives (e.g., *Adams*, *Jefferson*) may also become activated by the cue and compete for access and thus need to be suppressed in order to access *Madison*, according to inhibitory accounts of retrieval-induced forgetting. In contrast, if given an MC question with competitive alternatives provided (e.g.,

Adams, *Jefferson*), test-takers may be encouraged to consciously think about such competitors in selecting which president was the fourth (e.g., *Adams* and *Jefferson* held office prior to *Madison*, *Jefferson* was the third president, etc.), thereby strengthening information they spontaneously recall about these other presidents. Accordingly, MC tests (with competitive alternatives) might both reduce the possibility of retrieval-induced forgetting effects as well as encourage a type of spontaneous recall that later supports the enhanced recall of related, nontested information.

In Experiment 1, we explored this possibility by examining the effects of initial testing of some of the information presented in a prose passage on the later recall of related information using a variation of the retrieval-practice paradigm; specifically, we employed initial MC tests rather than cued-recall tests and then compared the recall of the previously tested items and related nontested items to that of control items from a passage not previously tested. We had two major questions in mind: (a) to what extent would the initial MC tests enhance the recall of previously tested information and (b) would the use of MC questions during initial testing enhance the recall of related information; that is, would the use of MC questions in the initial test allow related items to be facilitated instead of impaired—that is, escape retrieval-induced forgetting? In addition, we utilized a feedback manipulation to see whether being shown the correct answer after attempting to answer a question would affect later recall of both previously tested and related information. Although shown to improve recall of previously tested information, it is uncertain how feedback might affect recall of related information.

Experiment 1

Method

Participants A total of 112 students at the University of California, Los Angeles, participated for credit in an introductory psychology course.

Design We used a 2 (item type: previously tested, previously nontested related) \times 2 (feedback: present, absent) within-subjects design plus an independent control group.

Materials Two passages were constructed, one about Saturn and one about Yellowstone National Park, and ten pairs of MC questions were created for each passage. The two questions in each pair were semantically related in that both questions tested the same topic (e.g., geysers) and had the same four alternatives (e.g., *Old Faithful*, *Steamboat Geyser*, *Castle Geyser*, and *Daisy Geyser*), but different correct answers (e.g., *What is the tallest geyser in Yellowstone National Park?* Answer: *Steamboat Geyser*; and, *What is the oldest geyser in Yellowstone National Park?* Answer: *Castle Geyser*). Questions were divided into two 10-item sets for a given passage, with the two questions from each pair randomly assigned to a different set.

Procedure All participants were given 10 min to read the first passage and were instructed to continue studying it if they finished early. Participants in the testing condition were then given an initial 10-item MC test (i.e., all items in one of the question sets for that passage) with questions presented one at a time on the computer. For a given test, all questions were either followed by feedback (feedback present) or not (feedback absent) after the participant provided an answer. Feedback entailed the entire question being re-presented, with the answer printed in red. Following study and test of the first passage, participants followed the same procedure for the second passage except that if feedback had been provided in the first MC test, then it was absent in the second test and vice versa.

Participants in the control condition received no tests; rather, they engaged in a non-verbal filler task (i.e., playing Tetris) following their study of each passage (for the same amount of time as would have been needed to take the test).

Finally, both tested and control participants received a final cued-recall test after a 5-min retention interval during which they played Tetris. Forty questions were presented one at a time on the computer screen; as cued-recall questions, they did not appear with any answer alternatives. For the tested condition, except for the absence of alternatives, half of the questions were identical to the MC questions (i.e., previously tested) and half were the nontested related items (i.e., the remaining questions from the two 10-item sets that had not appeared in the initial MC tests). Related questions were always tested before previously tested questions. For the control condition, all questions were previously nontested and served as a baseline. Topic (Passage) order, question set, and feedback (after Passage 1 or Passage 2) were counterbalanced.

Results and Discussion

Initial MC Test Performance Participants in the tested condition correctly answered an average of 70% ($SD = 17\%$) of the questions on the initial MC tests.

Final Test Performance Final test performance is presented in Figure 1. As shown, we found evidence that taking an initial MC test improved the recall of both previously tested and previously nontested related information as compared to the control condition.¹

¹ Overall, participants in the nontested control group correctly answered 31% ($SD = 13\%$) of the questions on the final test, recalling marginally more answers in the first half of the test ($M = 33\%$, $SE = 2\%$) than in the second half ($M = 29\%$, $SE = 2\%$), $F(55) = 3.5$, $p = .07$, a finding consistent with previous accounts of output interference. Because of this marginal difference in performance for the first half and second half of the test, we compared recall for previously tested questions in the tested condition (which were always presented in the second half of the final test) with recall for questions in the control condition that

Recall performance of participants in the tested condition was compared to the corresponding performance of participants in the nontested control condition via planned independent-samples t tests and, importantly, benefits were found for both types of questions. Specifically, these comparisons revealed that (a) previously tested questions given feedback ($M = 65\%$, $SE = 3\%$) and previously tested questions not given feedback ($M = 51\%$, $SE = 3\%$) were both answered correctly more often than the control questions ($M = 29\%$, $SE = 2\%$), $t(110) = 10.88$, $p < .001$, and $t(110) = 6.45$, $p < .001$, respectively; and (b) questions related to previously tested questions that had received feedback ($M = 40\%$, $SE = 3\%$) and questions related to previously tested questions that had not received feedback ($M = 43\%$, $SE = 3\%$) were both answered correctly more often than the control questions ($M = 33\%$, $SE = 2\%$), $t(110) = 2.10$, $p < .05$ and $t(110) = 3.10$, $p < .01$, respectively.

Figure 1: Correct recall percentages as a function of item and feedback type in Experiment 1. White bars show baseline recall for initially non-tested questions by control participants. Error bars represent ± 1 SE.

To summarize, in Experiment 1, we found a generalized benefit of testing such that the answers to questions on a final cued-recall test were recalled more often when preceded by initial MC tests than when not. Most importantly, this benefit occurred even when the questions on the final cued-recall test were not identical, but only related to those on the initial MC tests, and even though answering such questions correctly on the final test involved recall of an answer that participants had needed to select against during the initial MC test. Thus, providing participants with practice on initial MC questions allowed related information not only to escape impairment but, indeed, to be enhanced. Although retrieval-induced forgetting is largely believed to occur as the result of the unconscious suppression of competitive alternatives, MC tests provide learners with the competitors and thus they can be consciously examined. For example, if students are given a set of alternatives that had all occurred in the required reading, as is the case for a MC question in our

were presented in the second half of the final test. Similarly, recall for nontested questions in the tested condition was compared with recall for the questions in the control condition that were presented in the first half of the test. This method of analysis provides a more conservative test of facilitation for related information.

experiment (e.g., 88 *Earth days*, 176 *Earth days*, 10 *Earth hours*, and 30 *Earth years* for the question: *How long does it take Saturn to revolve around the Sun?*), they could use these alternatives as a guide for searching their relevant knowledge set for the answer (e.g., 88 days and 176 days are wrong as they are related to Mercury; Saturn has a shorter day than Earth). Hence, even if students were unable to recall the answer to this particular question if asked in the format of a cued-recall question, if asked in the format of a MC question with possible alternatives provided, knowledge of related information presented in the passage might be utilized to reject incorrect alternatives; and, in this process, the student may spontaneously answer other related, but nontested questions. Indeed, we believe that such spontaneous retrievals may be the process by which the observed benefit for related but previously nontested items occurred in Experiment 1. For such a beneficial search process to be invoked, however, it would seem necessary that the incorrect choices be potential answers (i.e., competitive alternatives to the correct answer), thus requiring the student to select against them with the use of associated information from the passage. In contrast, without competitive alternatives, perhaps a benefit to related nontested information would not occur because the alternatives would not encourage this type of search strategy. We sought to explore this possibility in Experiment 2 by manipulating the competitiveness of the incorrect alternatives in the initial MC tests that followed the reading of prose passages.

Experiment 2

In Experiment 2, we tested whether the benefit of testing observed for related but previously nontested items in Experiment 1 arose from a type of search strategy engendered by the use of competitive alternatives in the initial MC tests, as described above. To do so, we manipulated the plausibility of the incorrect alternatives, hypothesizing that the more plausible the incorrect alternatives were as answers, the more competitive they would be and the more processing they would require in the attempt to reject them—processing that would likely involve retrieval of associated information from the passage and thus deeper processing of both the correct and the incorrect alternatives. Accordingly, we predicted that initial MC questions using more plausible incorrect alternatives would lead to a greater recall benefit for both previously tested information and previously nontested related information than would initial MC questions using less plausible incorrect alternatives.

Method

Participants A total of 28 students at the University of California, Los Angeles, participated for credit in an introductory psychology course.

Design We used a 2 (item type: previously tested, previously nontested related) X 2 (MC question type: competitive, non-competitive) within-subject design for the testing condition plus a control condition, with all participants serving in both conditions.

Materials Two passages were constructed, one about the Solar System and one about Ferrets, and eight question pairs were created for each passage. Related questions tested information from the same passage and the same type of information served as the correct answer for both questions (e.g., numbers, terms, proper names). To illustrate, the answers to two such questions (*How many inches long is an average ferret tail?* and *How many years ago were ferrets first domesticated, according to mitochondrial DNA evidence?*) were both numbers (i.e., 5 and 2500, respectively).

To utilize a MC format for each of these questions, four incorrect alternatives were chosen from other information presented in the passage. Two incorrect alternatives were highly related to one question in the pair (and thus, plausible answers for it) and the other two alternatives were highly related to the other question (and thus, plausible answers for it). Thus, for a given pair, there were six alternatives (including the two correct answers). Because all of the alternatives for a given pair had the same type of answers (e.g., numbers), each of the six alternatives could be used in constructing two three-alternative MC questions for each question in these pairs. By manipulating which alternatives were used, we created a competitive and non-competitive version of each question. For example, in competitive versions, the incorrect alternatives were 7-10 and 20 for the first question and 1500 and 3500 for the second question. For the non-competitive versions, the incorrect alternatives were 1500 and 3500 for the first question and 7-10 and 20 for the second question.

Next, two new questions were constructed for each question-pair to serve as the nontested related questions on the final cued-recall test. As in Experiment 1, for these new questions, correct answers were previously incorrect alternatives on the MC questions. For example, although 7-10 was used as an incorrect alternative on the initial test, it was the correct answer to the question, *“How long do ferrets typically live?”* Similarly, 3500 was the correct answer to the question, *“According to archaeological evidence, how long ago were ferrets domesticated?”*

In summary, the six possible alternatives for each of the eight question-pairs were manipulated so as to make both of the three-alternative questions in each pair competitive or non-competitive for a given participant. On the initial MC test, all participants answered eight competitive questions and eight non-competitive questions. The final test included previously nontested questions for which previously incorrect alternatives (either competitive or non-competitive) were now the correct answers.

Procedure All participants were given 10 min to read the first of two passages and were instructed to continue studying the passage if they finished reading early. Next participants either took a test or engaged in a non-verbal filler task. When the passage was tested, participants were given an initial MC test with 16 questions (i.e., eight question pairs) for which they gave verbal responses. Questions appeared one at a time on a computer, and no feedback was given. When the passage served as the nontested control passage, participants played Tetris following its presentation for 3 min (the same time needed to take the test). If given a MC test after the first passage, then that participant engaged in the non-verbal filler task after the second passage and vice versa.

Finally, after a 4-min retention interval during which all participants played Tetris, a final 64-question cued-recall test was given. The 32 questions for the tested topic (previously tested and previously nontested related) and the 32 questions from the nontested control topic were presented on a computer screen, one-at-a-time, and participants gave a verbal response to each. Questions from the previously tested topic were always tested last. Topic (Passage) order, plausibility of alternatives, and testing (after Passage 1 or after Passage 2) were counterbalanced.

Results and Discussion

Initial MC Test Performance On the initial MC test, participants correctly answered more non-competitive questions ($M = 86\%$, $SE = 3\%$) than competitive questions ($M = 66\%$, $SE = 3\%$), $t(27) = 5.67$, $p < .001$, confirming that competitive alternatives make questions more difficult to answer correctly than do non-competitive alternatives.

Final Test Performance Final test performance is presented in Figure 2. For previously tested questions, correct answers to competitive questions ($M = 37\%$, $SE = 3\%$) were recalled marginally less often than were correct answers to non-competitive questions ($M = 45\%$, $SE = 4\%$), $t(27) = 1.76$, $p < .10$, a pattern consistent with the initial MC performance. For previously nontested questions from the same topic, however, the effect was in the opposite direction: correct answers that had previously been incorrect competitive alternatives ($M = 47\%$, $SE = 5\%$) were recalled more often than were correct answers that had previously been incorrect non-competitive alternatives ($M = 36\%$, $SE = 4\%$), $t(27) = 2.55$, $p < .05$, confirming our prediction that initial MC questions with competitive alternatives would lead to enhanced recall of related information as compared to initial MC questions with non-competitive alternatives.

When compared to control items ($M = 27\%$, $SE = 3\%$), answers to both previously tested competitive questions ($M = 37\%$, $SE = 3\%$) and previously tested non-competitive questions ($M = 45\%$, $SE = 4\%$) were facilitated, $t(27) = 3.10$, $p < .01$ and $t(27) = 4.54$, $p < .001$, respectively, demonstrating a testing effect. For previously nontested

questions from the tested topic, those with answers that had previously been incorrect competitive alternatives ($M = 47\%$, $SE = 5\%$) were correctly answered more often than questions from the control passage ($M = 36\%$, $SE = 4\%$), $t(27) = 2.21$, $p < .05$, whereas those with answers that had been incorrect non-competitive alternatives ($M = 36\%$, $SE = 4\%$) were not, $t(27) = 0.1$, $p > .05$

Figure 2: Correct recall percentages as a function of item type and competitiveness of MC alternatives on the initial MC test in Experiment 2. Error bars represent ± 1 SE.

In Experiment 2, we manipulated the competitiveness of a given question by choosing incorrect alternatives that were either plausible or implausible answer choices to examine whether competitiveness of the alternatives was a critical factor in the facilitation of related information, and our results suggest this to be the case. Of concern, however, is whether the benefit we observed resulted from the increased processing of the incorrect alternatives as hypothesized, or simply occurred as an artifact of initial test performance. Because competitive questions were more difficult to answer than non-competitive ones, perhaps the benefit observed was merely a consequence of the participant being more likely—on the initial MC test—to select an incorrect competitive alternative than to select an incorrect non-competitive alternative, and then to recall that previously incorrect answer on the final test when given the related question (for which the answer might now be correct). For example, on the initial MC test, a participant might incorrectly choose 7-10 (instead of 5) when given the question, “How many inches long is an average ferret tail?” If the participant then gives 7-10 as the correct answer for the question, “How long do ferrets typically live?” on the later test, one cannot be sure whether that participant is giving that answer believing it to be correct or giving that answer because it was chosen before and is now primed as an answer for all questions where it is plausible.

If such generalized strengthening of alternatives is the mechanism that leads to this effect, then participants should not demonstrate the pattern of results previously shown for related questions when recall is conditionalized upon answering the corresponding MC question correctly. A conditional analysis demonstrated, however, that marginally more answers to related questions were recalled correctly when those answers were previously incorrect competitive alternatives ($M = 50\%$, $SE = 4\%$) than when they were previously incorrect non-competitive alternatives ($M = 41\%$, $SE = 4\%$), $t(27) = 1.91$, $p = .07$. Thus, the possibility that

this effect is driven by cases in which a participant chooses the incorrect answer and then carries it to a new question (where it then happens to be correct) seems unwarranted.

General Discussion

The present results imply that taking an initial MC test not only improves one's ability to recall *that* information on a later cued-recall test, but also improve one's ability to recall nontested, but related information on a later test—provided that the initial test utilizes incorrect alternatives that are competitive. Furthermore, although an MC question is often easier to answer than a comparable question in a cued-recall format (i.e., same question, without the choices), to the extent that the question has competitive alternatives, that question may invoke processes that are similar to those involved in recall (e.g., memory search, retrieval checks), thus leading to comparable benefits to the tested information. Moreover, use of MC questions may provide a way to insure that access to related nontested information is not impaired on a later test.

Educators may be concerned that the initial test provides participants with additional time to think about the tested topic, whereas no such additional time is allocated to the nontested control topic. Although a valid concern, our findings need to be viewed in the context of previous work using the retrieval-practice paradigm in which additional time is not allotted for nontested control materials and in which nontested information from a tested topic is rarely facilitated and, in fact, is typically impaired (e.g., Macrae & MacLeod, 1999; Carroll et al., 2007). Indeed, with a similar procedure and educational prose materials, but with an initial cued-recall test, Chan (2009) did not find facilitation for related information, even when the questions on the initial test were created to be facilitative for questions on the final test. One might thus argue that our finding of facilitation occurred because our MC questions—unlike cued-recall questions—exposed participants to the future answers for related questions (in the form of incorrect alternatives), thus providing shallow priming that leads to facilitation on the later test. Against such an argument, however, are the findings of Experiment 2 where alternatives were exposed in both competitive and noncompetitive conditions and yet facilitation only occurred when alternatives were competitive, thus ruling out an explanation in terms of priming. Instead, our findings are consistent with the explanation that competitive MC questions lead to enhanced performance for nontested related information, owing to the deeper processing of the incorrect alternatives that they engender, as compared to processing engendered by noncompetitive MC questions.

We believe that the present results have implications for both instructors and students. Instructors can create quizzes and study guides that improve retention for both initially tested information as well as related information that is not itself tested. Students can benefit from tests by thinking

about all of the alternatives—not only why a given answer is correct, but also why other answer choices are wrong.

Abstract

We examine representation assumptions for learning in the artificial grammar task. Strings of letters can be represented by first building vectors to represent individual letters and then concatenating the letter vectors into a vector of larger dimensionality. Although such a representation works well in selected examples of artificial-grammar learning, it fails in examples that depend on left-to-right serial information. We show that recursive convolution solves the problem by combining item and serial-order information in a stimulus item into a distributed data structure. We import the representations into an established model of human memory. The new scheme succeeds not only in applications that were successful using concatenation but also in applications that depend on left-to-right serial organization.

Keywords: Artificial grammar learning; Holographic representation; Exemplar model

Introduction

In an artificial-grammar learning (AGL) classification task, participants study strings of symbols. Following study, the participants are told that the studied items were constructed according to the rules of an artificial grammar and are invited to sort novel rule-based (grammatical) exemplars from novel rule-violating (ungrammatical) ones. Even though the participants are unable to describe the rules, they can discriminate the two classes of stimuli.

Initial accounts proposed that the participants abstracted the grammar and used that knowledge to judge the status of the exemplars (e.g., Reber, 1967, 1993). Later investigators argued that the participants judged grammaticality without reference to the grammar. To support the latter position, investigators identified several sources of information that discriminate the two classes of test strings. Brooks (1978) suggested that whole-item similarity between training and test strings is used to infer grammaticality. Perruchet and Pacteau (1990) argued that bigram overlap is used to infer grammaticality. Vokey and Brooks (1992) identified edit distance as a predictor, and Brooks and Vokey (1991) argued that patterns of repetition within a string are used to infer grammaticality. Knowlton and Squire (1996) identified associative chunk strength (ACS), and Johnstone and Shanks (1999) identified chunk novelty. Finally, Jamieson and Mewhort (2009a, 2010) showed that global similarity predicts performance in the task. Regression analyses

designed to sort the various predictors have confirmed a role for all of them (e.g., Johnstone & Shanks, 1999). Factorial designs that have pitted predictors against one another have been unable to identify a single dominant predictor (e.g., Kinder & Lotz, 2009; Vokey & Brooks, 1992).

We think that many of the predictors (e.g., ACS, bigram over, etc) point to a common underlying factor, namely left-to-right serial structure. If so, the problem is not to determine which predictor dominates but, rather, to decide how subjects encode material so that they have access to the left-to-right serial structure in the exemplars.

In this paper, we explore an encoding mechanism that folds several orders of left-to-right serial structure in a string into a coherent and distributed data structure (i.e., single letters, bi-grams, trigrams, and whole strings). To begin, we describe the representation scheme. After, we show that the new representations predict judgement of grammaticality when used in an established theory of retrieval (Jamieson & Mewhort, 2009a, 2010).

Holographic representation in memory

Many investigators have proposed that light holography provides a mathematical basis for memory representation (Borsellino & Poggio, 1973; Gabor, 1968; Khan, 1998; Longuet-Higgins, 1968; Poggio, 1973). Murdock's (1982, 1983, 1997) TODAM is probably the best-known use of the idea in experimental psychology. In TODAM, stimulus associations are formed using linear convolution and associations are unpacked using correlation (deconvolution).

More recently, Jones and Mewhort (2007) used recursive circular convolution (Plate, 1995) to develop a self-organizing model of semantic memory (BEAGLE). BEAGLE captures judgements of semantic typicality, categorization, priming, and syntax from word order. BEAGLE's ability to handle so many phenomena of semantic memory is in itself impressive. However, from our perspective, BEAGLE's strength is that it shows how holographic representation can account for complex decision behaviour without adding control structures (e.g., learning and the application of rules). BEAGLE's success suggests that holographic stimulus representation should be explored in related models of learning and memory. The present work adapts BEAGLE's representation scheme to represent strings in the artificial grammar classification task.

Recursive circular convolution

Circular convolution is a mathematical operation that forms an associative representation, \mathbf{z} , for two input vectors, \mathbf{x} and \mathbf{y} ,

$$z_i = \sum_{j=0}^{n-1} x_{j \bmod n} \times y_{(i-j) \bmod n}, \quad [1]$$

where i indexes the element in \mathbf{z} and where n is the dimensionality of \mathbf{z} , \mathbf{x} , and \mathbf{y} . Briefly, circular convolution forms the outer-product matrix—long used to represent associations in neural networks (e.g., Anderson, 1995)—and then collapses it into a vector (see Figure 1). Circular convolution is associative, commutative, and distributes over addition.

Figure 1. Collapsing an outer-product matrix with circular convolution, where \mathbf{x} and \mathbf{y} are the argument vectors and \mathbf{z} represents the resulting compressed vector from collapsing the outer-product matrix. The values i and j represent the row and column indices, respectively, for an element in the outer-product matrix.

In the work that follows, we apply circular convolution recursively to encode a series, such as a sequence of letters. Consider the string *ABCD*. To represent *ABCD* as a series, first, generate a unique random vector for each of the individual letters in the string $\{\mathbf{a}, \mathbf{b}, \mathbf{c}, \mathbf{d}\}$. Next, apply circular convolution in a recursive fashion to bind the first letter to the second, the product of that binding to the third, and so on, until each letter has been folded into the representation. At this point, using \mathbf{z} to represent the string *ABCD*, $\mathbf{z} = ABCD = ((\mathbf{a} * \mathbf{b}) * \mathbf{c}) * \mathbf{d}$, where $*$ denotes circular convolution. No matter the length of the string, \mathbf{z} has the same dimensionality as the input (i.e., letter) vectors.

Why holographic representation?

In previous studies of AGL, we represented exemplars by concatenating letters. For example, a string *ABCD* was represented by concatenating the vectors for *A*, *B*, *C*, and *D* to form a single vector $\mathbf{a} // \mathbf{b} // \mathbf{c} // \mathbf{d}$, where $//$ denotes concatenation. The scheme captured a swath of data from the artificial grammar task and from serial reaction time tasks (see Jamieson & Mewhort, 2009a, 2009b, 2010). Nevertheless, concatenated representations are problematic.

In models using vector representation, it is traditional to compute the similarity between \mathbf{x} and \mathbf{y} , using a vector cosine. Thus, with concatenated strings, similarity is computed by comparing information in corresponding serial positions of two strings (i.e., element-for-element). Because of the serial-position constraint, a model using the concatenated representation scheme treats the strings *ABCD* and *CDAB* as if they shared no overlapping features—a judgement that is at odds with data. In contrast, a holographic representation scheme distributes information throughout the vector so that each part of it contains some information about the whole. Thus, in difference to the concatenation scheme, the cosine calculation compares all parts of \mathbf{x} (i.e., *ABCD*) and \mathbf{y} (i.e., *CDAB*) simultaneously and, thereby, acknowledges similarity between *ABCD* and *CDAB*. Because participants appreciate the similarity between *ABCD* and *CDAB*, the holographic scheme is preferred.

Critically, holographic stimulus representation finesses the problem of encoding serial structure. Importantly, it does so without requiring a change in the similarity calculation or other aspects of retrieval. This occurs because a representation of *ABCD* that is formed using recursive circular convolution superimposes overlapping orders of serial structure onto a single distributed structure. Because different orders of serial information about a string are superimposed in a single representation, a standard cosine of two vectors supports parallel comparison of multiple orders of serial structure. The question we pose, then, is if we import the holographic representations into an established model of retrieval, will the previously successful model still work; that is, can we still explain peoples' judgements in the artificial grammar task?

Minerva 2

Minerva 2 is an established model of retrieval (Hintzman, 1986, 1988). When a participant studies an item, an event is encoded to memory as a unique trace.

In Minerva 2, a stimulus is represented by a vector of n elements; each element takes values: +1 or -1. To represent stimuli in the artificial grammar task, we first, generate a unique random vector for each of the letters in the English alphabet and then apply recursive circular convolution to those vectors to represent a string of letters. Thus, a string *TXXV* is represented by a trace: $((\mathbf{t} * \mathbf{x}) * \mathbf{x}) * \mathbf{v}$.

Memory is a matrix, \mathbf{M} . Encoding an event involves copying its corresponding vector representation to a new row in the memory matrix. Encoding is sometimes imperfect. Imperfect encoding is implemented by setting some vector elements to zero (indicating that the element is indeterminate or unknown). A parameter, L , controls the probability with which an element is stored. As L increases, encoding quality improves.

All retrieval is cued. When a retrieval cue is presented, it activates each trace in memory in proportion to its similarity to the cue. The activated traces are aggregated into a

composite called the *echo*; the contribution of each trace to the echo is based on its activation.

The similarity of trace, i , to the probe, P , is computed using a vector cosine, i.e.,

$$S_i = \frac{\sum_{j=1}^n P_j \times M_{ij}}{\sqrt{\sum_{j=1}^n P_j^2} \sqrt{\sum_{j=1}^n M_{ij}^2}}, \quad [2]$$

where P_j is the value of the j^{th} feature in the probe, M_{ij} is the value of j^{th} feature of the i^{th} row in memory. Like the Pearson r , the similarity of the i^{th} item to the probe, S_i , is scaled to the interval $[-1, +1]$. Similarity equals +1 when the trace is identical to the probe, 0 when the trace is orthogonal to the probe, and -1 when the trace is opposite to the probe.

The i^{th} trace's activation, A_i , is the cube of its similarity to the probe, i.e.,

$$A_i = S_i^3. \quad [3]$$

The activation function exaggerates differences in similarity between a probe and items in memory by attenuating activation of exemplars that are not highly similar to the probe. This allows traces most similar to the probe to dominate the information retrieved. Note that the exponent in the activation function preserves the sign of the argument, S_i .

The information retrieved by a probe is a vector, c , called the echo. The echo is computed by weighting each of the $i = 1 \dots m$ traces in memory by their activations and, then, summing all m traces into a single vector,

$$c_j = \sum_{i=1}^m A_i \times M_{ij}. \quad [4]$$

The information in the echo is converted to decision variable called echo intensity, I , by computing the cosine similarity (see Equation 2) of the echo and probe. In the context of the artificial grammar task (i.e., classification), echo intensity is a proxy for judgement of grammaticality.

In the remainder of this paper we apply the model to data from the judgment of grammaticality task.

Evaluating the model

The judgement of grammaticality task was introduced by Reber (1967). In his experiment, participants memorized grammatical exemplars. After, they judged the grammatical status of novel test probes. Reber's subjects discriminated novel grammatical from novel ungrammatical test probes, but they could not articulate the rules of the grammar.

We have shown previously that Minerva 2 captures discrimination of grammatical from ungrammatical test probes in Reber's (1967) task, without reference to grammatical rules (Jamieson & Mewhort, 2009a, 2010). But

we used concatenated stimulus vectors in that work. In the simulations that follow, we retest the model using the holographic rather than concatenated stimulus vectors.

To simulate Reber's (1967) task we began by representing his stimuli in our model.¹ First, we constructed a unique 100-element vector to represent each letter used to construct letter strings: $\{T, V, P, X, S\}$. Second, we generated a vector for each training and test string using recursive circular convolution. Third, we filled successive rows on the memory matrix with the training vectors. Fourth, we introduced moderate data-degradation to the items in memory, i.e., $L = 0.7$. Finally, we calculated the mean echo intensity for each of the 24 grammatical and 24 ungrammatical test strings.

The new model successfully discriminated grammatical from ungrammatical test items. The mean echo intensity for the 24 grammatical test strings was .57 ($SD = .03$); the corresponding value for the 24 ungrammatical test strings was .49 ($SD = .02$), $t(48) = 2.15$, $p < .05$.

In other simulations, we varied the integrity of data in memory (e.g., Jamieson, Holmes, & Mewhort, in press). As shown in Figure 2, the magnitude of the difference in mean echo intensity for grammatical and ungrammatical test strings (i.e., the model's discrimination of grammatical and ungrammatical items) grew as a function of L .

Figure 2. Mean echo intensity for grammatical and ungrammatical test strings as a function of data integrity in memory, L .

The simulation illustrates several points. First, it shows that the distributed stimulus representations generated using recursive circular convolution support discrimination of grammatical from ungrammatical test items. Second, because the model discriminated the two classes of stimuli without reference to grammatical rules, the simulation serves as an existence proof that grammatical strings can be

¹ Reber did not list the specific study and test items that he used in his original paper. He did, however, provide a list of representative strings from the same grammar in another source (Reber, 1993, p. 36). We took our strings from there.

discriminated from ungrammatical test strings without knowledge of the grammatical rules. Thirdly, the simulation shows that we can import holographic stimulus representations into Minerva 2 without a deleterious impact on the effects that the model captures using concatenated vectors (see Jamieson & Mewhort, 2009a, 2010).

Next, we test the new representation scheme by applying it to data collected by Kinder and Lotz (2009). Their data provide a more detailed challenge.

Kinder and Lotz (2009)

Kinder and Lotz (2009) engineered an artificial grammar to distinguish stimulus properties thought to predict judgements of grammaticality. They used the grammar to construct a list of 12 training items and 48 test items. The test items were of four different types. Type 1 and Type 2 items were ungrammatical; Type 3 and Type 4 items were grammatical. Type 1 test items violated both positional and sequential rules of the grammar; Type 2 items violated only sequential rules (i.e., the strings included at least one illegal bigram but all letters were in legal serial positions). Type 3 and Type 4 items obeyed positional and sequential rules of the grammar; but, Type 4 items had the additional property of being very similar to a specific training exemplar. Accordingly, if participants endorse Type 2 over Type 1 items, they must appreciate the positional dependencies of letters in the training set. If participants endorse Type 3 over Type 2 items, they must appreciate the difference between studied and unstudied chunks (i.e., bigrams and trigrams). If they endorse Type 4 over Type 3 items, they must appreciate whole-item similarity between training and test strings.

Figure 3. Empirical: Percentage of items endorsed as grammatical in Kinder and Lotz's (2009) Experiment 2.

Kinder and Lotz's (2009) results are reproduced in Figure 3. First, participants endorsed Type 2 over Type 1 items indicating they were sensitive to the positions of individual letters in the training strings. Second, participants endorsed Type 3 over Type 2 items, indicating they were sensitive to test strings' inclusion/exclusion of studied and unstudied bigrams. Finally, participants endorsed Type 4 over Type 3

items, indicating they were sensitive to whole-item similarity between training and test strings.

The pattern of results demonstrates that judgement of grammaticality is influenced concurrently by the positions of single letters in a string, by knowledge of small chunks (i.e., knowledge of bigrams and trigrams), and by knowledge of larger chunks (i.e., whole training strings). To claim a model as a competent account of decision in the judgement of grammaticality task, the model must accommodate concurrent sensitivity to the three sources of information.

Simulation of Kinder and Lotz (2009; Exp 2)

Kinder and Lotz's (2009) data provide a principled challenge to test the idea that holographic stimulus representation allows multiple orders of serial-structure to exert a concurrent influence on judgements of grammaticality. Hence, we tested our model using Kinder and Lotz's (2009) materials.² The simulation was otherwise the same as before.

The results of the simulation are presented in Figure 4; the means were computed across 50 independent replications of the procedure. We treat mean echo intensity as a proxy for mean judgement of grammaticality.

Figure 4. Simulation: Mean echo intensity for the four item types in Kinder and Lotz's (2009) Experiment 2.

As shown, the model reproduced the pattern of results from Kinder and Lotz's (2009) experiment. Firstly, mean echo intensity for Type 2 items was greater than for Type 1 items indicating that the model was sensitive to positional dependencies of individual letters in the training strings. Secondly, echo intensity for Type 3 items was greater than for Type 2 items indicating that the model was sensitive to bigram and trigram structure in the stimuli. Finally, echo intensity for Type 4 items was greater than for the Type 3

² A complete listing of Kinder and Lotz's (2009) materials is presented in their Appendix B. The simulations were identical for the two sets; a testament to their care at stimulus design.

items indicating that the model was sensitive to larger chunks of letters, possibly whole strings.

Importing a scheme for holographic stimulus representation into a Minerva 2-based account of retrieval allows the model to capture additional details of performance in the artificial grammar task. Minerva 2 now captures trends that previously required a very different kind of computational account (e.g., the SRN, see Elman, 1990).

General Discussion

Judgements of grammaticality reflect a concurrent consideration of discriminative cues (e.g., Johnstone & Shanks, 1999). To accommodate that fact, we developed a new kind of stimulus representation based on recursive circular convolution. The new representation folds information about several cues into a distributed data structure. More importantly, the holographic representation scheme supports parallel comparison of features in a string, unconstrained by serial position alignment. Using the holographic representations in a model of human memory captures judgement of grammaticality.

In previous work, Jamieson and Mewhort (2009a, 2010) demonstrated that judgment of grammaticality can be understood using Minerva 2—an exemplar model of memory. In that work, exemplars were represented by concatenating individual letter vectors. Judgement of grammaticality reflected a test probe's global similarity to the studied exemplars. The representation scheme worked because it preserved the spatial structure of the stimulus (i.e., letters from left-to-right). However, the account neglected to include information about left-right sequential properties of the exemplars—information that subjects notice during study. Because the model did not acknowledge sequential structure in stimuli, it incorrectly computed similarity between two exemplars based on bigram overlap; a factor measured by associative chunk strength.

The holographic stimulus representations developed here finesse the problem associated with the earlier scheme by folding information about serial-structure into the representation of a string. By using the holographic representations, the model now captures judgements that reflect serial structure (e.g., participants' appreciation of chunk overlap). Despite changes to the representation scheme in the model, we have not changed the model's account of retrieval and so we retain our previous conclusion: Judgement of grammaticality can be captured without an implicit rule-induction process that abstracts and applies grammatical information.

Kinder (2000; Kinder & Lotz, 2009) and others (e.g., Cleeremans, Servan-Schreiber, & McClelland, 1989) have argued for a Simple Recurrent Network (SRN) account of artificial grammar learning. The SRN accomplishes judgement of grammaticality by learning the sequential structure in a set of training sequences and then applying that knowledge to predict sequential regularities in test items. When the SRN can predict the sequential structure of

a test string, it judges the test string as grammatical (see Reber, 2002, for an analysis of the approach; see Vokey & Higham, 2004, for model comparison of the SRN and a related instance-based model). Cleeremans et al. (1989) showed the SRN develops a veridical representation of the grammar used to generate the training strings. By contrast, our account treats judgement of grammaticality as an episodic memory task. At study, the model encodes information about individual exemplars, including serial structure. At test, the model judges a test strings' grammaticality by its global similarity to the exemplars in memory. The two classes of model (Minerva 2 and the SRN) offer very different explanations of the cognitive processes that underlie judgement of grammaticality. So, which approach is to be preferred? We think the answer should be based on the nature of the experimental problem.

In the training phase of a standard artificial grammar experiment, participants are asked to memorize exemplars. At test, they are given the problem of inferring the grammaticality of test probes. Of course, people *can* learn sequential structure in stimuli instructions. But they do not have to learn it: the task does not cue them to do so. In our view, although learning sequential structure in a set of exemplars provides a possible mechanism, for the judgement of grammaticality task, it implies compulsory learning of sequential regularities even though that action is neither implied by nor cued by the task. Unlike the SRN, Minerva 2 assumes people notice sequential characteristics of each exemplar, but they do not learn the regularities in the set of exemplars. Moreover, because our account treats judgement of grammaticality as a retrospective judgement, it is not necessary to justify or to describe prospective abstraction of structure in the training set.

In developing our holographic representation scheme, we have been careful to avoid altering our model's assumptions about retrieval. In both our original and our present accounts, we assumed a perceptual system loads memory with what the subjects notice about each of the studied exemplars. Judgment of grammaticality reflects the global similarity of a test probe to training items. The difference in our new account is that the new model assumes that subjects notice more about the order of the symbols than the old model assumed; a claim echoed in post-experimental interviews with our subjects. At a broader level, our solution honours an insight from Simon's (1969) parable of the ant. Simon noted that an ant's path on a beach may be complex and difficult to describe. But, the complexity of the path may be driven by complexity in the beach rather than complexity in the ant. Simon used the parable to goad theorists into considering explanations for a behaviour based on the complexity of the environment before assuming that the behaviour reflects complex psychological mechanisms. Here, we have followed Simon's advice. Peoples' behaviour in the artificial grammar task appears complex and difficult to describe. However, the complexity is in the materials, not in the subjects. Judgement of grammaticality reflects the storage and retrieval of studied exemplars.

Abstract

Change blindness is a phenomenon that occurs when a person fails to notice changes in their perceptual field. Previous studies have shown that East Asians are sensitive to both contextual and focal changes while Americans are sensitive to focal but not contextual changes (Masuda & Nisbett, 2006). This difference was attributed to the fact that Americans have analytical and East Asians have holistic perceptions. This study questions whether Turkish students' attention to changes in pictures is more like Americans or East Asians. Half of the study was conducted in Turkey and the other half in America. Participants looked at photographs that flickered back and forth from an original picture and an edited photograph. The photographs were Turkish, American, or Neutral. Half were complex, half were simple, and half the changes were made in the foreground and half in the background. We found that both Turkish and American students found the foreground changes a lot faster than the background changes. These results suggested that Turkish people's perception is analytical like Americans'.

Keywords: Change blindness; cross-cultural research

Introduction

One reason that there are continuity errors in movies, which go mostly unnoticed by the audience, is that resource limits prevent us from attending to every element of a visual scene. In one famous study (Simons & Chabris, 1999), 192 participants were shown a video of 6 people in two teams passing a ball. The participants were asked to count and report the number of passes occurring between players of the same team. While they were doing this task, one of two unexpected things happened in the video: either a woman with an umbrella or a woman in a gorilla suit walked by. Overall, only 54% of the participants reported seeing the unexpected event. This means that 46% of them did not "see" a very odd event, immediately obvious to anyone watching the video unburdened by other task demands.

To systematically investigate the interrelation between attention and visual awareness, Rensink et al. (1997) created the "flicker paradigm". In the flicker paradigm two versions of a picture are shown one after another repeatedly with a blank screen in between (for a review, see Simons & Rensink, 2005). The two versions of the picture are generally identical except for one small change. In a typical application of this paradigm, participants are asked to find the changes between the two versions. They almost always

find all the changes if they are given enough time, but depending on the sort, size, and placement of the change, it can take several minutes or more. This failure to quickly notice changes in one's perceptual field is called change blindness.

Rensink, O'Regan and Clark (1997) ran a series of experiments investigating change blindness. In their first experiment they had their participants find the change in a regular flicker task. They found out that the participants took twice as long to find the changes in the background than it took them to find the changes in the foreground. In another experiment they gave the participants verbal cues where the change was. When the participants' attention was directed, they were significantly faster at detecting the changes. Moreover, there wasn't a difference between the time it took them to notice changes in the foreground and in the background. They concluded from these experiments that the "key factor" to notice a change is attention.

The facts that people need to pay attention to notice a change and that we naturally notice changes in the foreground, taken together, should mean that people pay more attention to the foreground. Masuda and Nisbett (2001) challenged this idea. They thought that since Westerners and East Asians have different attributions (Westerners attribute outcomes to individual factors, whereas East Asians to situational factors), they could have differences in perceptual orientations. They showed Japanese and American participants clips of underwater scenes and then asked to recount what they saw. Their results showed that Japanese participants stated significantly more information about the background than the Americans, whereas there wasn't a difference in their statements about the foreground. Moreover, Japanese participants referred to an object's relationship to the background twice as much as Americans.

Masuda and Nisbett (2006) extended these findings using the flicker paradigm. They hypothesized that Japanese would be more sensitive than Americans would be to changes made in the backgrounds of the pictures. Their results showed that Japanese participants were just as fast as Americans to find the changes in the foreground and were a lot faster than Americans to find the changes in the background. When they asked their participants to recall as many changes as possible in briefly shown flickering scenes, Americans remembered marginally more number of

changes in the foreground, whereas Japanese remembered significantly more number of changes in the background.

Nisbett and Miyamoto (2005) have attributed these differences in the attentional processes of Westerners and East Asians to Westerners' having analytical perceptions and East Asians' having holistic perceptions. Analytical Westerners attend to salient objects and their category memberships, whereas holistic East Asians attend to contexts and relationships. The authors think the reason behind this difference is the differences in social structures: the East Asian social world is interdependent, while the Western social world is individualistic.

While this proposal is compelling for two cultures that vary quite considerably in their social make-up, the predictions are less clear for cultures that may fall somewhere between classic "East" and "West" mentalities. In the present investigation, we seek to explore the attentional processes of just such a group: the Turkish. There have been very few studies done on Turkish people's perceptions. Hence, it is unclear whether Turkish perception is holistic or analytic. Turkey is located between the individualistic West and the collectivistic East. Moreover, although Turkish history is quite collectivistic, current trends and the growth of capitalism in Turkey suggest that people are becoming rapidly more individualistic (Çileli, 2000). Çileli administered surveys to hundreds of college-aged people in Ankara in 1989, in 1992, and in 1995. The participants scaled 36 values according to how they thought these values affected their lives. The values were divided into terminal and instrumental values; terminal values were about where one wanted their life to end up and instrumental values were about one's behaviors. The results in 1989 showed that most important values for the participants were self-respect, freedom, inner harmony, equality, independence, honesty, broad-mindedness and courage, whereas the least important values were having an exciting life, pleasure, national security, salvation, politeness, imagination, cleanliness and obedience. On the other hand, in 1992 and 1995 the results showed that most important values for the participants were inner harmony, happiness, mature love, exciting life, ambition, cheerfulness and capability, whereas the least important values were freedom, social recognition, comfortable life, true friendship, politeness, honesty, helpfulness and imagination. Çileli concluded from these results that Turkish people were becoming more hedonistic and competitive and hence more individualistically oriented. In short, Turkish people have a unique relationship with collectivistic and individualistic orientations, making them a particularly interesting test case for exploring how they perceive the world. The outcomes have implications for helping us better understand the social orientation of modern Turks and, furthermore, for providing additional support for proposals about how attention is involved in the visual perception of change.

In the current study we carried out a change blindness experiment with the flicker paradigm in which Turkish and American participants looked at some scenes which had

changes in the foreground or background. Our experiment was intended to explore whether and how Turkish and American perceptions differ. We recorded how long it took for the participants to find the change. We expected Americans to be quicker at detecting changes in the foreground than the ones in the background and Turks to be quicker at detecting changes in the background than the ones in the foreground. In other words, we expected to find that Turkish people had holistic perspective because we assumed Turkish culture to be primarily collectivists since the trend of individualism was fairly new, whereas Turks have always been interdependent. We also looked into how the culture of photographs affected the participants' reaction times. We used photographs that were taken in the USA or in Turkey and some photographs were neutral, as in they could belong to either country. We thought that Americans would be quick at finding changes in American and neutral pictures but slower at finding changes in Turkish pictures and Turks would be quick at finding changes in Turkish and neutral pictures but slower at finding changes in American pictures.

Methods

Participants

Our participants included two groups: American and Turkish. The American participants consisted of 15 Franklin & Marshall College students who were only fluent in English. A sign-up sheet was posted so students could sign up independently to participate in our study. We stated the requirements (being American and being fluent only in English) in our sign up sheet and included questions about nationality and language proficiency in our demographic questionnaire. The Turkish participants were 15 college students in Bilkent University in Ankara, Turkey. Again, a sign-up sheet was posted for students to choose a time to participate in our study. A requirement on the sign up sheet to participate was that the participants should be Turkish and speak only Turkish fluently. As we did with the American participants, we double-checked this by including questions about nationality and language proficiency in our demographic questionnaire. The participants of both groups received class credit for participating in this experiment. Of all the participants we had to disregard 2 participants because of failure to follow directions and 3 participants because they were outliers (their reactions times were two or more standard deviations above or below the mean). The final number of participants was 12 American (8 women, 4 men, age range: 18-23, $M = 19.8$) and 13 Turkish students (10 women, 3 men, age range: 18-23, $M = 20.8$).

Materials

The materials consisted of an iBook, various photos, and two computer programs (Adobe Photoshop and a Change Blindness application created at Franklin and Marshall College). The pictures were edited to be the same size and the focal/contextual changes were made with Adobe

Photoshop. They became flickering movies using the Change Blindness application. There were three categories of pictures: American, Turkish and neutral. American pictures were scenes only found in the United States and not in Turkey. American participants would be familiar with these scenes; whereas, Turkish participants would be unaccustomed to them. These scenes were a Halloween party, a street from Los Angeles, an intersection in the Times Square, a baseball figure, a football game, a house with Christmas lights, a statue of Abraham Lincoln, and a Hollywood star. Turkish pictures were scenes that could only be found in Turkey and not in the states. These scenes were familiar for Turkish participants but not for Americans. These scenes were people doing halay (a traditional Turkish dance), a saz ekibi (an orchestra of classical Turkish instruments), the blue mosque, a fancy evil eye, a chestnut stand on the sidewalk, a woman making gozleme (big Turkish crepes), kina gecesi (the pre wedding celebration where the women put henna on their hands), and the kiz kulesi (a very known building in the middle of Bosphorus). The neutral pictures were scenes that can be found in both countries. All participants would be accustomed to these scenes. These scenes were a family dinner, a girl with a birthday cake, three people in skiing outfits, a dorm room, a beach, girls eating dessert, a guy playing electric guitar and a dining hall.

A control variable for all the scenes was complexity because it has been suggested that complexity of a scene can prime the viewer to perceive holistically or analytically (Masuda & Nisbett, 2006). The photographs were all altered so they were of equal size. Each category has an equal number of simple and complex scenes. The simple scenes were scenes either with a straightforward focal point or with very few objects to focus on. The complex scenes had many objects and the subject of the scene isn't clear. In order to assess whether others think the photographs are simple or complex, we had non-participating students highlight the area of each photograph that they thought was the focal point. Simple scenes were defined as having only 1 area highlighted by all the people who did this pre-test. Complex scenes had 2 or more different areas of the picture highlighted. Half of all the pictures got a focal change (one that is in the area of the photograph that is the focus) and the other half received a contextual change (one that is made more in the background). We used the highlighted photographs to help us decide where the focus of each photograph was. In this way we were able to know where to make focal and contextual changes. The changes that were made to the photographs were taking an object away from the photograph. Half of the photographs shown to the participants started with the object in question and half started without it.

Each picture was made into a movie using the Change Blindness application with both versions going back and forth and a gray scene between them (for the flicker effect). The outline for a movie would be the original picture (560 msec), a gray scene (120 msec), the modified picture (560

msec) and a gray scene (120 msec). The movie played in a loop until the change was found. The Change Blindness application also recorded the reaction time of each participants' identification of the change in each picture. Fifteen files were created, each containing all 24 movies in different random orders. Based on their ID number, participants viewed one of the fifteen files.

Procedure

Participants signed up in posted time slots. They came to the study and sat at a table with the computer and a mouse in front of them. All participants were informed of what will be asked of them in the study. They signed an informed consent form indicating their willingness to participate in the experiment. They were assigned ID numbers that correspond with their data and demographics so confidentiality was preserved. Participants were given a demographics questionnaire including questions on age, gender, year in school, country of birth, and language proficiency.

As soon as they were ready, the experimenter started the Change Blindness application with the correct file of photographs for that participant. The participant was asked to click the provided mouse when they found the change. The computer program would then pause and record how long it took the participant to find the change in that flickering picture. The recorded time would be the reaction time of that participant to that picture. Then the experimenter asked the participant to show the change. All data in which the participant identified an incorrect change was disregarded. The participant was shown the each flickering picture (8 American, 8 Turkish and 8 neutral). After the participant was done, the experimenter gave them a copy of the informed consent, which included the experimenters' e-mail addresses. The American participants did this study in Franklin and Marshall College's Barshinger Life Sciences Building. The Turkish participants did this study in Bilkent University's Psychology building. This part was carried out in Turkish since the participants' most fluent language was Turkish. Therefore, the experimenter's script was in Turkish, as were all instructions, the demographics questionnaire, and the consent form.

The dependent variable was the reaction time. The independent variables were the place of the change, the category of the picture and the nationality of the participant. We analyzed the results with a 2 (Foreground/Background change) X 3 (Turkish/American/Neutral photograph) repeated measures ANOVA with nationality (Turkish/American) as a between-subjects factor. Moreover, we ran a 2 (Foreground/Background change) X 2 (Simple/Complex picture) repeated measures ANOVA with nationality (Turkish/American) as a between-subjects factor.

Results

We did not expect to find similar results for American and Turkish participants; however, our results showed that there were not significant differences between them. In other

words there was no main effect of nationality $F(1, 23) = .449$, $p = .510$. There was not an interaction between nationality and place of the change $F(1, 23) = .134$, $p = .717$; however, there was a main effect of the place of the change $F(1, 23) = 10.3$, $p = .004$. As can be seen in Figure 1 American participants found the foreground changes ($M = 22.5$, $SD = 3.51$) faster than they did the background changes ($M = 31.1$, $SD = 3.47$) and Turkish participants also found the foreground changes ($M = 24.0$, $SD = 3.38$) faster than they did the background changes ($M = 34.7$, $SD = 3.33$).

Figure 1: Mean reaction times of American and Turkish participants for finding the changes in the foreground and the background.

There was a main effect of the category of the picture $F(2, 22) = 15.1$, $p < .001$; however, there was not an interaction between nationality and category of picture $F(2, 22) = 2.12$, $p = .143$. That is to say Americans and Turks had similar reaction times within each category of picture. Americans were fastest in finding the changes in neutral pictures ($M = 16.4$, $SD = 2.83$) and took about the same time to find the changes in American pictures ($M = 27.3$, $SD = 4.80$) and Turkish pictures ($M = 36.8$, $SD = 4.70$) just like Turks were fastest in finding the changes in neutral pictures ($M = 19.0$, $SD = 2.72$) and took about the same time to find the changes in American pictures ($M = 38.8$, $SD = 4.62$) and Turkish pictures ($M = 30.3$, $SD = 4.52$). The mean times for finding the changes in the three categories of pictures for both nationalities are presented in Figure 2.

Figure 2: Mean reaction times of American and Turkish participants for finding the changes in the three picture categories

There was a main effect for complexity of the picture $F(1, 23) = 61.6$, $p < .001$ as shown in Figure 3. As one can see from Figure 3 the participants took significantly less amount of time to find the changes in the simple pictures than they did in the complex pictures. There was not an interaction between nationality and complexity $F(1, 23) = .315$, $p = .580$ which means that Americans' and Turks' reactions time were similar for both complexity conditions. There was not an interaction between complexity and location either $F(1, 23) = 4.02$, $p = .057$. The participants found the changes in the foreground fastest in both complexity conditions. There was not a three-way interaction between complexity, location and nationality $F(1, 23) = .187$, $p = .669$.

Figure 3: Mean reaction times of American and Turkish participants for finding the changes in simple and complex pictures.

Discussion

As the past research suggested we found that Americans find the foreground changes faster than background changes. We also found that this pattern of results held for the Turkish participants. These results did not support our hypothesis that Turkish people have a holistic perspective. These results suggest that Turkish people have an analytical perspective.

This finding can perhaps be explained by the changes Turkey has been going through. Capitalism is growing in Turkey, which encourages people to be more individualistic and hence more analytic. Every day Turkish people are trying harder to be more like Westerners. American movies influence what is shown in Turkish movie theaters and on Turkish television. Traditional Turkish dances are being regarded as lame, whereas hip-hop and break dances are being regarded as cool. A lot of Turkish values are getting lost and Western ideas are becoming more popular. In a study a group of Turkish high school students were shown the video clip of Rammstein's "We are all living in America" and were asked about their thoughts (Pehlivan, 2007). The general consensus of the students was that the USA was more advanced than Turkey and also than various African or East Asian countries. In other words they associate that advancement with the West. One of the students even called Turkey "an orphan" since he reasoned the Western countries were so much better than Turkey. These current individualist attitudes might account for our results.

A reviewer has pointed out to us that our results also might be taken to mean that people from collectivistic cultures can have analytical perspectives, and that the relativistic viewpoint of Masuda and Nisbett (2006) should perhaps be questioned. We believe our reviewer's concern is a valid one since there has been some evidence found in the favor of it. For example, de Fockert et al. (2007) have found that people from a very traditional culture in South Africa had extremely analytical perceptions. We do not agree with this point of view for the following reason. Past research has suggested that Turkish youth are becoming more and more individualistic. We believe that is why our results suggest that Turkish people have analytical perspective. To confirm our hypothesis it might be useful to compare older Turkish people to younger ones in this paradigm. We expect that older adults might be more collectivistic and therefore show a different pattern in a change blindness study. A clear-cut difference between the patterns of older and younger Turkish people would indicate two things. Firstly, it would indicate that our results from the current study could be explained by the transition Turkish culture is going through. Secondly, it would indicate that the idea that holistic cultures might have analytical perspectives did not hold true in the case of Turkish people. The current study is only a preliminary to further research on Turkish people's perceptions.

In fact, there is much more room for research in this area, which has in general been under-explored. A comparison

experiment between Turkish people and East Asians could be done in order to further investigate the possibility that Turks have an analytical perspective. A study like Masuda and Nisbett's (2001) would uncover whether Turkish people pay attention to background or the relationship between objects similar to East Asians. Another way of taking this research further would be by doing a real-life change blindness experiment like the study in which random people on the campus of Vanderbilt University were asked to remember the color of a binder the experimenter was holding, and the word inside the binder (Varakin, Levin, & Collins, 2007). The participants were unaware of many changes in their environment like the font of the word in the experimenter's binder. The participants in this study were all Westerners. The results could have been different if the participants were East Asian and even if they were Turkish. Just because Turkish people were similar to the Westerners at noticing changes in flickering images on a laptop does not guarantee that they would be similar to Westerners at noticing changes in real life change blindness experiments.

In our experiment we tried to get rid of confounds by having only American and Turkish participants so that the groups would be more homogenous, unlike the study in which different cultures of East Asia were grouped all these different cultures (Chinese, Japanese and Korean) under one group (Masuda & Nisbett, 2005). Furthermore, we tried to control for differences in the photographs as much as possible. We used half simple and half complex pictures in each category of culture of the photograph (American, Turkish, and neutral). Our purpose in controlling complexity was that we did not want to end up with one of our categories of pictures that consisted of only complex pictures. A reviewer has suggested that American and Turkish participants might have been affected differently by the complexity of the picture. Our results did not support this. We found that American and Turkish participants had similar reaction times for both simple and complex pictures.

In our experiment we were expecting the participants to be fastest in the pictures they were familiar with. There was a main effect of the category of the picture but it was not like how we expected it to be. All participants found the changes faster in the neutral pictures than the Turkish or American pictures. This could be because the changes in the neutral pictures might be slightly bigger than the changes in the other categories since we only approximate the size of the change. This difference could also be due to the subject of the pictures. Only half of the Turkish and the American pictures were about people but almost all of the neutral pictures were of people. The changes were not always made to the people but it could be that the participants were better at detecting changes in pictures of people. This unexpected effect emphasized that the pictures and the changes should be even more controlled. More control on the changes could be accomplished by having a constant change in all the pictures. For example, a cup would be appearing and disappearing in pictures. This cup could be in the

foreground or the background; hence, keep the size of change same no matter where it occurs.

The current study aimed to get some insight into Turkish people's perceptions. We ran a change blindness experiment on Turks and Americans. We were expecting to find that Turkish people have holistic perceptions like East Asians; however, our results suggest that they have analytical perceptions like Westerners. We believe that there needs to be more research done in this area to understand how exactly Turkish people perceive the world.

Acknowledgments

Prof. Michael Anderson served as scientific advisor for this project; we would like to thank him for his unwavering support and help. We would like to thank Bilkent University, especially Emre Ozgen for all their help. We would like to thank Prof. Krista Casler for her helpful comments on an earlier draft.

Abstract

Analogical mapping theories tend to focus on matching identical symbols (either for objects or the relations between them). In the domain of visual representations we implemented a mapping system that uses separate domain knowledge (a shape-type superclass hierarchy) to re-represent analogs such that identity can be found at different levels of abstraction. Such a scheme is useful where shape, and not the spatial layout of the analog images, is important to aligning visual objects.

Introduction

Mapping, a core part of analogy, is finding the alignments between the elements of two analogs. For example, in an analogy between a face and the front of a car, a mapping might include an alignment between the eyes and the windshield. Such an alignment might be based on the fact that the “perceptual” input to the car happens at the windshield for a car as do the eyes for a face.

Mapping is combinatorially complex, and this complexity is reduced by finding similarity between the elements to be mapped. In the example above, the alignment is justified by the *functional* similarity between the eyes and the windshield. In the discussion section we will describe different similarity measures for implemented mapping systems.

Our work focuses on mapping for purely *visual* analogs. That is, we are exploring different similarity measures that are appropriate for mapping the visual components of images. To return to the car/face example, rather than *functionally* aligning the eyes and the windshield, an agent that focused on visual similarity might align the eyes to the headlights because they both consist of two elements, are both round, and are horizontally oriented.

One way to find similarity between visual elements is by identification of identical symbols relating the elements. Most simply, if two elements are described in the representation as *square*, then the mapping agent can favor their alignment. Another way is to identify identical symbols that *relate* elements of the same image. For example, if in one image *element-x* is related to *element-y* with a symbol *is-above*, then a mapper interested in the structure of images might

want to align *x* and *y* to *f* and *g*, if indeed *f is-above g* in the other analog—regardless of what shape *x*, *y*, *f* and *g* are. Structure Mapping Theory (Gentner, 1983) uses identity of the symbols describing structure to find mappings between analogs.

Grouping

The Gestalt psychologists found that people perceptually grouped visual elements according to, among other aspects, shared orientation, color, and proximity. This provides psychological evidence for an explicit representation of visual element grouping. Broadly speaking there are two kinds of groups in our work: *aggregations* and *sets*. Aggregations are multiple visual elements that form one coherent shape (e.g. a square is an aggregate of four lines). Sets are groups of elements that are unconnected but similar in some way (e.g. nuts in a bowl).

Sets and aggregates appear at a certain level of abstraction, at which they can be aligned to each other as visual elements. An agent with a flexible representation can, however, zoom into these groups. There are two reasons an agent might want to do this: First, If the agent must decide which group to align to which other group, the conflict resolution might require an examination of the contents of that group. Second, it might be important to align group members. For example, imagine aligning two armies—at this level of abstraction armies can be moved and split apart, and it makes sense to have the armies’ generals simply be members of the army sets. But if the agent needs to reason about the generals in particular, it could be important to know that the general in one set aligns to the general in the other. In analogical problem solving, for example, certain operations need to be applied to elements of analogs.

Different levels of representation are needed for different transformations applied to the analog (Davies, Goel, & Nersessian, 2003). Likewise with aggregates, mapping one box to another is the right level of abstraction for motion of the entire set, but opening one side of the box by moving one of its constituent lines requires a mapping at the component level.

For these reasons it is helpful for an agent to be

flexible in its representations such that it can reason at multiple levels of grouping abstraction.

Shape-type Superclass Hierarchy

The above similarity notions use the nature of the analogs as given in the representation. However similarity can also be found through the application of domain knowledge to the analogs. In the visual domain, this can take the form of a shape-type hierarchy (See Figure 2.) For example, a right triangle and an isosceles triangle are similar because they are both triangles. Even in cases where the term *triangle*, and its relation to *right-triangle* and *isosceles-triangle* are not explicit in the representation of the analogs, an agent can use the domain knowledge of a shape-type hierarchy to find element similarity. We will show that abstraction using this hierarchy is particularly useful (compared to structure-mapping) for analogs in which the spatial arrangement of the visual elements is less important than the shapes of the objects represented. The examples we explicate below are of this type. Using abstraction has been used in Minimal Ascension (Falkenhainer, 1988) and in cross-domain analogical learning (Klenk & Forbus, 2007).

Our theory is that aggregation and set abstraction are useful representations for mapping *visual* analogs, and that re-representation using a shape-type hierarchy can address some cases of ontological mismatch, where similar ideas cannot be identified as such because they are represented with different symbols.

Model

In this section we will describe our theoretical models for the three kinds of visual abstraction in more detail.

Our representational architecture consists of propositions, each of which connects two symbols with a relation. For example

(butterdish looks-like rectangle)

connects the *butterdish* symbol to *rectangle* with a relation that the agent uses to align symbols with the same shape type. This uses the Covlan visual language (Davies & Goel, 2007).

Set and Aggregation Hierarchies

Sets are explicit visual objects with no shape. They have links to their members, and the members likewise have back-pointers to the sets. Sets can contain other sets as members. Sets get aligned to other sets through some similarity measure based on the shapes of their members, but the members themselves will not be mapped unless the agent has a specific reason to do so. The cognitive justification for this is introspective: we do not appear, for example, to align each paper clip in one pile to each binder

Figure 1: Component Aggregation Hierarchy

clip in another pile unless there is reason to do so, even though we might see the two sets as similar.

The same goes for aggregate objects. At the first pass of mapping, the aggregates are mapped to each other. In instances of conflict, the agent uses a measure of the shape similarity of the components to resolve it.

When there is a need to align the members or components, the entire mapping function can be recursively called on the sets or aggregates in question—that is, restart the mapping process as though the two aligned sets or aggregates were to be the two images to be mapped.

The simplest kind of aggregates are visual elements aggregated together. Using knowledge of a shallow *aggregation hierarchy* (see figure 1) the agent can bring more domain knowledge to bear on the aggregate objects to align the components. When called upon to do align the components of simple visual elements, to resolve conflicts the most specific element in either aggregate object is decomposed into its aggregate parts. Then the identity-based mapping system tries again. This process repeats until all the align-able sub-elements are aligned.

Shape-Type Hierarchy

Each level of the shape-type hierarchy is associated with a level number. The higher the number, the less abstract the shape is. Abstraction is changing a shape to its more abstract form. For example, abstracting a *square* (level 8) means transforming it to a *rectangle* (level 7).

Process

Mapping is iterative. A *mapping* is a set of *maps*, which are alignments between a visual element in one analog to an element in the other.

1. Create maps of identical shape types, including aggregates and sets, ignoring the components of aggregates and the members of sets. If there is a conflict with mapping aggregates and sets, break them up into their constituents and see which are the most similar (a simple vector analysis of the contents).
2. If there are no more shapes to map in either the target or the source analog, recursively run this

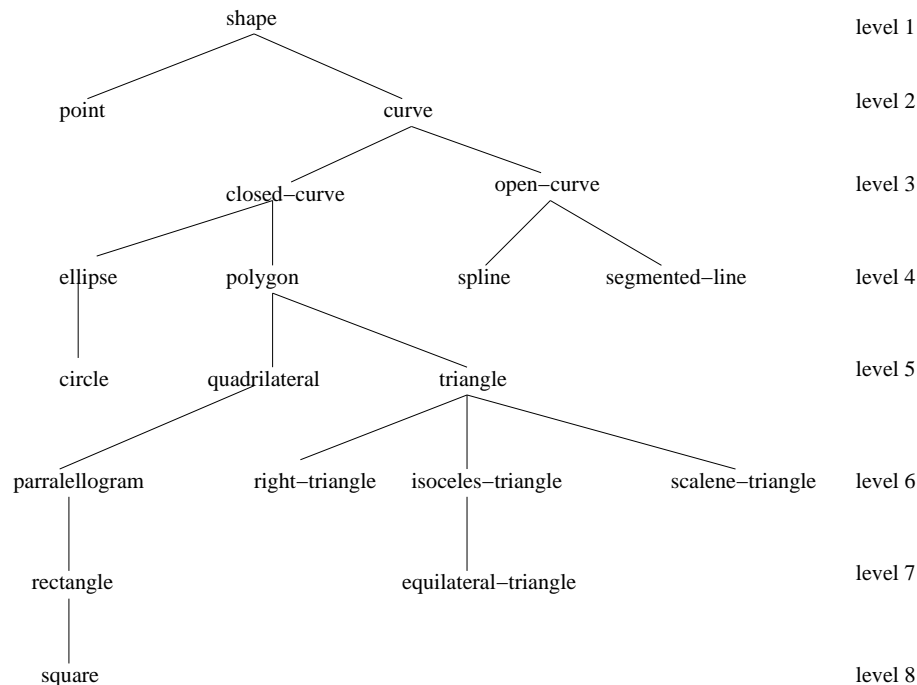

Figure 2: Shape Type Hierarchy

mapper on the members of sets and the components of aggregates, if any, then exit.

3. Abstract the highest numbered visual primitive in either analog one level. Go to step 1.

The visual elements need to be abstracted separately. If every element in the image is abstracted at once, matches will miss each other as they pass through levels of abstraction.

Implementation

We have some implemented the ideas above in a running computer program called *Thalassa*. *Thalassa* maps identical shapes and groups, and abstracts shapes with the shape-type hierarchy.

Thalassa has two basic components: a frame system and a “classical” problem solver. First, the “memory” of shape types and images with their elements and aggregate objects and such was built using a simple frame system. Relations of the sort (**building looks-like square**) lend themselves naturally to a frame-based representation, where the frame for **building** has a slot **looks-like** with the filler **square**. Likewise an image is a frame with a slot **contains-elements** whose filler is a list of elements (symbols naming visual element frames) in the system. Though the content of the frames in our actual implementation was sparse, the idea is that any extra information that might be useful to a larger problem-solving context could be added. For instance, surely people are aware of the location

(qualitative or relative) within an image of a particular visual element, and the frame representation naturally allows one to add a slot **has-location** (or what have you). The only information actually used in the implementation was the **looks-like** slot for each visual element and the **has-size** slot (which took sizes like **small**, **medium**, and **big**).

Problem Solver

The second part of the implementation was the problem solver itself. Following the problem space hypothesis, and using the Classical Problem Solver (Forbus & DeKleer, 1993), we transformed the mapping problem into a search problem. One can think of one “state” of the search as the current set of maps—that is, the list of elements in each of the two analogs that have been mapped so far. An operator generating a new state in the search can do one of two things: map as many elements with the same shape as possible (generating a new state for each partial matching possible), or else pick one element to abstract.

The actual data structure representing a “state” in the search had the following elements:

Source The name of the source image frame

Target The name of the target image frame

Maps The list of maps gathered so far

Unmapped Source Elements A list of source elements that have not been mapped onto target

Figure 3: These two analogs represent a table before and after dinner. The fork and spoon are aggregate objects. Pictured are plates, butter dishes, forks, knives, spoons, and napkins.

elements, initially set to all the source elements in the image.

Unmapped Target Elements A list of target elements that have not found source analogs, initially set to all the target elements in the image.

Needs Abstraction? A flag indicating that there are unmapped source and target elements that cannot be mapped without abstracting the shape types.

Abstractions A data structure that associates with each element (source and target) it's currently abstracted shape type. This is initially filled with the fillers from the **looks-like** slot, and as shapes are abstracted the contents slowly change.

The goal condition in this search is simply that either the **unmapped-source-elements** list or the **unmapped-target-elements** list becomes **nil**, in which case there are no more elements to match.

The next state operator **generate-new-mappings** simply checks the **needs-abstraction** flag, calling **abstract-one-element** if it is true, and **extend-mappings** otherwise. The **abstract-one-element** function is quite simple: it sorts the complete list of unmapped elements, choosing the one with the highest level arbitrarily (that is, if there are several, choosing the one at the front of the sorted list as an arbitrary choice) to abstract one level, if possible. It cannot abstract anything past **shape**, obviously (that being the top of the hierarchy), and so returns nothing if all of the shapes in the image are fully abstracted.

The **extend-mappings** function is much more complex. It has three parts: (1) generate all possible **maps-to** relations for each unmapped target element, separating them into whole mappings as it goes; (2) separate **maps-to** relations within each mapping that map onto the same source into separate whole mappings; and (3) generate a new state for each whole mapping.

Figure 4: In the lot source there is a group representing a 18 wheeler (an aggregate of a square representing the cab and a rectangle representing the trailer). Also in the image is a set of garbage cans. Note there are a different number of cans in the analogs. The irregularly shaped object is a puddle, and the lone rectangle is a dumpster.

The first part of this operation makes a list of all the elements that map to the given target (which is simply a list of all the unmapped sources that are identical under the **looks-like** relation and the current abstractions), and separates these into whole mappings, where one whole mapping has one **maps-to** relation for each target (there may be targets with no mapped sources, of course). It takes care to assemble all combinations when doing this.

The second part of the mapping looks within each mapping for two maps that map separate targets to the same source. If one is found, it is split into two mappings by removing one and then the other map from the mapping.

The third part simply takes each whole mapping, filters out those elements (sources and targets) which have been mapped from the unmapped elements lists, and generates a new state. A list of all new states is returned.

The search returns all mappings that it found. It's not clear to us that there is necessarily any cognitive plausibility in this decision, but for the sake of implementation we thought it best to have it return all mappings rather than choose one arbitrarily as the "best" mapping to return (one of the examples discussed below had several possible mappings).

One feature that has not been implemented in this version is recursing on aggregates and sets. Also, the system could often abstract in more than one way, and it's not clear that choosing one thing arbitrarily to abstract is the best decision; it seems wiser to have it abstract in all possible ways, generating new states (and hence new subtrees) in the search (space) for each one.

Figure 5: The faces example has similar faces reflected and rotated 180 degrees. Such transformations do not preserve many spatial relations, with certain exceptions such as containment and connections. The numbers represent the level of specificity of each shape in the shape-type hierarchy.

Test Examples

We ran this system on three test examples. The first, illustrated in Figure 3, was a table set up before and after a meal (not necessarily images from the same meal), where the elements are scattered about the table after the meal, and so structure would probably be uninformative. However, a fork looks like a fork, a plate looks like a plate, and so on. In fact, the system found four mappings: the fork could map to the fork or the spoon (and vice versa), and the napkin could map to the napkin or the butter dish (and vice versa). Everything else mapped to the element of the same name, thus giving four mappings.

The second, illustrated in figure 4, was supposed to be an overhead view of a parking lot, with a dumpster and a group of trash cans and a truck aggregate (cab and trailer) and a puddle all in different positions. this had only one mapping.

The third example, illustrated in figure 5, mapped a face to another face reflected and inverted. Again, only one mapping was found.

Discussion

We are theorizing about solutions to the cognitive problem known as the ontological mismatch problem: When two ideas that should be thought of as similar are not because they are represented with different symbols. This problem manifests itself in mapping because the labels for objects and relations often do not match exactly. For example, mapping *orbits* with *revolves-around*.

Our solution uses shape-type abstraction, which is a content account of the visual domain. EMMA (Ramscar & Yarlett, 2003) uses a content account as well to solve ontological mismatching for analogy. The knowledge EMMA uses is the correlation of word proximity in text (Latent Semantic Analysis,

LSA). Each word in LSA correlates with each other word. When trying to map, different words with a correlation above a certain threshold are considered equivalent, and can be mapped.

The Structure-Behavior-Function knowledge representation language (Goel et al., 1997) offers another means for resolving ontological mismatches. SBF language representations of systems include functional descriptions each device component.

Forbus et al. (1998, p.246) and Hummel and Holyoak (1997) both suggest that ontological mismatches can be resolved through re-representation using abstraction (e.g. *lift* and *push* can abstract to *move*). This idea also suggests a superclass hierarchy, but to our knowledge neither research group has implemented this.

Other implemented mappers rely on the identity of symbols (either of the mapped concepts or the relations between them) and on a canonicalized representation to avoid ontological mismatches.

Ours is a content based account that uses re-representation using domain knowledge of visual objects.

Conclusion

In this paper we have described a method based on domain knowledge for analogical mapping of visual representations. Specifically, we focused on grouping and shape-abstraction. The one-to-one mapping constraint is maintained for our system, but sets and aggregates are treated as object to be mapped. Our ideas are implemented into a running computer program called Thalassa. Future versions of Thalassa will be able to recursively map set members and aggregate components.

We conjecture that these content-based mapping strategies will prove superior to structure-mapping in cases when the analogs share similarly-shaped components but where the spatial arrangement of the objects is disordered. A full, cognitively plausible model of visual mapping will need to include both structure and object mapping. Future research will test these claims through computational comparison with structure-based mapping engines on several examples.

Abstract

Human sentence processing occurs incrementally. Most models of human processing rely on parsers that always build connected tree structures. But according to the theory of Good Enough parsing (Ferreira & Patson, 2007), humans parse sentences using small chunks of local information, not always forming a globally coherent parse. This difference is apparent in the study of local coherence effects (Tabor, Galantucci, & Richardson, 2004), wherein a locally plausible interpretation interferes with the correct global interpretation of a sentence. We present a model that accounts for these effects using a wide-coverage parser that captures the idea of Good Enough parsing. Using Combinatory Categorical Grammar, our parser works bottom-up, enforcing the use of local information only. We model the difficulty of processing a sentence in terms of the probability of a locally coherent reading relative to the probability of the globally coherent reading of the sentence. Our model successfully predicts psycholinguistic results.

Keywords: sentence processing; parsing complexity; local coherence; Good Enough parsing; Combinatory Categorical Grammar

Introduction

A major topic of inquiry in cognitive science is the process by which people produce and comprehend sentences. Human sentence processing is known to proceed incrementally: people construct syntactic and semantic interpretations gradually as a sentence unfolds, rather than waiting until after the whole sentence has been received. But although we know that syntactic information becomes available progressively while comprehending a sentence, it is still an open question to what extent decisions made early in the parsing process can constrain later decisions.

One phenomenon that can shed light on this question is local coherence effects. Local coherence effects arise when a sentence includes a substring with a plausible local interpretation that is incompatible with the global interpretation. (In other words, the interpretation is merely locally coherent, but not globally coherent.) A typical example (from Tabor, Galantucci, & Richardson, 2004) is:

- (1) **A/R:** The coach smiled at the player tossed a frisbee.

A typical reader, seeing this sentence for the first time, will find it difficult to understand and will likely judge it to be ungrammatical. But this difficulty is unexpected in light of similar sentences:

- (2) **U/R:** The coach smiled at the player thrown a frisbee.
(3) **A/U:** The coach smiled at the player who was tossed a frisbee.
(4) **U/U:** The coach smiled at the player who was thrown a frisbee.

These four sentences, all intended to be close paraphrases of one another, illustrate a puzzle: while the majority of readers reject (1), they accept (3) and (4), with mixed results for (2). These sentences differ on two dimensions: the past participle can be Ambiguous (such as *tossed*, which can be a past participle or a past tense form) or Unambiguous (such as *thrown*), and the relative clause can be Reduced (without *who was*) or Unreduced (with *who was*). Neither of these alternations generally changes the grammaticality of a sentence, so we would naively predict that if (4) is acceptable, then (1) is as well. Our challenge is to explain why this naive prediction is wrong. Intuitively, it seems that the local coherence of the substring *the player tossed a frisbee* in (1) as a plausible complete sentence is distracting from its globally correct interpretation as an object with a relative clause.

Tabor, Galantucci, and Richardson demonstrate the existence of local coherence effects as a psycholinguistic phenomenon in two different studies: in the first, they find increased reading times at the ambiguous past participle in (1). They present subjects with sentences from 20 sets of sentences like those seen above and measure reading times for each word using self-paced reading. In this methodology, longer reading times are taken to indicate increased processing difficulty. As expected based on previous studies (e.g. Ferreira & Clifton, 1986), they find substantially increased reading times for the Reduced cases as compared to the Unreduced cases, both on the past participle (e.g. *tossed*) and on the following word. Moreover, they find an unexpected interaction between Ambiguity and Reducedness: while the A/U reading times are not significantly different from the U/U reading times, the A/R reading times are substantially increased relative to the U/R reading times. This superadditive difficulty of the A/R condition is the signature of a local coherence effect.

In the second experiment, Tabor, Galantucci, and Richardson replicate the first using a grammaticality judgement task.

Figure 1: Grammaticality judgement data from Tabor, Galantucci, and Richardson (2004). The signature of a local coherence effect is the superadditive proportion of ungrammatical judgements in the Ambiguous/Reduced condition.

They find decreased acceptance of Reduced sentences as grammatical, with an interaction between Ambiguity and Reducedness such that A/R sentences are judged unacceptable superadditively often (see Figure 1). Once again, decreased acceptability judgements are taken to indicate processing difficulty.

Note that sentences in the A/R condition are not just standard garden path sentences. In a standard garden path sentence, the disambiguating information comes after the reader has already been led astray. In contrast, in sentences such as (1), the disambiguating information comes at the beginning of the sentence. Thus the reader in theory already knows that *tossed* cannot be a past tense form and must be a past participle. Yet despite that, these sentences cause processing difficulty.

A model of human sentence processing should be able to predict the difficulty of sentences with local coherence effects. However, most existing models cannot. In particular, most standard theories of parsing assume that that all accrued knowledge from the parsing process is taken into account at all times. Models following this assumption can straightforwardly account for standard garden paths because there is nothing inconsistent about initially misinterpreting a sentence before having access to the disambiguating information. But these models cannot take the same position in accounting for local coherence effects: when the disambiguating information has already been seen and *smiled* has already been recognized as the main verb of the sentence, they cannot entertain the inconsistent possibility that *tossed* is also a main verb. Computational implementations of wide-coverage parsers generally also make this assumption of global consistency (e.g. Roark, 2001; Sturt, Costa, Lombardo, & Frasconi, 2003; Demberg & Keller, 2008). For many applications, this

assumption may be convenient. But for a parser to be credible as a model of human sentence processing, it must be able to predict these psycholinguistic effects, which requires relaxing this assumption.

An alternate theory of sentence processing is Ferreira and colleagues' *Good Enough* (GE) parsing. Ferreira and Patson (2007) describe GE parsing:

People compute local interpretations that are sometimes inconsistent with the overall sentence structure, indicating that the comprehension system tries to construct interpretations over small numbers of adjacent words whenever possible and can be lazy about computing a more global structure and meaning.

The GE theory of parsing asserts that people do not construct full representations for sentences the majority of the time. Rather, they construct just enough to complete the task at hand, only constructing a further representation if necessary. Moreover, because people base their first-pass constructions on local information and generally construct only partial parse trees, these partial parses may contradict one another. A GE parsing account can thus easily account for local coherence effects. We will develop a computational model of why local coherence effects arise within the framework of GE parsing.

Previous Models of Local Coherence Effects

Two models have previously attempted to account for local coherence effects: Levy (2008) uses a noisy-channel model to argue that because there is uncertainty in linguistic input, the parse of a sentence should be modeled as a probability distribution over a set of candidate sentences (including the intended sentence and its near-neighbors). Given such a probability distribution, the effect of reading each word can be modeled and quantified in terms of a belief update. Levy predicts that a larger change in beliefs will correspond to greater processing difficulty and longer reading times. This in turn predicts local coherence effects because the rarer sentences provoke larger changes in belief.

Levy's model only considers fully connected and grammatical (partial) parses as candidates, thus it does not capture the intuition of GE parsing. An additional limitation of the model is that due to the computational load of calculating near-neighbors, it has only been implemented using a toy Probabilistic Context Free Grammar (PCFG), rather than a richer, wide-coverage language model.

The other previously existing model of local coherence effects comes from Bicknell and Levy (2009). They again model local coherence effects as arising from belief updates. Specifically, they model them as the consequences of an update from a bottom-up prior belief to a posterior belief that takes top-down information into account. They thus predict processing difficulty in the case of locally coherent substrings because the bottom-up statistics make strong predictions about the category of the substrings, which are then contradicted by top-down information.

This model begins to capture the idea of GE parsing by looking at substrings of different lengths. However, it has no way to integrate the information it receives from these different substring lengths because evaluating these substrings is post hoc, not an actual part of the parsing process. Additionally, like Levy’s (2008) model, it has only been implemented using a toy PCFG.

Thus there is currently no general, wide-coverage model of human parsing that implements a GE parsing strategy. Computational models of local coherence effects have instead had to account for the phenomenon indirectly, either through a noisy channel model or by predicting the effects without actually simulating the parsing process, and have been confined to parsing with small toy grammars. We will develop a model to address these shortcomings.

A New Model of Local Coherence Effects

Our goal is to model the process by which local coherence effects emerge as the result of Good Enough parsing, within the context of a wide-coverage parser. In the example sentence *The coach smiled at the player tossed a frisbee*, our intuition is that processing difficulty arises from the locally coherent reading of *the player tossed a frisbee*, which distracts from the globally coherent reading. Our model will capture this intuition by using a strictly bottom-up parser to remove the top-down influence of non-local constraints.

Strictly bottom-up parsing is frequently rejected as a plausible model for human parsing because, it is claimed, it does not allow for incremental interpretation. The standard argument says that a clause can only be interpreted when it is seen in full (i.e., at the end of a constituent). But in a strictly right-branching language, this means that nothing can be interpreted until the very end of the sentence because only then is any constituent completed.

To overcome this objection, our parser uses the Combinatory Categorical Grammar (CCG) formalism to represent linguistic structures. CCG was specifically designed to allow for incremental bottom-up parsing by using a more flexible notion of constituents.

Combinatory Categorical Grammar

Combinatory Categorical Grammar is a grammar formalism based on Categorical Grammar (CG). We base our description of it here on Steedman (2000).

CCG revolves around functional categories and rules for combining them. Categories can be either functions or arguments and are defined recursively: Base categories such as S and NP represent arguments. Functions are of the form α/β or $\alpha\backslash\beta$, where α and β are categories. To the right of the slash is the argument of the function, and to the left is its result. The direction of the slash indicates the directionality of composition: $/$ means the argument is to the right and \backslash means the argument is to the left. An English verb phrase, for example, will have the category $S\backslash NP$, indicating that it combines with an NP on its left and results in a sentence. We also allow a finite set of features on our base categories, such

Figure 2: Right- and left-branching CCG derivations for the sentence *John eats apples*. $(S\backslash NP)/NP$ is the CCG category for a transitive verb. Without type-raising, *eats* can only combine with *apples*, yielding the typical right-branching derivation in (a). With type-raising, *John* can combine immediately with *eats*, yielding the left-branching derivation in (b).

as person, number, and gender on NPs. These are notated as e.g. $NP[3sf]$.

A CCG derivation uses rules to combine categories. Pure CG relies on two rules, named $>$ and $<$, to combine categories:

- (5) $X/Y \quad Y \rightarrow X \quad (>)$
- (6) $Y \quad X\backslash Y \rightarrow X \quad (<)$

CCG introduces further combinatory rules that allow for more flexible notions of constituency than other grammar formalisms. In particular, it includes two lexical *type-raising* rules, named $>\mathbf{T}$ and $<\mathbf{T}$:

- (7) $X \rightarrow T/(T\backslash X) \quad (>\mathbf{T})$
- (8) $X \rightarrow T\backslash(T/X) \quad (<\mathbf{T})$

In these rules—which are here shown in the derivation, but in fact operate in the lexicon— T can be any lexical category taking X as argument. For instance, we could use $>\mathbf{T}$ to type-raise NP to $S/(S\backslash NP)$. Applying this rule limits the other categories the NP can combine with. Intuitively, we can think of the output of this rule as similar to an NP with nominative case-marking. It specifies not just that the word or phrase in question is a noun, but that it is a subject which must combine with a predicate.

These type raising rules allow us to parse a sentence incrementally by forming nontraditional constituents, leading to left-branching derivations (see Figure 2). CCG thus allows each new word of the input to be incorporated into the existing constituent structure as it is encountered, which makes incremental bottom-up parsing possible.

The Model

We take a bottom-up CCG parser as the basis of our model of human sentence processing. In order to predict processing difficulty caused by local coherence effects, we need a linking hypothesis to specify the relation between the parser output and psycholinguistic measures such as grammaticality judgements or reading times. Our linking hypothesis should embody the theory of Good Enough parsing, focusing on in-

interpretations of local substrings.

We adapt a model proposed by Jurafsky (1996) to predict garden path effects. To make graded predictions, rather than categorical distinctions, we will adopt a probabilistic framework, and consider the probabilities of various substrings of a sentence. In particular, we could consider either the inside probability $P(S \rightarrow \text{substring})$ (alternately written as $P(\text{substring} \mid S)$) or the inverse probability $P(S \mid \text{substring})$. We do not know of a computationally tractable way to calculate $P(S \mid \text{substring})$ from our parser. Calculating the inside probability, on the other hand, is a fundamental part of the parsing process. It is most parsimonious to base our model on the inside probabilities that are already being calculated.

Our intuition is that if an incorrect interpretation of a substring is highly plausible relative to the correct interpretation of the sentence, then it will cause processing difficulty. In a sentence such as *The coach smiled at the player tossed a frisbee*, the substring that we expect to cause difficulty is the locally coherent substring *the player tossed a frisbee*. We thus consider the ratio:

$$\frac{P(S \rightarrow \text{the player tossed a frisbee})}{P(S \rightarrow \text{The coach smiled at the player tossed a frisbee})}$$

In this case, the ratio will be high because *The player tossed a frisbee* is a relatively likely sentence. In the other three cases, the ratio will be low because none of the following are very plausible sentences:

- (9) the player thrown a frisbee
- (10) the player who was tossed a frisbee
- (11) the player who was thrown a frisbee

Although in theory this ratio could be as low as 0, in practice this does not occur because there is generally some (low probability) way to parse each phrase as a sentence. We take this ratio as a measure of processing difficulty.

Implementation

We implement our model using a Combinatory Categorical Grammar parser based on the Cocke-Kasami-Younger (CKY) algorithm. This algorithm was originally developed for Context Free Grammars and uses dynamic programming to parse from the bottom up: given a sentence, it first calculates the probabilities of all ways to generate each word using a rule $X \rightarrow \text{word}$. For each potential pair of categories X_1 and X_2 that could have generated adjacent words w_1 and w_2 , it then calculates the probabilities of all ways to generate that pair using a rule $X_3 \rightarrow X_1 X_2$. This allows us to calculate the inside probability $P(X_3 \rightarrow w_1 w_2)$. Continuing iteratively, we can calculate the inside probabilities of all substrings of the sentence.

We used a modified version of the StatOpenCCG parser, developed by Christodoulopoulos (2008), which is itself an extension of the OpenCCG parser (White, 2008). StatOpenCCG implements a statistical version of the CKY algorithm which operates using a generative head-dependency

model over CCG categories: From the parent (starting with a ROOT node), a head is generated with a certain probability. Then its sisters are generated with probability conditioned on the head category, the sister's direction from the head, and whether it is adjacent to the head. Although the number of CCG categories is theoretically infinite, our parser is constrained to only use categories that have appeared in the training data set. With this constraint, the runtime of the parser is bounded by $O(n^3)$. The parser has been trained on sections 1 through 22 of the CCGbank (Hockenmaier, 2003), a CCG version of the Penn treebank.

Our experiments use two different lexicons. The first lexicon is that taken from sections 1 through 22 of the CCGbank. However, this lexicon is too small to parse the majority of the sentences we wish to consider. To obtain a larger lexicon, we parsed six months of the New York Times (comprising approximately 50 million word tokens) taken from the Gigaword corpus (Graff, 2003). Sentences from the corpus were passed through the RASP tokenizer (Briscoe, Carroll, & Watson, 2006) and then parsed using the C&C CCG parser (Curran, Clark, & Bos, 2007). This state-of-the-art parser obtains labelled precision of 84.8% and labelled recall of 84.5% on section 23 of the CCGbank. It is extremely fast and provides the best parse accuracy from a CCG parser, making it convenient for obtaining large amounts of data to construct a larger lexicon. (However, it is not a cognitively plausible parser, as it relies on its supertagger and other cognitively implausible tricks to speed its parsing.) From this parsed sample, we extracted the lexicon for use in the StatOpenCCG parser (with the statistical parsing model over categories trained as before on CCGbank data). Although this lexicon of course contains quite a few errors, we verify that it nonetheless parses our test sentences correctly, placing the correct parses among the top results.

Experiments

We present two sets of experiments in which we test our model against the results from Tabor, Galantucci, and Richardson (2004). The first uses a small but high-quality lexicon to parse two test cases. The second uses a larger, error-ridden lexicon to parse a larger set of sentences. Recall that Tabor, Galantucci, and Richardson's (2004) study used 20 sets of sentences like those in (1)–(4).

Experiment 1: Test Cases using the CCGbank Lexicon

Because CCGbank is derived from a human-annotated treebank, the quality of the lexicon it yields is high. Nevertheless, it is small in comparison to human lexicons, and the passive relative constructions we are investigating are sparsely represented. In fact, the CCGbank lexicon contains only two words which are unambiguous ditransitive passive participles (i.e., $(S[\text{pss}]\backslash NP)/NP$ but not $(S[\text{dcl}]\backslash NP)/NP$ —where [pss] indicates a past participle used in a passive construction, and [dcl] indicates a declarative sentence). These two words are

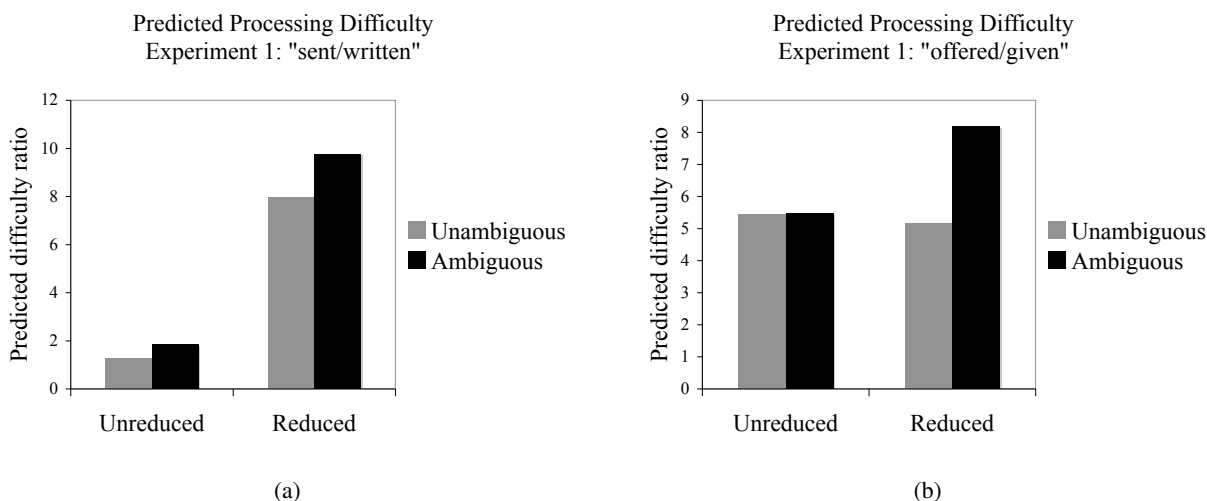

Figure 3: Results from Experiment 1, two test cases using the high-quality CCGbank lexicon. In both sets of sentences, the A/R case displays the correct pattern of superadditive difficulty.

written and *given*. Using these words, we construct two sentence sets, based on sentences used by Tabor, Galantucci, and Richardson:

- (12) He questioned a congressman (who was) sent/written a letter.
 (13) He addressed the woman (who was) offered/given a beer.

All words in these sentences are in the CCGbank lexicon. We parse them using our high-quality lexicon.

Results For these sentences, we obtain the predicted ratios:

$$\frac{P(S \rightarrow \text{locally coherent substring})}{P(S \rightarrow \text{whole sentence})}$$

Results are in Table 1 and Figure 3. We compare our results to the grammaticality judgements from Tabor, Galantucci, and Richardson (see Figure 1).

As we see in Figure 3(a), the set of sentences (12) displays the correct pattern of superadditive difficulty in the A/R case. While there is little difference in difficulty between the A/U and U/U conditions, there is a marked increase to the U/R condition, and a superadditive increase to the A/R condition. This mirrors the pattern seen in Tabor, Galantucci, and Richardson’s grammaticality judgements.

We see the same superadditive pattern of difficulty in our results for the set of sentences (13), shown in Figure 3(b). Somewhat surprisingly, the U/R condition is in fact predicted to be marginally easier than the Unreduced sentences in this set. This may be because *given* is an extremely common word. Although it is unambiguous in that it cannot be a past tense, it is in fact a highly ambiguous word, with 18 entries in the CCGbank lexicon. For instance, it can serve as a preposition, as in *Given the weather, I will stay inside today*. Regard-

Table 1: Predicted difficulty ratios from all experiments, alongside grammaticality judgements from Tabor, Galantucci, and Richardson (2004).

Type	TG&R	Exp1: written	Exp1: given	Exp2
U/U	.28	1.27	5.45	5.74
A/U	.28	1.85	5.46	8.46
U/R	.61	7.96	5.16	11.60
A/R	.78	9.76	8.18	12.34

less of this slight puzzle, the A/R case displays the correct pattern of superadditive difficulty.

Experiment 2: Using the Gigaword Lexicon

Using the Gigaword lexicon, we are able to parse 13 out of the 20 sentences in the Tabor study. (Sentences were excluded only if their past participles were not present in the lexicon. All other vocabulary items are present.) We standardize all sentences to begin with a pronoun. Additionally, for the sake of parsing efficiency, we do not include the *by* phrases that give the agent of the sentence. We further shorten two sentence sets in ways that do not affect the target part of the sentence.

Results Results from Experiment 2 are shown in Table 1 and Figure 4. We compare our results to the grammaticality judgements from Tabor, Galantucci, and Richardson (see Figure 1). We find the correct trend of difficulties, with the A/R condition most difficult, followed by U/R, followed by the two Unreduced cases. We do not find the exact pattern of superadditive difficulty in the A/R case, due to the fact that the A/U case is in fact predicted to be much more difficult than the U/U case, in contrast to the grammaticality ratings. Because the Gigaword lexicon is very error-prone, it is difficult

Figure 4: Experiment 2 results. We find the expected pattern of difficulty, but, due to the inflated predicted difficulty of the U/R case, do not see superadditive difficulty in the A/R case.

to draw any firm conclusions from this quirk in our results. However, we note that the A/R case is correctly predicted to be substantially more difficult than either of the Unreduced cases.

Conclusion

We have presented a model of local coherence effects using a wide-coverage bottom-up Combinatory Categorical Grammar parser. Our model can accurately predict which sentences humans will have difficulty in processing; specifically, it predicts the local coherence effects found by Tabor, Galantucci, and Richardson (2004). Our results support the psycholinguistic plausibility of CCG and the Good Enough theory of parsing by demonstrating that a parser that uses bottom-up local information can both perform well as a wide-coverage parser and predict specific psycholinguistic results.

Interestingly, the architecture of our version of the GE parser differs from Ferreira's original proposal. Ferreira (2003) proposes that GE parsing occurs via two separate strategies: one "algorithmic" and one "heuristic". In contrast, our parser does not include this separation: all analyses, both local and global, are produced by a uniform algorithm, and all are heuristically evaluated using the parsing model. This integration of strategies is a strength of our model, as it demonstrates how local coherence effects could emerge naturally as an inherent part of the parsing process.

In future work, we would like to make not just sentence-level predictions but word-by-word reading time predictions. Given that we have an entire parse chart, such predictions should be possible. We are currently choosing inside probabilities from two cells in the parse chart to compare, based on outside knowledge of where processing difficulty is likely to arise. We could do something similar for every cell in the chart, considering the inside probability of the substring it

spans relative to the probability of the sentence as a whole. With word by word predictions, we could model reading time data as well as grammaticality judgement data. Such a model would be applicable to a wide range of psycholinguistic data beyond local coherence effects.

Heuristics for Choosing Features to Represent Stimuli

Matthew D. Zeigenfuse (mzeigenf@uci.edu)

Michael D. Lee (mdlee@uci.edu)

Department of Cognitive Sciences, University of California, Irvine
Irvine, CA 92697 USA

Abstract

In this paper, we compare three heuristic methods for choosing which of a set of features to use to represent a domain of stimuli when we know the categories to which those stimuli belong. Our methods are based on three measures of category differentiation: cue validity, category validity, and their product, collocation. In a comparison of their ability to predict human similarity ratings in the Leuven Natural Concept Database, we find collocation to have the best performance, suggesting people use both cue and category validities in choosing which features to represent.

Keywords: Feature representation; basic-level categorization; similarity judgment.

Introduction

Of all the aspects of their world that could be represented, which do people actually choose? Imagine you are standing in front of a black dog named “Rover” with a small white patch of hair under its left eye. Which of its features do you choose to represent: its tail and four paws, its name, “Rover”, and the spot under its eye? The last two of these may be useful for a representation of this particular dog, but are probably less useful to representing dogs as whole. Conversely, the first two may be useful for representing dogs, but are probably less useful for distinguishing Rover.

One method of learning about which aspects of a particular set of concepts people represent is the feature generation task (Rosch & Mervis, 1975). Often in this task people are asked generate a fixed number of features for each exemplar in a domain. In some cases, additional participants are asked to rate whether an exemplar has a feature for each combination of features and exemplars in a domain (Deyne et al., 2008). This leads to a large number of features describing each exemplar; however, not all of these features will be important to a person’s representation.

Zeigenfuse and Lee (2008, 2010) provide a computational-level (Marr, 1982) approach to the problem. Similar to the theory of second-order isomorphism in perception (e.g. Shepard & Chipman, 1970), they argue that people represent those features that determine the similarity between objects and develop a model to infer which features are important using similarity judgments. Unfortunately, their method does not offer a psychological rationale for why one feature is important vis-à-vis an unimportant one, since it is more of a statistical solution than an account of feature importance.

This paper expands upon the computational approach of Zeigenfuse and Lee (2008, 2010) by exploring psychological theories of what makes a feature important. To this end, we propose heuristic methods for choosing important features based on how well a feature distinguishes categories from one

another. We use these heuristics to begin answering the question of specifying what properties of a feature cause people to represent it.

Representation and Basic-Level Categories

Our heuristics are based on measures of category differentiation that have been proposed to explain basic-level categorization. Basic-level phenomenology refers to people’s preference to categorize objects at a particular level in a category hierarchy, known as the basic level. Key finds are objects are categorized into basic-level categories more quickly than sub- or super-ordinate categories, basic level objects are named faster, objects are described preferentially with basic level names, more features are listed at the basic level than at the superordinate level, basic level names are learned before names at other levels, and basic level names tend to be shorter (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). These results suggest an intimate relationship between an object’s basic-level category and its mental representation.

Category-Based Measures

Category Differentiation Given a feature representation, many theories of basic-level categorization score potential categorizations of the concepts in a domain through the information its categories give about the features of category members and vice-versa. Examples include, cue validity (Rosch et al., 1976), category validity, collocation (Jones, 1983), feature predictability (Corter & Gluck, 1992), category statistical density (Kloos & Sloutsky, 2006), and strategy length and internal practicability (SLIP: Gosselin & Schyns, 2001). Inverting this logic, given a set of categories, we can score features on their usefulness in providing information about which of the set of categories a concept belongs to, the information knowing a concepts category provides about whether it has the feature, or a mixture of the two.

Usefulness Measures The heuristics described here for choosing feature representations are based on three measures of feature usefulness. Suppose we have a domain of categories $\{c_1, \dots, c_M\}$. Let \mathbf{f} be an arbitrary feature. The first heuristic is *maximum cue validity*, which we define as $\max_{1 \leq j \leq M} p(c_j | \mathbf{f})$. The quantity $p(c_j | \mathbf{f})$ is known in the literature as the cue validity of feature \mathbf{f} (implicitly, with respect to category c_j). Psychologically, it expresses how well having a feature predicts whether a stimulus belongs to a particular category.

We also look at *maximum category validity*, defined as $\max_{1 \leq j \leq M} p(\mathbf{f} | c_j)$. Here $p(\mathbf{f} | c_j)$ is often referred to as the category validity \mathbf{f} (again, implicitly, with respect to category

c_j). It expresses how well belonging to a category predicts whether a stimulus has a particular feature.

Finally, we look at *maximum collocation*, $\max_{1 \leq j \leq M} p(c_j|\mathbf{f})p(\mathbf{f}|c_j)$. The quantity $p(c_j|\mathbf{f})p(\mathbf{f}|c_j)$ is known as the collocation of feature \mathbf{f} and category c_j . This measure has previously been applied by Jones (1983) in his feature possession score account of category basicness. Here it is applied as a measure that integrates both cue and category validity.

Alternative Measures

We supplement the usefulness heuristics by two additional heuristics, included as baselines. The first of these is based around a measure we term *feature prevalence*, defined to be the proportion of exemplars in a domain which possess a given feature. The purpose of this heuristic is to compare the usefulness heuristics to a simple heuristic using only base-rate information. The second is a “random” heuristic, which simply selects subsets of features at random. This heuristic is intended to illustrate how our usefulness heuristics compare to an arbitrarily chosen heuristic for selecting features.

The remainder of the paper compares the five heuristics using human similarity judgments. We proceed as follows. First, we describe the data on which the heuristics will be compared, the Leuven Natural Concept Database (Deyne et al., 2008), a collection of normative data for semantic concepts. We then present the selection heuristics and how the representations chosen are used to generate similarity judgments. Next, we show the results of applying the heuristics to the Leuven database. We close by discussing what these results tell us about the features people choose to represent stimuli and the difference between natural and artificial kinds.

The Leuven Natural Concept Database

The Leuven Natural Concept Database (Deyne et al., 2008) contains normative data for semantic concepts falling into one of two domains, animals and artifacts. These data consist of typicality ratings, goodness ratings, goodness rank orders, generalization frequencies, exemplar associative strengths, category associative strengths, estimated ages of acquisition, word frequencies, familiarity ratings, imageability, and pairwise similarity ratings for concepts within a single category as well as exemplar-by-feature matrices and pairwise similarity ratings between a subset of the exemplars in a domain spread across its categories.

In our comparisons we make use of the exemplar-by-feature matrices and domain similarity ratings. The exemplar-by-feature matrices describe the exemplars of a domain in terms of a number of participant-generated features. For the animals domain, 129 exemplars, split among the categories birds, fish, insects, mammals, and reptiles, are described in terms of 765 features. For the artifacts domain, 166 exemplars, split among the categories clothing, kitchen utensils, musical instruments, tools, vehicles, and weapons, are described in terms of 1295 features. These features include both high frequency features such as “is a bird” and “is

made of metal” and low frequency features such as “stands in the crib at Christmas” and “stored in the cellar”.

Domain similarity judgments are pair-wise similarity judgments collected between exemplars in a set of consisting five exemplars from each of the categories in a domain. This results in sets of twenty-five exemplars for the animals domain and sets of thirty exemplars for the artifacts domain. Two distinct sets of exemplars were chosen for each domain, resulting four sets of domain similarity judgments.

Feature Selection Measures

Starting with a set of features that we wish to select a feature representation from (such as the 765 animal or 1295 artifact features in the Leuven sets), each heuristic chooses a feature representation using a two step process. First, the usefulness of each feature is computed under a particular usefulness measure. Then, we select those features whose usefulness is above a pre-defined threshold. For example, suppose we wish to use the collocation heuristic to choose among the seven features representing the exemplars of the three categories in Table 1. First, we would compute the maximum collocation over categories for each of the features (shown in the “Colloc.” column of Table 1). Then, we would select all those features for which the maximum collocation over the categories was above our threshold. In this example, were the threshold one-half, we would select features 1, 2, and 3. The same procedure can be used with the benchmark importance measure of Zeigenfuse and Lee (2008, 2010) to select a representation.

The features selected by these heuristics to generate similarities according to a common features model (Shepard & Arabie, 1979). Suppose we have a set of features $\{\mathbf{f}_1, \dots, \mathbf{f}_K\}$ from which we have selected a set of useful features indexed by $U \subseteq \{1, \dots, K\}$. The common features model says that similarity between concepts i and j is

$$s_{ij} = c + \sum_{k \in U} w_k f_{ki} f_{kj}, \quad (1)$$

where c is the universal similarity and w_k is the salience of feature f_k .

The remainder of the section is devoted to discussing for the benchmark and other heuristics in greater detail. In the first subsection, we summarize the benchmark measure of importance. In the second, we provide a rationales for each of the three category-based usefulness measures. In the final subsection, we provide rationales for the two baseline heuristics.

Benchmark

The Zeigenfuse and Lee (2008, 2010) method for learning which of a set of features people use to represent stimuli is based upon latent variable selection. In this framework, those features that are included in a concept’s representation are termed “important” features. For each feature, they define a variable z_k indicating whether feature \mathbf{f}_k is used in similarity

	Category 1	Category 2	Category 3	Cue	Cat.	Colloc.
Feature 1	• • • • •			1	1	1
Feature 2	• • • • •	•		5/6	1	5/6
Feature 3	• • • •			1	4/5	4/5
Feature 4	•			1	1/5	1/5
Feature 5	• • • • •	• •	• • • •	5/11	1	5/11
Feature 6	• • • • •		• • • • •	5/12	1	5/12
Feature 7		•	• •	2/3	1/3	4/21

Table 1: Representative features illustrating behavior of the usefulness measures.

judgments. Then, the similarity between concepts i and j is then

$$s_{ij} = c + \sum_{k=1}^K z_k w_k f_{ki} f_{kj}. \quad (2)$$

To learn which features are included in the representation, Zeigenfuse and Lee (2008, 2010) develop a Bayesian model and sample from the marginal posterior over the z_k using Markov Chain Monte Carlo (MCMC). In this framework, a feature’s importance is the marginal posterior probability the feature is represented. They found that a small number of important features are able to fit similarity almost as well as using all features.

Usefulness Measures

Different measures of usefulness correspond to different assumptions about what aspects of the environment lead a person to represent a particular feature. In the opening example, the small white spot under the dog’s eye and its name, “Rover”, may be useful for representing the family dog, but are probably not useful for representing dogs generally. This section outlines the psychological theories of feature importance embodied by each of the usefulness heuristics.

Maximum Cue Validity Maximum cue validity measures how concentrated a feature is in a single category. Formally, let r_k be the total number of objects with a particular feature f_k and let n_{jk} be the number of objects with the feature in category c_j . The cue validity of f_k is then $p(c_j|f_k) = n_{jk}/r_k$ and the maximum cue validity is the maximum of n_{jk}/r_k taken over j .

As illustrated by example features Table 1, maximum cue validity is large when most of the exemplars possessing a feature belong to the same category (Features 1 – 4), though this need not be a large number of exemplars (Feature 4). To see why, note that maximum cue validity is large if and only if there exists a category for which n_{jk} is nearly r_k . Since $n_{lk} \leq r_k - n_{jk}$ for $l \neq j$, $r_k - n_{jk}$ must be small and few exemplars with f_k can belong to c_l .

Maximum Category Validity Category validity measures how diffuse a feature is within a particular category. As with maximum cue validity, let n_{jk} be the number of exemplars in category c_j with feature f_k , and define a new quantity q_j to be the total number of exemplars belonging to c_j . Then,

the category validity of f_k with respect to category c_j is $p(f_k|c_j) = n_{jk}/q_j$ and the maximum category validity is the maximum of n_{jk}/q_j taken over j . Returning to Table 1, we see that features whose category validity is high (Features 1, 2, 5, and 6) are possessed by most of the exemplars in at least one category.

Maximum Collocation Maximum collocation is a measure of how simultaneous concentrated in and diffuse across a category a feature is. Using the terminology of the previous sections, the collocation of a feature f_k with respect to category c_j is $(n_{jk}/r_k)(n_{jk}/q_j)$. Maximum collocation is the maximum of this quantity taken over j .

Features with high collocation are possessed by most exemplars within a category and few outside it, as illustrated by the architypical Feature 1 in Table 1. Alternatively, Features 4 and 6 show why it is necessary for both of these to be true. Those features possessed by only a small fraction of exemplars within a single category will have high cue validity but low category validity (Feature 4). Those features possessed by most exemplars in more than one category will have high category validity but low cue validity (Feature 6).

Alternative Measures

The two baselines used here are intended to show both how well our usefulness heuristics performed against heuristics embodying contrasting assumptions. The first of these is based on the base rate of a feature across stimuli, which we refer to as feature prevalence. For feature f_k , the prevalence is $p(f_k) = r_k/K$, where r_k is as defined in the previous section. This shows that the ability of a feature to distinguish among categories does not affect its importance.

The random heuristic provides a different sort of foil for the usefulness heuristics. Many methods other than those included here could be imagined for selecting a sets of features. By selecting features at random, it allows us to compare the predictions of our heuristics to those an arbitrary method of choosing features.

Method Comparison

Here we describe a comparison of maximum cue validity, maximum category validity, and maximum collocation to each other as well as the benchmark and baselines using the Leuven Natural Concept Database (Deyne et al., 2008). In

the first section, we enumerate the procedure used to fit the domain similarity data. In the second, we present the results of this procedure for each of the heuristics.

Procedure

The fit procedures begins with the exemplar-by-feature matrices. Before applying any of the heuristics we filter out all features possessed by zero, one, or all of the 25 or 30 exemplars included in the domain similarity comparisons. Features possessed by one exemplar or fewer will not be used in any similarity comparisons, since $f_{ki}f_{kj} = 0$ for all distinct stimuli i and j . Features possessed by all exemplars will be used in every similarity comparison, so they can be included in the constant term c in Equation (2). Additionally, we find all groups of features possessed by exactly the same set of exemplars, and combine these into a single feature. Suppose f_k and f_l are features possessed by exactly the same set of exemplars. Then, $f_{ki} = f_{li}$ for all i and $w_k f_{ki} f_{kj} + w_l f_{li} f_{lj} = (w_k + w_l) f_{ki} f_{kj}$.

After pre-processing, for the benchmark and all of the heuristics except the random heuristic, we compute its corresponding measure using all of the exemplars in the domain, not just those included in the domain similarity judgments. The features are then sorted in order of decreasing value on these measures. Starting with only the top two features, we fit the common features model to the domain similarity judgments using non-negative least squares and compute the correlation between the fitted similarities and the actual similarities. We repeat this process with the top three features, the top four features, etc. To apply this procedure with the maximum collocation heuristic to the features in Table 1, we first compute the values in the collocation column. We then order the features in order of decreasing collocation, which in this case is 1, 2, 3, 5, 6, 4, 7. We first fit the model with features 1 and 2, then 1, 2, and 3, followed by 1, 2, 3, and 5, etc. Finally, for the random heuristic, we generated 100 random feature orders and apply this procedure to each of the orders.

Results

Figure 1 shows the correlation between observed and those fitted using the first x percent of features ordered by either cue validity, category validity, collocation, prevalence, or the benchmark. For example, on the collocation line (shown as a solid line) the correlation at a percentile rank of 20 percent is the correlation between the observed values and those fitted using the first 20 percent of features ordered by collocation. The smaller pane in the lower right-hand corner is a blowup of the lines in rectangular region extending from 0 – 20 in percentile rank and from 0.6 – 1 in correlation.

The gray shaded area shows 95% confidence intervals for the correlation between the values fitted using first x percent of features chosen by the random heuristic and the observed values. These orders give an estimate of how difficult the similarity data are to fit with a heuristic choosing x percent of the available features. A heuristic whose correlation is above the upper limit of the area fits better 95 percent of heuristics at

that percentage of features. Alternatively, a heuristic whose correlation is below the lower limit of the area fits worse than 95 percent of heuristics at that percentage of features.

Regardless of data set, the orders produced by the Zeigenfuss and Lee (2008, 2010) measure is always able to fit the similarities in the top 5 percent of ordering, justifying its use as a benchmark. The orders produced by feature prevalence nearly always perform worse than those generated by the other measures, often in the worst 5 percent of all orders. On the whole, cue validity, category validity, and collocation perform middling to well, rarely performing worse than feature prevalence.

For the animals data sets, cue validity outperforms category validity for small numbers of features (less than around 20 percent), category validity outperforms cue validity for larger numbers of features, and collocation is always commensurate to the best of these. For very small (less than around 10 percent) numbers of features, cue validity performs better than the benchmark; however, for larger numbers of features its performance is at best mediocre. After a slow start, category validity performs in the top 5 percent of orderings for larger numbers of features. Collocation always performs near the benchmark and is nearly always in the top 5 percent of orderings.

For the artifacts data sets, cue validity still performs better than category validity for very small (less than 10 percent) numbers of features, after which category validity performs better than cue validity. As with animals, collocation performs near or better than the best of these two measures. Category validity and collocation nearly always perform between the 5th and 95th quantiles of heuristics; however, for larger numbers of features (around 20 percent in the first set and around 40 percent in the second), cue validity performs in the bottom 5 percent of orderings.

Overall, these results suggest that both cue and category validity contain information about a feature's importance. Collocation always performs about the same as the best of cue and category validity, indicating that it tracks the best aspects of the two measures. This suggests that early on collocation is dominated by features with high cue validity, but later it is dominated by category validity.

Discussion

Cue and Category Validity

The major result of the previous section is that both cue and category validity seem to be important to choosing which of a set of features makes a good representation. Murphy (1982) suggests why this may be the case: cue validity cannot pick out basic-level categories because it can only increase for more inclusive categories. Consider the hierarchy of categories *animal*, *bird*, *duck*, in which *bird* is the basic-level category, and suppose we wish to compute the cue validity of the feature “has wings”. Let r_{wings} be the number of things with wings and $n_{\text{ducks,wings}}$, $n_{\text{birds,wings}}$, and $n_{\text{animals,wings}}$ be the number of ducks, birds,

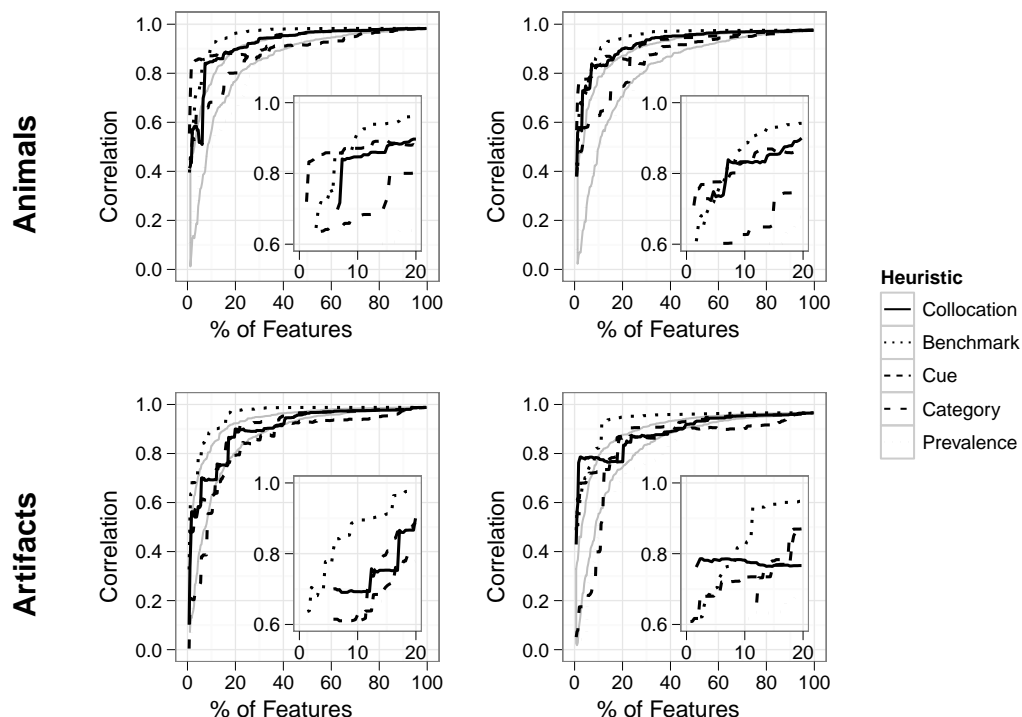

Figure 1: Model fit by the percent of features used for each of the four sets of domain similarities in the Leuven data set. The benchmark, three category-based heuristics, and feature prevalence baseline are shown as lines. In the legend, “collocation” corresponds to the maximum collocation heuristic, “benchmark” to the benchmark, “cue” to maximum cue validity, “category” to maximum category validity, and “prevalence” to feature prevalence. The gray area shows a 95% confidence interval for the fit of the random heuristic. The panels in the lower righthand corner of each of the plots enlarges the rectangular region from 0 – 20 in percent of features and from 0.6 – 1 in correlation in the main plots.

and animals with wings. Since ducks are birds and birds are animals, $n_{\text{ducks, wings}} \leq n_{\text{birds, wings}} \leq n_{\text{animals, wings}}$, so $n_{\text{ducks, wings}}/r_{\text{wings}} \leq n_{\text{birds, wings}}/r_{\text{wings}} \leq n_{\text{animals, wings}}/r_{\text{wings}}$. But the $n_{\text{wings}}/r_{\text{wings}}$ is just the cue validity of “has wings”, illustrating why, in settling on basic-level categories, people must be sensitive to more information than just cue validity. Since similarity is assumed to reflect representation, this should be reflected in measures used to select representations.

Along these lines, Tenenbaum and Griffiths (2001) offer a fuller explanation for why both cue and category validities should be important to choosing good representations. They argue that people generalize properties to novel instances only in the smallest set of instances consistent with known examples, a theory known as the “size principle”, and further that similarity is the degree to which the consequences of being one object generalize to another. By this logic, choosing features on the basis of cue validity will lead to categories which are overly restrictive and choosing features on the basis of category validity will lead to categories which are overly broad. Appropriate generalization, then, requires taking both types of information into account. Thus, we would expect a heuristic that does this, like collocation, to choose better representations than heuristics that do not.

Natural Versus Artificial Kinds

A final point worth mentioning is the difference in performance of the heuristics on data sets containing natural kinds versus those containing artificial kinds. Numerous authors have suggested that natural and artificial kinds are represented in fundamentally different ways (e.g. Keil, 1989). Results of Zeigenfuse and Lee (2010) support this theory, finding the ratio between the probability two stimuli within the same category have a feature and the probability two arbitrarily chosen stimuli have a feature is larger for natural kinds than artificial ones.

Here we find a similar result: for animals data sets collocation nearly always performs in the top 5 percent of heuristics, whereas for artifacts data sets, collocation performs about as well as an arbitrary heuristic. In theory this difference could come from either differences in the types of features represented or the ability of the common features model to fit similarity judgments among exemplars of that domain. The latter seems unlikely, however, given that the benchmark performs well for all four data sets it seems a common features similarity model is able to fit the data well.

This, then, suggests that the difference in fits comes from differences in the types of features people choose to repre-

sent. Among animals, people prefer features that are closely tied to a particular basic category. Among artifacts, they seem to prefer a different strategy, representing features for multiple levels in a category hierarchy or selecting features using different criteria.

Extensions

A detailed explanation of this difference may require extensions addressing one of both of these sources. The first of these begins from the recognition that the source of the apparent distinction between natural and artificial kinds may stem not from an actual difference but from an incorrect choice of selection heuristic. Thus, it makes sense to look at heuristics based on additional measures of category differentiation. The second supposes choosing just those features associated with basic-level category structure is not sufficient for selecting good feature representations.

Additional Heuristics In order to explore the first of these extensions, we could develop heuristics based on different measures, both those that have been proposed in the basic-level literature and outside it. Such measures could include the category likelihood ratio (Zeigenfuse & Lee, 2010), the mutual information between a category and a feature SLIP (Gosselin & Schyns, 2001). These last of these differs from the first two in that, in the first, each feature affects the quality of a categorization independent of all other included, whereas in the second two the effect of adding a new feature depends upon the features already included.

Category Hierarchies The second extension allows the method to deal with category hierarchies. The importance of structured representation in understanding human judgments of similarity has been illustrated by many authors (e.g. Markman & Gentner, 1993). Understanding how such structured representations influence those features represented is a crucial step towards bringing these models into contact with feature-based models such as Tversky's contrast model (Tversky, 1977). One potential method for achieving this would be to compute the collocation, or other measure, at each level in a category hierarchy and to use a weighted combination of the collocations as the selection criterion.

Conclusion

In this paper, we have presented three heuristic methods for choosing a feature representation based on measures of category differentiation. We find these heuristics to fit human data better than heuristics that do not take this information into accounts, achieving very good fits for natural kinds and above average fits for artificial kinds. Moreover, our results suggest both how concentrated in a particular category a feature is and how diffuse it is across exemplars in that category are important factors in whether a feature is represented as well as supporting a distinction between natural and artificial kinds. Though much still needs to be done, this work suggests people choose features in a systematic way and that

these regularities can be uncovered by investigating the relationship between categories and features.

Abstract

Extensive research measuring event-related brain potentials (ERPs) shows that semantic incongruity is indexed by the N400 effect and syntactic/structural incongruity is indexed by the P600 effect. We used these indices to examine how people coordinate their semantic and arithmetic knowledge when they read simple addition and division word problem sentences (e.g., “Twelve roses plus three daisies equals fifteen”). Prior work in problem solving has shown that word-problem solutions are modulated by analogical alignment of semantic and arithmetic relations, such that people avoid or commit errors on misaligned problems (e.g., Aligned: “Twelve roses plus three daisies equals fifteen”; Misaligned: “Twelve cookies plus three jars equals fifteen”). Here, we found that such analogical alignments modulate the comprehension of word-problem sentences. Specifically, we found that analogically Misaligned semantic relations elicited a P600 effect. Furthermore, an N400 effect was elicited by the last number word of Misaligned problem sentences, even when it was a mathematically correct answer. These results show that analogical alignment between semantic and arithmetic relations can be indexed with the P600 effect and provide a foundation for future ERP work on analogical reasoning.

Keywords: ERP; analogy; mathematical cognition; N400 effect; P600 effect

Introduction

A common task facing the cognitive system is *conceptual integration* of individual items into a meaningful whole. For example, language comprehension requires conceptual integration of consecutive words into meaningful sentences. Similarly, comprehension of arithmetic problems requires conceptual integration of numbers and arithmetic operators into correct mathematical expressions. In this paper, we explore the conceptual integration of simple arithmetic word problems, which are unique in that they require conceptual integration of language and of mathematics.

Conceptual Integration & ERPs

The process of conceptual integration, and the conditions under which it can be disrupted, have been investigated in a

variety of domains using event-related potential (ERP) methodology, which measures the electrical brain activity elicited by a particular stimulus. Work in this area has shown that two key aspects of conceptual integration, meaning and structure, are indexed by two distinct and highly reliable ERP components—the N400 and P600 components, respectively.

The N400 component is negative-going and peaks around 400ms after presentation of the stimulus. This component is highly sensitive to contextual semantic meaning. The magnitude of this component is larger for semantically incongruous compared to congruous items—a difference known as the *N400 effect*. The N400 effect was first documented in sentence processing. For example, the italicized word in the sentence, “The cat will *bake* the food” will elicit an N400 effect relative to, “The cat will *eat* the food” (Kutas & Hillyard, 1980). Subsequent work has shown that the N400 effect is elicited in response to conceptual incongruities in other domains. For example, incorrect answers to simple symbolic (e.g., “ $4 \times 4 = 21$ ”) and verbal (e.g., “Twelve plus three equals *sixteen*.”) arithmetic problems elicit an N400 effect (e.g., Niedeggen & Rosler, 1999; Fisher, Bassok, & Osterhout, 2009). Thus, the N400 effect is generally accepted to be a domain-general index of semantic congruence.

The P600 component is positive and peaks at around 600ms after stimulus presentation. A P600 effect is elicited by violations of syntax within a sentence (e.g., “The cat will *eating* the food I leave on the porch.”; Osterhout & Holcomb, 1992; Osterhout & Mobley, 1995) and by violations of structure, such as a wrong note played in a harmonic scale (Patel et al., 1998). Such violations of syntax or structure lead to larger P600 amplitudes, relative to control conditions (i.e., the P600 effect).

Furthermore, Osterhout and Mobley (1995) found that when there is any kind of violation within a sentence, syntactical or semantic, an N400 effect is also elicited by the ending word of the sentence, even though that word is perfectly correct. This last-item N400 effect is likely the result of the experimental paradigm typically used in

language research. Participants are typically asked to make binary judgments about the “acceptability” of the sentences they just saw (usually they are not instructed to look for any particular type of error). Thus, when participants reach the end of a sentence that contained a violation, the entire sentence must now be categorized as “unacceptable.” The N400 effect to the final word in the sentence may be a result of this judgment processing.

Despite the relatively broad range of studies of conceptual integration, to our knowledge, no previous studies have used these ERP indices to examine a) how people integrate concepts that are presumably organized in distinct conceptual networks and b) the integration of concepts via analogy. Both of these characterize the integration process involved in the solution of mathematical word problems, whereby people are required to apply arithmetic operations in a way that fits the relations among objects in the “real world.” This process involves analogical coordination of real world knowledge (e.g., *roses* and *daisies* are *flowers*) with one’s knowledge of arithmetic properties (One can add 3 *roses* to 5 *daisies* to create a bouquet of 8 *flowers*). As we explain in the next section, people are highly systematic in the way they coordinate their semantic and arithmetic knowledge. The purpose of our study was to use ERP to examine such cross-network, analogical conceptual integration and, in particular, to test whether the same ERP components that index violations of meaning and structure in language also index violations of analogical alignment.

Mathematical Problem Solving in the “Real World”

Research by Bassok and her colleagues has shown that, when people reason about mathematical word problems, they tend to align structurally analogous semantic and arithmetic relations (Bassok, Chase, & Martin, 1998). Specifically, people align categorically related objects (e.g., cars and trucks) with the commutative addition operation and align functionally related objects (e.g., jars and cookies,) with the non-commutative division operation. Violating such *semantic alignment* (e.g., having to add jars to cookies or having to divide cars by trucks) severely impairs problem-solving performance (Bassok, Wu, & Olseth, 1995; Martin & Bassok, 2005), and even blocks retrieval of arithmetic facts from memory (Bassok, Pedigo, & Oskarsson, 2008).

In the present study we investigated how people conceptually integrate semantic and arithmetic relations while reading simple addition and division word problems presented in a sentence format (e.g., “Twelve roses plus three daisies equals fifteen.”). We recorded ERPs as participants read these word-problem sentences. We analyzed the electrical waveforms elicited by the second object word in the sentence, which completed the semantic relation, and by the numerical mathematical answers (e.g., the two underlined words in, “Twelve roses plus three vases equals fifteen”). The semantic object relations were either analogically aligned (Aligned condition) or misaligned

(Misaligned condition) with the arithmetic relation in the word problem, and the mathematical answers were either correct or incorrect (see Table 1 for example stimuli). After reading each word-problem sentence, participants were asked to make judgments as to whether or not the problem was “acceptable.” As is standard practice in typical language research paradigms, we did not specify the criteria by which participants were to make their judgments.

Table 1: Example Stimuli

Object Alignment	Math Correct	Math Incorrect
Aligned Addition	Twelve limes plus three lemons equals fifteen.	Sixteen cars plus two trucks equals twenty.
Aligned Division	Fifteen roses divided by three bouquets equals five.	Six robins divided by two nests equals eight.
Misaligned Addition	Six questions plus three quizzes equals nine.	Eight cookies plus four jars equals two.
Misaligned Division	Eighteen skirts divided by two dresses equals nine.	Fifteen geese divided by three ducks equals six.

We had two main predictions. First, we expected that conceptual integration in Aligned word problems should be similar to conceptual integration in arithmetic problems, presented in sentence-form, which do not contain objects. Specifically, we expected that, in the Aligned condition, we would replicate the N400 effect elicited by mathematically incorrect answers to arithmetic problems (Fisher, Bassok, & Osterhout, 2009). Second, and most important, if conceptual integration via analogy is similar to conceptual integration in rule-governed sequence processing, then analogical misalignment of the semantic and arithmetic relations in the problem should elicit a P600 effect. In particular, we expected a P600 effect to occur at the second object word because that word completes a semantic relation that cannot be mapped onto the arithmetic relation in the problem, and thus constitutes a structural violation (e.g., Gentner, 1983). Furthermore, we expected that the mathematically correct answer (the final item of the word problem sentence) in Misaligned problems would elicit an N400 effect relative to correct answers in Aligned problems, replicating previous work by Osterhout and Mobley (1995).

Methods

Participants

The participants were 38 volunteer undergraduate students, graduate students, and staff from the University of

Washington (21 male, 17 female; $M_{\text{age}} = 22.23$ years, $SD_{\text{age}} = 4.98$ years) who were right-handed native English speakers. Participants were either given course extra credit or paid \$30 for their participation.

Stimuli

The stimuli were simple word problem sentences that were composed of digit pairs and object word pairs that were either categorically related or functionally related. The digit and object pairs were selected based on pilot testing, as described below.

Arithmetic Problems The arithmetic problems were composed of two operands and satisfied a number of constraints established by cognitive arithmetic literature and required for our experimental manipulations. First, the two operands could be both added and divided to yield a whole-number answer (e.g., $12 + 3$; $12 / 3$). Second, we excluded tie problems (e.g., $2 + 2$) and problems containing a one, zero, or 10 as an operand, as evidence from prior work suggests that these types of problems are processed differently, and often more easily, than other simple arithmetic problems (Ashcraft, 1992; McCloskey, 1992). Third, we only selected problems that fell into the “small” category of division problems, defined as having a divisor lesser than 25, in order to avoid some of the issues of the problem-size effect¹ (see Zbrodoff & Logan, 2004, for a review). Finally, we controlled for answer parity (LeMaire & Reder, 1999).

Within these constraints, we created a set of 24 problems, 12 addition and 12 division, that were equivalent in difficulty. These problems were selected based on results of a pilot study (error rate and response time), in which 154 undergraduate students solved 48 addition and 48 division problems meeting the above criteria. To create an answer verification task, we constructed two different incorrect answers for each problem. The “Close” incorrect answer for both operations was derived by adding or subtracting the value one or two to or from the correct answer (e.g., $12 + 3 = 14$). The “Other” incorrect answers for addition were the correct answers to division problems with the same operands (e.g., $12 + 3 = 4$), and the “Other” incorrect answers for division were the correct answers to addition problems with the same operands (e.g., $12 / 3 = 15$).

Object Pairs We initially constructed a set of 163 word pairs that we considered to belong to one of the two semantic relations categories—categorical or functional. The set contained 83 possible categorical pairs and 80 possible functional pairs consisting of concrete, plural nouns (e.g., “cats, dogs”). From this set, we constructed rating surveys that were completed by 202 undergraduate students

at the University of Washington as part of a class activity. Instructions asked students to rate, on a seven-point scale, either the extent to which the word pairs were *categorically* related or the extent to which they were *functionally* related. The average categorical and functional ratings in these two conditions were compared for each word pair using an independent t-test with an alpha level of .05. In order to be included in the final set, word pairs had to have significantly different categorical and functional ratings and an average rating of greater than 5 in one dimension and 4 or less in the other. Based on these ratings, we selected 48 categorical and 48 functional pairs. The word pairs in both relation conditions were equivalent in their average number of syllables and letters in each word.

Design

Operation (Addition vs. Division) was manipulated between participants ($N_{\text{Addition}} = 19$; $N_{\text{Division}} = 19$; participants were randomly assigned). Analogical alignment of the mathematical operation and the object sets (Aligned vs. Misaligned), and mathematical correctness of the problems (Correct vs. Close Incorrect vs. Other Incorrect) were manipulated within participants.

Verbal versions of the arithmetic problems (e.g., “Twelve plus three” in place of “ $12 + 3$ ”) were created and were then combined with object pairs to create simple word problem sentences (e.g., “Twelve limes plus three lemons equals fifteen.”). For the Addition problems, all of the Aligned stimuli were categorically related objects, and all of the Misaligned stimuli were functionally related objects; the reverse was true for the Division problems (see again Table 1). Thus, the same object sets were used for both operations, but for one operation the object sets were Aligned and for another they were Misaligned.

The experiment consisted of three blocks of trials. There were 96 trials in each block, for a total of 288 trials. Within each block, 50% of the trials were Aligned word problems, and 50% were Misaligned. Within each alignment type, 50% were mathematically Correct, 25% were Close Incorrect, and 25% were Other Incorrect. Trial order was pseudo-randomized within each of the three blocks. Each of the word pairs appeared once per block, and they were combined with different arithmetic problems each time.

Procedure

Participants were seated comfortably in front of a CRT monitor in an isolated room and fitted with electroencephalography (EEG) recording equipment. Each trial consisted of a fixation point (500ms), and each item of the word-problem sentence was presented alone on a screen (450ms/350ms ISI). The final inter-stimulus interval before the appearance of the YES/NO response screen was 1,000 ms (total trial duration was 7.1 seconds). Participants were given a hand-held controller and were asked to respond *YES* (response hand counter-balanced) using one button if they thought the problem was completely “acceptable” and *NO*, using another button if the problem was “unacceptable” in

¹ Note, however, that “small” division problems translate into “large” addition problems. As described in this section, the stimuli selection pilot study was conducted primarily to ensure that the problems selected were of equivalent difficulty.

any way. They were told that the instructions were intentionally vague because the criteria by which they would judge the problems were at their discretion. Furthermore, the task did not include object labels, which are usually required in word problem solving. Participants were asked not to blink between the onset of the fixation point and the appearance of the response screen. They were permitted to blink and take a short break while the response screen was displayed. Response time was not recorded and responses triggered onset of the next trial. A break was given after each block. The entire experiment time, including set-up, was less than two hours.

Data Acquisition & Results

EEG recording

Continuous EEG was recorded from 19 tin electrodes attached to an elastic cap (Eleetro-cap International) in accordance with the extended 10-20 system. Vertical eye movements and blinks were monitored by two electrodes, one placed beneath the left eye and one placed to the right of the right eye. The 19 electrodes were referenced to an

electrode placed over the left mastoid. Electrical signals were amplified, digitized at a rate of 250Hz, and bandpass filtered at 0.01-40Hz. Impedances at scalp and mastoid electrodes were held below 5 k Ω . Trials associated with blinking, excessive eye movement or amplifier blocking were removed prior to averaging (approximately 11% of all trials). Stimuli were displayed to participants on an 18" CRT monitor approximately three feet from the participants at eye-level with white font on a black background.

Behavioral Responses

Because participants were asked to make open-ended "acceptability" judgments, it is not surprising that there was variation in how they judged the Misaligned problems, particularly in the case where the problem was Misaligned but mathematically correct. These behavioral differences in acceptability judgments corresponded to differences in the magnitude of the overall ERP effects we report here. In this paper we do not discuss these individual differences, as they are not essential to our primary research question.

Figure 1: ERP responses to mathematically incorrect answers and semantic alignment.

ERP Responses

EEG amplitudes elicited by the second object word and by the last word (the mathematical answer to the problem) were averaged according to their respective Alignment and Answer conditions. Mean amplitudes were compared separately for the Addition and Division operations in the 250-450ms time window (N400 effect) and in the 500-700ms time window (P600 effect) following stimulus onset. For all analyses, separate ANOVAs² were conducted for midline (Fz, Cz, Pz), medial (Fp1, F3, C3, P3, O1, Fp2, F4, C4, P4, O2), and lateral (F7, T7, P7, F8, T8, P8) electrode sites, with electrode location and hemisphere included as factors in each ANOVA.

Incorrect Answers We first tested whether we replicated previous work with sentence-form arithmetic problems (Fisher, Bassok, & Osterhout, 2009), which found an N400 effect to incorrect numerical answers. We tested for this effect within the Aligned condition, which served as our baseline. Separately for Addition and Division, a 3-way (Answer Type - Correct, Close Incorrect, Other Incorrect) repeated measures ANOVA was conducted at each electrode grouping. Indeed, we found a main effect of answer types, such that mathematically incorrect answers elicited a significant N400 effect relative to correct answers for both Addition and Division word problems (see Figure 1) [Addition: $F_{\text{Midline}}(2,36) = 15.36$, $MSE = 11.99$, $p < .001$; $F_{\text{Medial}}(2,36) = 25.54$, $MSE = 17.71$, $p < .001$; $F_{\text{Lateral}}(2,36) = 22.29$, $MSE = 5.86$, $p < .001$; Division: $F_{\text{Midline}}(2,36) = 6.08$, $MSE = 8.10$, $p < .01$; $F_{\text{Medial}}(2,36) = 10.37$, $MSE = 13.69$, $p < .001$; $F_{\text{Lateral}}(2,36) = 7.24$, $MSE = 6.23$, $p < .01$] Planned contrasts revealed no significant differences between the Close and Other incorrect answer types except at the lateral electrode sites for Addition³.

Semantic Alignment When comparing ERP responses between semantic alignment conditions, we first compared the ERP waveforms elicited by the second object word in Aligned versus Misaligned problems (e.g., Twelve cars plus three trucks equals fifteen. vs. Twelve roses plus three vases equals fifteen.). Consistent with our predictions, we found that the second object word in the Misaligned condition elicited a P600 effect relative to the Aligned condition in both operations [Addition: $F_{\text{Midline}}(1, 18) = 5.28$, $MSE = 4.08$, $p = .03$; $F_{\text{Medial}}(1, 18) = 6.39$, $MSE = 6.66$, $p = .02$; $F_{\text{Lateral}}(1, 18) = 5.78$, $MSE = 1.68$, $p = .03$; Division: $F_{\text{Midline}}(1, 18) = 4.94$, $MSE = 4.25$, $p = .04$; $F_{\text{Medial}}(1,18) = 5.62$, $MSE = 7.16$, $p = .03$; $F_{\text{Lateral}}(1,18) =$

3.20, $MSE = 1.95$, $p = .09$]. As noted earlier, this effect occurred regardless of participants' behavioral response as to whether or not the problem was "acceptable."

Next, we compared ERP amplitudes elicited by the mathematically correct answer (the final item of the word problem sentence) between the Aligned and Misaligned conditions. Correct answers of Misaligned word problems elicited an N400 effect relative to the correct answers of Aligned word problems [Addition: $F_{\text{Midline}}(1,18) = 9.00$, $MSE = 13.69$, $p < .01$; $F_{\text{Medial}}(1,18) = 11.16$, $MSE = 23.81$, $p < .01$; $F_{\text{Lateral}}(1,18) = 8.62$, $MSE = 6.67$, $p < .01$; Division: $F_{\text{Midline}}(1,18) = 8.01$, $MSE = 15.67$, $p = .01$; $F_{\text{Medial}}(1,18) = 9.34$, $MSE = 32.98$, $p < .01$; $F_{\text{Lateral}}(1,18) = 7.26$, $MSE = 8.01$, $p = .02$].

This pattern of ERP results mirrors those found in studies of language processing (e.g., Osterhout & Mobley, 1995). That is, structural/syntactic violations within a sentence typically elicit a P600 effect, and the final word of sentences containing such violations elicits an N400 effect, even when those words contained no violations. In the case of our particular stimuli, the sentences were simple arithmetic word problems, and the structural violations were violations of analogical alignment between the semantic and arithmetic relations in the problem. The final words in the sentences were the mathematical answers to the word problems, and an N400 effect occurred for mathematically correct answers in the Misaligned, relative to the Aligned, condition.

Discussion

The goal of this study was to examine the conceptual integration process with respect to arithmetic word problems and how it compares to conceptual integration for sentences and other meaningful sequences. Arithmetic word problems are unique in that they combine elements of language and math and provide the opportunity for analogical alignment or misalignment between the semantic relations and the arithmetic relations in the problem (e.g., Bassok, Pedigo, & Oskarsson, 2008; Bassok, Wu, & Olseth, 1995).

Overall, our results provide evidence for the fluid integration of arithmetic and semantic knowledge during word problem processing. More broadly, our results suggest that the conceptual integration process does not change significantly when people must integrate concepts *across* two distinct knowledge networks. That is, the same ERP effects were elicited by violations of structure and meaning in word problems as are usually found in sentences and in arithmetic problems not containing objects. These results suggest that the N400 and P600 effects could be used as dependent measures in investigations of other situations wherein an individual has to integrate distinct types of knowledge, such as in reasoning problems that involve the applications of formal logic rules to object sets, or in song writing wherein one has to coordinate lyrics with a melody.

Moreover, in the word problems used in our study, semantic and arithmetic knowledge had to be coordinated via analogy. Thus, our results also demonstrate that the

² A Greenhouse-Geisser correction for sphericity violations was used when necessary

³ Specific results for different answer conditions and the interactions between the semantic alignment variable, the answer type variable, and behavioral response pattern are not central to the research question addressed here and thus are not elaborated upon for the sake of brevity.

P600 effect can serve as an index of the integrity of analogical structure within arithmetic word problems just as it indexes syntactic integrity in sentences (e.g., Osterhout & Holcomb, 1992; Osterhout & Mobley, 1995) and structural integrity in other meaningful sequences (e.g., Patel et al., 1998). As such, our results provide a foundation for future ERP investigations of the cognitive processes related to analogical reasoning, using the P600 effect as an index of structure-mapping (Gentner, 1983). That is, when the structures of two relations cannot be mapped in an analogy task (e.g., Bird:Nest as Bear:Cave vs. Bear:Desert; Spellman, Holyoak, & Morrison, 2001), the size of the P600 effect could be used to discriminate the degree of relational structure mismatch. Such investigations could examine the analogical conceptual integration within one domain (e.g., animals and their habitats) or across two domains of conceptual knowledge (e.g., Bird:Nest as Car:Garage).

Interestingly, we found these ERP effects for violations of analogical alignment and mathematical correctness across all participants even though we observed distinctly different patterns of “acceptability” judgments and corresponding ERP effect magnitude within our sample. Though we are unable to elaborate on these differences here, initial analyses suggest that these patterns are consistent with prior work in mathematical reasoning suggesting that some people are better than others at coordinating their mathematical and “real world” knowledge when constructing and solving more complex mathematical expressions than the ones presented in this study (e.g., algebraic equations; Fisher & Bassok, 2009). Because this ability is arguably relevant to our simpler task, it is not surprising that there are individual differences among our sample of participants such that some were more sensitive than others to violations of semantic alignment in simple word problems, particularly because our sentences did not include labels as part of the solution.

Of course, further work is required to fully explore these individual difference patterns and elucidate the reason behind them. To expand on our current findings, we also plan to more thoroughly investigate the processes of analogical conceptual integration. Lastly, in the future we hope other researchers will continue to use ERP for investigations of conceptual integration in more complex, knowledge-diverse situations.

Acknowledgments

Simplifying the Mapping from Referring Expression to Referent in a Conceptual Semantics of Reference

Jerry Ball (Jerry.Ball@mesa.afmc.af.mil)
Air Force Research Laboratory

Abstract

In Jackendoff's *Conceptual Semantics*, reference to objects, situations, places, directions, times, manners, and measures is supported, but reference is limited to instances of these conceptual categories. This paper proposes an extension of Jackendoff's referential types along an orthogonal dimension of reference which is cognitively motivated in suggesting the possibility of referring to types, prototypes and exemplars in addition to instances, as well as classes and collections of all referential types and vacuous instances and collections. The paper also introduces a bi-partite distinction between a situation model and the mental universe which helps to explain apparent non-referential uses of referring expressions. The primary motivation for expanding the ontology of referential types and distinguishing the situation model from the mental universe is to simplify the mapping from linguistic expressions to corresponding representations of referential meaning. The viability of this approach hinges on adoption of the mentalist semantics of Jackendoff. There is no direct reference to actual objects in the external world.

Keywords: referring expression; Conceptual Semantics

Introduction

In Jackendoff's *Conceptual Semantics* (Jackendoff, 1983, 1990, 2002, 2007), reference to places, directions, times, manners, and measures in addition to situations and objects is supported, but reference is limited to tokens or instances of these conceptual categories, adhering to the basic notion that reference is to individuals. This paper proposes an extension of Jackendoff's referential types along an orthogonal dimension of reference which is cognitively motivated in suggesting the possibility of referring to types, prototypes and exemplars in addition to instances. Reference to classes and collections of referential types and vacuous instances and collections is also considered.

The primary motivation for expanding the ontology of referential types is to simplify the mapping from referring expressions to corresponding representations of referential meaning. Hobbs (2003) pursues a similar strategy in arguing for logical representations that are as close to English as possible. Jackendoff's (1983, p. 13-14) *grammatical constraint* makes a related claim:

...one should prefer a semantic theory that explains otherwise arbitrary generalizations about the syntax and the lexicon...a theory's deviations from efficient encoding must be vigorously justified, for *what appears to be an irregular relationship between syntax and semantics may turn out merely to be a bad theory of one or the other* (italics added)

Taking the grammatical constraint seriously, we assume that if a linguistic expression has the grammatical form of a referring expression, then it is a referring expression. For example, a nominal like "a man" which contains the referential marker "a", indicates that the expression can be used to refer. Unless there is a very strong reason to assume that any use of this referring expression is non-referential, it is assumed to refer. Further, the referential marker "a" indicates reference to a single referent as does the head noun "man" (i.e. both are grammatically singular). This expression cannot be used to refer to multiple individuals.

Where other approaches argue for the non-referential use of referring expressions or for a complicated mapping from referring expression to possible referents (see discussion below), it is argued instead that referring expressions may refer to something other than an individual, and that the notion of reference is complicated by a secondary relationship between the referents in a situation model and objects in the mental universe. By expanding the ontology of referential types to include types, prototypes and exemplars, and classes and collections of these, it is possible to retain a simplified mapping from referring expression to referent—one which is consistent with the grammatical features of the referring expression. By introducing a bi-partite relationship between a situation model and the mental universe it is possible to explain apparent non-referential uses of referring expressions. The viability of this approach hinges on adoption of the mentalist semantics of Jackendoff. Reference is to mental encodings of external experience and these encodings can provide alternative construals of reality. There is no direct reference to actual objects in the external world.

Theoretical Background

Ball (2007) presents a linguistic theory of the grammatical encoding of referential and relational meaning which is implemented in a computational cognitive model of language comprehension (Ball, Heiberg & Silber, 2007; Ball et al., 2010) within the ACT-R cognitive architecture (Anderson, 2007). The basic structure and function of nominals and clauses is bi-polar with a *specifier* functioning as the locus of the *referential pole* and a *head* functioning as the locus of the *relational pole*—where relational pole encompasses objects (noun, proper noun, pronoun) and relations (verb, adjective, preposition, adverb). If the head of the relational pole is a relation, one or more *complements* or *arguments* may be associated with the relation. *Modifiers* may surround the specifier and head and may be

preferentially attracted to one pole or the other. A specifier and head (or reference point, specifier and head) combine to form a *referring expression*. A determiner functioning as an *object specifier* combines with a head to form an *object referring expression* or *nominal* (ORE \rightarrow Obj-Spec Obj-Head). A possessive nominal (e.g. “John’s” in “John’s book”) or possessive pronoun (e.g. “his” in “his book”) functioning as a combined reference point and specifier may also combine with a head to form an object referring expression (ORE \rightarrow Ref-Pt/Obj-Spec Obj-Head). In this case the object referring expression contains two referring expressions: 1) the reference point, and 2) the referring expression as a whole.

Ball (2010) extends the theory of referential and relational meaning to a consideration of grammatical features like definiteness, number, animacy, gender and case in object referring expressions. These features provide important grammatical cues for determining the referents of object referring expressions.

The referring expressions in a text instantiate and refer to objects, situations, locations, etc. in a *situation model* which is a representation of the evolving meaning of the text. The term “situation model” originates in the research of van Dijk & Kintsch (1983). Originally a situation model was viewed as a collection of propositions extracted from a text and elaborated with additional propositions introduced by schemas activated by the text and resulting from inference processes operating over the text. However, situation models have evolved away from being purely propositional (or relational) representations towards encoding referential, spatial, imaginal and even motor aspects of meaning (cf. Zwann and Radvansky 1998). We view the situation model as the cognitive locus of Jackendoff’s Conceptual Semantics. Jackendoff has adopted similar extensions in his recent work (Jackendoff, 2002, 2007).

A situation model is a mental scratchpad for maintaining information about the referents of the referring expressions in a text. However, referents can also be implicit in the text, inferred from background knowledge or encoded from the environment. The situation model is constructed in the context of a *mental universe*. The mental universe is the experience of the real world filtered through the perceptual and cognitive apparatus of an individual over the course of a lifetime. Like situation models, the mental universe may be full of counterfactual objects and situations. An individual may have a long history of experience of unicorns, both perceptual (e.g. from movies and picture books) and linguistic, despite the fact that unicorns only exist as figments of imagination in objective reality. The mental universe may also have well established and distinct referents for the morning star and the evening star, despite the fact that these referents map to the same planet in objective reality.

The combination of the mental universe and the situation model provide the basic sources for grounding the meaning of referring expressions. A referring expression may be bound to a referent in the situation model which may or

may not be ground in the mental universe. If the referent is ground in the mental universe then the individual has personal experience of the referent. If the referent is not ground in the mental universe, then the individual has only limited information about the referent and it may appear that the referring expression is non-referential. But as Lyons (1977) notes, allowing referring expressions to be non-referential is problematic for co-reference. “Two expressions cannot have the same reference, if one of them is not a referring expression at all” (Ibid, 191). In “John’s murderer, whoever he is...”, “he” co-refers with “John’s murderer”. The attributive use of a referring expression like “John’s murderer” is a type of reference which instantiates a referent into the situation model that is not grounded in the mental universe, but which supports co-reference.

The ontology of referential types presented in this paper follows from basic principles of *Cognitive Linguistics* (cf. Langacker, 1987; Lakoff, 1987) and *Cognitive Psychology* (Rosch, 1975; Collins and Quillian, 1969). There is extensive empirical evidence supporting the existence of conceptual categories corresponding to types, prototypes and exemplars. This paper takes the small step of suggesting that such conceptual categories can be referred to by linguistic expressions and explores the consequences.

The representation of referents in the situation model parallels the representation of referring expressions. Both are represented in ACT-R as chunks—i.e. frames with collections of slot-value pairs. Chunks are organized into an inheritance hierarchy which supports default inheritance and a distinction between chunk type and chunk instance. The value of a slot may be a chunk, supporting complex representations of structure needed for linguistic and Conceptual Semantic representation. With respect to object referring expressions which are the focus of this paper, a chunk representing an object referring expression is bound to a corresponding referent via a matching value in an index slot. Depending on the object referring expression, situation model and mental universe, the referent may be an instance, type, prototype, exemplar, class or collection.

An Expanded Ontology of Referential Types

First Order Predicate Calculus (FOPC) is typically grounded in a model theoretic semantics with an ontology limited to atomic individuals. The model consists of a domain and a set of individuals in that domain and nothing else. Typically these individuals are assumed to correspond to objects (or individuals) in the real world being modeled. In FOPC, a relation is modeled in terms of the set of individuals (for 1-ary relations or properties) or set of ordered sets of individuals (for n-ary relations, $n > 1$) for which the relation is true. A relation with its arguments bound to individuals in the domain is either true or false of those individuals and it is said that the reference of the proposition is one of the values true or false.

Situation Semantics (Barwise and Perry, 1983) extends FOPC by allowing situations to be individuals. Not only are situations true or false of sets of individuals in the domain

being modeled, but they are themselves individuals in the domain. We may say that situations have “first-class” status in situation semantics, whereas they are a second-order (or derived) notion in standard FOPC.

Situation Semantics is a step in the right direction. Whereas it might make reasonable sense to suggest that a predicate like “dog” denotes the set (or class) of individuals that are dogs (although psychologically humans cannot quantify over such a large set), it makes little sense to suggest that the predicate “run” denotes the set of all individuals who run, or that “kick” denotes the set of ordered sets of kickers and kickees, as is typical in FOPC treatments with a set-theoretic model limited to individuals that are essentially objects of various types (and sets of such individuals). (It is this sleight of hand in FOPC that collapses the distinction between nouns and verbs, treating both as predicates corresponding to sets of individuals.) It is much more reasonable to suggest that “run” denotes the set of all running events and that “kick” denotes the set of all kicking events. And if “run” denotes a set of running events and “kick” a set of kicking events, then allowing “run” to be used in an expression that refers to an instance of a running event, and allowing “kick” to be used in an expression that refers to an instance of a kicking event, follows quite naturally and is cognitively plausible. However, Situation Semantics stops short. What is needed is a referential ontology which supports a mapping from the types of referring expressions which are linguistically attested to the types of referents which are cognitively motivated.

With an ontology of referential types limited to individuals and sets of individuals, it is often assumed that a referring expression like “a car” in an expression like “a car is a vehicle” quantifies over the set of all individuals for which the predicate “car” is true (i.e. the set or class of objects of type “car”). In FOPC, this can be represented as

$$\forall x (\text{car}(x) \rightarrow \text{vehicle}(x))$$

However, from a grammatical perspective, “a car” is clearly singular, and from a cognitive perspective, quantifying over all individuals is cognitively implausible. The need to quantify over all individuals in the FOPC representation of the linguistic expression stems from the limited ontology available in FOPC for representing the meaning of indefinite referring expressions. Only the universal and existential quantifiers—which fail to capture the full range of quantification in natural language—are available.

Similarly, one FOPC representation for the expression “every man owns a car” is given by

$$\forall x (\exists y (\text{man}(x) \text{ and } \text{car}(y) \rightarrow \text{own}(x,y)))$$

However, in English “every man” is grammatically singular, and a mapping to the universal quantifier is problematic. Johnson-Laird (1983) introduced mental models as a way of overcoming the limitations of quantification in FOPC (among other things). He suggests that the expression “a car” in the sentence “every man owns

a car” maps to some representative subset of cars. This representative subset of cars corresponds to the representative subset of individuals referred to by “every man”, plus a subset of cars that are not owned. He (1983, p. 421) represents this as

$$\begin{array}{l} \text{man} \rightarrow \text{car} \\ \text{man} \rightarrow \text{car} \\ \quad (\text{car}) \end{array}$$

But if “every man” and “a car” are singular and not plural, then “every man” does not refer to multiple men and “a car” does not refer to multiple cars. Johnson-Laird’s treatment is cognitively plausible, but inconsistent with the grammatical form of the referring expressions. From a perspective which assumes that the number feature of a referring expression corresponds closely to the number feature of the referent of the expression, there are several cognitively motivated referents for expressions like “every man” and “a car” which do not violate the singular status of the linguistic expressions:

- Type
- Prototype/Exemplar
- Indefinite/Definite Instance

“A car” may refer to a type of object, namely the type of object that is a car. “A car” may also refer to a prototype that represents what is common to most cars, or it may refer to an exemplar which is an instance that is a representative car. Further, “a car” may refer to an indefinite instance with the determiner “a” marking the indefinite status of the referent of “a car”. Note that “indefinite instance” is used here as a referential type and not a type of referring expression. In all but a few cases, the type of the referring expression is an *indefinite, singular object referring expression* when grammatically marked by the determiner “a” and a singular head noun (“a few cases” being a notable exception where “a” combines with a plural head noun). Given the occurrence of the indefinite, singular determiner “a” and the singular noun “car” in this expression, “a car” cannot be used to refer to a definite instance of a car, or to a class or collection, but all the other referential types are potential referents of indefinite, singular object referring expressions. Likewise, “every man” may refer to a representative but indefinite, singular instance of a man as is suggested by the singular status of “every man”.

Reference to Definite and Indefinite Instances. The determiner “the” marks reference to definite instances. Consider the definite object referring expression “the car”. This definite expression indicates that there is already a referent in the situation model that is being referred to or that there is a salient “car” object in the mental universe that is being referred to and this object should be instantiated into the situation model. For a more complex example, consider:

A car is in the driveway. The car is red.

In the first sentence, the expression “a car” is indefinite and instantiates a new referent into the situation model—one that is not (known to be) ground in the mental universe. In the second sentence, the expression “the car” is definite and refers to the referent instantiated into the situation model by “a car”. Note that this referent is ungrounded in the sense that it has not been identified with any object in the mental universe, although it could be (e.g. “Oh, it’s your car”). It is the mental universe which ultimately grounds referents. In the first sentence, the expression “the driveway” is definite. In this case, the definiteness of “the driveway” indicates there is (or should be) a salient object in the mental universe that should be instantiated into the situation model. There are three primary types of definite reference: 1) reference to an existing referent in the situation model which is grounded in the mental universe, 2) reference to an existing referent in the situation model which is ungrounded in the mental universe, and 3) reference to an object in the mental universe which is not in the situation model, but is (or should be) salient. There are two primary types of indefinite reference: 1) reference to an object which is being introduced and should be instantiated into the situation model—this object is not known to correspond to any object in the mental universe, and 2) reference to a generic instance or type which exists in the mental universe and should be instantiated into the situation model.

Reference to Types. Type hierarchies are common in systems of knowledge representation and making types first class objects allows expressions like “a sedan is a (type of) car” or “a (type of) car I like is a sedan” to be represented as relating two types “a sedan” and “a car”. “A sedan” and “a car” refer to *instances of a type*. The suggested reference to a type rather than a class of instances is based on the singular status of these referring expressions (i.e. “a sedan” vs. “all sedans”). A type is a reified class. From a referential perspective, the type is atomic with no subparts and singular reference is appropriate. An instance is added to the situation model which is grounded in a type in the mental universe. From a relational perspective, “is” establishes a relationship of equality between the two arguments “a sedan” and “a car”. However, from a referential perspective, there are two basic possibilities: 1) both “a sedan” and “a car” may refer to types of objects which are equated, or 2) the occurrence of “a car” within the context of “is” suppresses the normal referential behavior of “a car” such that “is a car”—a *predicate nominal*—is treated as a non-referential expression which is ascribed to the subject “a sedan”. The typical treatment of predicate nominals suggests that they are non-referential (cf. Jackendoff, 2002). In a sentence like “John is a fool”, “is a fool” is treated as a predicate nominal that says something about the individual that “John” refers to and this sentence is often considered synonymous with “John is foolish”. From the perspective of the grammatical constraint, there is a problem with this treatment. Grammatically, “a fool” has the form of an indefinite, singular object referring expression and all object referring

expressions are capable of referring, regardless of context. In the case of a predicate nominal, the referent of the embedded object referring expression, if it is identified, is the same as the referent of the subject—they are co-referential. The assumption that “is a fool” is non-referential rests on the availability of a referring expression “John”, the referent of which the predicate nominal “is a fool” is predicated. In the absence of a separate referring expression, it is unclear how to treat the predicate nominal. For example, in “I wonder who is a fool”, if “who” is non-referential as Huddleston & Pullum (2002, p. 401) suggest, then what does “is a fool” get predicated of? An obvious suggestion is that “who” functions as an unbound variable (or variable bound via a lambda expression) which instantiates a referent whose grounding is yet to be determined, but which supports predication of “is a fool” and can be referred to subsequently as in the follow up “he better be careful”. In fact, it may turn out that nobody is a fool since “wonder” is non-factive (i.e. doesn’t entail the existence of its complement). Or it may be the case that the hearer can provide the grounding as in “It’s John”. In general, Huddleston & Pullum discuss a range of “non-referential” object referring expressions (they prefer to use the term NP) in which there is no object in the real world to which the expressions refer, overlooking the possibility of a more flexible notion of reference within a situation model embedded in a mental universe.

In Jackendoff (2002), types are treated as lacking an indexical feature. While this treatment is attractive in providing a simple distinction between types and tokens (i.e. tokens have an indexical feature, types don’t), the lack of an indexical feature implies an inability to refer to types. Yet, Jackendoff acknowledges the existence of NPs which describe types. These NPs are necessarily non-referential. When an NP occurs as a predicate nominal and functions as a kind (or type) as in “a professor” in “John is a professor”, this approach coheres. There is an object in the situation model to which the expression refers. But what happens when an NP describing a type occurs as the subject or object as in “A new kind of car is passing by” or “He wants a special kind of dog”? If the object referring expressions don’t refer, then it is unclear how the situation model can represent the meaning of these expressions. At a minimum, Jackendoff needs to allow reference to generic instances and argue that apparent references to types are really generic instance references. However, since there is strong evidence that types exist as mental constructs (cf. Collins & Quillian, 1969), we see no good reason to preclude reference to them.

Reference to Generic Instances. The plural variant of the expression “a sedan is a car” is “sedans are cars”. This variant suggests a representation based on a collection of generic instances rather than a type.

The generic instance category generalizes over prototypes and exemplars. It is difficult to distinguish reference to prototypes from reference to exemplars since they have much in common. A prototype may be viewed as a washed

out exemplar (some cognitive approaches treat prototype and exemplar as essentially synonymous). It is a washed out exemplar in that it is a generalization over the experience of particular instances of the type. In this respect, a prototype is more like a type than an instance, making the distinction between types and instances less clear cut than is typically assumed. The use of specific lexical items may help to make the distinction. Consider the sentence “the prototypical car is a sedan”. If the expression “the prototypical car” actually picks out a prototype for a referent, and the expression “a sedan” picks out a type, then equating a prototype with a type has the effect of defining the prototype to be of a particular type.

Allen (1986) discusses the semantics of generic NPs noting that “there is no marking for the generic within NP morphology” and that generics have “to be inferred from context”. Grammatically a singular object referring expression is either definite or indefinite. If the referent of the expression is a prototype or exemplar, then the reference is generic. In the expression “the sedan is a car” where there is no existing referent in the situation model for “the sedan” to refer to, “the sedan” presumably picks out a generic instance or type.

The motivation for distinguishing prototypes and exemplars is a cognitive one, although there is disagreement within the cognitive community as to whether or not both notions are needed. It may be sufficient to distinguish generic instances from types in the situation model without distinguishing prototypes and exemplars.

Reference to Classes, Collections and Masses.

Classes, collections and masses complicate reference in interesting ways. Classes and types are two sides of the same coin. The type is atomic and has no subparts. However, the elements of a class are salient and a plural nominal is used to refer to classes as in “all men”. Collections are also referred to by plural nominals as in “the men/all the men” where “the men/all the men” refers to some salient collection of men, and not to the entire class. In these expressions, the noun head “men” denotes the type, and the specifier and plural grammatical feature determine the nature of the referring expression (i.e. class or collection). Masses differ from classes and collections in that the elements of a mass are not salient. Singular nominals are used to refer to masses.

Mass and plural nouns, but not singular count nouns, may function as referring expressions without separate specification. In “rice is good for you”, “rice” does not refer to any specific instance of rice and in “books are fun to read”, “books” does not refer to any specific collection of books. Both expressions are indefinite. They refer to something non-specific: a type or generic instance for “rice” and a generic collection for “books”. Reference to a specific mass or collection requires a definite determiner as in “the rice is ready” and “the books are fun to read”.

The use of a plural nominal to refer to a class or collection suggests that the members of the class or collection are cognitively salient and may be separately

represented. This opens up the possibility of either referring to the class or collection as a whole or referring to the elements of the class or collection. However, for cognitive reasons having to do with the limited capacity of humans to attend to multiple chunks of information (e.g. Miller, 1956), it is assumed that any linguistic expression may only introduce a small number of referents into a situation model (cf. Johnson-Laird, 1983). In the “sedans are cars” example, the instantiation of a sedan collection and two generic instances of a sedan, and a car collection and two generic instances of a car is the minimal number consistent with the plurality of the object referring expressions. Given these referents, it is possible to refer to the collections as a whole, and it is also possible to pair the members of one collection with the members of the other collection. These alternatives correspond to the *collective* and *distributive* readings discussed in Lyons (1977). Lyons presents the example “those books cost \$5” which is ambiguous between a distributive—each book is \$5—and collective—all the books are \$5—reading. Distributive and collective readings involve inferential processes operating over collections and instances which are not part of the grammatically encoded meaning. However, addition of “each” to “those books cost \$5 each” imposes a distributive reading.

We can now see that Johnson-Laird’s representation of “every man owns a car” corresponds closely to a distributive reading (constrained to a small number of referents). We are also in a better position to consider the representation of “every man”. Although expressions with “every” are singular, suggesting selection of an arbitrary instance of a collection, in “Everyone left. They went to eat.”, subsequent references are plural. Further, “Everyone left. He went to eat” is infelicitous. There are two implications of these examples: 1) “every” instantiates or references a collection in the situation model, and 2) the arbitrary referent of “every” is not salient for subsequent reference. Even referring expressions with singular “a” as in “Everyone owns a car. They are indispensable.” support subsequent plural reference, although in this case “Everyone owns a car. It is indispensable.” is also felicitous. This may result from the flipping of the type/class coin. Subsequent singular reference is to the type (or generic instance), subsequent plural reference is to the class.

Reference to Vacuous Instances and Collections.

The empty set is a useful notion in set theory. The null symbol (or empty list) is a useful symbol in the Lisp programming language. In both set theory and Lisp, these are actual objects that can be referred to and manipulated. The grammatical and lexical structure of English strongly suggests the possibility of referring to a corresponding empty or vacuous object whose existence is taken for granted. Yet Martinich (1985, p. 3) argues that the existence of nothing is an “absurd view” which rests on “a misunderstanding of how language works”. However, not only does grammar suggest the existence of objects

corresponding to nothing, but it suggests that nothingness comes in lots of different types and collections. Consider

Nothing
No one, nobody
Nowhere, Never
No man, No dog
No men, No dogs

It is true that a logical representation for expressions like “no man” which requires quantifying over every individual in the model makes little practical sense

$\forall x (\sim \text{man}(x))$

but this is taken to be a problem for the logical representation of the meaning of negative expressions, rather than as a criticism of negative referring expressions in language. Allowing negative object referring expressions to refer to empty or vacuous objects and collections in the situation model which do not map to any objects or collections in the mental universe is perhaps the clearest demonstration of how to simplify the mapping from referring expression to referent, relative to other approaches.

Summary and Conclusions

This paper presents and supports an expanded ontology of referential types consistent with Jackendoff's Conceptual Semantics, basic principles of cognitive linguistics and empirical evidence from cognitive psychology. By expanding the ontology of referential types and introducing a distinction between situation model and mental universe, it is possible to simplify the mapping from referring expression to referent, relative to approaches with a more limited ontology and single semantic space.

We propose a bi-partite semantic space consisting of a situation model and mental universe that explains apparent non-referential uses of referring expressions, along with the existence of two partial orderings:

Universal (e.g., $\forall x$) >
Class (e.g., $\forall x (\text{man}(x))$ or “all men”) >
Collection (e.g. “some/the/all the men”) >
Mass (e.g. “mankind”) >
Instance (e.g. $\exists x (\text{man}(x))$ or “a/the man”) >
Null (e.g. “no man”)

Type > Prototype > Exemplar > Token (Individual)

The partial orderings are motivated by the linguistic expression of referring expressions, cognitive theory and a computational interest in simplifying the mapping from referring expressions to corresponding objects and situations. The partial orderings are not definitive. They capture important aspects of the mapping from referring expressions to referents, but there are more dimensions of meaning involved in this mapping than these two orderings can accommodate.

Abstract

This paper describes a computational cognitive model of human language processing under development in the ACT-R cognitive architecture. The paper begins with the context for the research, followed by a discussion of the primary theoretical and modeling commitments. The main theoretical commitment is to develop a language model which is at once functional and cognitively plausible. The paper continues with a description of the word recognition subcomponent of the language model which uses a perceptual span and ACT-R's spreading activation mechanism to activate and select the lexical unit that most closely matches the perceptual input. Next we present a description of the linguistic structure building component of the model which combines parallel, probabilistic processing with serial, pseudo-deterministic processing, including a non-monotonic context accommodation mechanism. A description of the mapping of linguistic representations into a situation model, follows. The paper concludes with a summary and conclusions.

Keywords: human language processing (HLP); functional; cognitively plausible; pseudo-deterministic.

Introduction

The capability to model the cognitive processes associated with language is a long sought-after goal of cognitive science. Computational cognitive process models help researchers to not only understand language processes in their own right, but to determine how they affect and interact with other cognitive processes (e.g., reasoning, decision-making, situation assessment, etc.). Scaled-up versions of these models also support the development of cognitive agents with communicative capabilities based on human linguistic processes (Ball et al., 2009; Douglass, Ball & Rodgers, 2009). In this paper we present a "snapshot" of a functional language comprehension model under development within the ACT-R architecture (Anderson, 2007). The model implements a referential and relational theory of human language processing (Ball, 2007; Ball, Heiberg & Silber, 2007) within ACT-R¹.

A key commitment of the language comprehension research is development of a model which is at once cognitively plausible and functional. We believe that adherence to well-established cognitive constraints will

facilitate the development of functional models by pushing development in directions that are more likely to be successful. There are short-term costs associated with adherence to cognitive constraints; however, we have already realized longer-term benefits. For example, the integration of a word recognition capability with ACT-R's perceptual system and higher-level linguistic processing has facilitated the recognition and processing of multi-word expressions and multi-unit words in ways that are not available to systems with separate word tokenizing and part of speech tagging processes. Using an available tokenizer and part of speech tagger would have initially facilitated development, but the cognitive implausibility of using staged tokenizing and part of speech tagging led us to reject this approach. The benefits that we have realized as a result of this decision are described below.

Theoretical & Modeling Commitments

There is extensive psycholinguistic evidence that human language processing is incremental and interactive (Gibson & Pearlmuter, 1998; Altmann, 1998; Tanenhaus et al., 1995; Altmann & Steedman, 1988). Garden-path effects, although infrequent, strongly suggest that processing is essentially serial at the level of phrasal and clausal analysis (Bever, 1970). Lower level processes of word recognition suggest parallel, activation-based processing mechanisms (McClelland & Rumelhart, 1981; Paap et al., 1982). Summarizing the psycholinguistic evidence, Altmann & Mirkovic (2009, p. 605) claim "The view we are left with is a comprehension system that is 'maximally incremental'; it develops the fullest interpretation of a sentence fragment at each moment of the fragment's unfolding".

These cognitive constraints legislate against staged analysis models. All levels of analysis must at least be highly pipelined together, if not, in addition, allowing feedback from higher to lower levels. They also suggest the need for hybrid systems which incorporate a mixture of parallel and serial mechanisms, with lower levels of processing being primarily parallel, probabilistic and interactive, while higher levels of analysis are primarily serial, deterministic and incremental.

To adhere to and take advantage of these cognitive constraints, we have developed a *pseudo-deterministic* human language processing model—i.e. a model that presents the appearance and efficiency of serial, deterministic processing, but uses a non-monotonic context

¹ At the time of publication the model contained 6,395 declarative memory elements and 548 production rules which cover a broad range of grammatical constructions.

accommodation mechanism and relies on lower level parallel mechanisms to deal with the ambiguity that makes true deterministic processing impossible. This model makes use of the architectural mechanisms in ACT-R that are most compatible with incremental and interactive processing. For example, parallel, probabilistic processing taps into ACT-R's declarative memory (DM) and parallel spreading activation mechanism, with ACT-R's DM retrieval mechanism supporting probabilistic selection—without inhibition between competing alternatives as is typical of connectionist models (cf. Vosse & Kempen, 2000). Serial, incremental processing is based on ACT-R's procedural memory which is instantiated as a production system. ACT-R at once constrains the computational implementation and provides the basic mechanisms on which the model relies. Other than adding a collection of buffers to support language processing by retaining the partial products of retrieval and structure building, and improving the perceptual processing in ACT-R, the computational implementation does not add any language-specific mechanisms. In the following sections we discuss important subcomponents of the model, such as how the model recognizes words, builds linguistic representations, and maps linguistic representations to a situation representation.

Reading & Word Recognition

A functional language model must deal with the linguistic input as is. In an experiment involving human subjects communicating via text chat (cf. Ball, et al., 2009), we collected a text chat corpus that is riddled with variability in word forms—e.g., misspellings like “altitde”, abbreviations like “alt.”, and concatenations like “speedrestriction” and “speed=200-500”. For competent readers, misspelled words activate the intended lexical items because they contain many of the same letters and trigrams (Perea & Lupker, 2003). Further, all the letters of a word can be transposed, yet still prime the intended word (Guerrera 2004). Key requirements of a functional language model are the ability to handle variability and misspellings in input forms, the ability to separate perceptually conjoined units (e.g. separating punctuation from words as in “He went.”, but not “etc.”); separating concatenated words, and the ability to recognize multi-word expressions (e.g. “speed up”) and multi-unit words (e.g. “ACT-R”, “a priori”).

To satisfy these requirements, the model includes a word recognition subcomponent that uses ACT-R's spreading activation mechanism combined with a multi-word perceptual span to influence lexical item retrieval. It is assumed that word recognition involves mapping orthographic input directly into DM representations without recourse to phonetic processing (although a phonetic mapping is not precluded). The model does not treat each word as a sum of its parts, ignoring the complete form altogether. Rather, if the text input as a whole does not match, and thereby activate an item in the lexicon, the closest match can be retrieved based on the cues that do match, such as letters, word-length, and trigrams.

In the model's DM, word chunks have slots for letters, word-length, and trigrams. Multi-unit words and multi-word expressions have this information for all of the constituent units. Text input is distilled into this information by the model and put into buffers to spread activation to words in DM containing matching information. The activation mechanism allows the model to retrieve words from DM that are not an exact match to the input. Letters and trigrams in the text input increase the activation of word chunks containing those letters and trigrams in the mental lexicon. The most highly activated word chunk, which need not be an exact match to the input, is retrieved. These processes and encodings are based on the Interactive Activation model of word recognition (McClelland and Rumelhart 1981), with the addition of trigrams based on “letter triples” (Seidenberg and McClelland, 1989).

Besides breaking words into letters and trigrams, we modified the ACT-R architecture to better interpret multi-unit words and multi-word expressions. By default, ACT-R splits input text into perceptual units based on spaces and punctuation—even word internal punctuation, where “ACT-R” becomes “ACT” “.” “R”—and processes each perceptual unit separately. We replaced this behavior with a perceptual span that is based on human reading span data and a multi-level splitting of the input within the perceptual span into larger and smaller perceptual units which spread activation in parallel. We also added multi-word expression chunks and multi-unit lexical chunks to DM. The overall effect is a significant reduction in the number of DM retrievals per space and punctuation delimited input. Words with internal punctuation and multi-word expressions can now be retrieved as a single perceptual unit despite their internal structure (Freiman & Ball, submitted).

The new perceptual span is considerably larger than ACT-R's punctuation and space delimited span. There is a great deal of evidence that the perceptual span of adult readers is about 14-15 letters to the right of fixation (McConkie & Rayner, 1975; Rayner, 1986). We implemented a span of up to twelve letters, with the greatest amount of activation spreading from the first few letters of the span and decreasing toward the end of the span. Just as for adult readers, information to the right of fixation is obtained when the next word is predictable from the preceding text (see Rayner 1975; and Binder, Pollatsek, & Rayner, 1999).

Within the context of a functional language model—i.e. one that must interpret and act on the linguistic input, we are also attempting to model adult human reading rates (Freiman & Ball, submitted). Adult humans read at a phenomenal rate of 200-300 (space delimited) words per minute (Carver, 1973a; 1973b). The ACT-R architecture supports the timing of cognitive processes down to the msec level. The real-time it takes for a model to run can also be measured. Although we have not yet succeeded in achieving adult reading rates, we have improved the reading rate of the model significantly in both cognitive and real-time: 143 words per minute in ACT-R cognitive time (important for

cognitive plausibility); and 249 words per minute in real-time on a single-core, 2.1 GHz Windows Vista machine with 2 gigabytes of RAM (important for a functional model). Ultimately, we believe that achieving adult reading rates hinges on minimizing the amount of structure building and maximizing the average size of linguistic units which are retrieved. We are pursuing mechanisms and representations that will make this possible.

Building Linguistic Representations

The word recognition subcomponent typically delivers a lexical item categorized for part of speech to the higher level component that builds linguistic representations of referential and relational meaning. For example, consider the processing of “the pilot”. The processing of “the” leads to its identification as a determiner via retrieval from DM. Selection of this lexical item is based on the probabilistic, context-sensitive mechanism discussed in the previous section. The subsequent processing of the determiner “the” leads to the projection or construction of a nominal construction. The processing of the word “pilot” in the context of the preceding word “the” and the projected nominal leads to retrieval of a DM chunk identifying “pilot” as a noun. The noun “pilot” is then integrated as the head of the nominal projected during the processing of “the”.

Similar parallel, probabilistic mechanisms operate at the phrasal and clausal level, selecting between competing phrasal and clausal alternatives, and potentially interacting with lower level probabilistic mechanisms. As an example of this potential interaction, consider the processing of personal pronouns like “he” and “it”. At the lexical level, these words are categorized as pronouns, but they are also closely associated with the nominal phrasal category since they typically function as the head of a complete nominal. Processing personal pronouns may involve their recognition as pronouns followed by projection of a nominal phrase from the pronoun, but it may also be that the perceptual form can directly lead to retrieval of a nominal phrase, without the intermediate step of identifying the word as a pronoun. The word recognition component, which prefers larger and higher level units, may deliver a pre-compiled nominal unit corresponding to the pronoun, rather than a lexical unit to the higher level construction process, blurring the distinction between lexical and phrasal units. The determiner “the” may behave similarly, resulting in direct retrieval of a nominal with an empty head, without the intermediate step of identifying “the” as a determiner.

The parallel, probabilistic mechanism which is capable of retrieving existing phrasal and clausal representations as well as lexical units, competes with a mechanism which builds novel representations. DM retrieval has priority over this alternative construction mechanism. However, lexical units are more likely to be available for retrieval than phrasal and clausal representations. Further, the parallel, probabilistic mechanism is not capable of building any structure—building structure is the function of the serial construction mechanism.

There are two basic ways of building structure: 1) integration of the current linguistic unit into an existing representation which contains an expectation for the linguistic unit (i.e. substitution), and 2) projection or construction of a novel representation coupled with integration of the current linguistic unit into the novel representation. For example, the processing of the word “pilots” recognized as a plural noun by the word recognition component can lead to projection of a nominal and integration of “pilots” as the head of the nominal. On the other hand, if “the” has already projected a nominal and set up the expectation for a head to occur, the processing of “pilots” can lead to its integration as the head of the nominal projected by “the”.

The structure building mechanism is incremental in that it executes a sequence of productions that determine how to integrate the current linguistic unit into an existing representation and/or which kind of higher level linguistic unit to project. These productions execute one at a time within the ACT-R architecture which incorporates a serial bottleneck for production execution. Although supported by extensive empirical evidence, the serial production execution bottleneck is a characteristic of ACT-R that distinguishes it from other production system architectures which support parallel production execution.

The structure building mechanism uses all available information in deciding how to integrate the current linguistic input into the evolving representation. Although the parallel, probabilistic mechanism considers multiple alternatives in parallel, the output of this parallel mechanism is a single linguistic unit and the result of structure building is also a single representation. The structure building mechanism operates in a *pseudo-deterministic* manner. It is deterministic in that it builds a single representation which is assumed to be correct, but it relies on the parallel, probabilistic mechanism to provide the inputs to this structure building mechanism. In addition, structure building is subject to a mechanism of context accommodation capable of making modest adjustments to the evolving representation (Ball, 2010a). Although context accommodation does not involve backtracking or reanalysis, it is not, strictly speaking, deterministic, since it can modify an existing representation and is therefore non-monotonic. For example, in the processing of the expression “the altitude restriction”, when the word “altitude” is processed, it can be integrated as the head of the nominal projected by “the”. But when “restriction” is subsequently processed, the context accommodation mechanism can adjust the representation, shifting “altitude” into a modifying function so that “restriction” can function as the head. This context accommodation capability can apply iteratively as in the processing of “the pressure valve adjustment screw” where “screw” is the ultimate head of the nominal, but “pressure”, “valve” and “adjustment” are all incrementally integrated as the head prior to the processing of “screw”. Note that at the end of processing it appears that “pressure”, “valve” and “adjustment” were treated as

modifiers all along, giving the appearance that these alternatives were carried along in parallel with their treatment as heads.

Context accommodation uses the full available context to make modest adjustments to the evolving representation or to construe the current input in a way that allows for its integration into the representation. As an example of construal, the verb “kick” is construed as an object and functions as the head of a nominal when it occurs in the context of “the”, as in “the kick”. Function overriding and function shifting are two additional mechanisms of context accommodation. We have already seen an example of function shifting (e.g. “the altitude restriction”). In the processing of “no altitude or airspeed restrictions”, the conjoined head “altitude or airspeed” can override the initial treatment of “altitude” as the head of the nominal, with the subsequent shifting of “altitude and airspeed” into a modifying function during the processing of “restrictions”. At a lower level, there are accommodation mechanisms for handling conflicts in the grammatical features associated with various lexical items. For example, the grammatical feature *definite* is associated with “the” and the grammatical feature *indefinite* is associated with “pilots”. In “the pilots”, the *definite* feature of “the” blocks the *indefinite* feature of “pilots” from projecting to the nominal. See Ball (2010b) for more details.

Context accommodation need not be computationally expensive—a single production may effect the accommodation, just as a single production may effect integration without accommodation. In this respect, context accommodation is not a reanalysis mechanism that disrupts normal processing—it is part and parcel of normal processing. Reanalysis mechanisms need only kick in when context accommodation fails and larger adjustment is needed. The mechanism of context accommodation is most closely related to the limited repair parsing of Lewis (1998). Context accommodation may be viewed as a very modest form of repair. According to Lewis (1998, p. 262) “The putative theoretical advantage of repair parsers depends in large part on finding simple candidate repair operations”. The mechanism of context accommodation provides evidence for this theoretical advantage.

Overall, the highly interactive, parallel, probabilistic mechanism for selecting between competing alternatives combines with the incremental, serial construction and context accommodation mechanisms to provide an efficient, pseudo-deterministic language processing capability.

Mapping into the Situation Model

Although we borrow the term (cf. Zwann & Radvansky, 1998), we define *situation model* as a domain-specific mental representation of a set of objects, actions, events, and relationships related to a task, sufficient for reasoning about a set of actions within that task. The situation model is separate from the model’s world knowledge but is related to and affected by world knowledge.

The situation model is implemented in three main subcomponents: the ACT-R module definition, a set of domain general production rules, and a set of domain specific production rules. The module is instantiated like other ACT-R modules (Anderson, 2007), and includes the module buffers and handlers for module requests and queries.

The main situation buffers are: sm-subject-context, sm-related-object-context, sm-sit-context, sm-action-context, sm-event-context, and sm-prior-attention. They are named and designed to reflect the semantics of the represented situations. The buffers will contain chunks representing the objects, actions, events, and relationships discussed or encountered in the task environment. The top level chunk types were based upon the Suggested Upper Merged Ontology (SUMO) (Niles and Pease, 2001) and are: Action, Attribute, Concept, Event, Object, Relation, and Situation. All entities represented in the situation model will be sub-typed from one of these top level chunk types. Because the situations being represented in our model may span multiple sentences, the contents of the sm-subject-context buffer will frequently not equate to the subject of an individually processed sentence. Rather, the contents of the sm-subject-context buffer should be thought of as the central topic or theme of the discourse at an individual moment. The situation chunk-type and its sub-types can be thought of as instances of *schemata* or structures for mental models of stereotypical situations (Alba, 1983). In our implementation, the situation chunk contains the relevant gist of the situation, where the “gist” can be thought of as an index to a specific category of situation.

It is the responsibility of the modeler to define any needed specific chunk subtypes. Because ACT-R’s chunk inheritance mechanism does not permit inheritance from multiple supertypes, it is expected that there will be some redundancy in the definitions of the chunk subtype hierarchy. While this redundancy will create some inefficiency in the type hierarchy design, it should not preclude the modeling of necessary elements.

The domain general productions manage the relationships between elements within each individual situation. For instance, in a situation involving an uninhabited air vehicle altitude restriction for a reconnaissance waypoint, a situation chunk would contain a subject slot and a related object slot. The subject slot value would refer to the reconnaissance waypoint and the related object slot value would refer to the waypoint’s altitude restriction. The domain general productions provide the mechanisms that manage the references between the situation elements.

The domain specific productions primarily consist of task knowledge and responses to the situations, events, actions, and objects that are learned from interacting with a specific task environment. It is the modeler’s responsibility to define the needed domain specific productions. A central goal of current research is to discover regularities and useful abstractions within the domain specific production rules that can be generalized.

The situation model represents the domain specific objects and situations to which the linguistic representations refer. The linguistic comprehension system interfaces to the non-linguistic situation model via the identification of referring expressions in the linguistic input. For example, recognition of a nominal, or object referring expression, results in the mapping to a corresponding object in the situation model. There are two basic cases: 1) recognition of a definite object referring expression typically results in identification of an existing object in the situation model or surrounding context, and 2) recognition of an indefinite object referring expression typically results in the introduction of a new object into the situation model. Extensions to these basic cases are considered in Ball (2010c) which expands the ontology of referential types to include types, collections, exemplars, prototypes and even negative instances. The extended ontology has the important benefit of simplifying the mapping from referring expressions to situation model entities.

An object referring expression from the comprehension system is mapped to the situation model when the head of the object referring expression is identified. For example, if the input is “the altitude”, then recognition of “altitude” as the head triggers the mapping to the situation model. Note that if the input is actually “the altitude restriction”, an altitude object will still be mapped to at the processing of “altitude”. At the processing of “restriction” an “altitude restriction” object will be mapped. Further, if a post-head modifier occurs as in “for Waypoint-A” in “the altitude restriction for Waypoint-A”, the mapping may need to be modified following processing of the post-head modifier. The model does not currently attempt to map to an object on the basis of pre-head modifiers as in “the red...” although there is evidence that humans may do so in Visual World Paradigm tasks (Tanenhaus et al., 1995). It should be noted that object referring expressions contain ambiguous words, not word senses or abstract concepts. It is the mapping to objects in the situation model which disambiguates the words in the linguistic representation.

Other challenges include anaphora and co-reference resolution. We currently use grammatical features to constrain the possible co-referents of a pronoun (e.g. “it” is *inanimate* and *singular*). We plan to adhere to the constraints of binding theory with respect to binding pronouns and anaphors (Chomsky, 1981) and to adopt mechanisms of Centering Theory (Grosz, Joshi & Weinstein, 1995) in a more complete implementation. We are not proposing a general solution in our research program; however, we expect to implement an initial capability for co-reference resolution by relying on ACT-R's chunk merging feature. So long as the specific context for a chunk is the same for newly introduced references to previously referenced knowledge elements, some amount of the new references automatically merge with previously constructed chunks in DM. For a more general solution, existing approaches to co-reference resolution are being investigated for inclusion in our design.

Summary and Conclusions

This paper describes a model of human language processing which is intended to be both functional and cognitively plausible. It includes a linguistic structure building mechanism which combines a serial, deterministic processing mechanism with a non-monotonic mechanism of context accommodation, and a lower level parallel, probabilistic mechanism for selecting between competing alternatives. Overall, the model is pseudo-deterministic—it presents the appearance and efficiency of deterministic processing, and can handle much of the more mundane ambiguity evident in human language via the parallel, probabilistic and non-monotonic context accommodation mechanisms. The model adheres to well-established cognitive constraints on human language processing including incremental and interactive processing. This commitment led to the integration of a cognitively plausible word recognition subcomponent, rather than adopting an off-the-shelf tokenizer and part of speech tagger that lacked cognitive plausibility.

A key attribute of the language comprehension model is the capability to handle variability and mismatch at all levels of analysis from word recognition, through the generation of linguistic representations and the mapping into the situation model, to the determination of the conversational implicatures not literally described in the linguistic input (although the capability to handle conversational implicatures is not yet implemented). There is no level of analysis at which variability and mismatch can be ignored.

The language comprehension model is a key component of a larger synthetic teammate model which is capable of functioning as the pilot in a three-person simulation of an uninhabited air vehicle reconnaissance mission task (Ball, et. al, 2009). The main objective of the synthetic teammate project is to develop cognitive agents capable of being integrated into team training simulations while maintaining training efficacy. To achieve this goal, synthetic teammates must be capable of closely matching human behavior. To this end, we have developed and integrated models of several important cognitive capacities into a composite synthetic teammate model. In addition to language comprehension and situation modeling, these capacities include the ability to perform the UAV piloting task, and language generation and dialog modeling capabilities.

Although we do not report a direct comparison of model results to human data, Cassimatis, Bello & Langley (2009) argue that models of higher-level cognitive processes, such as language comprehension, may be better evaluated on model breadth, parsimony, and functionality. Ball (2008) provides similar arguments for a functional approach, but makes a stronger commitment to cognitive plausibility. The synthetic teammate is capable of receiving text communications from a teammate, reading the text, producing linguistic representations of the text, and mapping the representations into a situation model. Based

on the contents of the situation model, the synthetic teammate then interacts with its task environment, or responds to communications with its own text messages. We believe that this demonstrates the functionality and capability of the presented language comprehension model.

Abstract

Recent experiments have shown the importance of statistical learning in infant language acquisition. Computational models of such learning, however, often take the form of corpus analyses and are thus difficult to connect to empirical data. We report a cross-situational learning experiment which demonstrates robust individual differences in learning between infants. We then present a novel generative model of cross-situational learning combining two competing processes – *habituation* and *association*. The model's parameters are set to best reproduce each infant's individual looking behavior from trial-to-trial in training and testing. We then isolate each infant's word-referent learning function to explain the variance found in preferential looking tests.

Keywords: statistical learning; computational modeling; cognitive development; language acquisition

Introduction

Language acquisition should be hard but young children nonetheless move from babbling to complex sentences in a remarkably short time. One might thus expect the underlying language learning mechanism to also be complex, involving constraints and biases (Markman, 1990) and sophisticated inferences (Xu & Tenenbaum, 2007). However, even if the final mechanism is complex, it must begin with something simple – language learners develop. By understanding the tools available to very young learners, we may develop insight into how more complex mechanisms are created and how they might be understood as products of simpler mechanisms.

One candidate for a simple mechanism is the accumulation of associations between words and objects in a child's ambient environment (Hollich, Hirsh-Pasek, & Golinkoff, 2000, Smith, 2000). If the co-occurrence structure of the world is informative, such that words frequently occur with the objects they label, a child who can attend to this information could find a wedge into learning the more complicated structural aspects of her language (Landau, Smith, & Jones, 1988).

Recently, Smith and Yu (2008) have provided evidence of just such a sensitivity in 12 and 14-month-old infants. In the cross-situational learning paradigm, infants are exposed to a series of individually ambiguous learning trials containing multiple words and objects. While each trial contains several potential mappings, some of which are spurious, a child who can attend to the overall co-occurrence structure can unambiguously determine the correct mappings.

Attempts to understand the mechanism underlying this competence, however, have been aimed primarily at the abstract computational level. Computational models have taken the form of corpus analyses (Fazly, Alishahi, & Stevenson, in press, Frank, Goodman, & Tenenbaum, 2009, Yu, 2008) and thus have resisted direct comparison to empirical data. To understand the mechanisms available to budding language learners, however, models must account for and explain the *behavior* of young infants.

Because preferential looking is the primary measure of learning in studies of preverbal infants, it is this looking data that computational model must explain. Yu and Smith (in press) took a first step towards this goal. Using an associative model, they found that the *number* of words for which an individual infant showed preferential looking behavior was predictable from that infant's own eye movement in training. This might seem to fit an associative learning mechanism: one learns to associate words to the objects at which one is looking when one hears the words. However, Yu and Smith were unable to predict *which* word-referent mappings were learned. If associative learning is the relevant mechanism, something is still missing.

We propose to take two more steps towards understanding the mechanism supporting cross-situational learning. First, whereas Yu and Smith's model was descriptive – using patterns in training behavior to predict test behavior – we present a *generative* model of eye movements. That is, we construct a model which produces eye-movement behavior matching that of infants during training, and then show that the same model accounts for the test data. Second, we predict not only *how many* word-referent mappings each infant learned, but also *which ones*. This modeling is done at the *individual infant* level, allowing us to explain behavior as it unfolds trial-by-trial throughout training and testing.

To motivate our model, we first present results from a cross-situational learning experiment with 15-month-old infants. Analysis of preferential looking test results shows robust individual differences among infants, underscoring the importance of understanding cross-situational learning at a process level. We then construct a model that generates fixations through the competition of two well-known processes that organize infant behavior and learning – *association* (Smith, 2000) and *habituation* (Hunter & Ames, 1988). Model parameters are fit to best account for each individual infant's looking behavior over the course of the experiment, and then inferences about learning are drawn from these parameter fits.

Experiment

Method

Infants were exposed to a cross-situational word learning task (Smith & Yu, 2008; Yu & Smith, in press). Each child viewed a series of trials pairing two novel objects with one novel label. While the correspondence between words and objects on an individual trial was ambiguous, cross-trial co-occurrence statistics between words and objects indicated the correct pairings. After 60 training trials, preferential looking tests were used to determine whether infants had learned the correct pairings.

Participants. Twenty-five 15-month-old infants (14 females, $M = 14$ mos, 23 days, range: 13;22 to 16;4) composed the final sample. Twelve additional infants were excluded due to fussiness ($N=11$) or experimental error ($N=1$).

Stimuli. Six pseudoword labels were recorded by a female native English speaker in isolation and presented to infants over loudspeakers. Six novel two-dimensional objects, each a unique bright color, were presented to infants two at a time on a 47" by 60" white screen. All stimuli were constructed to be comparable to those used in previous cross-situational learning experiments (Smith & Yu, 2008, Yu & Smith, in press).

Procedure. Infants sat on their mother's laps 3.5 feet away from a large white projection screen. Direction of gaze was recorded by a Tobii X60 eye-tracker as well as a camera directed at the child's eyes. Parents were instructed to shut their eyes during the course of the experiment so as not to influence infant behavior.

Training consisted of 60 2-second long training slides. Each slide presented two objects, one on each side of the screen, and was accompanied by one of the recorded labels. A slide's label was presented 700ms after the objects' onsets. On each slide, one of the objects was the label's correct referent and one was a foil. This correspondence was uncorrelated with spatial location, but could be determined from cross-trial co-occurrence statistics: each label occurred 10 times with its correct referent and only 2 times with each of the other objects. Training trials were interspersed with presentations of Sesame Street characters intended to maintain infant attention. Total training lasted approximately 4 minutes.

Following training, infants were exposed to 6 testing trials, each 8 seconds long. Test trials began with approximately 1 second of silence, followed by six repetitions of a label – each separated by 1 second. Two objects were visible for the entire 8 seconds – the label's correct referent and a distractor object. Each of the 6 labels was tested once, and each object appeared equally often as a target and a distractor. Figure 1 illustrates the time course of training and testing with sample trials.

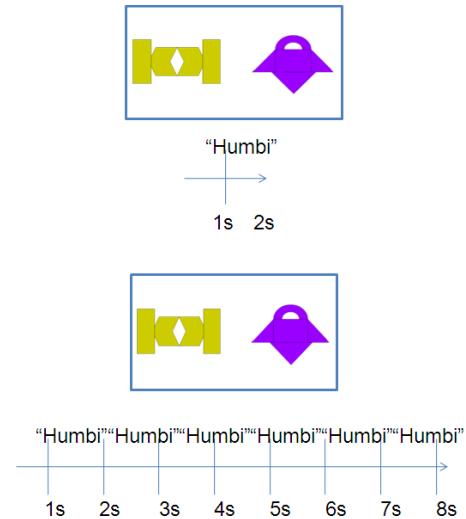

Figure 1: The time course of training (above) and testing (below) trials. Infants saw two objects and heard a label produced either once (training) or 6 times (test). The first 1 second window of each was silent; every subsequent window contained an auditory label.

Data. Gaze position was recorded via eye-tracker at a rate of 50Hz. Because of movement or looking away during the experiment, there were some discontinuities in automatic gaze recording. On average, 57.8% of each infant's gaze points were recorded. Naïve coders blind to the contents of each slide coded each of the remaining frames for direction of gaze (left, right, away/unknown). After hand-coding, 74.5% of all gaze points were mapped to a screen position where one of the objects appears.

Results and Discussion

Infants looking times to target and distractor objects on each of the 12 preferential looking test trials were submitted to a 2 (Target/Distractor) x 6 (Word) x 25 (Subject) mixed ANOVA. The analysis revealed no main effects, but showed a highly significant interaction between Target/Distractor and Subject ($F = 3.66$, $p < .001$, $\eta^2 = .1$). Individual infants thus showed reliably different looking patterns at test: some looked reliably longer at targets than distractors; others looked reliably longer at distractors than targets (Figure 2). This is consistent with previous work on slow vs. fast habituators (Cashon & Cohen, 2000, Schöner & Thelen, 2006).

Why should there be reliable individual differences? It is well known that the function that maps learning onto looking is *nonmonotonic* – it switches directions (Hunter & Ames, 1988 – Figure 3). This complicates the interpretation of looking behavior, with some investigators of word learning behavior suggesting that increased looking to the target indicates learning (e.g. Golinkoff, Hirsh-Pasek, Cauley, & Gordon, 1987) whereas others interpret increased looking to the distractor as evidence of learning via violation of expectation (e.g. Stager & Werker, 1997).

Figure 2: A plot of mean(std error) preferential looking to target for each infant. Values greater than .5 indicate an average preference for the target; those less than .5 indicate preference for the distractor.

The above analysis indicates that individual infants show reliable looking patterns when tested for their preference to look to or away from a label's referent. However, since individual infants show different patterns, it is unclear how to interpret their behavior. For which infants should we infer learning? In the following computational modeling effort, we propose to show that an unambiguous answer can be found through model selection. If we are explicit about the mechanisms which combine to generate looking behavior, we can ask if a learning mechanism is necessary to explain individual infants' looking behavior at test.

Computational Model

Throughout the experiment, infants were exposed to a series of slides presenting two objects along with an auditory label word. Infants responded to these stimuli - at any point in time - by fixating one of the two objects on the screen. Our goal was to derive a generative model for each infant that produced fixation patterns that best approximated his or her own generated fixations.

Because of the structure of the training and testing trials, we divided the time course of fixations into a series of 1 second bins (Figure 1). Proportion of looking to each of the two on-screen objects was calculated in each such window, and model was fit to this data.

Conceptually, the model is simple. Let us suppose that fixation patterns within a given window are generated by the combination of two processes: *habituation* to each of the objects on the screen, and *association* between each of the objects and the label being heard. Let us also suppose that each of these processes is a function of looking time to the input. However, because we do not know the true form of these functions (although see Schöner & Thelen, 2006), we *approximate* them with arbitrary degree polynomials. These

polynomial approximations allow us to make inferences about the shape of the functions without making claims about their exact form.

We use each infant's individual training data to infer the *habituation* and *association* functions which best account for that infant's behavior. Because one cannot learn what one does not see, habituation and association are functions of gaze duration rather than occurrence frequency. We thus produce an explicit *linking function* from learning to looking at test, and this function is used to infer what each child learned from her looking behavior in training. Doing so allows us to move beyond preferential looking as a measure of learning, and to make deeper and more specific conclusions about the mechanisms supporting cross-situational learning in real time.

Data

In the experiment, infants were exposed to 60 training trials followed by six test trials. The label for each 2s trial was heard 700ms into the trial. Adding 367ms to the label's onset to account for processing time (Swingley & Aslin, 2000) results in two ~1s windows (Figure 1, top). In the first window, we assume that fixations are being driven by the objects (*habituation*) only, and in the second we assume that fixations are driven both by the objects (*habituation*) and the co-occurring word (*association*).

Test trials had a similar structure (Figure 1, bottom). Each began with a short period of silence, followed by the onset of a label which was then repeated 5 more times at 1 second intervals. We divide each testing trial into 7 1s windows: 1 in which fixations are driven only by the objects, and 6 in which fixations are driven by both objects and the label. The natural logarithm of the odds of looking at each of the on-screen objects was computed in each window, and these are the data to which the model was fit. Log odds is similar to proportion of looking, but has nicer mathematical properties for this particular analysis (see also, Barr, 2008). Any windows in which there was no fixation data for an infant were left out of that infant's dataset.

Figure 3: A schematic of the infant looking preference function reproduced from Hunter and Ames (1988). Because the function is *nonmonotonic* – direction of preference changes in opposite directions across time – looking time data resists straightforward interpretation.

Model Description

In a given window, each of the two objects had an activation level as described below. Odds of looking to each of the objects were computed using the ratio form of the Luce choice axiom (Luce, 1959). We additionally adjust the odds ratio in two ways.

Because saccades are controlled by a vision system subject to physical constraints, and because we model looks in 1 second windows, the current window depends on the location of the eye in the last window. For this reason, as an approximation, we modify $OddsLook_t(O)$ by a parameter p times the odds of looking in the previous window to the object in O 's current location. Further, infants are known to display preferences for one side of the screen over another. For this reason, we build in a constant term b which models each infant's potential preference for the left or right side of the screen.

Thus, on trial t , if objects O_1 and O_2 are present,

$$OddsLook_t(O_1) = \frac{e^{Act_t(O_1)}}{e^{Act_t(O_2)}} \times \left(b \cdot ((Loc(O_1) = left)) \right) \times (p \cdot OddsLook_{t-1}(Loc(O_1)))$$

Silent Window. In a window in which no label is present, activation is driven by an infant's *habituation* to each of the objects present. Habituation to an object was approximated by an arbitrary degree polynomial function *habit* evaluated on the cumulative looking time to that object so far in the experiment. Estimation of the parameters of this function for each infant will be described below.

$$Act_t(O) = habit(O)$$

Label Window. For windows in which a label was heard, we assume that activation is also driven by the association between each object and the label W . For these windows,

$$Act_t(O) = habit(O) + assoc(O, W)$$

Association and Habituation. Each infant's individual *habituation* and *association* functions were approximated by arbitrary degree polynomial functions. For each infant, all possible orders 0 to 2 were tried for each function, with the optimal parameters fit as described below. The final order of each function was chosen using AIC to be the most parsimonious fits for the infants looking behavior.

Formally, if t_o is cumulative looking time to an object, and $t_{o|w}$ is cumulative looking time to an object in the presence of a word,

$$habit(t_o) = \sum_{n=1}^{N_h} h_n \cdot t_o^n \quad assoc(t_{o|w}) = \sum_{n=1}^{N_a} a_n \cdot t_{o|w}^n$$

Thus, one infant might have a quadratic *habituation* function ($N_h = 2$) and a linear *association* function ($N_a = 1$), while for another infant the best model may have been a linear *habituation* ($N_h = 1$) function and no *association* function (0 degree) at all.

Model Fitting

In order to determine the best approximation to each infant's individual learning functions, we constructed all 9 possible combinations of orders 0 to 2 for both *association* and *habituation* functions. The optimal parameters for each function were selected to best account for the infant's fixation data. Subsequently, model selection using AIC was performed for each infant by selecting from these models the one which also gave the best account of the individual infant's testing eye fixations without overfitting.

Results and Discussion

On average, the best generative model for each infant predicts a significant ($r = .307, p < .001$) proportion of the variance of looking. In comparison, a null model, which includes only a side bias (b) and inertia (p) term for each infant picks up a significantly small proportion of the variance ($r_g = .307, r_n = .203, t = 2.68, p = .01$).

Figure 4: Log odds looking to the left side of the screen for one infant across both training and testing. Positive log odds indicate a preference for the left. Black dashed lines separate every 10 training trials and the black solid line indicates the start of testing. Infant behavior is the blue line with solid markers, model behavior is the red line with asterisk markers.

This indicates that *habituation* and *association* account for a significant proportion of each infant's looking behavior, both in training and testing. Further, functions which are appropriate for describing training can also describe test behavior. An example of the model's fit to one infant is shown in Figure 4 above.

Now that we have found the best model which accounts for each infant's looking behavior, we can determine which infants are likely to have learned word-referent mappings. Preferential looking behavior, while a good measure of learning at a group level, can be quite difficult to interpret at the individual level (Aslin, 2007; Houston-Price, Nakai, 2004; Hunter & Ames, 1988). There are several reasons for this. First, as mentioned above, the function which links learning to looking is *nonmonotonic*, and different infants learn at different rates. Hence whether preference for target or distractor should indicate learning in an individual infant is unclear. Second, as we have explicitly modeled, there are two principled reasons to move one's eyes in this task – in response to the objects on the screen (habituation), and in response to the relationship between objects and words (association). If we are interested in word-object mapping, then movement resulting from the first process adds noise to our measurement. Because both processes were modeled explicitly, however, we can probe association directly.

For each infant, model selection was used to determine which order polynomial best matched his or her association and habituation functions. If the optimal order of association for an infant was nonzero, then we can infer that the infant learned associations between words and objects. Thus, another way to measure whether an infant learned word-object associations is to ask about the order of that infant's association function. Of the 25 participants, 11 were best described as being driven by an associative process ($N_a > 0$). We can then look at what these association functions predict in the infant's test behavior.

Figure 5: Distribution of association and habituation orders which best account for each infant. The scale on the right ranks infants from strongest preference for distractor (bottom) to strongest preference for target (top). Association order is correlated with strength of absolute preference.

Figure 6: Theoretical association functions for each infant plotted over the course of 30 seconds of co-occurrence. The scale on the right ranks each infant by the strength of their preference for target or distractor. Throughout the entire 30 seconds, there is a significant correlation between the strength of the preference and the strength of the theoretical association function.

Figure 5 shows the distribution of association and habituation orders of the polynomial functions which best accounted for each individual infant's looking behavior. Points representing individual infants are color-coded by the strength of their preference for target (green) or distractor (blue). Analysis shows that the order of an infant's association function is strongly correlated with the strength of that infant's absolute mean preference in the 6 preferential looking trials ($r = .55, p < .01$). That is, the stronger an infant's preference at test (either for target or distractor), the higher the order of the association function that best described his or her data.

Second, because we have explicitly determined the polynomial function which best describes each infant's association learning, we can examine these functions in isolation. Figure 6 shows the association function for each infant plotted over 30 1 second exposures to a hypothetical word and object. We can compare the ordering of these functions – rank them in the order of their value after each window – and compare this to the mean preference for the target exhibited by each infant over the 6 test trials. The correlation between ordering and mean preference is significant at the .05 level over the entire course of the comparison, and peaks at four seconds ($r_4 = .771, p < .001$). This finding indicates that these theoretical learning functions are in deeply linked to preferential looking performance at test. The functions thus allow us to predict which infants will show *familiarity* preferences at test, and which infants will show *novelty* preferences. The two figures also reinforce the fundamental importance of understanding individual differences if we are to understand statistical learning. The 25 individual infants displayed the entire gamut of possible learning functions, and these functions fit sensibly to their looking performance at test.

General Discussion

Learning word-referent associations in cross-situational experiments, and in the world, must depend on moment-to-moment *behavior of individual infants* – what is looked at and when – and the co-occurrence of objects seen and words heard. Looking behavior, in turn, depends on previous experience in multiple ways and through multiple mechanisms. Two of these fundamental mechanisms are *habituation* and *association*. Repeated experience with an object increases the tendency to look away, but repeated experience with the object in a word's context increases the tendency to look towards the object in its presence.

The present analyses show what can be gained by attempting to understand the dynamic processes that underlie the *behaviors* used as indices of learning. Constructing trial-by-trial models of individual infants looking behavior in word-referent learning yields two major benefits. First, since looking behaviors themselves are commonly used as indices of learning, it allows us greater certainty in inferring learning in infants. Second, because we can track individual infants across the course of learning, it gives us a deeper theoretical understanding of how the mechanisms underlying this learning.

This work thus makes both specific and general contributions. First, the generative model of eye movements in cross-situational learning explains individual infant behavior in both training and testing. Second, we have delineated the interacting effects of two competing processes which produce infant eye fixations – habituation and association – and showed how they can be analyzed independently. Third, our experiment and model demonstrate the possibility of understanding cross-situational learning at the individual infant level, of making sense of the different ways in which different infants learn. Finally, we have demonstrated a novel methodology for analyzing infant learning tasks. In addition to the insight gained from preferential looking analysis, this work shows a promising role for model selection and the construction of explicit functions linking learning to looking.

Abstract

Previous research shows that people can acquire an impressive number of word-referent pairs after viewing a series of ambiguous trials by accumulating co-occurrence statistics (e.g., Yu & Smith, 2007). The present study extends the cross-situational word learning paradigm, which has primarily been used to investigate the acquisition of 1-to-1 word-referent mappings, and shows that humans can concurrently acquire both 1-to-1 and 1-to-many mappings (i.e., a category relation), even when the many referents of a single word have no unifying perceptual features. Thus, humans demonstrate an impressive ability to simultaneously apprehend hierarchical regularities in their environment.

Keywords: statistical learning; cross-situational learning; category learning; mutual exclusivity; language acquisition

Introduction

In order to make sense of their world, human infants must learn relationships between words and referents in their environment. Infants simultaneously come into contact with many diverse, novel objects and equally diverse words that name them. Thus, there is much potential for acquiring erroneous word-referent mappings, given only a single situation. Despite this, both infants and adults have a remarkable ability to learn many novel word-referent associations quickly and accurately. Cross-situational word learning (CSWL) studies give us insight into how people are capable of learning multiple word-referent associations from individually ambiguous situations. Previous CSWL studies have shown that both infants and adults are able to learn simple 1-word to 1-referent mappings with astonishing speed (Kachergis, Yu, & Shiffrin, 2009; Smith & Yu, 2008; Klein, Yu, & Shiffrin 2008; Yu & Smith, 2007). In adult studies, participants are typically instructed to learn which words go with which referents, and are then presented with a few consistently co-occurring objects and spoken pseudowords on each of a series of training trials. On every trial, each pseudoword corresponds to a particular on-screen object, but the intended referent is never indicated. In a typical cross-situational training block, participants attempt to learn 18 word-referent pairs from 27 twelve-second trials consisting of four spoken words and four displayed objects (i.e. a 4x4 design). On average, participants in this condition

managed to learn half of the 18 pairs by relying on cross-situational statistics (Yu & Smith, 2007). Further studies have shown that human learning often reflects statistics manipulated during training such as pair frequency, contextual diversity (the diversity of other pairs each pair appears with over time), and within-trial ambiguity (the number of co-occurring words and referents per trial) (Kachergis, *et al.*, 2009).

However, simple 1-to-1 mappings are only a subset of the types of word-referent relations that exist in natural languages. 1-to-many mappings include referents that have one common label shared among them, such as a category or concept label. For example, both an apple and a banana may be labeled ‘fruit.’ Learners must learn to map both the superordinate label (‘fruit’) and each basic level name (‘banana’ ‘apple’) to the appropriate referent. Even in a learning paradigm like the 4x4 cross-situational learning condition discussed above, which is simpler than the real world, it is difficult to imagine that learners consider all 16 possible pairings, as might be necessary to learn higher-order relations. Constraints such as mutual exclusivity (ME) can drastically reduce the complexity of such ambiguous situations by limiting the possible pairings to a single word for each object (and vice-versa). Consider Markman and Wachtel’s study (1988), in which a child was placed in front of a learned object (ball) and an unlearned object (gyroscope) and was prompted to retrieve the ‘toma.’ While ‘toma’ could be another name for the ball, the child moves to the unlearned object, exhibiting ME. However, despite its power to speed learning, the strict use of ME as a constraint in cross-situational learning would also make it impossible to learn non-1-to-1 mappings.

To determine whether learners use the ME constraint when learning names for previously unknown objects, Yurovsky and Yu (2008) presented learners with ME-violating mappings in the CSWL paradigm. An ME-violating mapping is a word (or object) that is consistently paired with more than one object (or word). Participants were trained on 12 words and 18 referents, where 6 words were paired with 12 referents (i.e., 2 referents per word), known as *double* words, and the other 6 words were paired 1-to-1 with the remaining 6 referents, known as *single* words. Participants had to decide how to manage two names that co-occur with one referent in the same set of trials. The results showed that participants had equal performance in learning both single and double words if each double word’s two referents were interleaved rather than temporally separated (i.e. one referent was shown in the first half only

and the other appeared only in the last half). Moreover, learners acquired more than half of both early and late pairings; thus, some must have violated ME.

In contrast, Ichinco, Frank, and Saxe (2009) presented participants with a study to demonstrate ME as a guide to learning word-to-referent associations. Participants were shown an additional referent (or word, in a different experiment) on each trial, alongside four previously-seen word-referent pairs. Both groups received training on a standard cross-situational task, which was followed by further training. In this training, a new stimulus (word or object, between groups) was added on each trial alongside four pairs from the early training. Rather than forming a 1-to-2 mapping with the additional object (or 2-to-1, for the extra word) on each trial, participants learned 1-to-2 (or 2-to-1) relations on average for only one item and consistently favored mutually exclusive mappings.

Thus, depending on how ME-violating word-referent mappings are added to the cross situational paradigm, learners vary their use of the mutual exclusivity constraint. In the Yurovsky & Yu study, additional referents are presented in the absence of old ones: when participants hear a word and see two referents consistently co-occurring with it, they may be more likely to violate ME and form a 1-to-2 mapping. In Ichinco, *et al.*'s study, all 1-to-1 mappings from the early stage occur simultaneously with the new mappings. Participants may have failed to learn the new mappings due to blocking, a known associative learning effect in which a previously learned pairing interferes with the acquisition of a new pairing involving old stimuli.

In the present study, in order to eliminate biases that participants may adopt as a result of training order, we provide participants with cross-situational training that is simultaneously consistent with both 1-to-1 (basic-level name to referent) and 1-to-many (superordinate-level name to multiple referents) relationships on every training trial. For example, in Experiment 1, on each 3x2 trial, two words are basic-level names for the visible referents, and a third will act as a superordinate-level identifier. These superordinate level labels hence refer to four referents, including two that are not on present on a given trial. Thus, participants are simultaneously faced with two labels for each referent, and one of these labels also applies to three other referents. In Experiment 2, we give learners a more complex learning scenario: 4x2 trials on which two labels map 1-to-1 to the objects and each of the other two labels refer to one of the present objects, and three unseen objects. In both experiments, participants must learn the unique name for a referent as well as a label it shares with three other objects, some of which are not present on a given trial.

One block in each experiment is composed of objects that share some unifying perceptual feature like a hook or arrow shape, somewhat like objects belonging to natural categories. We test for generalization using stimuli in which the objects share each category's identifying feature from

training, but the objects have different textures and shapes than those from training.

Experiment 1

In Experiment 1, participants were merely instructed to learn which words go with which objects—with no mention of the potential to form 1-to-many relations—and were then given a sequence of cross-situational training trials, each consisting of three words and two referents. Unbeknownst to learners, two of the words on each trial map 1-to-1 to one of the visible referents, and the third word refers to both objects, and also will consistently appear with two other referents during training. Participants must determine which words specify a 1-to-1 reference to an object and which word specifies a 1-to-many reference to both objects on each trial. If participants assume ME, participants will either learn 1-to-1 mappings or 1-to-many mappings, but not both.

Figure 1: In Experiment 1, participants are trained on both 1-to-1 (e.g., A-a and B-b) and 1-to-many mappings (e.g., X-{a,b,c,d}) in the context of 3 words and 2 referents per trial. One word is the superordinate-level name that refers to both referents on each trial (shown in red).

In order to see if 1-to-many associations are facilitated by stimuli structure, subjects were trained on two different conditions (in three blocks in fixed order): **Block 1** was an *arbitrary category* condition, in which the objects had no obvious shared perceptual features but were consistently labeled by some other word. **Block 2** was a *natural category* condition, in which the objects in each category share a salient feature (e.g., a hook or arrow shape). **Block 3** was another *arbitrary category* condition (with different stimuli) to gauge attention shift after learning natural 1-to-many groupings. Given the salient features present in Block 2, performance in learning 1-to-many relationships will likely increase relative to Block 1, as participants' attention will be drawn to the 1-to-many relations due to the salient features acting as learning cues. Their performance on block 3 will indicate if this attentional shift is carried over from the natural category block.

Subjects

Participants were 33 undergraduates at Indiana University who received course credit for participating. None had participated in other cross-situational experiments.

Stimuli

Each training trial consisted of two objects shown on a computer screen and three pseudowords played sequentially. In each of the two arbitrary category conditions, the 12 referents were difficult-to-name, unrelated objects. For the

natural category condition, the 12 objects had one of three features protruding from the shape. The 45 computer-generated pseudowords are phonotactically-probable in English (e.g. “stigson”), and were spoken by a monotone, synthetic voice. 36 words are assigned to each referent, creating arbitrary word-object pairs which were randomly assigned to three sets of 12 1-to-1 mappings. One set of stimuli composed the natural category stimuli for the second block; the other sets composed of arbitrary strange objects for the first and third blocks. For the 1-to-many mappings, the remaining 9 pseudowords are assigned to three sets of four 1-to-1 mappings. Thus, in each block there are three groups (i.e., categories).

		Words											
		X (12)				Y (12)				Z (12)			
Referents		A	B	C	D	E	F	G	H	I	J	K	L
	a	6	2	2	2	0	0	0	0	0	0	0	0
	b	2	6	2	2	0	0	0	0	0	0	0	0
	c	2	2	6	2	0	0	0	0	0	0	0	0
	d	2	2	2	6	0	0	0	0	0	0	0	0
	e	0	0	0	0	6	2	2	2	0	0	0	0
	f	0	0	0	0	2	6	2	2	0	0	0	0
	g	0	0	0	0	2	2	6	2	0	0	0	0
	h	0	0	0	0	2	2	2	6	0	0	0	0
	i	0	0	0	0	0	0	0	0	6	2	2	2
	j	0	0	0	0	0	0	0	0	2	6	2	2
	k	0	0	0	0	0	0	0	0	2	2	6	2
	l	0	0	0	0	0	0	0	0	2	2	2	6

Figure 2: The accumulated stimulus co-occurrence matrix for each block in Experiment 1. Each word co-occurred with its intended referent 6 times (A-a, B-b, ...) Note that each referent appeared twice with every other referent in its category, but never with referents from other categories. Each 1-to-many label appeared 6 times with each of its intended referents, and 12 times overall.

In the natural category condition, each of the three 1-to-many labels consistently maps to a salient feature present on the stimulus. An additional 12 pairs of testing stimuli were used for a generalization task, using the same category labels that correspond with the stimuli according to their feature.

Figure 3: **Left:** In the natural category condition, objects with multiple types of textures and three different protruding shapes were used in training. **Right:** In the arbitrary category condition, objects had no apparent unifying feature.

Procedure

Participants were informed that they would experience a series of trials in which they would hear some words and see some objects. They were also told that their knowledge of which words belong with which objects would be tested at the end. Training for each condition consisted of 36 trials. Each training trial began with the appearance of two objects, which remained visible for the entire trial. After 2 s of initial silence, each word was heard (randomly ordered; 1 s of silence between each word) followed by 2 s of silence, for a total of 9 seconds per trial. After each training block, their knowledge was assessed using 12-alternative forced choice (12AFC) and 3AFC testing: on each test trial a single word was played—a 1-to-1 label or a 1-to-many label—and the participant was asked to choose the appropriate object from a display of all 12 objects (for 1-to-1 labels) or from 3 objects (for 1-to-many labels). For 3AFC testing, one representative from each category was used. The test slides for generalization were the same as the 1-to-many test slides except that the only previously-seen parts of the stimuli were the distinct, protruding shapes (e.g., a hook) that were seen in training to distinguish the different categories. Different stimuli were used in each block. Condition order was fixed.

Results & Discussion

Figure 4 shows the results across all three blocks for each pairing type. Unexpectedly, even in block 1 participants learned a significant number of 1-to-many mappings ($M = .49$, one-sided $t(32) = 4.95$, $p < .001$, chance = .33) and learned a significant proportion of 1-to-1 mappings ($M = .52$, one-sided $t(32) = 12.99$, $p < .001$).

Exp. 1: Learning by Block and Pairing Type

Figure 3: Mean performance for each experimental block by pairing type. Block 1 and 3 were arbitrary groupings and Block 2 was a category grouping; thus, generalization of category type was tested. Error bars show +/-SE. Blue dotted line indicates chance for 1-to-1 learning; black dotted line indicates chance for 1-to-many learning.

After the introduction of a unifying feature, learning of 1-to-1 pairings in block 2 decreased relative to block 1 ($M = .35$, paired $t(32) = 3.07$, $p < .01$). The perceptual similarity of category members in block 2 may have caused participants to focus on learning 1-to-many mappings, and thus drew attention away from 1-to-1 mappings. In addition, their ability to apply the superordinate name to new referents was reflected in their significantly above-chance (.33) performance on a generalization task ($M = .53$, one-sided $t(32) = 3.78$, $p < .001$).

Presented with a second arbitrary category condition in block 3, learning of 1-to-1 pairings was significantly lower compared to block 1 (paired $t(32) = 2.96$, $p < .01$), but performance on 1-to-many testing remained higher ($M = .57$, paired $t(32) = 6.69$, $p < .001$). That is, following the natural category condition in block 2, participants continued to focus on 1-to-many mappings, but still learned 1-to-1 mappings at a proportion over three times chance.

Overall, participants showed evidence of learning both 1-to-1 and 1-to-many mappings in every condition—even in the first condition, when they had no instructions telling them what type of relations would be present, and the referents belonging to each 1-to-many relation (i.e., an arbitrary category) had no unifying perceptual features. Moreover, we observed a shift in learning from block 1 to block 3: after the perceptually-similar category referents of block 2, participants learned more 1-to-many pairings in block 3 than block 1, and fewer 1-to-1 pairings. In Experiment 2, we investigate whether learners can still simultaneously acquire both 1-to-1 and 1-to-many mappings in a still more complex learning situation.

Experiment 2

Experiment 1 showed that humans can simultaneously learn superordinate and basic level names for referents. On each trial, there were two basic level names (1-to-1) and one superordinate level name (1-to-many). Thus, the mutual exclusivity constraint was relaxed and complex relations were formed, with two words referring to each object. After all three conditions in Experiment 1, participants still performed significantly above chance on 1-to-1 associations as well as on 1-to-many associations. However, an alternative learning scenario is an environment in which objects from different categories are learned simultaneously. For example, two referents such as an apple and a carrot could be presented. In this case, each referent has its own superordinate level name (fruit and vegetable, respectively). The learner would need to learn both the superordinate label and basic name label for each object while needing to assign each term to its appropriate referent. The potential for error is much greater because the learner is presented with a more ambiguous learning situation than in Experiment 1, where the superordinate label refers to both displayed referents. Experiment 2 thus presents learners with a four word and two referents (i.e. 4x2) on each trial, where two words are category labels referring to a single referent each, and two

words are subordinate level names corresponding to one referent each (see Figure 5).

Figure 5: Participants are given 1-to-1 and 1-to-many mappings (e.g. A-a, C-c and X-{a,c,d}) in the context of 4 words and 2 referents per trial.

This extension of the cross-situational paradigm provides additional ambiguity beyond Experiment 1: presented with two more labels than referents on each trial, participants must now learn that the more frequent labels are superordinate, and apply not only to one of the objects on that trial, but also to three other objects seen on other trials. However, given the above-chance performance and particularly exceptional 1-to-many learning, participants may be able to tune themselves into the ambiguous superordinate label to referent pairings after the natural category condition in a manner similar to participants in Experiment 1.

Subjects

Participants were 24 undergraduates at Indiana University who received course credit for participating. None had participated in other cross-situational experiments, including the previous experiment.

Stimuli & Procedure

During training, two objects were shown on a computer screen with four spoken words played sequentially upon presentation of the objects, with time per word equal to that of Experiment 1. New sets of words and referents were used for this experiment. Training for each condition consisted of 36 trials, each lasting 12 s. due to the addition of a spoken category label. Immediately after training for each block, participants were tested for knowledge of the 1-to-1 relations using 12AFC and 1-to-many relations using 3AFC as in Experiment 1. Generalization was also tested for the natural category stimuli. Condition order was fixed.

Results & Discussion

Figure 6 shows results across all three blocks for each pairing type. In Block 1 with arbitrary category referents, participants learned only 1-to-1 names ($M = .50$; one-sided $t(23) = 7.76$, $p < .001$) while 1-to-many performance was at chance ($M = .39$, one-sided $t(23) = 1.76$, $p > .05$). Unlike in Experiment 1, block 2 did not see a performance shift. While performance was significant in learning 1-to-1 ($M = .46$; one-sided $t(23) = 6.45$, $p < .001$) associations, 1-to-many associations were still difficult to acquire, and were not learned significantly above chance ($M = .42$; one-sided $t(23) = 1.85$, $p > .05$). Participants may have still not surmised that there was categorical structure involved due to the

confusion of four words per trial (including two category labels). Performance on the generalization task was also at chance, confirming that participants had not yet ascertained the presence and structure of the 1-to-many mappings.

Exp. 2: Learning by Block and Pairing Type

Figure 6: Mean performance by pairing type for each block. Error bars show +/-SE. Dotted lines indicate chance: blue for 1-to-1 pairings (.08); black for 1-to-many pairings (.33).

However, block 3 performance was significantly above chance for both 1-to-1 ($M = .57$; one-sided $t(23) = 7.98$, $p < .001$) and 1-to-many ($M = .46$, one-sided $t(23)$, $p < .001$) associations. Thus, although the higher degree of ambiguity in Experiment 2 made participants take longer to catch on to the presence of multiple superordinate labels on each trial, in the final block they were able to learn these 1-to-many relationships in addition to the 1-to-1 relationships. In comparison to block 3 of Experiment 1, 1-to-many learning in Experiment 2 was significantly lower (Welch's $t(55.0) = 2.08$, $p < .05$), showing that the superordinate label structure (2 per trial) in Experiment 2 was indeed harder than the structure (1 superordinate label per trial) in Experiment 1.

However, even when participants were uncertain about the meaning of the superordinate labels in blocks 1 and 2, they learned a significant number of 1-to-1 mappings. In block 3 performance, not only did participants learn a significant number 1-to-many mappings, they also learned more 1-to-1 mappings than in the previous two blocks (block 2: paired $t(23) = 2.44$, $p < .05$, block 1: paired $t(23) = 2.03$, $p = .05$). The natural category condition once again provided a clue as to what learning strategy participants need to utilize. However, the significantly lower performance for block 1 in Experiment 2 as compared to Experiment 1 may also indicate interference due to confusion over the two extra labels.

In both experiments, it is important to note that since both 1-to-1 and 1-to-many word-referent mappings learned involving the same referents, each referent was thus part of

a 2-to-1 word-referent mapping. Thus, it is possible to determine whether participants learned mappings that violate mutual exclusivity. In both experiments, participants were tested on each referent twice: for the 1-to-1 label (chance=1/12) and 1-to-many label (chance=1/3). Thus, learning that respects ME occurred when participants learn either 1-to-many or 1-to-1 mappings, but not both, and learning that violates ME occurred when participants learn both. As shown in Figure 7, across both experiments and in every block, the average participant learned a significant number of pairings that violate ME as they learned both 1-to-1 and 1-to-many mappings.

Figure 7: Comparison of proportion of learned ME violating vs. respecting pairs by block for each experiment. Chance (dotted line): Respects=1/3+1/12; Violates=1/3•1/12=.03

General Discussion

While the mutual exclusivity constraint can be a powerful tool for learning 1-to-1 mappings, the hierarchical structure of the real world—which is reflected in natural language—requires people to learn word-referent mappings that are not mutually exclusive. The present study demonstrates that learners learn both 1-to-1 and 1-to-many mappings from situations in which these regularities are simultaneously present.

By the end (block 3) of both experiments, performance for both 1-to-1 and 1-to-many testing was significantly above chance. Experiment 1 shows that participants on

average performed strongly on 1-to-many associations, particularly after the introduction of within-category perceptual similarity in block 2. This may be due to the natural stimuli serving as a primer for learning 1-to-many mappings in block 3. However, although there appears to be a trade-off in learning both types of relationships, participants nevertheless managed to learn both superordinate and basic level names in the first block of Experiment 1. Experiment 2 showed participants could not only learn superordinate and basic level names but can also handle an additional layer of ambiguity when the two referents on a trial belonged to two different superordinate categories. Consistent with Experiment 1, an increase in 1-to-many performance was seen after block 2 was observed in Experiment 2, but 1-to-many performance was overall lower than in Experiment 1. Correspondingly, generalization of superordinate labels to novel objects was also difficult for learners. The more complicated structure (four labels and two referents per trial, representing two categories) in Experiment 2 produces many more possible pairings per trial for a learner to consider. Naturalistic learning situations are even more complex, with multiple co-occurring words, events, and objects (Hart & Risley, 1995); Experiment 2 simulates a more natural scenario in which multiple referents with vague relationships to their superordinate labels are presented. This suggests that infant learning of higher order relations could be guided by creating more unambiguous learning scenarios in order to reduce the likelihood of attribution error.

Interestingly, participants were equally likely to know the superordinate level names (e.g., fruit) regardless of their performance learning basic level names (e.g., apple). Is this due to the mutual exclusivity constraint? In the 3x2 design of Experiment 1, participants were more likely to form a 1-to-many relationship if they do not know the superordinate level name than if they know both ($P(\text{Know Superordinate Name} \mid \text{Not Know Basic Name}) = .31$; $P(\text{Know Superordinate Name} \mid \text{Know Basic Name}) = .19$). The same relationship held in the 4x2 design (.25, .18 respectively). Therefore, participants seemed to form superordinate level relationships more easily rather than basic level relationships.

While the ME constraint may be useful in learning 1-to-1 relationships, the present study's experiments show that participants will focus on forming 1-to-many relationships rather than 1-to-1 relationships if the need to learn higher order relationships becomes apparent, which is often the case in category learning. The strong performance in 1-to-many learning independent of 1-to-1 performance may indicate that people are particularly tuned to learning complex relationships. Every day, we use categories as functional filters of our world to constrain the amount of information we must process at lower (basic) levels (Goldstone & Kersten, 2003). Furthermore, the addition of an exemplar to a category gives us more information about other novel candidate members of the category, allowing

learners to generalize as demonstrated in Experiment 1. In future work, we hope to replicate our findings in infants as well as focus on what learning strategies are used by both infants and adults. We also expect that these findings will be useful in constraining formal models of cross-situational word learning.

Abstract

Investigations into the semantics of the spatial and non-spatial uses of *in* and *on* have tended to assume that a type-level similarity exists between these two prepositions. However, their syntactic distributions, while overlapping, are not equal in scope (Navarro, 1998). In this paper, we ask whether these distributional differences might be related to semantic differences between the two terms. The preliminary evidence collected here suggests that *in* and *on* have slightly different levels of interpretability, even in their prepositional uses. Thus, both semantically and syntactically, the assumption of type-level similarity may need to be qualified.

Keywords: Semantics; prepositions; metaphor; language

Introduction

Investigations into the semantics of prepositions such as English *in* and *on* have tended to treat these lexical items as though they are different tokens of the same semantic and syntactic type. Such treatment seems to follow from the generative grammar tradition in which lexical category – rather than meaning – determines syntactic behavior. For example, Cook and Newson (2007) suggest “that arguments are interpreted in a particular way due to the structural positions they occupy” (p. 263). This assumption is also reflected in introductory linguistics and psycholinguistics text books, which state that words belonging to the same lexical category, or word class, are typically interchangeable syntactically (cf., Carroll, 2004; O’Grady, Archibald, Aronoff, & Rees-Miller, 2005). Together these suggest that different lexical items drawn from the same word class may interact with the rest of language in very similar ways.

Even in more cognitive views of language, we find evidence that prepositions are treated as a lexical category without indication that the individual differences between the prepositions will have important repercussions for the functions of the individual lexical items within the linguistic system. As a case in point, type-level equivalence has been assumed in examinations of the semantics of prepositions (e.g., Coventry & Garrod, 2004; Feist, 2000, 2008, in press; Feist & Gentner, 2003; Tyler & Evans, 2003; Vandeloise, in press). Much of this work focuses on the criteria that distinguish the meaning of one preposition from that of another, without discussion of the possibility that prepositions may differ in additional ways beyond their

meanings. For example, while Tyler and Evans (2003) do acknowledge the importance of context in establishing the meaning of a lexical item and the fact that different prepositions will occur in different contexts, such contextual factors do not lead to different proposals regarding the nature of the meanings of individual prepositions.

However, evidence from corpus-based studies of prepositions challenges this assumption of distributional equivalence. For example, in his investigation into the semantic structure of English topological prepositions, Navarro (1998) found a differentiation between *in* and *on* based not only on their meanings but also on their syntactic distributions. While *on* tends to occur primarily in prepositional constructions, *in* is also quite prevalent within “a wide range of morphosyntactic usages that make it controversial to categorise it on behalf of a single syntactic construction” (Navarro, 1998, p. 273), including use as a full adverb, as an adverbial particle of a phrasal verb, and as a prefix for nouns, adjectives, and adverbs. This difference in syntactic distribution suggests that, despite their similarity as topological prepositions, *in* and *on* may behave quite differently within the language system as a whole.

Following up on these observations, we searched for uses of *in* and *on* in the more than 400 million word Corpus of Contemporary American English (COCA; www.americanacorporus.org). Our first observation was that the frequencies of occurrence of *in* and *on* are highly unequal overall, with *in* (7,333,378 instances) appearing more than 2½ times more frequently than *on* (2,723,768 instances). Secondly, and more importantly, we examined the combinatorial possibilities for both *in* and *on* across a set of naturally occurring uses within a limited syntactic context (i.e., prepositional phrases containing the preposition immediately followed by a noun). Within the hundred most frequent collocations for each preposition, we observed an inequality in the distribution of uses, $\chi^2(1, N = 200) = 21.34$, $p = .0003$ (see Table 1).

Table 1: Noun types collocating with *in* and *on*

	Proper Nouns	Noun Phrases	Idioms	Concrete Nouns	Abstract Nouns
<i>In</i>	2	6	5	33	54
<i>On</i>	2	23	2	45	28

Taken together, these results suggest an imbalance between *in* and *on* that has yet to be thoroughly investigated.

Clearly, *in* and *on* have different meanings, which will result in the two prepositions collocating with different sets of nouns. However, these differences have not thus far led to a challenge to the assumption of type-level similarity based on their shared lexical category. As such, the differences in distribution and in combinatorial possibility that have been observed in corpus-based studies of *in* and *on* remain unexplained by the current state of thinking regarding their meanings.

There are two possible explanations for the observed differences between *in* and *on*. First, it may be that the differences are an artifact of the searches that yielded them, and that these differences would disappear given a large enough sample drawn from the corpus. In this case, the assumption of type-level similarity would remain intact, with the differences, which would be attributable to differences in meaning, limited to differences in the sets of nouns that collocate with each, but not to differences in the sizes of the sets or in the ranges of meaning types within the sets.

The second possibility is that *in* and *on* differ not only in meaning, but in *meaning potential*, with *in* able to collocate with a wider range of nouns than can *on*. In this case, the particular semantics of *in* and *on* will have a direct influence on their potential to combine with other lexical items, rather than that potential being determined by their belonging to the lexical class of prepositions, and the assumption of type-level similarity inherited from generative grammar will need to be abandoned.

In order to discriminate between these two explanations, we will seek evidence regarding the reality of the noted imbalance using a separate methodology. If the evidence gathered from an experimental investigation of the combinatorial possibilities of *in* and *on* fails to replicate the corpus evidence, this would support a type-level similarity-based explanation wherein the noted imbalance is an artifact of the corpus searches performed. If, on the other hand, the experimental data replicates the imbalance noted in the corpus, this would support the explanation that the range of combinatorial possibilities of a lexical item is not determined by its lexical class. Rather than having their influence limited to the specific referential situations within which prepositions are deemed appropriate, meaning differences may significantly determine prepositions' ranges of combinatorial possibilities.

In order to experimentally examine the combinatorial possibilities displayed by the prepositions *in* and *on*, we asked English speakers to interpret prepositional uses of *in* and *on* presented in the same novel syntactic and semantic contexts (i.e., the same novel sentence frames). If there is an imbalance in the combinatorial possibilities of these prepositions, then we should see different levels of interpretability for the two prepositions. To be clear, while we anticipate their different meanings to result in different interpretations of the sentences, if there are indeed

differences in *interpretability* these should be evident in the rates at which participants attempt to provide interpretations for the novel sentences. Such an imbalance in interpretability between these lexical items when presented in identical sentence frames would suggest that the assumption of type-level similarity within lexical classes is unwarranted.

Experiment 1

Experiment 1 tested whether novel non-spatial uses of the preposition *in* would be more easily interpretable than matched non-spatial uses of the preposition *on*. If so, participants should make more attempts to interpret sentences containing *in* than sentences containing *on*.

Method

Participants A total of 82 UL Lafayette students participated in this experiment in exchange for course credit. One student, a native speaker of Vietnamese, was subsequently removed from further analysis; a second participant was removed for not following the task instructions. The 80 remaining participants were all native speakers of English. Of these, 39 took part in the *in* condition and 41 took part in the *on* condition.

Materials The stimuli consisted of forty sentences constructed from twenty sentence frames. Sentence frames were in the form *These Xs are Y*; each *Y* was a non-spatial prepositional phrase (i.e., *in* or *on* followed by an abstract noun), and each *X*, a concrete noun. Each sentence frame had both an *in* variant and an *on* variant (see Table 2).

In order to provide the prepositions with a neutral playing field, the sentence frames needed to constitute unfamiliar contexts for both prepositions under consideration. At the same time, we wanted the interpretability of each sentence as a whole to hinge on the interpretability of its prepositional phrase. Thus, in constructing our sentences, we (1) selected abstract nouns that would be considered unfamiliar prepositional objects for both *in* and *on* and (2) chose as the sentential subjects nouns which would be as stable in their meanings as possible.

To accomplish these goals, we searched for twenty abstract nouns that do not frequently occur as objects of either *in* or *on*. Francis & Kučera's (1982) rank list of lemmas was used to formulate a list of highly frequent nouns from which we could extract 100 that could potentially serve as abstract prepositional objects. Beginning with the most frequent lemma, one of us (B.B.) categorized each noun as either concrete or abstract. Nouns were categorized as concrete if they could refer to a concrete object, a concrete set of objects, a part of a concrete object, or the location of a concrete object; otherwise, they were labeled as abstract and set aside for potential use as a non-spatial prepositional object. Two-hundred and twenty-eight nouns had to be categorized in order to find 100 that fit the abstract criterion.

Table 2: The twenty sentence frames used to construct the experimental stimuli.

Sentence frames	
1	These houses are in/on system.
2	These rooms are in/on reason.
3	These cars are in/on idea.
4	These streets are in/on result.
5	These lights are in/on month.
6	These books are in/on hour.
7	These roads are in/on sense.
8	These tables are in/on moment.
9	These pictures are in/on voice.
10	These walls are in/on century.
11	These buildings are in/on situation.
12	These plants are in/on term.
13	These windows are in/on difference.
14	These floors are in/on statement.
15	These radios are in/on feeling.
16	These boats are in/on organization.
17	These parks are in/on basis.
18	These mountains are in/on event.
19	These blocks are in/on opportunity.
20	These apartments are in/on association.

We then compared our concreteness categorization with concreteness judgments collected from the MRC Psycholinguistic Database (Wilson, 1988; http://www.psy.uwa.edu.au/mrcdatabase/uwa_mrc.htm) for each of the 228 categorized nouns. Of the 201 queries that resulted in concreteness ratings (concrete, $n = 117$; abstract, $n = 84$), the mean concreteness rating for the nouns we labeled as concrete ($M = 507.99$) was significantly higher than for the nouns we labeled as abstract ($M = 357.51$; $F(1, 199) = 175.52, p < .0001$).¹

Next, we searched COCA for combinations of *in* and *on* with each abstract noun. The 20 abstract nouns chosen for the experiment were those for which (1) combinations with both *in* and *on* produced frequency totals lower than 100 and (2) the absolute differences between the frequencies of combinations with *in* and *on* was at a minimum. A post-hoc one-way ANOVA revealed that the average frequency of *in* combinations ($M = 32.70$) was not significantly different from the average frequency of *on* combinations ($M = 23.75$), $F(1, 38) = 2.77, p = .1040$.

Because we wanted the interpretability of our sentences to hinge on the prepositional phrase and, hence, the compatibility of the preposition and the abstract noun, we needed the other content words to be more stable in their meanings. Previous research has suggested that object terms may be more stable in their meanings than other terms (Feist & Cifuentes Férez, 2007; Gentner & Asmuth, 2008; Gentner & France, 1988). Thus, only count nouns that were

considered by the experimenters to normally refer to inanimate concrete objects – especially when considered as a group of objects (i.e., when the noun is preceded by the adjective *these*) – were selected for use as sentential subjects.

Finally, to ensure that the *in* variants and the *on* variants of our resultant sentences were equally novel, a frequency search was conducted in COCA for each of the subject noun-prepositional phrase combinations (e.g., *house* together with *in system*). This search revealed that none of the final combinations appeared in the corpus.

Procedure Participants were randomly assigned to interpret either the *in* variants or the *on* variants. They were presented with all twenty sentences in their assigned condition in a randomized order on a computer screen. For each sentence, they were asked to either explain its meaning in the text box provided or, if they were unable to formulate a meaningful interpretation, to simply type *uninterpretable* in the text box instead of an interpretation.

Design We used a 2 (Preposition: *in* or *on*) \times 20 (Sentence Frame) design with preposition as a between-subjects factor and sentence frame as a within-subjects factor.

Analysis and Results

Stimuli Check Before turning to our results, we ask whether the sentential subjects were less likely to shift in meaning within the context of the sentences than were the objects of the prepositions, as required by the design. To test this, we calculated for each sentence (e.g., *These houses are in/on system.*) the proportion of times the nouns used as sentential subjects (e.g., *houses*) and those used as prepositional objects (e.g., *system*) in the stimulus sentences were reproduced in the participants' interpretations. A one-way ANOVA revealed that sentential subjects were reproduced in interpretations significantly more often ($M = .74, SD = .12$) than their prepositional object counterparts ($M = .29, SD = .17$; $F(1, 38) = 94.25, p < .0001$), suggesting that any differences in the interpretability of the sentences would have more to do with interpretation of the prepositional phrases than with interpretation of the subjects within the wider context of the sentence, as was required by our experimental design.

Interpretability A repeated measures ANOVA on sentence interpretability revealed a significant main effect of sentence frame, $F(19, 60) = 10.89, p < .0001$, indicating that participants found some sentence frames to be more interpretable than others. Because the interpretability of the sentences was dependant on the interpretability of the prepositional phrases, this result suggests that the abstract nouns were not equally interpretable as objects of the prepositions.

Of greater relevance to the question of differences in combinatorial possibilities between the two prepositions, we observed a marginally significant sentence frame by

¹ Of the 27 noun queries that did not result in concreteness ratings, 11 were labeled as concrete and 16 as abstract.

preposition interaction, $F(19, 60) = 1.72, p = .0574$. Post-hoc t -tests comparing the proportion of participants willing to provide interpretations between conditions for each sentence frame, individually, revealed four significant differences in which interpretability was higher for participants in the *in* condition than for participants in the *on* condition and no significant differences in the opposite direction.

Although the ANOVA did not reveal a significant main effect of preposition, we did observe a trend in the predicted direction whereby participants who interpreted *in* sentences were more likely to provide interpretations ($M = .58, SD = .19$) than participants who interpreted *on* sentences ($M = .51, SD = .28$). Furthermore, we note that the lack of a significant difference between the two conditions may have been driven, in part, by the large variances in interpretability of the two groups. Therefore, we were interested in any broader patterns in the data that might be hidden within or beneath this high variability.

We turn first to the variances of interpretability for the two groups of participants. While a significant difference between the variances of interpretability for the *in* condition and the *on* condition would not be the original effect we were looking for, it would suggest an imbalance, or difference, between how the different groups responded to the prepositions in question. The data show that the interpretability of the *in* variant sentences resulted in lower standard deviations ($SD = .19$) than the *on* variant sentences ($SD = .28$). When interpretability was averaged across sentence frame, Levene's test for homogeneity of variances revealed that the mean interpretability of the *in* condition was significantly less variable than the mean interpretability of the *on* condition ($F(1, 78) = 11.79, p = .0010$). This difference in interpretation variability, while subtle, is suggestive of a difference between the two prepositions.

To see whether any broader patterns were underlying this high variability, we next categorized each of the participants as either high-percentage interpreters or low-percentage interpreters. Since overall interpretations were provided for 54.06% of the sentences, participants who provided interpretations for ten or fewer of the twenty sentences were considered low-percentage interpreters and participants who provided interpretations for more than ten sentences were considered high-percentage interpreters. In the *in* condition, 29 participants were categorized as high interpreters and 10 as low interpreters; in the *on* condition, 20 participants were categorized as high interpreters and 21 as low interpreters. This difference between conditions was significant, $\chi^2(1, N = 80) = 5.60, p = .0179$. Taken together, these results hint at an effect of preposition on interpretability.

Discussion

Although the data hint at an imbalance between the potential interpretability of the prepositions *in* and *on*, we did not find the main effect of preposition that we had originally predicted. The lack of a result is particularly curious because, in a separate attempt to create novel non-spatial

uses of *in* and *on* that would be considered by participants to be nonsensical, we had the subjective experience that nonsense *on* metaphors were easier to construct than nonsense *in* metaphors. While this phenomenological experience was reflected in the trends from Experiment 1, the lack of a significant main effect of preposition suggests one of two possibilities. One possibility is that our phenomenological experience may simply be different in kind from the phenomenological experience of our participants. In fact, Sandra and Rice (1995) warn researchers against relying exclusively on their own linguistic intuitions since these might differ dramatically from the intuitions of the general population.

Another possibility is that our subjective experience was driven by the task at hand. It may be that attempting to gauge the interpretability of both prepositions within the same semantic and syntactic contexts is what highlights their differences in interpretability. This difference – between the task leading to our subjective experience and the experimental task performed by our participants – is not unlike the difference between a within-subjects experimental design and a between-subjects experimental design. Birnbaum (1999) argues that participants are exposed to different contexts depending on whether they are taking part in a within-subjects experiment or a between-subjects experiment, and it is this difference in context that could result in widely divergent results from the two kinds of experiments. For example, in the between-subjects design of Experiment 1, the context for each sentence was a set of sentences involving novel prepositional phrases built upon a single preposition. In contrast, the context of our subjective experience was the creation of novel prepositional phrases built upon both *in* and *on*, facilitating a comparison between them. This comparison is more like the everyday experience of using language, in which novel sentences are encountered in the context of similar structures built around a variety of lexical items. Similarly, a within-subjects design in which participants would be exposed to both *in* sentences and *on* sentences would allow for an implicit comparison of the two prepositions, akin to the range of contexts which speakers are exposed to in everyday language use. As a result of these differences in context, the lack of a between-subjects effect for preposition might reflect more about variation in the interpretability of the novel sentence frames than about similarity in the interpretability of novel *in* and *on* prepositional phrases.

Thus, Experiment 2 was designed to test whether the lack of a strong result in Experiment 1 was due to differences between the linguist and the language user or to differences between a task involving consideration of multiple prepositions and one involving consideration of a single preposition.

Experiment 2

Using a completely within-subjects design, Experiment 2 tested whether novel non-spatial uses of the preposition *in* would show higher interpretability than matched non-spatial

uses of the preposition *on*. If so, participants should make more attempts to interpret sentences containing *in* than sentences containing *on*.

Method

Participants A total of 20 University of Louisiana at Lafayette students participated in this experiment in exchange for course credit. Two students were removed from further analysis because they identified themselves as native speakers of Igbo and Arabic, respectively. The 18 remaining participants were native speakers of English.

Materials The materials were the same as those used in the first experiment.

Procedure The procedure was the same as in the first experiment, except that participants saw all 40 of the stimulus sentences.

Design We used a 2 (Preposition: *in* or *on*) x 20 (Sentence Frame) design. Both were treated as within-subjects factors.

Analysis and Results

Interpretability Unlike in the between-subjects design of Experiment 1, a two-way repeated measures ANOVA on the results of Experiment 2 revealed a main effect of preposition ($F(1, 17) = 11.87, p = .0031$), whereby participants were significantly more likely to attempt interpretations of *in* sentences ($M = .64, SD = .48$) than interpretations of *on* sentences ($M = .54, SD = .50$), as predicted.

In addition, as in Experiment 1, we observed a significant main effect of sentence frame ($F(19, 323) = 3.45, p < .0001$), confirming that the sentence frames were not all equally interpretable. Furthermore, as in Experiment 1, we observed a significant preposition by sentence frame interaction, $F(19, 323) = 1.64, p = .0453$ (see Figure 1). In support of our prediction, post-hoc contrasts revealed that for six sentence frames the *in* variant sentence was more interpretable than the *on* variant sentence, while for no sentence frame did participants find the *on* variant sentence to be more interpretable than the *in* variant sentence.

Discussion

In contrast to our own subjective experiences considering the interpretability of novel prepositional phrases headed by *in* and *on*, in Experiment 1 we failed to find a significant difference in the interpretability of sentences utilizing the preposition *in* and sentences utilizing *on*. The question we wanted to address in Experiment 2 was whether the difference between our experiences and the results of Experiment 1 were due to differences between the analyst and the language user (cf., Sandra & Rice, 1995) or due to differences between considering the interpretability of two prepositions and considering the interpretability of just one. In contrast to Experiment 1, in Experiment 2 we observed a difference in interpretability between *in* sentences and *on*

sentences when participants were asked to interpret both kinds of sentence, suggesting that it was the task itself that masked the differences in interpretability in Experiment 1.

In line with the observed distributional differences from the corpus-based work (see Introduction), Experiment 2 revealed that *in* can more easily appear in novel combinations with other lexical items than *on* can. This difference in interpretability between *in* and *on* suggests that the two prepositions may be operating at slightly different semantic levels.

Figure 1: Proportion of participants providing interpretations for each sentence frame paired with each preposition. Each sentence frame is represented in the graph by its prepositional object.

General Discussion

Corpus-based studies of *in* and *on* have yielded observations of differences in morphosyntactic distribution (Navarro, 1998), overall frequency, and the range of non-spatial uses of the prepositions, calling into question the validity of the type-level similarity suggested by traditional treatments of prepositions in linguistics. In this study, we asked whether these differences correspond to differences in interpretability between the two prepositions, suggesting that the noted imbalance is in fact real and supporting the interpretation that the observed differences are due to a difference in meaning potential between *in* and *on*.

Across two studies, we found that *in* and *on* did evidence semantic differences in their combinatorial potentials. When participants were asked to interpret both novel *in* prepositional phrases and novel *on* prepositional phrases, we found that they were more likely to reject as uninterpretable sentences involving *on* phrases than sentences involving *in* ones, echoing the trend in interpretability found when participants were asked to interpret just one kind of sentence. In addition, we found that all sentences for which there was a significant difference in interpretability were more often interpreted in the *in* variant than in the *on* variant. In no case did we find the *on* variant to be more interpretable than the *in* variant in our novel contexts.

Taken together, this pattern of results suggests that, in addition to having different meanings, the prepositions *in* and *on* have different semantic combinatorial possibilities.

While this result is suggestive, further investigation is necessary to understand the strength and scope of the differences between *in* and *on*. For example, in balancing the frequency of co-occurrence of the abstract nouns and the two prepositions, we considered only the frequency of the collocations between the prepositions and the abstract nouns with no intervening lexical items, leaving aside co-occurrences at greater distances (e.g., *in a sense*, which is very high in frequency). However, our participants could potentially have used these phrases, if familiar, to interpret the novel sentences (e.g., *These roads are in a sense*). Alternatively, participants may simply have been more likely to attempt an interpretation because of the high frequency of co-occurrence between the preposition and the noun at two-step (e.g., *in a sense*) and three-step positions (e.g., *in the traditional sense*). In order to gain a clearer understanding of the differences between *in* and *on*, we are planning a follow-up experiment in which these frequencies will also be balanced.

Conclusions

Taken together, the differences in distribution, frequency, and semantic combinatorial possibility argue against the assumption of a type-level similarity between *in* and *on*. In addition, the fact that all three types of data point toward *in* having a wider range of applicability than *on* suggests that these three phenomena may be linked.

Our results suggest that the overall combinatorial possibilities for *in* may be higher than those for *on*. In particular, this might result in a wider range of metaphorical extensions for *in* than for *on*. As a result, investigations into the semantics of non-spatial uses of these prepositions would benefit from taking into account the differences in meaning potential between these prepositions and the possibility that the structure of the extensions and their relations to spatial uses may similarly differ.

A computational model of cognitive interference without neural inhibitory mechanisms

Abstract

Interference between one cognitive behavior or sensory stimulus and subsequent behaviors is a commonly observed effect in the study of human cognition and Psychology. Traditional connectionist approaches explain this phenomenon by mutually inhibiting neural populations underlying those behaviors. Here, we present an alternative model, relying on a more detailed use of synaptic dynamics, in which populations of purely excitatory neurons can nonetheless interfere with each other, causing inhibition of activation for a varying amount of time. The fundamental, biologically motivated, mechanism in the model relies on current “spilling over” from an active neural population into another one, thereby depleting the latter population’s synaptic resources. The principles underlying the model may find applications even in the design of problem-solving artificial neural networks.

Keywords: Neural modeling; Synaptic dynamics; Cognitive Interference.

Introduction

The effects on cognitive performance of *interference* in the process of associating temporally contiguous behaviors or events is a well studied phenomenon in the research disciplines of psychology and animal learning. Simply, it consists of the effects on working memory or memory recall of the presence of stimuli (or motor activations) that are non-critical to the learning of particular response/event associations. In the case of animal learning, it is best understood as entailing distractor stimuli introduced prior to (proactive) or after (retroactive) a task stimulus designed to be reliably predictive of another (e.g. rewarding) stimulus. In human learning, interference can manifest in learning deficits subsequent to pairing either context relevant (Oliveri et al., 2004) or incongruent (Buccino et al., 2005) motor actions and verbal descriptions. In every day human activities, the interference effect has implications for recall of important events, e.g. eye witness testimony (see Bouton, 2007).

Laboratory controlled studies of interference often utilize the delayed matching-to-sample (DMTS) paradigm whereby the subject is required to produce the desired behavioral response over a pre-determined delay period (or inter-stimulus-interval). In such cases, interference is a function of the strength of a ‘distractor’ stimulus and may induce forgetting (*cf.* Roberts & Grant, 1978), impaired learning (Revusky, 1971) or memory retrieval deficits (Gordon et al., 1981).

Some forms of associative learning may be more or less prone to the interference effect. Recent neuro-scientific evi-

dence has uncovered that areas of motor and premotor cortex that become active during physical movement overlap with areas activated during the reading of the specific affected movement, e.g. hand, foot (Hauk et al., 2004). Buccino et al. (2005) for instance found an interference effect when human subjects, required to produce hand or foot responses to particular verb forms, produced physical movements apt to the action described in the particular sentence. Latency of response increased in this case as compared to when a movement was required that was inapt to the particular action described (see Chersi et al., 2010, for a more detailed discussion).

Models exist that attempt to capture empirically demonstrated features of the interference phenomenon specified at the level of both connectionist and more neurobiologically motivated levels of abstraction. A seminal model of McGeoch (1932) proffered a connectionist account of interference whereby responses learned during a given time window would compete for retrieval by way of mutual inhibition. Essentially, this offered a classical account of ‘distractor’ stimuli inhibiting the influence of task-specific stimuli. The learned associative strengths of the responses determined the ‘winner’ which was, however, premised on the biological implausibility of there being independence, as opposed to overlap, between the available responses.

Mensink & Raaijmakers (1988) provided a stochastic search model of retrieval that was able to describe behavioral data accounting for many of the effects of interference, e.g. proactive inhibition, retroactive inhibition, spontaneous recovery - where previously learned associations become behaviorally extinguished but, presumably still reside in memory.

More recently, neural models have been put forward to account for the ability of organisms to retain spatial information about stimuli over delay periods in the face of distracting (interfering) stimuli. Spencer et al. (2009) have described how the tuning of parameters of an interaction kernel on a dynamic neural field representing spatial working memory permits the development of activation peaks. These peaks are sustained through the use of tuned local excitation and global inhibition parameters on the kernel that afford more or less robustness to noise and distractor stimuli presented to the spatial field. Self-sustained activity can be achieved through bistable unit dynamics (*cf.* Amari, 1977) such that input or noise in-

duced supra-threshold individual unit activity may be maintained even following the withdrawal of the input. Neural field and bistable dynamics through the effective coupling of spatially mapped locally excited activation peaks in different fields provide mechanisms for coping with interference effects over delays between events of motor sequences to be associated.

The assumption in the above-mentioned models and theory is that interference (or distracting stimuli) induce inhibitory effects on the activity of applicable functional circuits or psycho-behavioral states whereas chaining of activations within populations of units entails excitatory activity. In dynamic field theory, for example, distracting stimuli induce elevated levels of global inhibitory activity serving to suppress existing continuous attractor states (i.e. activation peaks) potentially below threshold levels thus serving as a medium for forgetting.

Connectionist and population coding models seeking to enhance comprehension of the interference effect typically do not concern themselves with the biophysical details of the neuron units implied in the modeling approach, relying simply on ‘point-to-point’ synaptic transmission. However, considering that associations of activation may be somatotopically realized in the brain, i.e. via neighboring or overlapping populations of neurons (e.g. Chersi et al., 2010), and that current in a given population typically overlaps with or may otherwise ‘spill over’ into another population, it may be instructive to produce more detailed neural models taking into account these effects in order to better understand neural substrates of behavior.

A precedent for modelling the effects of a non-synaptic neuromodulatory process only recently thought to play a significant cognitive role exists. Nitric oxide (*NO*) gas is an inter-cellular signalling mechanism found in various structures of the brain. *NO* emissions affect neighbouring cells according to a slow diffusive dynamic different to standard point-to-point synaptic transmission. *NO* diffusion has been modelled (Philippides et al., 1998) and an analogue has been applied in the domain of cognitive robotics (Husbands et al., 1998). Recent evidence also suggests a functional role in homeostatic regulation of essential metabolic variables (e.g. Canabal et al. 2007).

The particular inter-cellular signalling mechanism we are concerned with here involves current that affects neighbouring regions of cells through non-standard synaptic transmission. A complete discussion of the different mechanisms that can cause current from one neural population to leak, or “spill over” into another population is beyond the scope of this paper. However, an interesting example of such a current spillover can for instance be observed when ionic neurotransmission at the synaptic cleft is not fully absorbed by the post-synaptic receptors of the receiving cell. Ions spill over the synaptic cleft and can thereby affect neighboring neurons, possibly of other populations leading to slow-rising increases in excitatory post-synaptic currents in the affected

Figure 1: **Schematic of the neural model.** Two connected populations represent the neural substrate of a behavior. The behavior is triggered if the second population fires after triggering current arrives at the first one (large arrow). Weak spillover current, by itself insufficient to trigger the behavior, can also arrive at the first population (small arrow)

cells. Spillover has recently been recognized as a modulatory effect that may play a significant role in brain functioning, e.g. in the communication between the brain stem and cerebellum (Nishiyama & Linden, 2007), illustrating that neural communications do not necessarily rely solely on canonical synaptic transmission.

Here, we propose a neural model of the interference effect based primarily on synaptic dynamics. We model a sequence of two neural connected populations and show that, if spillover current from neural circuits external to the model reach the first population, activation of the second population may be prevented. Since we are mainly interested in the possible effects of the spillover current, we do not model or make assumptions on the precise underlying mechanisms. Nonetheless, we show that interference effects can be observed even though all currents are excitatory. Our model thus departs from the classically conceived models focusing on inhibitory inter-population inducement of interference. Our aim is to demonstrate that neural or neural network models of interference may be insufficient when focused solely on inter-population ‘point-to-point’ synaptic transmission effects. Accounting for biophysical dynamics when designing computational models or artificial neural networks may provide valuable insights to the fields of animal learning and psychology.

Methods

Neural and synaptic dynamics

We model the neural and synaptic dynamics following a standard model. The synaptic dynamics in particular take into account the fact that synaptic transmitters (or simply resources) are finite and both short term facilitation and depression can result from their dynamics (See Tsodyks et al., 1998, for a detailed discussion). Briefly, depression is caused by recognizing that synaptic resources may be “active” (in the synaptic cleft or at the post-synaptic receptors), “inactive” (returning to the pre-synaptic terminals and thus unavailable) or “recovered” (at the pre-synaptic terminals and available for release into the synaptic cleft on arrival of pre-synaptic current) and making the post-synaptic current dependent on the proportion

of active resources. The corresponding mean field equations are adapted from Tsodyks et al. (1998) with minor modifications to make the bounded nature of the resources explicit:

$$\frac{d\langle\rho\rangle}{dt} = \frac{1 - \langle\rho\rangle}{\tau_{rec}} - \min(\langle\rho\rangle, \langle U_{SE}^1 \rangle \langle\rho\rangle E(t)) \quad (1)$$

$$\frac{d\langle\alpha\rangle}{dt} = -\frac{\langle\alpha\rangle}{\tau_{in}} + \min(\langle\rho\rangle, \langle U_{SE}^1 \rangle \langle\rho\rangle E(t)) \quad (2)$$

where ρ and α denote recovered and active resources respectively. Only recovered resources can generate post-synaptic current (by becoming active) and active resources affect the amplitude of post-synaptic current (Eqn. 5). The firing rate $E(t)$ is discussed further below. U_{SE}^1 is a time-varying and firing-rate dependent parameter which models short term synaptic facilitation believed to be caused by residual calcium in the synaptic cleft. It is governed by the following equations:

$$\frac{d\langle U_{SE}^- \rangle}{dt} = \frac{\langle U_{SE}^- \rangle}{\tau_{facil}} + \min(1 - \langle U_{SE}^- \rangle, U_{SE} (1 - \langle U_{SE}^- \rangle) E(t)) \quad (3)$$

$$\langle U_{SE}^1 \rangle = \langle U_{SE}^- \rangle (1 - U_{SE}) + U_{SE} \quad (4)$$

Population dynamics

To model the effect one population of excitatory neurons may have on another, we also follow the model by Tsodyks et al. (1998). The mean firing rate of a given population r is thus dependent on the incoming current from other populations r' and external current I_r arriving directly at population r :

$$\tau_e \frac{dE_r}{dt} = -E_r + g\left(\sum_{r'} J_{rr'} \alpha_{r'} + I_r\right) \quad (5)$$

where $J_{rr'}$ denotes the absolute strength of the connections from r' to r multiplied by the average number of such connections and $\alpha_{r'}$ is given by Eqn. 2. It can be noted here that the original model is more complex since it also caters for inhibitory populations, but those aspects are not relevant to the present work. g , finally, is a transfer function, for which we use a standard sigmoid with a threshold:

$$g(x) = \max\left(0, \frac{2}{1 + e^{(4-x)/3}} - 1\right) \quad (6)$$

Two or more populations governed by the above dynamics can then be seen to form the neural substrate of an observable behavior. In our model, the parameter choices are: $\tau_{rec} = 1000\text{ms}$, $\tau_{in} = 100\text{ms}$, $\tau_{facil} = 530\text{ms}$, $U_{SE} = 10^{-6}$ and $J = 4$. These parameters have been chosen to produce bell-shaped activation curves in the neural populations (rather than undesired firing patterns). They mostly (except where discussed below) affect the firing rates of the neural populations but the precise choices are not critical for illustrating the effect described in the present work.

Figure 2: **The effects of weak, moderate and strong spillover current.** Solid (broken) line represents firing rate in first (second) population. Spillover current begins at $t=0$, behavior triggering at $t=1600\text{ms}$. (A) Spill-over current is insufficient to prevent activation of second population during behavior triggering. (B) Spill-over current causes significant but sub-threshold activation in the first population and prevents triggering of the second population later on. (C) Spill-over current is sufficient to prematurely trigger the behavior.

Results

We model two connected populations of neurons (Fig. 1) which are meant to represent the neural substrate (or part thereof) of an observable cognitive behavior. Such an arrangement is for instance thought to underlie action execution in the motor cortex (Chersi et al., 2006). The behavior is “triggered” if external current arriving at the first population is of sufficient amplitude to cause activation in the second population. In other words, a behavior is successfully triggered if the second population fires after the first one was stimulated (Fig. 2A, after 1500ms). We call *triggering current* any current that, in the absence of spillover current effects, is sufficient to trigger the behavior.

Conversely, we model spillover current as a type of external current arriving at the first population but of insufficient amplitude to cause the activation of the second population (Figs. 2A and B, the first 1000ms). For the present illustrative purposes, the spillover current is modeled as lasting 100ms and increasing linearly by a small amount I_{spill} during that time. After 100ms, the current dies away instantaneously. I_{spill} has a range of possible values, with the exact choice affecting overall behavior, which is explored below. It should be noted that the observation of the reported interference effect does not critically depend on this particular choice for modeling the spillover current. Of importance is merely the fact that supra-threshold activation is generated in the first population in some way.

To illustrate the effect spillover current can have (Fig. 2),

we first determine a sufficient triggering current for the behavior in a control case with no spillover current. We then measure the post-triggering firing rate of the second population in situations where the triggering current was preceded by a spillover current δt ms earlier. Any change in firing rate compared to the control case is of interest.

Interference without inhibition

Figure 3: Interference effect. Y-axes indicate spill-over current strength I_{spill} , normalised so that values of interest fall between 0 and 1. Rectangle indicates this region of interest (bounds of I_{spill}). X-axes indicate values for δt , the waiting time between end of spillover and start of behavior-triggering current. Figures are grayscale ranging from black (0) to white (maximal values of the plotted parameters). **(A)** Firing rate of the second population determined by chosen values of I_{spill} and δt . Black region indicates no firing (and therefore interference). Other regions show firing rates all at similar, close to maximal levels. The interference effect thus either causes a strong suppression of firing rate or no significant effect at all. Further, the δt values for which the interference effect is observed depend on the value of I_{spill} (see text). **(B)** Time delay between peak of activation in first population and corresponding peak in second population. If the second peak was inhibited, this information does not exist (solid gray area). Region with $I_{spill} > 1$ shows premature activation (little to no time delay, dark colors) of second population due to excessively high values of I_{spill} (see Fig. 2C). Region with $I_{spill} < 0$ shows normal separation between peaks (see Fig. 2A). Region within rectangle ($0 \leq I_{spill} \leq 1$) shows separation similar to the normal case with $I_{spill} < 0$ but not to the premature activations observed when $I_{spill} > 1$. Thus, if both populations fire, I_{spill} does not significantly affect the timing between peaks in the region of interest (rectangle).

Since spillover current that is too low (Fig. 2A) or too high (Fig. 2C) is not going to cause any interesting effects, we define lower and upper bounds of I_{spill} as follows: the spillover current should be strong enough to cause some measurable

effect during an attempt at triggering the behavior but weak enough not to cause this triggering by itself (e.g. Fig. 2B). We define “measurable effect” simply as a difference in time-course and/or peak values in the firing rate of the second population, thus not excluding the possibility of a facilitation effect.

We find, however, that any spillover current sufficient to cause a measurable effect prevents activation of the second population (Fig. 3). The duration of this interference can vary and depends on the strength of the spillover current (Fig. 3A). For values near the lower boundary, the effect disappears if the behavior is triggered around 460ms or later after termination of the spillover current. Near the upper boundary, the interference window can last up to about 2800ms. For very small values of the spillover current, it is possible to avoid the interference effect if the behavior is triggered very shortly after the end of the spillover current (up to 340ms in the best case), since synaptic resources are depleting more slowly.

The maximal duration of the interference window is mostly affected by the choice of τ_{rec} . Interestingly, however, it is not reached monotonically. Rather, as can be seen in Fig. 3A, a threshold value for spillover current exists below which the interference effect disappears after a fraction of its maximal effect. Above the threshold, the interference effect lasts for its entire possible duration.

It would theoretically be possible for the spillover current to cause a delayed activation in the second population, rather than complete inhibition. This would be apparent if the time between the peak activation of both populations was a function of the strength of the spillover current. However, at least within the context of the work presented here, no such effect was found. Fig. 3B shows that, if the spillover current is within its bounds, it will either cause complete interference or, with a sufficient waiting period between spillover and behavior-triggering current, no effect at all. It should be noted however, that on a behavioral level, delays can still be observed. This would correspond to a control mechanism which re-triggers the behavior after noticing that the initial attempt was not successful. Modeling these control mechanisms in detail is, however, beyond the scope of this work.

Fundamental cause

Since the behavior of the system described here is modulated only by synaptic dynamics, the cause for the observed interference effect is also found therein and illustrated in Fig. 4. Any activity within the first population will cause a reduction of recovered synaptic resources (as they become active). Since the amount of synaptic resources activated by incoming current is proportional to the recovered resources, fewer recovered resources mean smaller increase in current. If I_{spill} is very small, recovered resources do not deplete drastically during spillover current (Fig. 4A) and a following triggering current can have normal effects. If I_{spill} is larger, the recovered resources do deplete drastically but over a relatively long time-course (Fig. 4B). This slow depletion allows active resources to inactivate quickly enough to keep the proportion

Figure 4: **Synaptic resources.** Solid (broken) line represents recovered (active) synaptic resources from the first population corresponding to the firing rates seen in Fig. 2. Spillover current begins at $t=0$, behavior triggering at $t=1600\text{ms}$. (A) Spill-over current causes a small decrease in recovered synaptic resources but the triggering current can activate sufficient amounts to cause firing in the second population. (B) Spill-over current causes complete but slow depletion of recovered resources. Not enough resources can recover and the fraction activated by the triggering current is insufficient to cause firing in the second population. (C) Spill-over current causes complete and fast depletion of recovered resources. Consequently, the proportion of active resources becomes sufficiently high to trigger the behavior prematurely.

of active resources below the necessary threshold for triggering the second population. At the same time, the depletion is significant enough that a later triggering current cannot activate a sufficient proportion of resources either - we observe interference. Finally, a very large value of I_{spill} works just like a triggering current: recovered resources activate quickly enough to push the proportion of active resources over the triggering threshold before it can decrease again due to inactivation.

Thus, the interference effect described here relies on a slow but significant depletion of synaptic resources. In theory, the effect of reduced available resources could be offset by the synaptic facilitation mechanism implemented here. However, since τ_{facil} is usually shorter than τ_{rec} , this is not observed in the present model.

Effects of parameter choices

Naturally, the exact values, most notably for the lower and upper boundaries of the spillover current, depend on the values chosen for the synaptic parameters in the model. The most important ones are the synaptic strength and the proportion of synaptic resources liberated. We do not address these effects in detail here but did find in a brief exploration that, as long as parameters are kept within ranges that allow a bell-shaped activation of both populations as seen in Fig. 2A after

the 1500ms mark (as opposed to, e.g. self-sustaining, chaotic or oscillatory behavior), spillover current always appears to cause interference effect.

Discussion

The model presented in this paper departs from the more classical artificial neural network models in its use of more detailed biophysical dynamics. By taking into account the fact that synaptic resources are finite, we have been able to inhibit the execution of a behavior even though all currents within the model are excitatory. While our model merely provides an alternative account compared to those relying on inhibitory dynamics, it does not necessarily replace them. However, it does illustrate the power of more detailed biophysical dynamics in a model. There is therefore a necessity to move beyond simple point-to-point artificial neural networks if the purpose of such a network is to explain cognitive phenomena.

Although we do not provide an extensive parameter exploration here, the findings are rather robust. The parameters of the synaptic model affect the firing behavior of the populations more than the effect of the spillover current (the main exceptions to this are of course τ_{rec} and τ_{facil}). Likewise, we do not need to formulate any strong assumptions on the precise nature of the spillover current because the critical aspect is merely the activation generated within the first population. The effect is thus general but further work would be needed to explore the effects of different values for τ_{rec} and τ_{facil} respectively. For instance, one could discover values for which the spillover current causes both facilitation and interference (or only facilitation). However, it should be noted that this would mainly be interesting from a theoretical perspective, since typical short term facilitation time-courses tend to be faster than depletion ones (Tsodyks et al., 1998). In fact, related work (Chersi et al., 2010) which is concerned with modeling both interference and facilitation effects simultaneously has found that in such cases, neural dynamics including inhibitory currents may provide a better explanation.

Besides their role as explanatory tools for cognitive phenomena, neural networks also find applications as computational problem-solving tools. By illustrating the effects synaptic dynamics can have on the overall output of our model, we show that moving beyond the traditional connectionist models of nodes simply connected by a signed weight can be worth considering. While this will not extend the set of computations that a neural network can perform, it may simplify the topology or facilitate training. Such benefits have for instance been previously found in GasNets (Husbands et al., 1998). These networks have proven particularly amenable to efficient search of task solution space as cognitive robotics controllers situated according to spatial and temporal environmental constraints. This adaptive potential is tapped using a diffusive, non-purely point-to-point synaptic modulatory network. Exploration of the interaction of classically conceived synaptic transmission and less orthodox means of inter-cellular communication may provide scope to investi-

gate spatial and temporal interactions relevant to the study of cognitive phenomena particularly in an embodied context (*cf* Parisi, 2004). Again, these are possibilities that need to be explored further in future work.

Conclusions

We have presented a model that can explain temporal interference effects without relying on inhibitory dynamics in the underlying neural circuitry. Rather, the behavior is explained solely by synaptic dynamics which are modeled in a simple yet biologically plausible way. The contributions of this work are twofold: (1) We provide an alternative explanation for a range of interference effects which does not rely on explicit inhibitory dynamics. (2) We highlight the benefits of modeling synaptic and biophysical dynamics in more detail, both as a computational tool which may find applications even in artificial neural networks and as an explanatory mechanism as illustrated in the present paper.

Phonetic training makes word learning easier

Abstract

Motivated by the idea that differences between adult and child language learners may stem in part from initially minor differences (such as in phonetic perception) that cascade throughout other aspects of language learning, we explored to what extent training adults on a novel phonetic contrast results in improved learning of words that incorporate that contrast. Results indicate that distributional training on a novel phonetic contrast improves word learning as well as the ability to discriminate a related contrast. We discuss implications for how adults' phonological abilities in affect other aspects of language learning, and also for understanding the effectiveness of different phonetic training regimes.

Keywords: language acquisition; phonetic learning; second language learning

Introduction

Children and adults differ both qualitatively and quantitatively in their ability to acquire a new language. Adults have difficulty with many aspects of language acquisition, from phonetic perception (Werker & Tees, 1984; Werker & Lalonde, 1988; Kuhl, 2004) to language processing (Clahsen & Felser, 2006) to certain aspects of syntax (e.g., Johnson & Newport, 1989; Birdsong, 2006). Scientists have proposed many theories to account for the difference between children and adults; these theories differ in both the degree and type of contribution made by pre-existing language-specific biases. Although nearly everyone agrees that (due to the inherent logical problem of induction posed by language learning) some bias must be necessary to explain successful language acquisition, explanations about the nature of the bias – and the difference between children and adults – vary considerably.

Some argue that there is a fundamental difference between first and second language acquisition: that acquisition in children is guided by an innate Universal Grammar and language-specific acquisition procedures, but that adult acquisition is directed by more domain-general learning mechanisms (e.g., Bley-Vroman, 1990). There are many other possibilities, however, since children and adults differ profoundly in their cognitive capabilities and typical linguistic input. Children have significantly poorer cognitive skills, including memory and processing speed; perhaps these differences aid children to learn language by enabling them to isolate and analyze components of a linguistic stimulus (Newport, 1988) or to over-regularize inconsistent input (Hudson Kam & Newport, 2005; Singleton & Newport, 2004). Another possibility is that learning a second language is made more difficult due to interference from the first language; indeed, the evidence that experience with a first language influences acquisition of a second is extensive (e.g., Mayberry, 1993; Iverson et al.,

2003; Tan, 2003; Weber & Cutler, 2003; Hernandez, Li, & MacWhinney, 2005). This explanation overlaps considerably with the related point that adult brains are in many ways less plastic, and therefore less malleable in response to novel input (Elman et al., 1996; MacWhinney, 2005). Other explanations suggest that adults and children differ in their style of learning (Ullman, 2004) as well as the nature of the social support (Snow, 1999) and linguistic input (Fernald & Simon, 1984) they receive. Of course, many of these possibilities may be true simultaneously.

This work investigates yet another possibility – that small differences in children's abilities along one dimension or aspect of language can have cascading effects, resulting in larger differences in other aspects of language. These initial minor differences might be due to language-specific skills that naturally decay over time, or could be due to domain-general changes in the underlying cognitive abilities that subserve them. Key to this idea is the notion that, because language is such an intertwined, multi-dependent system, small differences in one aspect of language can be steadily amplified when it comes to the acquisition of other aspects. This idea is similar to the neo-constructivist view of Karmiloff-Smith (1998): both suggest that differences in eventual linguistic performance may derive from cascading effects that result from variation in more basic skills. That view focuses on abnormal development in children, however. Our work is motivated by an extension of this viewpoint: the notion that some of the well-attested differences between child and adult learners may result from the more minor, lower-level differences between adults and children. To investigate this, we begin by identifying aspects of language acquisition where one might expect to see cascading effects, and investigate whether performance in one improves performance in the other.

What minor difference between adults and children might have significant cascading effects onto other aspects of language? One possibility derives from children's well-attested superior phonological processing and perception abilities. Young infants can distinguish between phonemes in all natural languages, but lose that ability by the age of 10-12 months if they have not received sufficient linguistic input for a language containing that phoneme (Eimas, Siqueland, Jusczyk, & Vigorito, 1971; Werker & Tees, 1984; Kuhl, 2004). Adults who begin acquisition of a language later in life, even after decades of experience using the language, show phonological deficits in perception, production, and processing (e.g., Flege, 1995; Pallier, Colomé, & Sebastián-Gallés, 2001; Sebastián-Gallés & Soto-Faraco, 1999).

Moreover, it is quite difficult to train adults to learn a phonetic contrast that does not exist in their native language. Various training regimes exist; some rely on implicit learning of the phonemic categories based on distributional information (Maye & Gerken, 2001, 2002; Shea & Curtin, 2005; Hayes-Harb, 2007), while in others explicit feedback is given (Jamieson & Morosan, 1989; Bradlow, Akahane-Yamada, Pisoni, & Tohkura, 1999; McCandliss, Fiez, Protopapas, Conway, & McClelland, 2002). Although it is possible to train adults to discern non-native phonetic contrasts, the resulting phonetic representations are often fragile. For instance, when trained through implicit distributional learning, adults show little ability to generalize their knowledge to other non-native contrasts that differ along an analogous phonetic feature (Maye & Gerken, 2001), even though infants are able to do so (Maye, Weiss, & Aslin, 2008).

Why might difficulties in phoneme perception be responsible for adults' relatively poor performance on other aspects of language? It is well-known that adults have difficulty rapidly processing fluent speech in their second language (e.g., Guillelmon & Grosjean, 2001; Clahsen & Felser, 2006), which may be in part due to difficulty in perceiving and representing the phonemes that make up that speech. Difficulties in rapid processing could lead to difficulties in segmenting words and mapping those words onto their correct referents; difficulties in identifying words – particularly function words, which are generally shorter and more phonologically impoverished than content words – might result in more difficulty identifying the appropriate parse for sentences and therefore the correct underlying grammatical structure. Consistent with this, phonological working memory is correlated with second language skills in adults (e.g., Perani, 2005), and speech processing efficiency is related to other aspects of linguistic competence in children (Tsao, Liu, & Kuhl, 2004; Fernald, Perfors, & Marchman, 2006). Empirical evidence reveals that knowledge of lower-level aspects of language (such as phonological perception or statistical segmentation) can help in the acquisition of more complex linguistic phenomena (Werker & Yeung, 2005; Mirman, Magnuson, Graf Estes, & Dixon, 2008). Recent computational work suggests that word learning and phonetic category learning are more effective when occurring simultaneously (Feldman & Griffiths, 2009), and that knowledge of phoneme distributions may aid in speech segmentation and identification of lexical categories (Christiansen, Onnis, & Hockema, 2009). However, there is no work we are aware of that explores whether the ability to recognize a phonetic contrast assists adults in other areas of language.

The work here addresses that issue. We train adult learners to perceive a non-native phonetic contrast and then evaluate how this affects their ability to learn novel words containing the phonetic contrast in question. Our results are relevant not only to the possibility that deficits in phonetic skills may have cascading effects through other aspects of language; they are also relevant to the question of how generalizable adult phonetic learning is. As mentioned previously, existing work

suggests that although adults can be trained to distinguish novel contrasts, this ability is fragile, and they have difficulty generalizing that contrast to analogous contrasts (Maye & Gerken, 2001). However, this work used synthesized stimuli not found in any natural language, and training included many filler items, so that there was effectively less than five minutes of exposure to the phonemes of interest. Would adults be able to generalize with more exposure or on a more naturally-produced contrast? In other training regimes adults show robust differences in both perception and production of a novel contrast (Lively, Logan, & Pisoni, 1993; Bradlow et al., 1999; McCandliss et al., 2002), but these regimes differed in many ways from Maye and Gerken (2001): they were significantly longer, used more natural stimuli, and involved explicit training with feedback, among other differences. Most importantly, most of these studies did not evaluate generalization to a novel but similar phonetic contrast. Among those that did, generalization to the novel contrast was successful, but the training paradigms involved giving explicit feedback rather than distributional training (e.g., McClaskey, Pisoni, & Carrell, 1983; Wang, Spence, Jongman, & Sereno, 1999). It is therefore unclear whether the limited generalizability observed in Maye and Gerken (2001) is due some inherent inability to generalize based on distributional information, or is due to other details in the training regime. In this work, we incorporate an implicit distributional training regime similar to that of Maye and Gerken (2001), but one of longer duration and with more natural stimuli. Do these changes in training result in improved generalizability, both in terms of novel but similar phonetic contrasts, but also in terms of the ability to use the new phonetic categories when learning new words?

Method

We trained 61 participants recruited from the student population¹ at the University of Adelaide on two tasks: a phonetic training task and a word-learning task. Participants² were randomly assigned to either a CONTROL or a TRAINED condition, which differed in terms of the nature of the phonetic training given.

Task 1: Phonetic learning

Training. The first task consisted of phonetic training based on distributional learning, similar to the task in Maye and Gerken (2001). Subjects in the TRAINED condition were trained on the unaspirated velar plosive voiced/voiceless contrast (/g/-/k/), which occurs in languages such as Hindi but not in English (both phonemes sound like a “g” to an English

¹No participants were native speakers of a language with the phonetic contrast we sought to train. 52 were native English speakers. To ensure that native language was not a factor, we performed all analyses on the full population as well as the English speakers only. Results were identical, so we report the full population results.

²Of the original 61 subjects, 9 were excluded from the final analysis (5 due to technical difficulties, 1 for failure to follow instructions and 3 who performed at chance levels on the control task, indicating inattention). This left 25 participants in the CONTROL condition and 27 in the TRAINED condition.

Figure 1: Distribution of stimuli used in phonetic training, defined along a continuum based on VOT. Tokens 2 and 7 occurred four times as often as tokens 1 and 8.

speaker). The /g/ and /k/ phonemes differ in terms of voice-onset time (VOT), such that /g/ contains a pre-voicing component while /k/ does not. It is therefore possible to gradually convert /g/ tokens into /k/ by successively removing parts of the pre-voicing component. Doing so yields a continuum of eight tokens from /g/ to /k/, separated by an average of 17ms in VOT from each other, and identical to each other except for the pre-voicing. As in Maye and Gerken (2001), we presented subjects with a bimodal distribution of these phonemes, as illustrated in Figure 1; thus, some tokens (e.g., 2 and 7) occurred four times as often as others (e.g., 1 and 8). Stimuli were recorded from a male native speaker of Hindi and edited using Praat phonetics software. Each of the phonemes occurred in one of three vowel contexts (/a/, /i/, and /u/).

In order to control for time spent listening to speech sounds across groups, subjects in the CONTROL condition also listened to a distribution of phonemes. However, they heard tokens from a phonemic contrast they could already recognize: the dental plosive aspirated/unaspirated voiced/voiceless contrast (/d/-/t^h/, which sound like “d” and “t” respectively to a native English speaker). As before, these phonemes were used to create a continuum of eight tokens extending from /d/ to /t^h/ . Since these phonemes differ along aspiration as well as voicing, the tokens were created by removing voicing and then adding aspiration in continuous steps.

In both conditions, participants listened to a total of 912 tokens presented in random order and separated by 250 ms each, for a total of approximately 11 minutes of exposure to the sounds. During stimulus presentation the participants were told not to speak or read, but also that they need not consciously concentrate on the sounds. To alleviate boredom, they were allowed to doodle while listening.

Testing. Discrimination of the phonetic contrast was tested by presenting participants in both conditions with trials in which they heard three phonemes, two of which were identical. They were asked to press a button indicating whether the third phoneme they heard was the same as the first or the second (the distribution of correct answers was balanced across trials). There were three kinds of trials, defined by the nature of the phonemes tested. On *control* trials, the phonemes

already existed in English (/d/ and /t^h/). On the *trained* trials, the phonemes were the ones that the TRAINED group had been trained on (/g/ and /k/). Finally, on the *untrained* trials, subjects were presented with a phonetic contrast that also does not exist in English and that is also defined by voice onset time, but differs in place of articulation – the unaspirated bilabial plosive voiced/voiceless contrast (/b/ and /p/, both of which sound like “b” to an English speaker).³ The *untrained* trials enabled us to evaluate whether our subjects could generalize any learning to similar phonemes that differed on the same feature. There were 12 test trials for each contrast, totaling 36 testing trials in all; no feedback was given, and the order of all test trials was randomized.

Task 2: Word learning

Training. The word learning task was a standard task in which participants were presented with 12 different image types distributed over three stages of 36 trials each, making 108 trials in all. One each trial, an image was paired with a word, and the participants were instructed to try to learn the word-picture mapping. Words consisted of minimal pairs differing in initial position on each of the contrasts: *trained*: [g]ipur, [k]ipur, [g]anug, and [k]anug; *control*: [d]ipur, [t^h]ipur, [d]anug, and [t^h]anug; and *untrained*: [b]ipur, [p]ipur, [b]anug, and [p]anug. To ensure that the words differed only in the initial sound, words were created by splicing the same stem (-anug or -ipur) to the initial phonemes. The images corresponded to some of the earliest words spoken by children,⁴ and were thus presumed to be highly familiar to all participants. The specific image-word pairing was randomized for each participant. The order of presentation of images was also random, with the constraint that each word-image pair was presented three times during each stage.

Testing. There were three testing sessions of 12 trials each, occurring after each stage. During each test trial, one of the 12 images was presented and participants heard two minimal pairs differing along the contrast in question (*trained*, *untrained*, or *control*). Thus, a participant might see a picture of a cat and hear [b]ipur followed by [p]ipur. Their task was to indicate whether the first or second word they heard was correct. No feedback was given.

Results

Task 1: Phonetic learning

Phonetic learning was evaluated by comparing performance on the phonetic test. As Figure 2 illustrates, participants in the TRAINED condition outperformed those in the CONTROL

³For *trained* and *control* trials, the exemplar tested on corresponded to token 1 and 8 from each continuum. Due to a coding error, the exemplar in the UNTRAINED trials corresponded to tokens 2 and 7 rather than 1 and 8. If anything, this is a more stringent test of generalization, but also means that it is more difficult to compare performance on the UNTRAINED trials to the other two. We discuss the implications of this in subsequent sections.

⁴They consisted of images of babies, balls, books, cats, chairs, birds, beds, cars, cookies, cups, dogs, and shoes.

Figure 2: Phoneme discrimination test results. Participants who received distributional training outperformed participants in the CONTROL condition, but all participants performed above chance on all stimuli, suggesting that the test itself may have trained them. Error bars reflect standard error.

condition on both the *trained* and *untrained* stimuli.⁵

Interestingly, participants in both conditions performed above chance on the *trained* and *untrained* stimuli.⁶ This suggests that the phonetic testing itself may have trained the participants in the CONTROL condition, which is not an unreasonable suggestion since it closely corresponds to the “prototype” training employed by Jamieson and Morosan (1989) or the “two-seven” condition of Hayes-Harb (2007). To evaluate to what extent such training occurred, we split scores on the phonetic test in half and compared performance on the first six test trials for each stimulus type with performance on the final six test trials of each. As Figure 3 indicates, both groups improved significantly over the course of the test.⁷ There was no difference between the CONTROL group’s performance in the final half of testing and the TRAINED group’s performance in the first half: in other words, training during testing was so effective that it resulted in performance equivalent to having listened to distributional information for over 10 minutes.

It is also evident that performance on the *trained* stimuli was superior to performance on the *untrained* stimuli. This is true even for participants in the CONTROL condition, for whom there should have been no difference between the two types of stimuli (since they had heard neither before). This is probably an artifact of the coding error described earlier in which the *untrained* test stimuli consisted of tokens 2 and 7, rather than tokens 1 and 8 as for the *trained* stimuli. The *trained* stimuli were therefore probably both more effective at teaching participants the contrast, and also easier to differentiate (and hence get correct on the test). Consistent with the hypothesis that this was a training effect, analysis of the

Figure 3: Were participants trained over the course of phonetic testing? Performance on the first half of testing is compared to performance on the second half. Both the TRAINED and CONTROL groups performed significantly better over the course of testing on the *trained* stimuli. While there was a positive trend, the difference in performance on the *untrained* stimuli for either group across the two halves of testing was not significant. The differential effects on *trained* and *untrained* stimuli is probably because the *trained* stimuli were easier to discriminate (tokens 1 and 8) than the *untrained* stimuli (tokens 2 and 7).

first trial of testing reveals that participants in the CONTROL condition performed equally, no better than chance, on both *trained* and *untrained* stimuli. In any case, the important finding – that subjects were able to generalize their phonetic learning to an untrained but related contrast – is unaffected by this detail.

Task 2: Word learning

Are participants able to generalize their phonetic discrimination abilities to a new task (word learning), as well as a new contrast? If the phonetic representations acquired are fragile enough, it is possible that they might not, since word learning incorporates many skills: hearing and identifying the phoneme in the context of an entire word; mapping that word onto an image; and doing so while simultaneously trying to learn other word-image mappings. If the task is difficult enough and the representation weak enough, one might expect that it would not transfer.

To answer this question we compared overall performance on the word-learning task, the results of which are shown in Figure 4. As one would expect, participants in both groups were able to identify the *control* words above chance. The TRAINED group performed above chance on the *trained* words, which began with the sound they were trained on; however, they performed at chance on the *untrained* words.⁸ By contrast, the CONTROL group was unable to distinguish words beginning with any of the unfamiliar phonemes above chance. There was no difference in performance over the

⁵For *trained*: $t(50) = 2.11, p = 0.04$, *untrained*: $t(39) = 2.68, p = 0.011$, both two-tailed. Note that the degrees of freedom for the *untrained* trials were adjusted from 50 to 39; this was because Levene’s test for equality of variance indicated unequal variance.

⁶TRAINED group on *trained* stimuli: $t(24) < 0.001$; on *untrained* stimuli: $t(24) = 5.03, p < 0.001$; CONTROL group on *trained* stimuli: $t(26), p < 0.001$; on *untrained* stimuli: $t(26), p < 0.01$.

⁷Difference between the first and second half of the test trials for the CONTROL participants: $t(26) = 1.87, p = 0.036$; for the TRAINED participants: $t(24) = 2.12, p = 0.022$, both one-tailed.

⁸Differences from chance (50%) performance for the TRAINED group: on words with the *control* contrast: $t(24) = 8.118, p < 0.001$; on words with the *trained* contrast: $t(24) = 2.941, p = 0.007$; on words with the *untrained* contrast: $t(24) = 0.282, p = 0.781$. For the CONTROL group: on words with the *control* contrast: $t(26) = 7.710, p < 0.001$; on words with the *trained* contrast: $t(26) = -0.090, p = 0.929$; on words with the *untrained* contrast: $t(26) = 0.991, p = 0.331$. All tests are two-tailed.

Figure 4: Word learning results. Participants in both groups were able to identify the correct words for the *control* stimuli above chance. The TRAINED group was above chance on words beginning with the sound they were trained on, but not on the related untrained sound. The CONTROL group, which was not trained on any phonemes, was unable to learn words beginning with both the *trained* and *untrained* sounds.

course of the word-learning task for any condition on any stimuli, suggesting that the task did not itself train phoneme discrimination.

Discussion

Motivated by the idea that differences between adult and child language learners may stem in part from initially minor differences that cascade throughout other aspects of language learning, we explored to what extent training adults on a previously unheard (novel) phonetic contrast results in improved learning of words that incorporate that contrast. Adults were assigned to either a TRAINED or CONTROL condition and trained distributionally, as in Maye and Gerken (2001). Both conditions were exposed to a bimodal distribution of phonetic sounds defined by voice onset time, but differed on whether the modes of the distribution mapped onto an existing phonetic contrast (the CONTROL condition: /d/ and /t^h/) or a novel contrast (the TRAINED condition: /g/ and /k/). We found that training on the phonetic contrast improved the learning of words beginning with that contrast, as well as the ability to discriminate a related contrast. These results have implications for how phonological abilities in adults affect other aspects of language learning, and for understanding how well distributional training enables phonetic generalization.

One interesting aspect of our findings is that as tasks became increasingly far removed from the original training, the ability to generalize diminished. The TRAINED group was able to generalize their phonetic learning to be able to discriminate a related but untrained contrast on a phonetic perception task, but when word learning was involved, they were only capable of learning words that began with the contrast they had been trained on. The CONTROL group was able to learn the *trained* and *untrained* contrast on the basis of the phonetic testing regime, but the resulting knowledge was more fragile than in the TRAINED group: their were unable to apply this ability to the problem of word learning. These re-

sults, in combination with the findings of other training studies (e.g., Bradlow et al., 1999; Maye & Gerken, 2001; McCandliss et al., 2002; Hayes-Harb, 2007), suggest that the ability to generalize phonetic learning (either to a related contrast or to another task) may depend strongly on the depth and nature of the training involved. It is possible that additional training would improve the ability to generalize even further. Relatedly, it is possible that our phoneme test did not measure phonetic category learning *per se*, and was more a measure of the raw ability to discriminate acoustically between two phonemes; if so, the limited generalization may have been due to the fact that our participants simply improved in their discrimination ability, but did not acquire phonetic categories in any reasonable sense (although the border between these two options is rather fuzzy). In general, the precise effect of training amount or type on generalization ability, and the nature of its dependence on the quantity and type of input, are matters for future study.

Our work was inspired in part by the idea that apparently major differences in language learning abilities may to some extent stem from smaller differences that have a cascading effect over time. While our findings are consistent with this notion, much work remains to be done to explore it more thoroughly, especially in the realm of adult language learning (research by Karmiloff-Smith and colleagues explores a similar idea in the area of language disorders). On one hand, it may appear unsurprising that being able to hear a phonetic contrast makes it easier to learn words that differ on that contrast. On the other hand, one might have expected phonological perception to have no effect on word learning: despite their poor perception, adults are arguably superior to children when it comes to acquiring vocabulary. Further work is essential, both for exploring whether linguistic abilities besides phonological perception affect other aspects of language, and for exploring whether phonological perception has effects on aspects of language besides word learning. This can include training studies like ours, as well as studies that evaluate how different aspects of language acquisition are affected by individual differences in adult phonetic perception (which are known to exist: see, e.g., McCandliss et al., 2002; Golestani & Zatorre, 2004; Perani, 2005; Golestani & Zatorre, 2009).

We conclude by noting an interesting puzzle: although the idea that deficiencies in one area of language acquisition can have cascading effects throughout other areas makes sense and is well-supported in the child acquisition literature (e.g., Tsao et al., 2004; Werker & Yeung, 2005; Fernald et al., 2006), so is the idea that jointly learning two aspects of language can improve performance in both (e.g., Feldman & Griffiths, 2009; Frank, Goodman, & Tenenbaum, 2009; Maurits, Perfors, & Navarro, 2009). However, the former implies that deficits in one area should propagate to another, while the latter implies that deficits in one area may be compensated for or overcome by skills or information from another. It is possible that both are true for different areas or in different ways, but as yet we know very little about the mechanisms or details

underlying either, so it is difficult to know for sure. As usual, further research is necessary.

Abstract

In Exp. 1, the authors report an influence of temporal contiguity in stimulus exposure on later judgments of similarity. Exposure to transformational information – that is, information that ‘connects’ two similar, but perceptually distinct stimuli – was found to have no influence on later judgments of similarity. In Exp. 2, exposure to transformational information was also found not to influence later property generalization; however, exposure to within-category structure that promoted a sense of ‘surprise’ (i.e., contained clear discontinuity) led to a reduction in later property generalization between two similar, but perceptually distinct stimuli. This latter effect was confirmed in Exp. 3 while ruling out any influence of temporal factors.

Keywords: Spontaneous categorization; within-category structure; similarity; generalization; transformational knowledge; temporal dynamics; perceptual learning; sensory preconditioning.

Introduction

Similarity and categorization are intimately intertwined: stimulus similarity is assumed to form the basis for many of our natural categories (Hampton, 2001), but categorization can also alter perceived similarity (Harnad, 1987). When taught that stimuli are members of the same category, participants will perceive these stimuli to be more similar than participants who are not (e.g., Livingston, Andrews, & Harnad, 1998). The reverse is also true: when taught that stimuli are members of contrasting categories, participants will perceive these stimuli to be more different (e.g., Goldstone, 1994). Moreover, given the lawful relationship that exists between similarity and stimulus generalization (Shepard, 1987), it is not surprising that many studies have shown that stimulus generalization is directly influenced by the ‘classificatory status’ of stimuli: when stimuli are ‘classified together’ (or acquire equivalence), increased levels of stimulus generalization are found between these stimuli. In contrast, when stimuli are ‘classified apart’ (or acquire distinctiveness), decreased levels of stimulus

generalization are found between them (see Honey, Close, & Lin, 2010). In other words, categorization can warp psychological similarity space (Nosofsky, 1989).

While interesting, almost all studies to date that have indexed an influence of categorization on later judgments of similarity and stimulus generalization (commonly termed *categorical perception* (CP)) have employed supervised training procedures (but see Gureckis & Goldstone, 2008). Consequently, as Gureckis and Goldstone have noted, “it remains a somewhat opaque question if learned CP effects are restricted to cases where subjects make a differential response to each category or if other aspects of category organization, such as the similarity structure or distribution of items within a category, may also exert an influence on perception” (2008, p. 1876). This is important because although one may presume that the mechanisms of supervised categorization drive all classification, evidence has shown that this is unlikely to be the case (Pothos & Chater, 2002). To fully assess categorization’s influence on later behavior, therefore, one needs to look to unsupervised categorization – that is, categorization that occurs in the absence of any external feedback.

Fundamentally, unsupervised categorization tasks afford an assessment of the principles that underlie categorization in an unconstrained manner, allowing greater insight into people’s natural categorization biases (or preferences). However, much of the unsupervised categorization that occurs in the laboratory has been considered very different to that which occurs naturally (see Clapper & Bower, 1994; Love, 2002). Crucially, whereas any natural unsupervised category formation will have unlikely been the primary purpose of an interaction (meaning that any category formation is incidental), in laboratory investigations of unsupervised categorization, explicit instruction to categorize is generally given, meaning that any category formation is intentional (Love, 2002). Unlike the majority of laboratory-based unsupervised categorization, then, natural incidental categorization requires that a person first realize there is

some structure present, and then utilize this structure to guide their classifications¹. The experiments presented in this paper, therefore, sought to assess how the similarity structure (i.e., the distribution of items) within a category influences incidental categorization, as indexed by the later perceived similarity of category items, and the level of generalization between category items.

What aspects of within-category structure might influence whether stimuli are incidentally classified together or apart? Zaki and Homa (1999) have proposed that the acquisition of an object concept will be facilitated by exposure to that object's successive changes (that is, exposure to transformational information). Based on this hypothesis, it seems plausible to suppose that transformational information should encourage the incidental 'classification together' of similar, but distinct stimuli (but see the categorical perception effects of Newell & Bühlhoff, 2002). Another factor that might also encourage the 'classification together' of stimuli is temporally contiguous stimulus exposure (see, e.g., Bateson & Chantrey, 1972). Empirical investigation into the phenomenon of perceptual learning has shown that the temporal dynamics of stimulus exposure influence whether an increase or decrease in later perceived stimulus similarity (and stimulus generalization) is found (see Goldstone, 1998; Hall, 1991). More specifically, when two similar stimuli are exposed in close temporal contiguity, the perceived similarity of (and the level of generalization between) these stimuli should increase, relative to situations where no stimulus exposure is given and where stimulus exposure is not particularly temporally contiguous (see Bateson & Chantrey, 1972; Bennett & Mackintosh, 1999). Finally, a number of theories of spontaneous category learning link the formation of new categories (or clusters) to unexpected changes in stimulus structure. For example, Clapper and Bower (1994, 2002; see also SUSTAIN, Love, Medin, & Gureckis, 2004) propose that if a novel stimulus is perceived as sufficiently 'surprising' (sufficiently dissimilar) to previously stored stimulus encounters, then a new category (cluster) will be invented to accommodate that stimulus. Consequently, if a strong set of norms has been established about, for example, Category A membership (i.e., through a number of exposures to Category A exemplars), then it is more likely that a Category B exemplar will be accommodated in a newly invented category (cluster). Exposure to only a single Category A exemplar before exposure to a Category B exemplar, by contrast, will likely not lead to these stimuli being 'classified apart' (Clapper & Bower, 1994, 2002; Love et al., 2004).

In summary, much evidence has shown that categorization (using supervised training procedures) can

alter the perceived similarity of stimuli, and concomitantly, the level of generalization between stimuli. While there is some preliminary evidence that similar alterations in perceived stimulus similarity can be found following unsupervised categorization (Gureckis & Goldstone, 2008), little research has directly assessed how the similarity structure (i.e., the distribution of items) within a category influences incidental categorization. Moreover, the discrimination based studies that have indexed an influence of categorization on stimulus similarity and stimulus generalization have typically employed designs in which participants engage in hundreds of experimental trials. However, it seems reasonable to suppose that people's sensitivity to category structure (if sufficiently obvious) should be immediate. This means that under certain conditions, incidental categorization should be a rapid process that can occur following only minimal stimulus exposure.

Experiment 1

In Exp. 1, we were interested in investigating those factors that should encourage incidental 'classification together' under conditions of minimal stimulus exposure. Specifically, we sought to test the hypotheses that transformational information and temporally contiguous stimulus exposure should encourage the 'classification together' of two similar, but distinct stimuli, as indexed by a later increase in their perceived similarity to one another.

Method

Participants 48 Cardiff University undergraduate students took part either for partial fulfillment of course credit or a small payment of £2, with 16 participants in each condition (see Table 1).

Table 1: The three conditions employed to assess within-category structure in Exp. 1.

Condition	Preexposure	Test
Baseline	A / - / - / - / - / F	A - F
Sys_trans	A / B / C / D / E / F	A - F
Contiguous	A / F	A - F

Stimuli The stimuli were individually rendered images taken with permission from Hahn, Close and Graf (2009). They were basic level objects from six biological categories (bird, fish, head, mushroom, starfish, turnip) and one artifact category (light bulb; see Figure 1). For every category, two objects formed the endpoints of each morph continuum (the 1% and 100% morph stimuli), from which 20%, 40%, 60% and 80% morph images were rendered (here, the 1%, 20%, 40%, 60%, 80% and 100% images are referred to as A, B, C, D, E and F, respectively). All morph images had a size of 256 × 256 pixels and were presented in gray scale on a 15-in.

¹ This contrasts with laboratory-based unsupervised categorization where the explicit instruction to categorize will likely promote a belief in participants that their task is to find some experimenter defined category structure.

computer monitor. Participants were seated approximately arms length from the monitor for the duration of the experiment.

Figure 1. Illustration of the morph stimuli employed. The stimuli shown here are the 1%, 20%, 40%, 60%, 80%, and 100% morph images, respectively.

Design and Procedure Exposure condition was manipulated as a between-participants factor and participants in all conditions were exposed to the seven different object categories. On a given trial, participants were sequentially preexposed to a set of morph stimuli from one of the object categories. Within each of the three exposure conditions, half of participants received presentations of the morph stimuli in the order A to F, and half of participants received presentations of the morph stimuli in the order F to A. Each stimulus was presented for 3000 ms, and the temporal spacing between presentation of stimulus A and stimulus F was held constant in the Baseline condition and condition Sys_trans by introducing a fixation cross when no morph (object) stimulus was scheduled to be presented in the Baseline condition, relative to condition Sys_trans. Following stimulus preexposure, a 1000 ms inter-stimulus interval (blank screen) separated presentation of the test screen, on which was presented stimulus A and stimulus F. Within the subconditions created in each exposure condition following the previous counterbalancing operation, half of participants saw stimulus A surrounded by a red border on the test screen, and half of participants saw stimulus F surrounded by a red border on the test screen. Within each of the subconditions created by the previous counterbalancing operations, half of participants received presentations of stimulus A on the left-hand side of the test screen and presentations of stimulus F on the right-hand side of the test screen, and half of participants received the reverse. On the test screen, participants were simply asked to rate how similar they thought the object framed in red was to the object not framed in red, using a 1 (very dissimilar) to 9 (very similar) rating scale presented at the bottom of the test screen. Responses were made using the keys “1” through “9” on a standard keyboard. Following a response, a 1000 ms inter-trial interval (blank screen) separated participants’ exposure to the next object category. Exposure to the seven object categories was random for all participants in each of the three exposure conditions.

Results

For the purpose of analyses, participant similarity judgments were averaged over the seven object

categories. Figure 2 displays the results of interest: participants’ overall mean similarity rating, split by preexposure condition. Inspection of this figure reveals that similarity ratings in condition Contiguous were higher than in the Baseline condition and condition Sys_trans. Similarity ratings in condition Sys_trans differed little from those in the Baseline condition. A one-way ANOVA revealed a significant effect of exposure condition, $F(2, 45) = 7.31, p < .003, \eta^2 = .25$. Tukey HSD post-hoc tests revealed that, overall, participants in the Contiguous condition reported significantly higher ratings of similarity than participants in the Baseline condition ($p < .05$) and Sys_trans condition ($p < .002$). Overall similarity ratings did not differ significantly between the Baseline and Sys_trans conditions ($p > .05$).

Figure 2. Results of Exp. 1: overall mean similarity rating, plotted by preexposure condition. Error bars indicate the standard error.

Discussion

In Exp. 1, the perceived similarity of stimuli A and F was influenced only by the temporal contiguity of preexposure to these stimuli. One interpretation of this result is that only the Contiguous condition was sufficient to encourage the ‘classification together’ of stimuli A and F. This ‘classification together’ can be conceptualized in a number of ways: one way of conceptualizing such is in terms of the formation of a blended representation of stimulus A and stimulus F (i.e., AF; see Hall, 1991). Alternatively, an account can be considered with respect to the assumption that temporally contiguous stimulus exposure provides the optimal conditions under which an excitatory association can form between two similar stimuli (Hall, 1991). Formation of such an A–F association would dictate that stimulus A will evoke a representation of stimulus F, creating a situation in which these stimuli will come to be perceived (somewhat) equivalently. Such *acquired equivalence* would lead to a concomitant increase in the perceived similarity of stimuli A and F (see Hall, 1991).

Interestingly, the results of Exp. 1 do not support the proposal of Zaki and Homa (1999). A number of possibilities exist for this failure: first, Zaki and Homa’s (1999) proposal may simply be wrong. Second, the within-category similarity structure of condition

Sys_trans may have resulted in both associationistic and comparator processes operating (Honey, Bateson & Horn, 1994). If one assumes that the influence of these two processes was relatively balanced in condition Sys_trans, then this would have resulted in little change in the perceived similarity of stimuli A and F, relative to their baseline similarity.

In Exp. 2, we sought to further assess the influence of within-category structure using a property generalization task at test. Here, we were interested in investigating whether we could find evidence for ‘classification apart’ – driven by a surprise-driven category invention mechanism (Clapper & Bower, 1994, 2002) – under conditions of minimal stimulus exposure. To this end, we compared a skewed stimulus structure (condition Surprise) to the Baseline and Sys_trans conditions of Exp. 1, and a further scrambled transformational information condition (condition Scram_trans).

Experiment 2

In Exp. 2, we sought to assess the hypothesis that the Surprise condition – in which participants were exposed to a skewed stimulus structure – would lead to the ‘classification apart’ of stimuli A and F, as indexed by a later reduction in the level of property generalization between them. Such a finding would provide support for a surprise-driven category invention mechanism operating in incidental categorization (Clapper & Bower, 1994, 2002).

Method

Participants 64 Cardiff University students took part for partial fulfillment of course credit, with 16 participants in each condition (see Table 2).

Table 2: The four conditions employed to assess within-category structure in Exp. 2.

Condition	Preexposure	Conditioning	Test
Baseline	A / - / - / - / F	A+	F
Surprise	A / B / C / - / - / F	A+	F
Sys_trans	A / B / C / D / E / F	A+	F
Scram_trans	A / E / C / D / B / F	A+	F

Stimuli, Design and Procedure The same stimuli used in Exp. 1 were employed. As for Exp. 1, on a given trial, participants were sequentially preexposed to a set of morph stimuli from one of the object categories. Within each of the four exposure conditions, half of participants received presentations of the morph stimuli in the order A to F, and half of participants received presentations of the morph stimuli in the order F to A. Each stimulus was presented for 3000 ms, and the temporal spacing between presentation of stimulus A and stimulus F was held constant across conditions by introducing a fixation cross when no morph (object) stimulus was scheduled to be presented, relative to conditions Sys_trans and

Scram_trans. Within the subconditions created by the previous counterbalancing operation applied in each preexposure condition, following a 1000 ms inter-stimulus interval (blank screen), half of participants were then presented with stimulus A, and half of participants were then presented with stimulus F. Situated above the stimulus was a sentence that informed participants about a particular property that the stimulus had: for example, “This person comes from a small, remote island in the Pacific Ocean”. This information remained on the screen until the space bar was pressed, at which point participants were immediately presented with the test screen. On the test screen, participants were simply asked to rate on a scale from 1 (very unlikely) – 9 (very likely) how likely they thought it was that the stimulus now presented to them shared the property of the previously seen stimulus. If participants had previously been presented with stimulus A, then at test, they were presented with stimulus F, and if they had previously been presented with stimulus F, then at test, they were presented with stimulus A. The 1 – 9 rating scale was continuously presented beneath the test stimulus, and responses were made using the 1 – 9 keys on the top of a standard computer keyboard. A 1000 ms inter-trial interval (blank screen) separated participants’ likelihood ratings and their exposure to the next object category. Exposure to the seven object categories was random for all participants in each of the four preexposure conditions.

Results

Again, for the purpose of analyses, participant similarity judgments were averaged over the seven object categories. Figure 3 shows the results of the generalization test: the overall mean likelihood ratings that the test stimulus shared the property of the previously seen stimulus, split by preexposure condition. Inspection of this figure reveals that participants in the Surprise condition reported lower mean likelihood ratings than participants in the other three preexposure conditions; likelihood ratings in the other three conditions were all very similar.

A one-way ANOVA² confirmed that there was an overall effect of preexposure condition, $F(3, 40.51) = 2.85, p < .05, \eta^2 = .12$. Dunnett T3 post-hoc tests (equal variances not assumed)³ revealed that, overall, participants in the Surprise condition reported significantly lower mean likelihood ratings than participants in the Baseline condition ($p < .05, r = .35$). No other post-hoc comparisons were significant (all $ps > .05$).

² Due to a lack of homogeneity of variances between conditions, the Brown-Forsythe correction was applied.
³ Tukey HSD post-hoc tests were not performed (as in Exp. 1) due to the lack of homogeneity of variances between conditions.

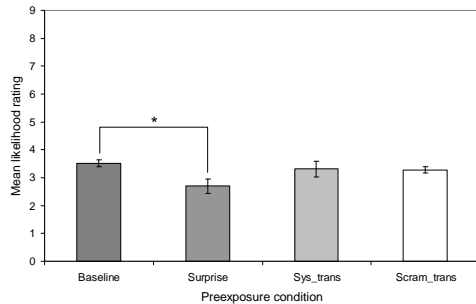

Figure 3. Results of Exp. 2: overall mean likelihood ratings, plotted by preexposure condition. Error bars indicate the standard error.

Discussion

The results of Exp. 2 are broadly consistent with the predictions of a surprise-driven category invention mechanism operating in incidental categorization (Clapper & Bower, 1994, 2002; also Love et al., 2004). This assumes that only the within-category similarity structure of the Surprise condition encouraged participants to invent an extra category (cluster) in which to accommodate the lone distinct stimulus, meaning that stimuli A and F were ‘classified apart’. As a consequence of this, property generalization between A and F in the Surprise condition was reduced (Harnad, 1987).

In line with the results of Exp. 1, it is apparent that transformational information did not encourage the ‘classification together’ of stimuli A and F and a concomitant increase in the level of property generalization between A and F (condition Baseline vs condition Sys_trans). Moreover, there is no evidence to suggest that systematic transformational information influenced participants’ response behavior differently to non-systematic transformational information (condition Sys_trans vs condition Scram_trans; cf. Zaki & Homa, 1999).

What aspect of the within-category structure of the Surprise condition encouraged the assumed ‘classification apart’ of stimuli A and F? Inspection of this structure reveals that not only does it have a similarity structure likely to engage a surprise-driven category invention mechanism, but also a distinct temporal structure. That is, while the three stimuli with the highest perceptual similarity were presented in a temporally contiguous manner, a temporal gap of six seconds separated presentation of the distinct stimulus from the highly similar stimuli. It is possible, therefore, that it was this temporal discontinuity, rather than the perceived perceptual discontinuity, that engendered the assumed invention of a new category (cluster) in which to accommodate the distinct stimulus.

Experiment 3

Exp. 3 replicated Exp. 2 with one exception: in order to determine if the temporal discontinuity contained within

the Surprise condition of Exp. 2 was critical in producing the significant difference between the Baseline and Surprise conditions, the stimuli in condition Surprise_2 were preexposed with even temporal spacing.

Method

Participants 32 Cardiff University students took part for a small payment of £2, with 16 participants in each condition (see Table 3).

Table 3: The two conditions employed to assess within-category structure in Exp. 3.

Condition	Preexposure	Conditioning	Test
Baseline	A / - / - / - / F	A+	F
Surprise_2	A / B / C / F	A+	F

Stimuli, Design and Procedure The only difference to Exp. 2 was that during the preexposure phase of the Surprise_2 condition, presentations of the morph stimuli were separated by a 2000 ms long fixation cross. This maintained the equivalent temporal spacing between presentations of the object category endpoints (A and F) across the two conditions.

Results

Figure 4 shows the results of interest: the overall mean likelihood ratings split by preexposure condition. Inspection of Figure 4 shows that, overall, participants in the Surprise_2 condition reported significantly lower likelihood ratings than participants in the Baseline condition, $F(1, 30) = 6.14, p < .02, \eta^2 = .17^4$.

Figure 4. Results of Exp. 3: overall mean likelihood ratings, plotted by preexposure condition. Error bars indicate the standard error.

General Discussion

The method of these studies provides a fast and effective way of assessing the influence of within-category structure (i.e., the distributional properties of the stimuli)

⁴ Due to a violation of normality in the data (Shapiro-Wilk test of normality, $p < .007$), we confirmed this result using the non-parametric Mann-Whitney U test, $U(16, 16) = 56.50, p < .008, r = .49$.

on people's incidental categorization behavior, as indexed by their later judgments of stimulus similarity and stimulus generalization. Indeed, one particularly notable feature of the designs of Experiments 1 – 3 is that participants only received a single presentation of each scheduled stimulus during preexposure.

Two main findings were made: First, transformational information did not encourage 'classification together', which would have resulted in a later increase in the perceived similarity of stimuli A and F (Exp. 1) and an increase in the level of property generalization between these stimuli (Exp. 2). Second, when perceptual discontinuity existed in the presented within-category structure, this resulted in a reduction in the level of later property generalization between stimuli A and F (Exp. 2 and Exp. 3). This result is consistent with the assumption of a surprise-driven category invention mechanism operating in human incidental categorization (Clapper & Bower, 1994, 2002; also Love et al., 2004), and supports previous work by Gureckis and Goldstone (2008). Importantly, the results of Exp. 2 demonstrate that this reduction in stimulus generalization was not simply a product of the amount of stimulus preexposure.

In conclusion, the present results support the idea that perceived discontinuity in the environment (be this temporal or perceptual) guides people's incidental categorization behavior, as indexed by their later judgments of stimulus similarity and stimulus generalization (Anderson, 1991; Rosch & Mervis, 1975). Finally, one of the particularly nice aspects of the design of Exps 2 and 3 is that it can be readily transposed to assessments of incidental categorization in nonhuman animals and prelinguistic children.

Abstract

Comparing the responses of participants in reasoning experiments to the normative standard of Bayes' Theorem has been a popular empirical approach for almost half a century. One longstanding finding is that people's belief revision is conservative with respect to the normative prescriptions of Bayes' Theorem, that is, beliefs are revised less than they should be. In this paper, we consider a novel explanation of conservatism, namely that participants do not perceive information provided to them in experiments as coming from a fully reliable source. From the Bayesian perspective, less reliable evidence should lead to more conservative belief revision. Thus, there may be less of discrepancy between normative predictions and behavioural data than previously assumed.

Keywords: Belief revision; Conservatism; Bayesian; Experimental Pragmatics.

Introduction

Bayes' Theorem provides a normative rule for updating beliefs in the light of new evidence, and therefore provides a valuable tool for studying human reasoning. In particular, participants' responses in experiments can be compared to normative predictions derived from Bayes' Theorem. There is a wealth of experimental data using the framework of Bayesian probability to study almost every aspect of human reasoning including judgement (Tversky & Kahneman, 1983), decision making (Edwards & Tversky, 1967), conditional reasoning (Evans & Over, 2004; Oaksford & Chater, 2003), category based induction (Kemp & Tenenbaum, 2009) and argumentation (Hahn & Oaksford, 2007).

Demonstrations of seemingly non-Bayesian reasoning behaviour abound, but the debate about whether people's reasoning behaviour can be considered normative has continued because deviations from supposedly rational standards have led to discussion about the standards themselves.

For example, Simon's notion of 'bounded rationality' (Simon, 1982) has led some researchers to focus on the adaptive value of cognitive strategies as the gold standard for rationality (Gigerenzer & Todd, 1999). Others (Hilton, 1995; Noveck & Sperber, 2004; Schwarz, 1996) have asked whether participants and experimenters share the same normative model – that is, are participants in reasoning experiments doing what experimenters *think* they are doing? These researchers propose that many of the most seemingly compelling demonstrations of irrationality may be attribut-

able – at least in part – to the *pragmatics* of the experimental setting.

One question of fundamental importance in the debate about Bayesian rationality is whether or not people revise their beliefs in line with Bayesian predictions when they encounter new evidence. A consistent finding is that people are *conservative* relative to the predictions of Bayes' Theorem (Edwards, 1968; Fischhoff & Beyth-Marom, 1983; Slovic & Lichtenstein, 1972). The provision of new evidence does not seem to have the impact on people's existing beliefs that Bayes' Theorem predicts it should.

In the following section we review some putative explanations for conservatism. We then propose that a consideration of the pragmatics of belief revision experiments suggests a novel explanation for conservatism: Participants do not treat the evidence they receive in belief revision experiments as fully reliable, and therefore do not 'maximally' revise their beliefs. Bayesian theory itself requires that less reliable evidence should lead to more conservative updating. Thus, conservatism in belief revision may reflect, at least in part, a normatively appropriate response to receiving evidence from a less than fully reliable source.

Conservatism

Conservatism in belief revision is a well-documented experimental finding. In a variety of different contexts, people have been shown to revise their beliefs more weakly than Bayes' Theorem predicts that they should when they encounter seemingly diagnostic evidence. In a typical conservatism experiment, participants are shown two 'bookbags', and told that they are filled with different distributions of red and blue 'chips' (Edwards, 1968; Peterson & Miller, 1964; Peterson, Schneider & Miller, 1965). For example, Bag A might contain 60% red chips and 40% blue chips, while Bag B contains 40% red chips and 60% blue chips. One of the bags is 'selected at random', and chips sequentially drawn from it (in reality, the distribution and the ordering of the chips is typically predetermined by the experimenter). Participants must judge which of the two bookbags the chips are being drawn from, using each new piece of evidence to update their existing beliefs.

Bayes' Theorem is a normative rule for updating beliefs based on new evidence:

$$P(H | E) = \frac{P(H)P(E | H)}{P(H)P(E | H) + P(\neg H)P(E | \neg H)} \quad \text{Eq. 1}$$

It allows calculation of posterior belief, $P(H/E)$, that is, one's belief in the hypothesis in light of the evidence received. The posterior is determined by one's prior degree of belief, $P(H)$, and the diagnosticity of the evidence received, that is, how much more likely it is that the evidence observed would have occurred if the hypothesis were true, $P(E/H)$, in this case the chips were drawn from Bag A, as opposed to if it were *false* (i.e., the chips were drawn from Bag B), $P(E/\neg H)$. In signal detection terms, these two quantities correspond to the *hit rate* and *false positive rate* associated with the evidence. The ratio between them, which captures the diagnosticity of this evidence is referred to as the likelihood ratio. The posterior degree of belief brought about increases as this likelihood ratio increases, as seen in Figure 1.

Figure 1: Impact of amount of evidence and source reliability (likelihood ratio) on posterior belief in a hypothesis. The figure plots posterior degrees of belief after receiving a unit of evidence of given diagnosticity, starting from a prior of .4. Each line represents a different likelihood ratio.

Each drawn chip represents a new piece of evidence, and thus provides information about which of the two 'hypotheses' is likely to be true (i.e., which of the two bookbags the sample is drawn from). As more evidence is obtained, participants should come to believe that one hypothesis is more likely to be true than the other. The dominant finding from the 'bookbag and poker chip' experiments is that this happens more slowly, and to a lesser extent than Bayes' Theorem predicts it should (Edwards, 1968; Peterson & Miller, 1964; Peterson, Schneider & Miller, 1965).

The finding that people tend to consistently underestimate the diagnostic impact of evidence unsurprisingly triggered a great deal of debate. Edwards (1968) suggested that people could either be mis-aggregating or misperceiving the true diagnostic value of evidence. Both of these explanations assume, however, that the 'true' value of the evidence is

objectively known and available to both participant and experimenter (an assumption that we discuss in more detail below). By contrast, Slovic & Lichtenstein (1971) proposed a range of possible explanations for experimental conservatism in belief revision, including the idea that participants in reasoning experiments may anchor themselves to their initial beliefs and be unwilling to change them in the light of new evidence. This explanation does not assume that participant and experimenter necessarily assign the same weight to the evidence, but instead holds that people are too wedded to their initial assessments to properly incorporate new evidence.

In their review of the literature, Erev, Wallsten & Budescu (1994) conclude that while conservatism in belief revision is a fairly robust experimental finding, the locus of conservatism in participants' revisions of their opinions has never been definitively established. Mis-aggregation, misperception, and 'anchoring' are all explanations of conservatism that infer a normative fault in participants' responses – that is, participants' responses are viewed as non-Bayesian. But does conservatism in experimental demonstrations of belief revision really indicate a normative fault in participants' reasoning?

Edwards (1968) proposed a third explanation: Conservatism could simply be an experimental artefact. Edwards suggested that people become confused in experimental contexts that involve complex tasks, find it difficult to process all the explicit numerical information, and thus make performance errors. Slovic & Lichtenstein (1971; see also Erev et al., 1994) observed that people find the presentation (and production) of numerical probabilities difficult to deal with (as they do not typically come across explicit numerical probabilities in their daily lives). In addition, Slovic & Lichtenstein suggested that people are unwilling to use the extreme values of response scales, and that their responses therefore converge on central values. Similarly, Lopes (1985) suggested that non-Bayesian behaviour might be less likely to occur in situations where stimuli were more clearly 'marked' in support of or against a given hypothesis. Lopes (1987) succeeded in improving the match between participants' responses and normative predictions in a belief revision experiment by instructing them to separate their judgments into two steps. First participants labelled a piece of evidence as either favouring or countering a hypothesis, and then they made an estimate of how *much* it favoured one hypothesis of the other.

This second class of explanations locate the normative fault not with participants' responses, but with the nature of the experimental setting. Might conservatism in belief revision be more attributable to faulty assumptions on behalf of the experimenter than faulty reasoning on behalf of the participants?

The Pragmatics of Experiments

The normative construal of an experimental task can have wide-ranging implications (Hilton, 1995; Noveck & Sper-

ber, 2004; Schwarz, 1996). The key insight is that in order to be able to accurately understand behaviour in an experiment, it is vitally important to have a complete understanding of what the *participants* in the experiment think they are doing, in case it differs from what the *experimenters* think they are doing. Yet in many experiments the routine assumption is that participants' representation of the experimental task simply matches that of the experimenter.

Increasingly, some researchers have based their analyses of reasoning, judgement or decision making behaviour on the pragmatic, Gricean notion of *conversational implicature* – information that is not contained in the literal content of an utterance, but that can be implied from the context in which it is given (Grice, 1975). The notion of implicature is central to an understanding of the pragmatics of experiments: participants may infer more about the experiment than is contained in the literal content of the instructions. Similarly, experimenter and participant might have different ideas about what key task parameters are – such as the diagnosticity of the evidence in belief revision experiments.

Why might participants differ in their assessment of how diagnostic the evidence in belief revision experiments is? One possible explanation is that participants simply do not maximally trust the evidence they receive. In fact, several studies have investigated the idea that participants' trust in the context of experiments may be affected by participating in previous experiments – particularly if these experiments involved a deceptive manipulation.

Kelman (1967) proposed that the frequent use of deception in social psychological experiments was creating a new, suspicious breed of participant, who did not trust the experimenter and would be unlikely to react in a natural way. Christensen (1977) investigated the idea of the 'negative subject' empirically, and found that participants who were exposed to a prior experimental manipulation (not necessarily a deceptive manipulation) produced 'negative subject' responses, as demonstrated by a failure to exhibit verbal conditioning as effectively as subjects who had not received a prior manipulation. Similarly, Cook & Perrin (1971) found that experiencing deception caused a decrement in incidental learning in an immediately consecutive task – participants were more vigilant to the messages they were presented with, and therefore scrutinised them more carefully.

More recently, McKenzie, Wixted & Noelle (2004) observed that many demonstrations of supposedly irrational behaviour in the laboratory rely on the assumption that participants believe "key task parameters that are merely asserted by experimenters" (p947). McKenzie et al. then considered seeming rationality deficits in the context of changes in confidence judgments across yes-no and forced choice formats of the same cognitive task. Here previous empirical research has suggested that people's performance is sub-optimal or irrational by comparison with the appropriate normative model. McKenzie et al. explicitly modelled participant skepticism toward aspects of the experimental materials. By including a 'believability' or 'confidence' parameter, the authors hoped to establish whether performance on

such tasks was truly irrational (non-normative), or whether participants might actually be responding reasonably, given their understandable skepticism about task realism. Participant performance was found to be entirely in keeping with this modified normative model and hence rational.

The findings from McKenzie et al. (2004) suggest that the believability of experimental materials is likely to have a profound effect on experimental data. Noting that psychological experiments routinely involve systematic deception, the authors suggested that "maybe the only irrational thing to do in any experiment is to fully believe anything the experimenter tells you" (p.956).

This is a strong statement to make about the demands of the experimental setting. We do not wish to convey that participants in psychological experiments actively undermine experimental manipulations by seeking to discredit the information they receive. But the opposing assumption – that all information given to participants by experimenters is taken at face value – seems equally implausible. It seems possible that participants do not treat information they are given in experiments as deriving from a maximally reliable source.

Bayesian Updating & Source Reliability

In Bayesian terms, a reliable source will provide more diagnostic evidence; as a result, evidence from that source will lead to higher posterior degrees of belief than evidence from an unreliable source (Figure 1 above). In other words, a less reliable source leads to more conservative belief revision. If participants treat experimental evidence as obtaining from a somewhat unreliable source, their belief updating *should* be somewhat conservative in relation to a normative standard based on the assumption that the source is reliable.

There are two ways in which source reliability might be factored into a Bayesian model of a given task. The first is to consider source reliability as an endogenous variable; that is, inherent characteristics of the evidence and characteristics of the source providing that evidence are (implicitly) combined into a single, overall likelihood ratio (as in e.g., Birnbaum & Mellers, 1983; Birnbaum & Stegner, 1979; Corner & Hahn, 2009). The second possibility is to model source reliability exogenously as an explicit variable (as in e.g., Bovens & Hartmann, 2003; Hahn, Harris & Corner, 2009; Hahn & Oaksford, 2007; Pearl, 1988; Schum, 1981). This latter case involves a cascaded inference in a hierarchical model. Figure 2 shows a simple hierarchical model in which to capture an evidence report from a partially reliable source. This model captures explicitly the fact that what is received is a *report* of some evidence through a partially reliable source, not the evidence directly. In other words, it naturally captures cases of testimony where evidence of an event is based on witness description, not on first hand experience.

Figure 2: A hierarchical model in which the reliability of the reporting source is captured exogenously. Three levels are distinguished: the underlying hypothesis H , the evidence E , and the source's actual report of that evidence E_{rep} .

The likelihood ratio associated with such an evidence report, E_{rep} , is described by Eq. 2 (below):

$$\frac{P(E|H)[P(E_{rep}|E,H) - P(E_{rep}|\neg E,H)] + P(E_{rep}|\neg E,H)}{P(E|\neg H)[P(E_{rep}|E,\neg H) - P(E_{rep}|\neg E,\neg H)] + P(E_{rep}|\neg E,\neg H)}$$

Here, $P(E_{rep}|E,H)$ represents the probability of an evidence report, E_{rep} , to the effect that the evidence E obtains, given that both E and H (the hypothesis) are true, and so on (see also Schum, 1981). It can be seen that the evidential characteristics of the report vis à vis the hypothesis are a multiplicative combination of the diagnosticity of the evidence itself and the characteristics of the reporting source, that is, the source's own hit and false alarm rate regarding the true state of that evidence. If the witness is completely reliable and reports only the true state of the evidence, then Eq. 2 reduces simply to the standard relationship between evidence and hypothesis. Where the evidence is entirely deterministic and arises if and only if the hypothesis is true (i.e., $P(E|H)=1$, $P(E|\neg H)=1$), the hit and false positive rates of the witness completely determine the characteristics of the report. From this latter case, it can also be seen that partial reliability of the witness necessarily reduces the overall diagnosticity of the evidence received. How diagnostic the report can be, and hence what posterior degree of belief it can bring about is capped by the reliability of the witness (see also Hahn et al., 2009).

Simulating Bookbags and Pokerchips

How, then, can such a model be applied to the bookbag and pokerchip paradigm on which the vast majority of the evidence for conservatism is based?

We suggest that the conservative belief revision displayed in experimental settings may reflect rational responses to information from an information source that is less than perfectly reliable. Specifically, participants might not believe the asserted premise that the experimenter is drawing chips randomly from the bag. Such skepticism seems inherently sensible in light of the fact that draws in classic bookbag and poker chip tasks were frequently *not* random.

Instead, the experimenter could determine the colour of the chip to be drawn by a tactile cue. The 'random' laying of a hand on one poker chip, which is followed by a movement to another (experimenter desired) chip on the basis of a tactile cue could be construed as a mis-reporting of the nature of the initial, randomly chosen poker chip through the experimenter. Once the experiment is conceived of in this light, it is straightforward to model the effect of experimenter (un)reliability on belief revision, and we can show that such a model captures major effects demonstrated in the conservatism literature.

On this account, the participant is attempting to determine the truth of a hypothesis (e.g., that a bookbag contains predominantly red chips) on the basis of some evidence (the random drawing of a red or blue chip) that is reported by a source (the experimenter). The assumed characteristics of a single draw are represented by the model in Figure 2. H_{red} is the hypothesis in question, that is, whether the bag from which the chips are being drawn is a red bag. E represents the random drawing of a red chip; E_{rep} is the experimenter's report as to whether a red chip was randomly drawn - delivered in the form of the actual chip produced for the participant. This final piece of information is the only one at the participants' disposal in assessing the probability of H_{red} .

In these studies, prior degrees of belief are communicated to participants by explaining to them the number of bags of different composition and that this proportion should constitute their prior (see e.g., Phillips & Edwards, 1966). Consequently, under the assumption that the experimenter is a perfectly reliable source, who is merely exactly reporting the exact result of a random draw from the bag, participants posterior degree of belief should be determined completely by the diagnosticity of a given draw of red or blue. The diagnosticity of the chip drawn is fully determined by bag composition, that is, the relative proportion of red and blue chips within a bag. Because draws are independent, the overall diagnosticity of the evidence received across n trials thus far is a simple multiplicative function of the diagnosticity of a single draw.

To capture the fact that participants might (justifiedly) not consider the experimenter to be fully reliable, we likewise treat individual trials as independent, so that repeated draws correspond to repeated trials in the application of the model in Figure 2, which captures the believability of a single piece of testimony from one witness (Schum, 1981).

Arguably, this is not an *appropriate* model of what is going on in this task. All draws are coming from a single source and are ultimately neither random nor independent. However, the participant has no way of knowing what the purpose of the experiment is, and as a consequence, no way of knowing how the experimenter might be deviating from the model of independent random draws that the experimenter has explicitly set out. Consequently, the only model the participant arguably *can* establish if they are to engage in the task at all, is one of independent, random draws, in which experimenter distrust is captured simply through some additional, generic perturbation of those draws. This,

however, is readily captured through the repeated application of Eq. 2. Conceptually, the model of Figure 2 reflects, on the part of the participant, an inference to the chip that the experimenter would have drawn had he/she been drawing randomly from the bookbag. Once participants are assumed to treat the experimenter as a partially reliable source in this way, conservatism is unavoidable.

Unavoidable conservatism becomes apparent in the simulation of an idealized participant for a classic bookbag and pokerchip experiment. For these simulations, the prior probability of the bag containing predominantly red chips, $P(H_{red})$, was .5. In order to manipulate the diagnostic value of a single chip, the proportion of the predominant chips in any bag was either .6 or .7 (as in Phillips & Edwards, 1966, Experiment 1). To simulate belief revision on the basis of an imperfect information source, the sensitivity and specificity of the source, $P(E_{rep}|E)$ and $P(\neg E_{rep}|\neg E)$ were set to .6 (and thus the false positive rate $P(E_{rep}|\neg E)$ was .4). For the sake of simplicity, we only detail here the results of a simulation in which each of 10 draws from the bag (as reported by the experimenter) were red chips. The same general result, however, holds for sequences that also include some drawing of blue chips ($\neg E$). Belief revision occurs after each draw, with the prior probability of the hypothesis updated at each step.

Simulation of this model¹ produces not just basic conservatism, but also replicates the more specific findings of conservatism experiments. These are the findings that “conservatism increases as the diagnostic value of a single chip increases” and that “conservatism remains approximately constant as the diagnostic value of the sample increases” (Phillips & Edwards, 1966, p. 353). In other words, greater conservatism is observed for bags where the predominant color constitutes 70% of all chips than for those where it constitutes 60%. In order to facilitate comparison, we present results in terms of accuracy ratios as typical in conservatism research (as in Peterson & Miller, 1965; Peterson et al., 1964; Phillips & Edwards, 1966). The accuracy ratio is the ratio between participants inferred (and conservative) log likelihood ratio, and the ‘true’ log likelihood ratio corresponding to the task parameters as asserted by the experimenter. In our case, it is the ratio between the log likelihood ratio of the partially reliable and the fully reliable source. An accuracy ratio of less than 1 indicates conservatism (with smaller values indicating greater conservatism).

The results in Figure 3 clearly show that conservatism obtains regardless of bag composition, but that it is greater for the 70% bag, than for the 60% bag, in line with the experimental data of Phillips and Edwards. Finally, the accuracy ratios are constant across trials, in line with the experimental finding that conservatism remains approximately constant as the diagnostic value of the sample increases (Phillips & Edwards, 1966).

Figure 3: Accuracy ratios for a simulated participant who assumes that the experimenter is only partially reliable ($P(E/H) = .6$ and $P(\neg E/\neg H) = .6$). Different lines (.6 and .7) refer to bags of different composition (60% and 70% dominant chip color).

Finally, we note that there is nothing special about the specific values chosen here; these general relationships obtain across the range of meaningful values for source hit rate and false positive rate (i.e., wherever the hit rate exceeds the false positive rate).

General Discussion

In summary, the simple assumption that participants treat experimenters as partially reliable sources in classic conservatism studies generates, at least qualitatively, the main findings of such studies. It would be desirable in future work to not only model participant data exactly, but also to provide independent support for the source reliability account through experimental manipulation. For example, one might test whether conservatism vanishes if participants are allowed to make draws themselves, a methodological variant that has been found to reduce seeming base rate neglect (Gigerenzer, Hell & Blank, 1988).

In the meantime, these simulation results underscore why it cannot simply be assumed that participants take information presented to them by experimenters at face value. In the real world, most information sources are only partially reliable, and experimenters are no exception. Hence experimental demonstrations of conservatism do not necessarily indicate a gap between normative predictions and participants' responses – more conservative belief revision is the normatively appropriate response to less reliable evidence.

We are not suggesting that participants actively distrust or seek to undermine experimental materials. The tendency to treat experimental evidence as less than fully reliable is a mundane, default response to the experimental setting. Quite simply, participants know they are in an experiment, and do not necessarily (or automatically) assign as much weight to experimental evidence as they might in a non-laboratory situation. So, while participants in the classic ‘bookbag and poker chip’ experiments (Edwards, 1968) are unlikely to

¹ Model simulations were created using the GeNIe modeling environment developed by the Decision Systems Laboratory of the University of Pittsburgh (<http://dsl.sis.pitt.edu>).

have actively distrusted the experimenters, they are equally as unlikely to have treated the evidence as maximally reliable. Only when this possibility is either accurately modelled or empirically ruled out can the results of belief revision research fully be interpreted.

Abstract

The influence of expertise on viewing soccer matches is already an area of extensive research focusing on training. However, free viewing of soccer matches did receive less attention. In an explorative eye-tracking study we compared the viewing behavior of novices, amateur players, and professional players watching soccer scenes freely. Overall, novices seem to view a soccer match quite similar to professional players, whereas amateurs engage in more visual work. The viewing behavior differs when watching soccer freely or with a task in mind – a result worth a second glance.

Keywords: Soccer, viewing behavior, eye tracking, expertise

Introduction

Watching soccer without the corresponding experience and domain knowledge is a real challenge. Without knowledge about standard situations and tactical behavior, an unskilled observer is restricted to following the ball's trajectory mainly. On the other extreme, a good commentator is able to take in the whole scene at once and comment on the events and possible next moves. But what is it that enables an experienced soccer viewer to direct his or her attention more strategically and to take in more relevant information in comparison to an inexperienced one?

To answer this question, we review existing research on eye-movements in sports and their relation to expertise. We present a study that compares the television viewing behavior of soccer laypersons, amateurs, and professional players.

Eye-Movements in Watching Television

In general, viewing television is a complex activity (Josephson & Holmes, 2006): A huge amount of information has to be processed at a speed, which cannot be controlled by the viewer. Kirkorian (2007) assumes that watching television is nearest to perceiving scenes (e.g., Henderson, 2007). Both convey complex visual stimuli, but instead of viewing only one scene, television includes a series of static frames.

To examine visual information processing, *eye tracking* technology provides a means to observe a viewer's point-of-gaze (e.g., Rayner, 1998). In the past, eye tracking focused mainly on scene perception and reading under laboratory conditions (Henderson, 2007; Rayner, 1998); only in the last years, applications in more everyday settings (e.g., Hayhoe

& Ballard, 2005; Mayr, Knipfer, & Wessel, 2009) became possible with the emergence of more usable technology.

Central eye-movement measures are fixations and saccades. Saccades are shifts from one point of gaze to another; fixations indicate visual attention to that information (Rayner, 1998). In scene perception, top-down and bottom-up influences control where one looks (Henderson, 2007). Bottom-up influences are stimulus-driven, whereas top-down influences are viewer-driven.

Bottom-up influences are mainly based on the visual salience of the stimulus, i.e., color, saturation, and – which is especially important in television – movement (Mahapatra, Winkler, & Yen, 2008). Also, research on eye-movements during film watching shows that a high degree of the fixations is within the center of the screen (Goldstein, Woods, & Peli, 2007). An open question is whether this is due to a trend to fixate the center or due to movie making conventions placing the most relevant information in the center of the screen.

Top-down influences on the other hand are a viewer's knowledge about the stimulus, his or her domain knowledge, and his or her goals (Henderson, 2003). It was shown that expectations about camera angles, cuts and close-ups determine television viewing behavior (Kirkorian, 2007). These expectations are learned and, therefore, get stronger with viewing experience.

Another top-down influence is the viewer's domain knowledge. Chase and Simon (1973) showed that due to their higher knowledge on possible configurations experts in chess can easier create chunks of information. A similar mechanism can be assumed in soccer experts and was already shown to be influential (Ward & Williams, 2003).

A third top-down influence is the existence of specific goals. Only little research exists on humans watching television freely, i.e. without any task or instruction (see Goldstein et al., 2007, for an exception). However, Spanne (2006) showed that similar to viewing natural scenes (DeAngelus & Pelz, 2009) viewing behavior of movies differs according to the task at hand and in free viewing. But until now no research on free viewing behavior in soccer exists. Rather, most research asked players to anticipate the next move, recall the players' positions (e.g., Ward & Williams, 2003), or actively pass the ball (Helsen & Starkes, 1999).

As watching soccer for leisure purposes is a free viewing condition, it has to be questioned whether existing research

on the influence of expertise on watching soccer with a specific task holds under this condition as well.

Expertise in Soccer and Viewing Behavior

Research on eye-movements in sports focused on the sportsmen’s performance and how it relates to perceptual processes mainly (see Memmert, 2009, for a review). The aim of such research was on the one hand to train the sportsmen’s viewing behaviour and, thereby, to improve their performance; on the other hand, this research aimed at testing theories of expertise, perception, and attention under ecologically more valid conditions (Casanova, Oliveira, Williams, & Garganta, 2009).

In comparison to amateurs, professional soccer players can better use advance visual cues, they can better recall and recognize visual patterns, they engage in more effective search behaviour, and can better judge situational probabilities (Casanova et al., 2009). With respect to the viewing behaviour, experts have fewer fixations (Helsen & Starkes, 1999), but those last longer than the fixations of amateurs (Williams, 2000). It is assumed that during those longer fixations, experts take in information not only from central, but also from more peripheral areas (Casanova et al., 2009; Ghasemi, Momeni, Rezaee, & Gholami, 2009).

Informative visual cues in soccer are, next to the ball and the goal, the player’s teammates and opponents, but also free spaces. Amateurs fixate on the more obvious informative areas only (players, ball), whereas professional players fixate on more sophisticated informative areas like possible free spaces as well (Casanova et al., 2009).

In dependence of the player’s position, the number of players visible and the viewers’ tasks, different viewing patterns were observed (Poulter, Jackson, Wann, & Berry, 2005; Williams, Janelle, & Davids, 2003).

Pattern recognition is an important skill in watching games – especially in team sports, like soccer (Ward & Williams, 2003). Experts have a higher repertoire of patterns stored in their long-term memory and can more effectively retrieve appropriate patterns based on visual input (Casanova et al., 2009). Williams, Hodges, North, and Barton (2006) showed that the relation between players and the presence of key players are important features that facilitate pattern recall in soccer experts.

Research Questions

Based on the existing research on expertise in soccer, this study examines free viewing behavior while watching soccer without a concrete task. As prior studies compared only professional and amateur soccer players, we included a third less skilled group in our study: Novices, with little or no knowledge in soccer so far (like Poulter et al., 2005). In detail, we address the following research questions:

Do soccer laypersons, amateurs and professional players differ in their *soccer viewing behavior*? As reported in previous research (Casanova et al., 2009; Williams, 2000) we assume that professional players show less, but longer fixations than amateurs, and that they have better peripheral

perception. No hypothesis for novices can be build upon the existing knowledge base.

Do professional soccer players pay more attention to *informative regions* than amateurs? Casanova and colleagues (2009) report that amateurs do focus on less informative regions like the ball and the players. We therefore assume that professional soccer players do fixate more informative regions than amateurs. As the informative content of some visual cues has to be acquired with soccer domain knowledge (e.g., free kick), we hypothesize that novices to soccer do fixate only the most obvious informative regions, i.e. the ball, the player in possession of the ball, and the goal.

Are experts better at *anticipating* the next pass? Ward and Williams (2003) found that professional soccer players are better in predicting the next pass in 11 to 11 simulations. We assume that this superior predictive performance also coincides with fixations on the according player and that amateurs and novices do have less fixations in this area prior to the pass.

Method

The study was conducted in November 2009. Professional soccer players’ viewing behavior was recorded at the training camp of their Austrian first league soccer club Magna Wiener Neustadt. The viewing behavior of amateur soccer players and novices was recorded at the Austrian open research night at Danube University Krems.

Sample

The viewing behavior of 7 professional soccer players, 8 amateur soccer players, and 11 soccer novices was recorded. Three participants (1 amateur, 2 novices) with corneal irregularity and varifocals were excluded from further analyses, as there eye gaze data could not be recorded validly. An overall sample of 23 participants remained (see table 1).

The age distribution is similar in all three groups ($F_{2,22} = 1.43, p > .05$). Though more female participants were soccer novices, this difference reached no significance ($\chi^2 = 5.35, df = 2, p > .05$).

Table 1: Descriptive statistics.

	professionals	amateurs	novices
N	7	7	9
age	30.9 (5.4)	39.9 (9.6)	33.4 (12.8)
male	100 %	86 %	55 %

Material

Some studies on soccer expertise used recordings from a single camera which takes in the whole soccer field instead of television reports (Vaeyens, Lenoir, Philippaerts, & Williams, 2007; Williams et al., 2006). As our study focuses on watching soccer on television, we used original soccer reports from different not well-known games. We chose

four scenes with an overall duration of 3'43 mins: Scene 1 consists of a cascade of successful passes. Scene 2 is a free kick sequence. Scene 3 deals with a questionable offside decision. Scene 4 shows a quick offense over the whole field.

Measures

Eye movements were recorded using an SMI iView X™ RED eye tracker at a temporal resolution of 60 Hz. It tracks the corneal reflection of the pupils and allows relatively free movement of the head when seated approximately 60 cm from the tracking device. As it allows eye tracking with glasses and contact lenses, a wide range of participants could be included.

Expertise was assessed with multiple questions: whether participants' had experience in actively playing soccer in a club or not, how often they watched soccer on television (never, seldom, several times a year, several times a month), and how they evaluate their own soccer knowledge in comparison to a famous soccer player on a rating scale.

Participants who actively played soccer in a club, watched soccer more frequently by trend ($t = -1.98$, $df = 16$, $p < .1$) and had higher knowledge ($t = 3.12$, $df = 16$, $p < .01$). Therefore, a differentiation based on experience in playing soccer seems to be a valid measure of expertise.

Procedure

Each participant was tested individually. After an explanation on the purpose of the study, the functionality of the eye tracking device was explained to the participants. The device was calibrated using a five-point-calibration. Then the participants were instructed to watch the scenes freely, as they would usually watch soccer.

Participants viewed the soccer scenes on the 17" computer screen integrated in the eye tracking device. The experimenter was seated next to the participant with a control screen of the participant's gazes to intervene, if the gaze was lost by the eye tracking system (see figure 1).

After viewing the scenes, participants received some questions on demographic data and their soccer expertise.

Figure 1: Experiment setup at the training camp (left) and at the long research night (right).

Figure 2: Dynamic AOIs for two frames from the passing scene (top) and the free kick scene (bottom). Filled circles and ellipses denote the dynamic AOIs. The smaller bold rings represent the fixations of amateurs, novices (both red), and professional soccer players (blue, green).

Analyses

Eye tracking data were analyzed with BeGaze™ analysis software. We segmented the videos based on single scenes and extracted the fixations (number, duration) and saccades (number, amplitude).

To analyze the visual attention given to highly informative regions, the soccer scenes were coded in accordance to predefined Areas of Interest (AOIs) similar to Helsen and Starkes (1999), dependent on the scenes. In the following, two of four analyzed scenes are described in detail to exemplify the analysis procedure.

Scene 1 is shown from an overview perspective without close-ups. It consists of a cascade of successful passes for 33 seconds in the middle of the field. At least five players of the offending team and four players of the defending team can be seen. In this scene each player and the ball were coded as an AOI (see figure 2, top). To gain more information on peripheral perception of the ball's surrounding, we used 5 AOIs of different size with the ball at its center. The AOIs' radiuses grew approximately with the size of an average player. As a measure of anticipation, we coded the player who will be the recipient of the next pass as an AOI.

Scene 2 is a free kick sequence next to the goal (13 sec.), representing a typical standard situation in soccer. All players except for three of the offending team can be seen

(see figure 2, bottom). In this free kick situation, the viewers had approximately five seconds to follow the players' prearrangements before the free kick was carried out. The different roles were coded as individual AOIs; namely goalkeeper, referee, free kick shooter, the player next to the free kick shooter, and the bunch of players in front of the goal.

The ability to define dynamic AOIs allowed us to analyze eye movement parameters for each AOI automatically. The main measurements are the number of fixations per AOI, the glance time (where all saccades, including the entry and exit saccade, and all fixation times on an AOI are summed up), and the fixation duration in percent (fixation time in ms divided by the difference of end- and start-time).

Eye tracking data were exported and further analyzed in SPSS to examine differences between professional players, amateur players, and novices in soccer.

Results

Viewing Behavior

As a first indicator of viewing behavior we compared the fixations' number and average duration between the expertise groups across all scenes.

Overall and in contrast to our first assumption, the professional players did not make more fixations than the amateur players ($t = 0.65$, $df = 13$, $p > .05$). Still, as was assumed, their fixations endured longer ($t = -1.99$, $df = 13$, $p < .05$). Interestingly, novices' viewing behavior did not differ from professional players'. But they did make less fixation than the amateur players ($t = 2.37$, $df = 16$, $p < .05$).

Peripheral Perception

As stated earlier, the ball plays the decisive role in soccer and drives the game. Let us take a closer look at the ball and the space around it. As described in the analysis section, we analyzed areas of five different sizes around the ball. The AOI ball 1 equates an AOI with a radius of approximately the size of one player; ball 2 has the radius of two players and so forth.

While the smallest AOI around the ball showed no differences, amateurs differed from the professional players and novices for the bigger ones (see table 2). With increasing size of the AOI ball, professionals fixated this AOI less and had lower glance durations in this AOI. This is an indicator that they perceived the region surrounding the ball already with their central fixation in the nearer ball area; whereas amateurs had to fixate the outer areas as well to take in this information.

As for the overall viewing behavior, we found no remarkable differences between novices and professionals.

Seeking for Relevant Information

For the passing scene (scene 1), the AOIs of the offending and defending players were analyzed for a period of 15

seconds. This analysis offers some details about viewers' visual search patterns for relevant information.

Amateurs more often and longer fixated one player who had a rather longer ball possession time (*amateurs vs. professionals*: glance duration: $t = -2.86$, $df = 13$, $p < .05$; fixation count: $t = -2.98$, $df = 13$, $p < .01$; *novices vs. amateurs*: glance duration $t = -4.28$, $df = 16$, $p < .01$; fixation count. $t = -3.61$, $df = 16$, $p < .01$). One player who was an attractive alternative to pass to was fixated earlier by professionals than by novice viewers ($t = 4.58$, $df = 9$, $p < .01$). This attractive pass alternative had a defensive counterpart who covered him a bit later in the sequence. This defensive player turned out to be an interesting fixation object for professionals in contrast to amateurs (glance duration: $t = -2.63$, $df = 13$, $p < .05$; fixation count: $t = -2.32$, $df = 13$, $p < .05$) For professionals vs. novices a trend exists in the same direction.

As an indicator of anticipation, we also analyzed fixations to the player receiving the next pass prior to ball contact. No difference existed between participants of different expertise in the number of fixations and in their glance duration.

Knowledge-Driven Viewing

Scenes with an inactive ball provide more time for top-down, knowledge-driven processing of the scene. The beginning of scene 2, before the ball was shot, was therefore very interesting to analyze.

Table 2: Eye tracking performance matrix for AOIs of different sizes around the ball. The label of the group with higher values is plotted in case there is a trend. Asterisks denote significant differences.

higher for ...		novices or amateurs	novices or profess.	amateurs or profess.
ball 1	glance dur.	-	-	-
	fix. count	-	-	-

	fix. time %	amateurs	-	-

In the free kick sequence (scene 2), professional players fixated free regions (that is, regions without players) longer than amateurs ($t = -2.41$, $df = 13$, $p < .05$). Further, professionals more often fixated the player next to the free kick shooter ($t = -2.62$, $df = 13$, $p < .05$). Both, amateurs' glances (duration: $t = -2.31$, $df = 16$, $p < .05$) and professionals' (duration: $t = -2.21$, $df = 13$, $p < .05$), stayed longer in the area where most players were and where the ball will most likely be played to – in comparison to novices (see figure 2, bunch at the bottom). No significant differences were found between professionals, amateurs and novices in their viewing behavior on the goalkeeper, the free kick wall, the referee, and actions of single offensive or defensive players.

Discussion

Watching a soccer match freely is an everyday activity that is not connected to any task. Prior research on viewing behaviour during watching soccer was insofar restricted as participants were asked to answer questions, anticipate behaviour, or recall information (e.g., Ward & Williams, 2003). Human eye-movements in a free viewing condition of moving visual stimuli were recorded only seldom until now (Mayr et al., 2009; Spanne, 2006) and never for watching a soccer match. This study is the first to analyse the influence of expertise on viewing behaviour.

Still, some of the results which were gained under task conditions hold under free viewing as well: We observed longer fixations in professional than in amateur players like found in many other studies (Casanova et al., 2009, Williams, 2000). In addition, they exhibited higher peripheral perception skills like reported in prior research (Casanova et al., 2009; Ghasemi et al., 2009): Professional players fixate less often the wider area surrounding the ball compared to amateurs. Fewer fixations do not mean that professionals perceive less parts of the game but rather that they perceive more relevant visual cues with fewer fixations.

We assumed that professional soccer players pay more attention to informative regions. This top-down controlled viewing behaviour should increase with higher domain knowledge. Indeed, we ascertained that professional players fixated some informative regions (certain key players, free regions) which amateurs fixated only to a lesser extent. Other areas, like the bunch of players during the free-kick, were perceived by professional and amateur players to a similar extent. Due to our comparison with novices we could show that this perception is knowledge-driven as well.

In contrast to prior research, we observed some profound differences as well: Our assumption that professional players would anticipate the next pass visually is not supported by our participants' viewing behaviour. It remains to be studied whether this difference is due to the absence of an according task or due to the short duration of the analysed scene. Further analyses of longer sequences would be necessary to validate this finding.

In contrast to prior research (Casanova et al., 2009; Williams, 2000) we found no differences between the number of fixations by amateurs and professionals. As this visual indicator depends on the number of players displayed in a scene (see Vaeyens et al., 2007), a more differentiated analysis might reveal differences according to the proportion of the field displayed.

Prior research on *soccer expertise* compared only professionals with high and low performance (e.g., Vaeyens et al., 2007), professionals with amateurs (e.g., Ward & Williams, 2003), or people with high vs. low self-reported soccer knowledge (Dijksterhuis, Bos, van der Leij, & van Baarne, 2009). To our knowledge barely any research extended these boundaries of expertise so far to include also professional soccer observers (like referees, see Ghasemi et al., 2009, for an exception) or novices without any soccer knowledge (see Poulter et al., 2005, for an exception). Though the first gap remains to be filled, this study was able to shed some light on the viewing behaviour of novices:

In contrast to our assumption that novices would mainly focus on the ball (as the most obvious, and highly salient informative region) they watched similarly to professional soccer players. A possible explanation for this similarity could be that though they looked on the same region, they extracted different information.

Novices as well as professionals focused on the ball less time than the amateur players. This result raises the question, why amateurs do view a soccer match differently from professional players and novices? Maybe the amateurs were very motivated to compare their own gazes to those of professionals in comparison to the more carefree novices. They seemed to seek for as much information as possible, especially in regions of 8-10 meters around the ball. They also had a higher fixation dispersion than professionals and novices ($F_{2,21} = 3.34$, $p < .1$). Another explanation could be that the situation was not as goal-free as intended, because different learned viewing behaviors were activated: Professional soccer players frequently watch soccer matches to analyze their behavior for training purposes. Amateur soccer players in contrast watch the game not only to "read" it, but mainly to reach the soccer fan's "fever pitch".

Limitations

This study is limited by the artificial experimental setting of watching a match in front of a computer screen instead of a wide-screen television (cp. Josephson & Holmes, 2006). Even though nowadays soccer matches are often watched on youtube, a typical match-viewing situation is characterized by a stimulating, emotion-rich environment.

A second limitation of our results is the methodology used: Eye tracking methodology can only show the gaze focus, but not the focus of attention (e.g., Treisman, 2006). A triangulation with other methodologies would be necessary, but would restrict the free-viewing paradigm.

Further Research Questions

One of the main novelties in this study is the free viewing paradigm applied to watching soccer. It would be interesting – also in the sense of the limitations – to analyze free viewing in different environments (i.e., stadium, private TV, public viewing areas).

Qualitative analysis of the professional players' viewing behavior indicated differences between playing positions: Whereas goal keepers observed the behavior of the goal keepers to a higher extent, trainers scanned the soccer field more frequently. A more differentiated analysis of experts is needed (see also Casanova et al., 2009).

Further research should also compare passive sport experts, i.e. real viewing experts (e.g., referees – see Ghasemi et al., 2009) vs. couch potatoes, and active sport experts, i.e. professional vs. amateur players, in their viewing behavior.

Soccer is a male-biased sport – and so is research on it. With one exception (Poulter et al., 2005), no women were included in prior studies on soccer expertise. We would therefore like to encourage further research on female soccer players and their passive counterparts.

Acknowledgments

We are grateful for the willingness of the SC Magna Wiener Neustadt's players to participate in this study. Further thanks are given to the visitors at the "Lange Nacht der Forschung 09" (the Austrian open research night) for their interest and to ecoplus for supporting our travel expanses.

When Robot Gaze Helps Human Listeners: Attentional versus Intentional Account

Maria Staudte & Matthew W. Crocker

Department of Computational Linguistics

Saarland University

Saarbrücken, Germany

{masta, crocker}@coli.uni-saarland.de

Abstract

Previous research has shown that listeners exploit speaker gaze to objects in a shared scene to ground referring expressions, not only during human-human interaction, but also in human-robot interaction. This paper examines whether the benefits of such referential gaze cues are best explained by an attentional account, where gaze simply serves to direct the listeners visual attention to an object immediately prior to mention, or an intentional account, where speaker gaze is rather interpreted as revealing the referential intentions of the speaker. Two eye-tracking studies within a human-robot interaction setting are presented which suggest that close temporal synchronization of speaker gaze and utterance is not necessary to facilitate comprehension, while the order of gaze cues with respect to order of mentioned references is. We interpret this as evidence in favor of an intentional account.

Keywords: human-robot interaction; gaze; visual attention; referring expressions

Introduction

Gaze has been widely studied as an indicator for overt visual attention during language processing. Previous studies revealed that speakers look at entities shortly before mentioning them (Griffin & Bock, 2000; Meyer, Sleiderink, & Levelt, 1998), while listeners rapidly inspect objects as they are mentioned (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). This shows that gaze during situated language production and comprehension is tightly coupled with the unfolding speech stream, reflecting both speakers' intentions and listeners' understanding on-line. In face-to-face communication, the speaker's gaze to objects in a shared scene provides the listener with a visual cue to the speaker's focus of (visual) attention (Emery, 2000; Flom, Lee, & Muir, 2007). By revealing a speaker's focus of visual attention, such gaze cues potentially offer the listener valuable information to ground and disambiguate referring expressions, to hypothesize about the speaker's communicative intentions and goals and, thus, to facilitate comprehension (Hanna & Brennan, 2007).

In human-robot interaction, robot gaze that was synchronized with speech in a human-like manner has been shown to be similarly useful for grounding and resolving spoken references (Staudte & Crocker, 2009b). Further evidence supported the hypothesis that the utility of robot gaze originates from people's inferences of referential intentions from gaze (Staudte & Crocker, 2009a). However, it remained an open question whether such human-like synchronization of gaze and spoken references is necessary for gaze to be beneficial.

Firstly, we hypothesize that people indeed infer referential intentions from robot gaze cues. And secondly, we hypothe-

size that this assignment of *intentional* states makes the utility of gaze relatively flexible with respect to temporal synchronization. That is, despite a substantial shift of gaze cues with respect to corresponding speech cues, the conveyed intentions of the speaker may still facilitate utterance comprehension. If, in contrast, gaze is only a purely visual cue that happens to direct listeners' *visual attention* to an object which is then mentioned, we hypothesize that close temporal synchronization would be necessary for any benefit of gaze. We present evidence from two experiments supporting an intentional account of processing and interpreting robot gaze.

Does robot gaze reflect referential intentions?

In previous experiments, Staudte and Crocker (2009b) showed that people follow and use robot gaze, similar to human gaze, and faster resolve referring expressions in the robot's utterance only when the gaze cue identified the actually mentioned object. Two different explanations of this result are conceivable. The influence of robot gaze could possibly be explained in terms of a purely "bottom-up" process: Robot gaze draws attention to one object (cf. Langton et al., 2000, for reflexive orienting in response to gaze cues) and the utterance subsequently draws attention to the same (congruent) or another object (incongruent). Thus, incongruent gaze elicits an *additional* shift of visual attention before utterance comprehension is completed. This additional shift could simply add to the total time needed to comprehend and respond, thus, accounting for an increase in response times (we will refer to this as the *Visual Account*). However, the effect of robot gaze could also be explained in terms of a (mis)match in expectations (elicited by robot gaze) and the actual utterance. Previous studies on the interpretation of human gaze have revealed that gaze is an extremely versatile cue which reflects attentional states as well as mental states such as goals, desires and intentions (Baron-Cohen, 1995). We therefore hypothesized that people's use of robot gaze may also be driven "top-down", by the belief that robot gaze also reflects attentional and intentional states and, thus, reveals what the robot intends to mention (*Intentional Account*). That is, participants may have thought that the robot attended to one object because it intended to mention it and, therefore, an incongruent reference would have led to a revision in referential expectations which slowed people. In a follow-up experiment, participants were asked to correct false robot utterances and were free to decide which objects they mentioned in their cor-

rection sentence (Staudte & Crocker, 2009a). Participants' responses suggested that their understanding about what the robot had originally intended to say was indeed affected by its gaze.

Another way to potentially distinguish between Intentional and Visual Account is to consider the relevance of temporal synchronization of gaze and speech cues. Recent findings from a study on the influence of *indirect*, human speaker gaze on utterance comprehension suggest that there is only limited flexibility in the requirement of synchronization of such a gaze cue with speech, while maintaining its utility for the listener (Kreysa, 2009). Kreysa (2009) found that gaze cues with a small shift with respect to their natural temporal co-occurrence still facilitated task completion whereas a greater shift (by more than 2 sec) was no more beneficial than random cues. Interestingly, the importance of synchronization between gaze and speech may illuminate the nature of gaze influence. On the Visual Account, the influence of gaze is attributed to the induced attention shift towards the right object at the right time such that changes in the temporal synchronization of gaze and speech should clearly affect the utility of gaze. Under the Intentional Account, in contrast, people would interpret robot gaze with respect to the robot's intentional states such that synchronization would not be critical. Understanding someone's (referential) intentions should persist and influence utterance comprehension as long as they seem relevant.

While Kreysa's results (2009) suggest that the effect of human gaze cues on utterance comprehension is flexible to some extent, gaze cues used in her studies were indirect and not necessarily qualitatively equal with the direct perception of speaker gaze. Depending on how people perceive speaker gaze compared to Kreysa's cursor, two different behaviors in response to substantially shifted robot gaze is possible: Robot gaze may be similar to a gaze cursor, a *visual cue* that may (reflexively) direct attention and, thus, is only helpful for processing referring expressions when it occurs within a short time window around the spoken reference. A substantial shift of gaze relative to speech would result in longer response times than the original synchronization. Alternatively, speakers' looks towards an object may be perceived as more *intentional* than a gaze cursor and as more robustly assigning relevance to the object in focus (similar to human gaze). Participants may persistently maintain and use this information when it seems relevant, leading to equal response time for shifted and synchronized gaze. Equally, non-congruent gaze cues may thus – even when shifted to precede the utterance – disrupt comprehension and cause slower response times.

We present results from two experiments which suggest that the utility of gaze is *not only* a matter of attention cueing to the right object at the right time. Rather people seem to interpret robot gaze as an indicator to the robot's referential intentions, leading to a persistent influence of gaze.

Original

Reverse

Sync: <c>"The pink pyramid is shorter than <p> the cylinder."
Prec: <c><p>"The pink pyramid is shorter than the cylinder."

Figure 1: Sample scene from experiments, with original/reversed sentences and synchronized/preceding robot gaze (first at cylinder (<c>), then at pyramid (<p>)).

Experiment 1

In this study, we investigated whether referential robot gaze needs to be temporally synchronized with speech (in the way human gaze is synchronized) in order to be beneficial, or whether robot gaze conveys referential intentions that have a more persistent effect on utterance comprehension. Thus, we manipulated synchronization in two ways. While robot gaze was always directed to the mentioned objects, we manipulated the factor Order of Mention (sequence of mentioned objects crossed with sequence of 'gazed at' objects) which led to original (coherent) or reverse order of references (see Figure 1). The second factor, Synchronization, manipulated the temporal delay between gaze/visual references and corresponding linguistic references.

Method

Participants Thirty-two native speakers of German, mainly students enrolled at Saarland University, took part in this study (26 females). All participants reported normal or corrected-to-normal vision.

Materials We created 1920x1080 resolution video-clips showing a PeopleBot robot (kindly provided by the CogX-project, <http://cogx.eu>) onto which a pan-tilt unit was mounted. This pan-tilt unit carried a stereo camera which appeared as the head and eyes of the robot. The video-clips each showed a sequence of camera-movements consecutively towards the central object and then the peripherally located object. The utterance was a synthesized German sentence using the Mary TTS system (Schroeder & Trouvain, 2001).

In these videos we manipulated two factors: Order of Mention (original, reverse) and Synchronization (synchronized, preceding), so each item appeared in four conditions. The temporal delay between gaze and speech was roughly 5.3 seconds in the preceding condition and 1 second in the syn-

chronized condition. A sample scene is given in Figure 1 as well as examples for each type of sentence order and robot gaze synchronization. In condition original-synchronized, gaze and speech cues were coherent and synchronized in a human-like manner while the condition reverse-synchronized showed cues that were concurrent but reverse to each other.

Eight lists of stimuli were created, accounting for four experimental conditions and their counter-balanced versions. In addition to 24 items, 36 fillers were shown such that participants saw a total of 60 trials. The order of item trials was randomized for each participant individually and items were always separated by at least one filler.

Procedure An EyeLink II head-mounted eye-tracker monitored participants' eye movements on a 24-inch monitor. Before the experiment, participants received written instructions about the experiment procedure and task: They were asked to attend to the presented videos and judge whether or not the robot's statement in each was valid with respect to the scene. In order to provide a cover story for this task, participants were further told that the results were used as feedback in a machine learning procedure for the robot.

Analysis Videos were segmented into Interest Areas (IAs). That is, each video contained a region labeled "NP2 referent" which marked the object mentioned last in the robot utterance (i.e., before sentence validation was possible). Further, we recorded and analyzed participant fixations on this area. The speech stream was segmented into two Interest Periods (IPs). IP1 was defined as the 1000ms period ending at the onset of the second noun (in NP2). Importantly, it contained the robot's gaze towards the target object as well as verbal content preceding the target noun. IP2 was defined as the 700ms period beginning with noun onset in NP2. These IPs roughly segmented the sentences as follows: "*The cylinder is taller [than the pink]IP1 [pyramid]IP2*". Defining IP1 and IP2 in this way made it possible to distinguish once again between gaze-mediated inspections in IP1 and utterance-mediated inspections in IP2. Trials that contained at least one *beginning* inspection towards an IA within an IP (coded as "1") were contrasted with trials that did not contain an inspection in the same slot ("0"). As a result, mean values represent inspection probabilities for a given IA and IP. For inferential analyses, we considered inspections on the NP2 referent as well as response time, recorded from NP2-noun onset to the moment of the button press. The analyses were carried out using mixed-effect models from the lme4 package in R and Chi-Square tests to assess the contribution of a predictor through model reduction (Baayen, Davidson, & Bates, 2008; Bates, 2005).

Results

Eye movements Mean inspection probabilities for the NP2 referent are depicted in Figure 2. Note, that the manipulation of Order of Mention coincided with a difference in location of the NP2 referent. That is, in original order, the NP2 referent is located in the periphery of the table (pink pyramid), while in

reverse order it is located in the center of the scene (cylinder), as depicted in Figure 1. Results from inferential statistics on inspection data are reported in-text where necessary and are otherwise omitted due to space limitations.

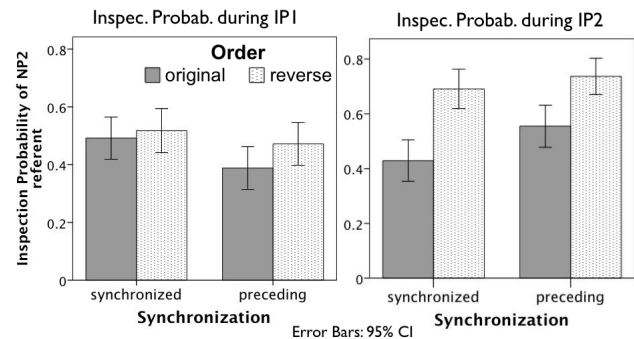

Figure 2: Inspection probability of NP2 referent in Exp1, for all conditions in IP1 (left graph) and IP2 (right graph).

In IP1, model reduction revealed a main effect of Synchronization on inspections on the NP2 referent ($\chi^2(1) = 4.03, p < .05$). People inspected the NP2 referent with lower probability when robot gaze preceded the utterance. Moreover, we did not observe a main effect for Order of Mention, i.e., people inspected the NP2 referent equally often irrespective of where this referent was located (centrally, peripherally) or whether the robot concurrently fixated this object. Interestingly, people were equally likely to inspect the NP2 referent in condition original-synchronized (when robot gaze identifies the actual NP2 referent) as in condition reverse-synchronized (when gaze does not). This result indicates that people may use the already mentioned reference (NP1) and the available visual cues to, at least *visually*, anticipate the NP2 referent even when cues were reversed.

In IP2, we observed a somewhat different inspection pattern. Order of Mention had a main effect on inspection probability ($\chi^2(1) = 35.67, p < .001$) such that participants inspected the (mentioned) NP2 referent significantly more often in the reverse condition than in the original (coherent) order condition. That is, when the robot fixated the peripheral object during IP1 and then mentioned the other, central object in IP2 (<central cylinder>"The pink pyramid is taller than <periph. pyramid> the cylinder.") participants were more likely to inspect the object mentioned in NP2 (centrally located cylinder) than in original order.

There are two possible explanations for these high probabilities of inspecting the NP2 referent in reverse order: Either participants inspected this central object more often because it was more salient due to its central location, predicting easy and quick reference resolution. Alternatively, the increased inspections on the NP2 referent in reverse condition reflect difficulty to resolve the reference as it includes conflicting information (gaze identified the pyramid while the mentioned noun referred to the cylinder). Thus, the response time results should reveal which of the two explanations is more likely.

Response Time Model reduction showed that Synchronization had no effect on response times. That is, participants were equally fast to determine the validity of the robot statement in synchronized and preceding conditions. Since no interaction between the two factors Synchronization and Order of Mention was observed, we excluded Synchronization as a predictor from our linear mixed-effects model. Model reduction further revealed a main effect of Order of Mention ($\chi^2(1) = 45.19, p < .001$, see also Figure 3 for averages).

Figure 3: Avg. response times in all four conditions (Exp1).

The finding that Synchronization did not affect response time while Order of Mention did, cannot be explained by the Visual Account since both manipulations made robot gaze direct people’s visual attention to relevant objects at non-synchronized points in time – and always prior to the last referring expression (NP2). Instead, the Intentional Account seems to provide more appropriate explanations for these results: The precise temporal synchronization is not crucial for people to interpret and use robot gaze as a cue to the robot’s intentions. The inferred (referential) intentions, however, are expected to be executed in the *same order* as they were indicated by robot gaze. Thus, reversed order, even in the case of preceding gaze, slows people in utterance comprehension.

Discussion

By manipulating the order of references in the sentence, the location of the NP2 referent was effectively also manipulated. Since the center of the scene is the most salient area, this may have affected the effort needed to resolve a referring expression which identified the central object compared to one that identified an object in the periphery of the scene. Since in the reverse order condition, NP2 identifies the central object, this appears to benefit reference resolution given that the central object is most salient. However, response time results revealed that people were in fact *slower* in reverse order to judge sentence validity, compared to original order. This effect of Order of Mention suggests that reverse order was indeed more difficult to process than originally ordered cues, supporting the interpretation that people’s increased inspections on the NP2 referent reflected *increased effort* to resolve the reference (due to conflicting information).

Experiment 2

In this experiment we further investigated whether the order of referring expressions in the robot utterance (accompanied only by neutral gaze) affects how fast people resolve these expressions and validate the utterance. Original and reverse sentence order were, thus, paired with neutral robot gaze and compared. This baseline condition showing neutral gaze allowed us not only to determine any effects of sentence order itself, but also to assess the actual benefit of original order versus a potentially disruptive effect of reversed gaze and speech cues. Since the temporal shift between synchronized and preceding condition did not affect people’s responses, we did not include a preceding gaze condition again. We manipulated Order of Mention (*original, reverse*) and Synchronization (*synchronized, neutral*).

Synchronized robot gaze was again always directed first to the central object and then to the peripheral object. Using the sample sentence from the previous experiment “The orange cylinder is taller than the pink pyramid”, the robot would first look at the cylinder and then to the peripherally located pyramid. The neutral gaze condition showed an initial glance down at the scene before the robot looked straight ahead and began to speak. We included an additional adjective for the central object (the “orange cylinder”) in order to make sentences completely symmetric in both sentence orders. This symmetry also allowed us to change the onset for response time recordings from NP2-noun onset to NP2-adjective onset. Since the adjective already uniquely identifies the referent this most appropriately captures actual response time. Otherwise sentences and scenes were similar to the material used in Experiment 1.

Method

Participants & Procedure Thirty-two native speakers of German and mostly students at Saarland University took part in this study (21 females). All reported normal or corrected-to-normal vision. Task and Procedure were identical to Experiment 1.

Materials The manipulation of Order of Mention (original, reverse) and Synchronization (synchronized, neutral) resulted in four conditions. A set of 20 items was used as well as a set of 32 fillers which were evenly distributed across conditions. Participants therefore saw a total of 52 trials.

Analysis IAs used in this experiment were identical to those in Experiment 1. IP1 was again defined to begin 1,000ms prior to noun onset (in NP2). However, in this experiment IP1 did not stretch to noun onset but already ended with *adjective onset*. Thus, IP1 had no fixed duration but an average length of 600ms. This shortening of IP1 was done to incorporate the fact that the prenominal adjective already uniquely identified the referent. Consequently, IP2 was defined to stretch from adjective onset to 700ms after noun onset and had a mean duration of 1,100ms. Thus, sentences were segmented as follows: “The cylinder is taller [than the]_{IP1}

[pink pyramid]_{IP2}”. Defining IP1 and IP2 in this way made it possible to distinguish once again between gaze-mediated inspections in IP1 (before the linguistic reference in NP2) and utterance-mediated inspections in IP2 (taking into account that the color adjective linguistically identifies the NP2 referent). Moreover, response time was defined to begin with NP2-*adjective onset* instead of the previously used noun onset for the same reason, that is, accounting for the nominal adjective as already identifying the final referent.

Results

Eye movements Mean probabilities for inspecting the NP2 referent are given in Figure 4. In IP1, both Order of Mention and Synchronization had main effects on inspection behavior (Synchronization: $\chi^2(1) = 5.83, p < .05$ and Order of Mention: $\chi^2(1) = 24.90, p < .001$). Participants generally inspected the NP2 referent more frequently when gaze was synchronized than when it was neutral. Moreover, model reduction revealed a significant interaction of the two predictors Order of Mention and Synchronization ($\chi^2(1) = 14.08, p < .001$). That is, the effect of Order of Mention varied depending on the Synchronization: Firstly, the neutral gaze condition reveals that Order of Mention by itself affected people’s visual attention. In the reverse-neutral condition the NP2 referent was inspected significantly more often than in original-neutral. We argue that this effect is due to the NP2 referent being central and being additionally highlighted as the robot initially looked downwards. Secondly, the graph also reveals that the peripherally located object (NP2 referent in original order) was inspected more often when gaze was synchronized (original-synchronized) than when it was neutral (original-neutral), suggesting that a gaze cue in original (coherent) order helped people to visually anticipate the NP2 referent. In contrast, gaze cues in reverse order did not affect the inspections on the NP2 referent (central object) compared to reverse-neutral. Instead, the NP2 referent was rather frequently inspected in reverse order even when robot gaze was neutral throughout the utterance. This indicates that the central object was indeed more salient than the peripheral object.

Figure 4: Inspection probability on NP2 referent in Exp2, for all conditions in IP1 (left graph) and IP2 (right graph).

In IP2, Order of Mention had a main effect on inspection probabilities ($\chi^2(1) = 51.99, p < .001$). That is, during NP2

noun mentioning, people inspected the NP2 referent more frequently in reverse order than in original order. As in Experiment 1, this suggests that people visually attended more closely to the mentioned object when the referring expression required more effort to be resolved.

Response Time Model reduction revealed a significant interaction of both predictors, Order of Mention and Synchronization ($\chi^2(1) = 16.85, p < .001$). Consequently, both predictors were included in the model fitted to response times. This model is specified by our dependent variable response time, the two predictors Order and Synchronization, and two random factors accounting for subject and item variation ($DV \sim Predictor1 \times Predictor2 + randomFactors$, see also Table 1). Both factors had a marginal main effect, however, the interaction is clearly more relevant for interpretation as is explained below. Firstly, pairwise comparisons reveal the following significant differences: Between reverse-neutral and reverse-synchronized ($p < .001$), reverse-synchronized and original-synchronized ($p < .05$), reverse-neutral and original-neutral ($p < .001$) and a marginally significant difference between original-synchronized and original-neutral ($p = .07$). These results suggest that order of references in a sentence indeed affected participant behavior, as already suggested by the inspection data in IP1. The response times in both neutral conditions show that people were significantly faster to validate the robot’s utterance in the reverse-neutral condition than in original-neutral. This result is consistent with the findings of visual anticipation of the NP2 referent (for neutral gaze), i.e., when order was reversed people anticipated the NP2 referent, when order was original they hardly did. This suggests that reverse order of mention was generally *easier* to process than original order of mention. However, synchronization of gaze cues reversed this effect: Participants were significantly slower when gaze was synchronized and in reverse order (resulting in concurrent but conflicting referential cues) than when gaze was synchronized and in original order (concurrent and coherent order of cues).¹

¹The response time pattern in Experiment 2 was largely independent of the chosen onset. That is, results were qualitatively equal for starting recording at NP2-adjective onset or at NP2-noun onset.

Figure 5: Avg. response times in all four conditions (Exp2).

Table 1: Model fitted to response time data. The last column shows p-Values calculated through Monte-Carlo-sampling.

Predictor	Coeff.	SE	t-value	pMCMC
(Intercept)	1475.79	55.19	26.741	<.001
Order-reverse	96.24	40.36	2.384	<.05
Synchr.-neutral	68.89	39.60	1.740	.075
reverse.:neutral	-230.67	55.94	-4.124	<.001

Model : $RT \sim \text{Order of Mention} \times \text{Synchronization}$
 $+ (1|\text{subject}) + (1|\text{item})$

Discussion and Conclusion

Results from Experiment 1 suggest that gaze cues are equally beneficial when preceding the spoken references as when they occur concurrently. However, the interpretation with regard to the influence of cue ordering was difficult as the manipulation of order was potentially confounded with the sentence order (i.e., referent location in the scene). This was addressed by adding a neutral gaze condition in Experiment 2 which revealed that reverse sentence order was *easier* to process than original sentence order. Thus, despite the advantage of reverse sentence order, synchronizing (reverse) robot gaze cues disrupted people whereas adding original (and coherently) ordered gaze cues to original sentence order significantly enhanced response time of this sentence order. The results for synchronized robot gaze may therefore be interpreted with respect to gaze and speech cue synchronization only: Synchronizing (reversed) gaze cue with reverse order of mention *increased* response times, while synchronizing (coherent) gaze cues with original order of mention *reduced* response times, when each is compared to its neutral gaze baseline.

The presented results thus suggest that large temporal shifts of robot gaze with respect to its 'natural' synchronization do not substantially affect the utility of the gaze cues whereas the order of the cues does. This contradicts the predictions derived from the Visual Account. The Intentional Account, in contrast, provides a plausible explanation for these results: The precise temporal synchronization is not critical since people interpret and use robot gaze as a cue to the robot's intentions. This may also explain why Kreysa (2009) found that substantial temporal shifts reduce the gaze cursor's utility while robot gaze and speech synchronization, in contrast, appears rather flexible. The order of cues, however, affects the utility of robot gaze since the order of inspections reflects the speaker's intentions regarding order of mention. Thus, people seem to expect that the inferred referential intentions be realized in the corresponding order (Griffin & Bock, 2000). If this expectation is not met, gaze cues may even disrupt comprehension, as the comparison with neutral gaze suggests. Consequently, the presented evidence for a flexible use of robot gaze during utterance comprehension further supports the hypothesis that people assign attentional and intentional states to the robot. Thus, future research could use such a robot interaction setting to generally address ques-

tions such as the extent to which people infer intentions or other information from their partner's gaze. While it is not entirely clear whether robots and agents provide an unrestricted experimental test bed such that results generalize to human-human interaction, our results, among others (Breazeal, Kidd, Thomaz, Hoffman, & Berlin, 2005), suggest that people do establish basic joint attention also with robots (or artificial agents in general). However, this phenomenon is likely to depend on people's beliefs in the agent's competence or appearance, in particular, when signaling information processes and functionalities different from those of a human.

Abstract

An important aspect of human sociality is our ability to understand the actions of others as being goal-directed. Recently, the now classic rational approach to explaining this ability has been given a formal incarnation in the Bayesian Inverse Planning (BIP) model of Baker, Saxe, and Tenenbaum (2009). The BIP model enjoys considerable empirical support when tested on ‘toy domains’. Yet, like many Bayesian models of cognition, it faces the charge of computational intractability: i.e., the computations that the model postulates may be too resource demanding for the model to be scalable to domains of real-world complexity. In this paper, we investigate ways in which the BIP model can possibly parry the charge. We will show that there are specific conditions under which the computations postulated by the model are tractable, despite the model being rational and Bayesian.

Keywords: goal inference, inverse planning, computational complexity, intractability, NP-hard, fixed-parameter tractability

Introduction

Imagine a mother and her son, sitting in the same room, when she hears his stomach rumble. She sees her son get up, walk to the kitchen and start searching for something. At first he finds a sour apple, which he discards in search of something else. Then the mother sees her son finding a delicious candy bar. When he starts to eat it she realizes her son is trying to still his hunger and at the same time wanting to eat something sweet. In this scenario, the son goes through a process of *planning*, choosing his actions to achieve his goals. The mother observes the actions of her son and based on her observations infers the goals she thinks her son is trying to achieve. This process is called *goal inference*.

In line with a long tradition of explaining the human ability to understand actions as goal-oriented (Dennett, 1987; Charniak & Goldman, 1991; Csibra, Gergely, Biró, Koós, & Brockbank, 1999; Cuijpers, Schie, Koppen, Ernhagen, & Bekkering, 2006), Baker, Saxe, and Tenenbaum (2009) have proposed that goal inference can be seen as a form of *inverse planning*, just as vision is a form of inverse graphics. Baker et al. go beyond existing psychological approaches by providing a precise formalization of ‘inverse planning’ in the form of a Bayesian inference model. We will refer to this model as the BIP model of goal inference (where BIP stands for Bayesian Inverse Planning). The BIP model has been tested in several experiments, and Baker et al. (2007, 2009) observed that it can account for the dynamics of goal inferences made by human participants in several different experimental settings.

According to the BIP model, observers assume that actors are ‘rational’ in the sense that they tend to adopt those actions

that best achieve their goals. Given the assumption of rationality, and (probabilistic) knowledge of the world and how actions are affected by it, one can compute the probability that an agent performs an action given its goals, denoted

$$P(\text{action} \mid \text{goal}, \text{environment}) \quad (1)$$

When observing a given action, the probability in (1) can be inverted using Bayes’ rule to compute the probability of a given goal:

$$P(\text{goal} \mid \text{action}, \text{environment}) \propto$$

$$P(\text{action} \mid \text{goal}, \text{environment}) P(\text{goal} \mid \text{environment}) \quad (2)$$

Of all the possible goals that an observer can (or does) entertain, the goal that maximizes the probability in (2) best explains why the observed action was performed and is the goal that is inferred.¹

Given that the BIP model belongs to the class of (rational) Bayesian inference models—and Bayesian inference is known to be intractable if no additional constraints are imposed (e.g. Chater, Tenenbaum, and Yuille (2006); see also Kwisthout (2009))—the question arises if the computations that it postulates can scale to situations of everyday complexity. As Gigerenzer and colleagues put it:

The computations postulated by a model of cognition need to be tractable in the real world in which people live, not only in the small world of an experiment with only a few cues. This eliminates NP-hard models that lead to computational explosion, such as probabilistic inference using Bayesian belief networks ... including its approximations. (Gigerenzer, Hoffrage, and Goldstein (2008) p. 236)

Although we share the stance of Gigerenzer et al. (2008) towards intractable (NP-hard) models of cognition, we are not as pessimistic about the viability of Bayesian models. In our view, the key to understanding the computational feasibility of a Bayesian (or any cognitive) model lies in studying domain-specific constraints that hold in the model’s domain of application (e.g., action understanding or vision) and investigating if and how such constraints may render the computations postulated by the model tractable for its domain,

¹In other words, in the BIP model, goal inference is conceptualized as a form of probabilistic inference to the best explanation, a.k.a. *abduction* (e.g. Charniak and Shimony (1990)).

despite the intractability of those computations in general. In this paper we set out to perform such an investigation for the BIP model of goal inference.²

The remainder of this paper is organized as follows. We first introduce specific versions of the BIP model that Baker et al. (2007, 2009) formulated to account for their experimental data and observe that these versions are tractable but also too specific. We then propose a generalized model that breaks some implausible constraints in the original models. After this we introduce a method that we use to analyze the computational (in)tractability of the generalized model. We then give an overview of the (in)tractability results, and discuss their implications for Bayesian models of goal inference and for dealing with the intractability of Bayesian models in general.

Computational Models

Baker et al. (2009) propose three different versions of Bayesian Inverse Planning (M1, M2 and M3) to account for data gathered in several maze experiments. These two-dimensional maze experiments, based on earlier work (Gergely, Nádasdy, Csibra, & Biró, 1995; Schultz et al., 2003), were designed to assess subjects' inferences about the goals of a planning agent. Subjects were shown videos of agents moving in a maze, such as those in Fig. 1, and under different timing and information conditions had to infer the goal of the agent. In these experiments *changes in location* were considered *actions* and the *location* of the agent is considered its *state*. Specific locations (A, B and C) were possible *goals*.

All three models M1–3 can be seen as special cases of a more general BIP model, as depicted in Fig. 2, in which there is a goal structure template **G** that can encode different types of goal structures.³ The simplest goal structure is present in M1 where the observer assumes that the agent has one single goal that does not change over time (Fig. 3(a)). In M2 the model allows the observer to infer the agent has a different goal at any given time (Fig. 3(b)). This models the ability of people to infer changes in an agent's goal over time. For instance, if someone is inspecting the contents of her fridge, you may infer she wishes to cook dinner, but when she closes the fridge, puts on her coat, and leaves the house, you may

²The authors are well aware of common claims of approximability of Bayesian inferences, and that approximation is generally believed to provide a way to overcome the intractability of Bayesian models. In this paper, we will depart from this standard viewpoint for two reasons. First, the claims of approximability seem at worst incorrect and at best unfounded; for instance it is known that approximating the most probable explanation in a Bayesian network is itself also intractable (Abdelbar & Hedetniemi, 1998). Second, we believe that there are other, better ways of dealing with the intractability of cognitive models, viz., by identifying model constraints that render otherwise intractable models tractable (van Rooij, 2008).

³In the original BIP models (M1, M2 and M3) Baker et al. used additional parameters to model the effect of noise (β), the probability of changing a goal in M2 (γ) and the probability of having sub-goals in M3 (κ) to fit the model to the experimental data. As these parameters are assumed constants, they can be safely ignored for the purposes of our analyses.

Figure 1: An illustration of the types of stimuli used in the maze experiments of Baker et al. (2009). Participants observe an agent (and the trail history as memory aid) move inside the maze, and are asked to judge which of the three possible goals (A, B or C) is most likely the agent's goal. Here (a) depicts an early judgement point where both human participants and the model infer B as most likely goal. (b) depicts a later judgment point where both human participants and the model infer A as most likely goal. (c) A possible BIP model (in this case M1) for the early judgement point.

infer she is going to eat out. Finally, in M3 the goal structure encodes hierarchical goals (Fig. 3(c)), such that the observer can infer changes in the agent's sub-goals, which are subserving a common high-level goal. For instance, when you see someone gathering kitchen utensils, each individual gathering can be a sub-goal but the high-level goal is to cook dinner.

Even though inference in Bayesian networks is hard in general, the BIP models proposed by Baker et al. are tractable.⁴ This tractability is in some sense an artifact of the simplified experiments for which these models were designed. In the experiments an agent never has more than one (high-level) goal at any given time. This property does not seem to hold in general, however. Reconsider, for instance, the scenario in our opening paragraph. There the mother infers that the son wants to satisfy his hunger *and* he wants to eat something sweet. This type of goal inference where multiple goals are inferred at the same time cannot be modelled by M1, M2 or M3. To accommodate for this observation, we propose an extension called MULTIPLE GOALS BIP or MGBIP. Fig. 4

⁴For the formal proof of these claims we refer the reader to the Supplementary materials available online at <http://tinyurl.com/suppl2010>

Figure 2: A graphical representation of the dynamic Bayesian network that describes the general form of BIP. Nodes represent variables, for example state node S_t is a variable and it can assume values corresponding to the state of the agent at time t . Arrows represent dependencies, for example the probability that a state S_{t+1} has a certain value depends on the previous state S_t and previous action A_t . States and actions are observed, i.e. the values of the states and action variables are given as input to the model. Given these observations the most probable combination of values for the goal variables in G . Finally, shaded nodes are observed and their values considered part of the input of the model. Examples of the possible contents of G are illustrated in Fig. 3

illustrates the dynamic Bayesian network of MGBIP.⁵

Because it is more general, MGBIP has wider range of applicability than M1–3. The introduced generality also comes at a cost: Whereas M1, M2 and M3 are tractable, MGBIP is intractable, in the sense that there are no tractable (more precisely: polynomial time) algorithms that can implement this model.⁴ Even so, in real-world situations humans are often able to quickly infer an agent is pursuing multiple simultaneous goals. This suggests that, if MGBIP is to be psychologically plausible, we need to assume that some domain-specific constraints apply in those situations that render the goal inferences tractable under the MGBIP model (despite the model being intractable without such additional constraints). The next section describes how we set out to identify such possible constraints.

Identifying Sources of Intractability

In order to find constraints on the input domain of MGBIP that render the (restricted) model tractable, we adopt a method for identifying sources of intractability as described in (van Rooij, Evans, Müller, Gedge, & Wareham, 2008) (see also van Rooij and Wareham (2008)). The method works as follows.

⁵Baker et al. (2009) also note, that the simplified models M1–3 unlikely suffice to model human action understanding in general and they argue that the models will need to be extended in various directions if they are to apply to real-world scenarios. Our extension can be seen as one such possible direction in which to extend the model. Other directions of extension are possible as well (see e.g. (Ullman, Baker, Macindoe, Goodman, & Tenenbaum, 2009)).

(a) M1

(b) M2

(c) M3

Figure 3: Graphical representation of G for M1, M2 and M3. In M1 (a) goals are modeled by a single static goal. All actions are dependent on this goal. In M2 (b) goals can change over time. Actions at time t are dependent on goals at time t . In M3 (c) goals can consist of multiple subgoals. Actions at time t are dependent on subgoals at time t .

First, one identifies a set of model parameters $K = \{k_1, k_2, \dots, k_m\}$ in the model M under study (for us, MGBIP). Then one tests if it is possible to solve M in a time that can grow excessively fast (more precisely: exponential or worse) as a function of the elements in K yet slowly (polynomial) in the size of the input.⁶ If this is the case, then M is said to be *fixed-parameter (fp-) tractable* for parameter set K , and otherwise it is said to be *fp-intractable* for K .

Observe that if a parameter set K is found for which M is fp-tractable then the problem M can be solved quite efficiently, even for large inputs, provided only that the members

⁶More formally, this would be a time on the order of $f(k_1, k_2, \dots, k_m)n^c$, where f is an arbitrary computable function, n is a measure of the overall input size, and c is a constant.

Figure 4: Graphical representation of the dynamic Bayesian network that describes MULTIPLE GOALS BIP (MGBIP).

of K are relatively small. In this sense the “unbounded” nature of K can be seen as a reason for the intractability of M . Therefore we call K a *source of intractability* of M .

The MGBIP model has several natural parameters, each of them a candidate source of intractability. In this paper we consider, five such parameters (see Table 1 for an overview and Fig. 5 for an illustration).

First consider parameters T , denoting the maximum number of observations the observer makes, and $1/T$, denoting the poverty of observations. Note that T is small if few observations are made, and $1/T$ is small if many observations are made. Based on intuition one might think, the less information we have, the harder it is to understand actions. This makes $1/T$ a candidate source of intractability. However as T grows, so does the size of the network and the necessary number of calculations and this also makes T a likely candidate source of intractability.

Second, parameter k is the maximum number of multiple goals that (the observer assumes) the agent can pursue. This parameter is also an excellent candidate source of intractability, because large k ’s introduce an exponential number of combinations of possible multiple goals leading to a combinatorial explosion.

Third, the parameter g is the maximum number of goal values per goal variable. As the number of possible values that a goal variable can take increases the necessary number of calculations, also g is a candidate source of intractability.

Finally, the parameter $1 - p$ measures how far the most likely goal inference is from being completely certain (here p is the probability of the most likely explanation). If $1 - p$ is small, this means that the most likely explanation is much more likely than any competitor explanation. If the value is large, it means that the most likely explanation has many competitor explanations of non-negligible probability (see e.g. Table 2). It seems intuitive that finding the most likely explanation is easier in the former case than in the latter case, and therefore also $1 - p$ can be considered a candidate source of intractability.

Table 1: A list of parameters with short descriptions and their values based on the running example.

parameter	description	value
T	maximum observations	6
$1/T$	maximum observation poverty	$1/6$
k	maximum # multiple goals	2
g	maximum # goal values	3
$1 - p$	distance from certainty	0.4

Figure 5: Illustration of the Bayesian network and different parameters of the MGBIP model applied to the “mother observes son”-example.

Table 2: Example probability distribution over the combinations of goal values. In this example $p = 0.6$ and $1 - p = 0.4$.

satisfy hunger	desire sweet	P
big hunger	yes	0.05
medium hunger	yes	0.05
little hunger	yes	0.6
big hunger	no	0.3
medium hunger	no	0.0
little hunger	no	0.0

We have now reviewed five parameters that—on intuitive grounds—may be considered candidate sources of intractability in the MGBIP model. It is known, however, that human intuitions about what makes a computation tractable or intractable can be mistaken. Therefore it is necessary to verify such intuitions by means of mathematical proof.

Results

In this section we present our fp-(in)tractability results for the different parameters of the MGBIP model, and we explain how these results bear on the question ‘which constraints render the MGBIP model tractable?’. Full details and proofs can

be found in the Supplementary materials.⁷

Result 1. MGBIP is fp-intractable for every subset of parameters $K \subseteq \{T, 1/T, g\}$.

Result 1 shows—contrary to the intuitions sketched in the previous section—that none of the parameters T , $1/T$ and g , nor any combination of them is a source of intractability for MGBIP. This means that even if we assume that one or more of these parameters is small for the domain of application, goal inference under the MGBIP model is still intractable.

Besides this negative result (Result 1), we also have two positive results (Results 2 and 3).

Result 2. MGBIP is fp-tractable for parameter $\{k\}$.

Result 2 confirms parameter k is a source of intractability. This means that goal inference is tractable under the MGBIP model provided only that we impose the constraint that (the observer assumes that) the agent can pursue only a handful of goals simultaneously. Importantly, this is true regardless the size of T , $1/T$, g or $1 - p$. This is quite a powerful result, with great potential for explaining the speed of real-world goal inferences within the confines of a BIP model. After all, it seems to be a plausible constraint that real-world agents do not (typically) pursue a large number of goals in parallel at the same time (possibly also to keep their own planning tractable).

Result 3. MGBIP is fp-tractable for parameter $\{1 - p\}$.

Finally, Result 3 confirms parameter $1 - p$ is a source of intractability. This means that goal inference is tractable under the MGBIP model for those inputs where the most probable goal explanation is quite probable. Again, this is true regardless the size of T , $1/T$, g or k . Also, this result has potential for explaining the speed of real-world goal inferences within the confines of a BIP model, at least for certain situations—viz., those situations where the actions of the observed agents unambiguously suggest a particular combination of goals. For all we know, real world cases of speedy goal inference may very well match exactly these situations. Whether or not this is indeed the case is an empirical question which can be addressed by testing the speed of human goal inference for different degrees of goal ambiguity.

Discussion

We have analyzed the computational resource requirements of the Inverse Bayesian Planning (BIP) model of goal inference in order to study its viability as a model of inferences made by resource-bounded minds as our own. We generated several interesting theoretical findings. First, we observed that the three specialized models—M1, M2, and M3—that were developed by Baker et al. (2007, 2009) to account for their experimental data in maze experiments are in fact computationally tractable. This means that these specialized

Bayesian models do not seem to make unrealistic assumptions about the computational powers of human minds/brains, even when operating on large networks of beliefs and observations. That being said, these models do seem to be theoretically problematic for a different reason: they are too specialized to count as models of goal inference in general.

The over-specialization of M1, M2 and M3 is revealed when pondering the assumptions that these models make about the agent and the observer. For instance, all three models assume that (the observer assumes that) the agent can pursue at most one goal at a time. In the real-world, however, people often can and do act in ways so as to try and achieve two or more goals at the same time, and observers can also often understand what these simultaneous goals are from observing the actors behave in systematic ways. Recall, for example, the scenario from our Introduction where the son searches the kitchen for a candy bar. Under different circumstances, the mother may understand that her son has the goal to still his hunger (goal 1), to satisfy his craving for sweet (goal 2), to see how many bars are left (goal 3), to pretend that he did not hear his mom's request to clean up his room (goal 4), to bring back a candy bar for his mom (goal 5), etc., or any combination of these goals.

To accommodate the fact that real-world goal inference is not restricted to one goal at a time, we defined a more general BIP model—having M1, M2 and M3 as special cases—which we refer to as MULTIPLE GOALS BIP, or MGBIP for short. Complexity Analysis of the MGBIP model revealed that it *is* computationally intractable (i.e., NP-hard), meaning that this model, in all its generality, does indeed make unrealistic assumptions about the computational powers of human minds/brains. We took this negative theoretical result to mean that—if the BIP model is to account for human goal inference at all—it must be the case that in those situations where humans are able to infer multiple simultaneous goals quickly and effortlessly, specific constraints apply that render the inferences under the MGBIP model tractable.

To investigate which types of constraints could render the MGBIP model tractable, we used a methodology for identifying sources of intractability in NP-hard computational models (e.g. van Rooij and Wareham (2008)) and derived several theoretical results. For instance, we ruled out the possibility of explaining speedy real-world (multiple) goal inferences by an appeal to small values of T (modeling situations when goals can be inferred using only few observations) or an appeal to large values of T (modelling situations where a lot of information is available on which to base a goal inference). Similarly, we ruled out that the speed of such inferences could be explained by an appeal to a small number of values per goal node. Besides these negative theoretical results, we also had two important positive results. For one, we established that as long as the number of goals that can be simultaneously pursued, k , is not too large then goal inference is tractable under the MGBIP. Secondly we have shown that goal inference is tractable under the MGBIP model whenever the probability

⁷See <http://tinyurl.com/suppl2010>

of the most likely combination of simultaneous goals, p , is not too far from 1.

Whereas our negative theoretical results are useful to clarify that tractability is not a property that is trivially achieved (and often our intuitions about what constraints would render a model tractable can be wrong; cf. van Rooij et al. (2008)), our positive results show that a model of action understanding can nevertheless be rational, Bayesian, and tractable. Moreover, the nature of the constraints that need to be introduced to render the Bayesian Inverse Planning model of goal inference tractable yield new empirically testable predictions.

For instance, based on our results, we predict that human participants will be able to make quick and accurate goal inferences in the types of experimental set-ups such as used by Baker et al. (2007) (but see also Csibra et al. (1999)), but only if the number of simultaneous goals that the observed agents are pursuing is not too large, or the probability of the most likely combination of goals is not too small, or both. If both of these constraints were to be alleviated at the same time, we would predict that human performance on the goal inference task would deteriorate significantly. If our prediction were to be confirmed then this would provide corroborative support for the BIP model of goal inference, and validate that our theoretical results help explain the tractability of human goal inferences. If, on the other hand, the prediction were to be disconfirmed, then this would suggest that either the BIP model fails as an account of human goal inferences, or some constraint other than the ones we considered also suffices to render the BIP model tractable. The latter option may then be one that BIP modelers may be interested in pursuing further.

In closing, we remark that our approach can be seen as exemplary of a general strategy for dealing with intractability in Bayesian models, whether of action understanding or otherwise. Our approach reveals that—contrary to popular belief—Bayesian models *can* possibly scale to complex, real-world domains. To achieve this, Bayesian modelers need only identify constraints that apply in the real-world and suffice to render their models' computations tractable. By restricting Bayesian models in this way these models also become better testable: the constraints required to guarantee tractability of the models yield new predictions (specifically, about the speed of inferences) that can be used to perform more stringent tests of such models.

Abstract

Recent research indicates that when solving algebraic story problems, adding a diagram is beneficial for seventh and eighth grade students, however, sixth graders—particularly low-achieving ones—do not benefit from the diagrams. In the present study, we further investigate the diagrammatic advantage in low-achieving pre-algebra students and examine whether and how picture algebra instruction improves diagram comprehension and use in the target population. Results replicate the lack of diagrammatic advantage in this population for two types of diagrams. Picture algebra instruction on mapping information in word problems to one type of diagrams yields improvement in both diagrammatic forms, but not story problems without diagrams; a diagrammatic advantage emerges following this instruction. Though low-achieving students may fail to use diagrammatic representations to their benefit when solving word problems, instruction on the use of one specific form may be sufficient to facilitate a more general diagrammatic advantage.

Keywords: Multiple representations; Algebraic problem solving; mathematics education

Introduction

Problem representation is a critical issue in education, as the way that information is conveyed to students can have a great impact on the degree to which they learn. (e.g., Cummins, Kintsch, Reusser, & Weimer, 1988). In the domain of mathematics, use of more grounded representations rather than more abstract ones (e.g., verbal descriptions of situations as opposed to equations), has been found to be useful for presenting simple algebra problems (Koedinger, Alibali, & Nathan, 2008); this practice may be especially useful for making problems concrete when students are early in their transition to algebraic thinking and are not yet capable of the abstract thinking necessary to comprehend equations (Koedinger & Nathan, 2004).

Another way that instructors often attempt to make problems or situations more concrete is to include external representations. External representations are an important part of mathematics education (Seeger, 1998), and are intended to increase understanding of mathematical concepts by allowing children to build relations between mathematical ideas (Hiebert & Carpenter, 1992). Pictorial representations, such as diagrams, charts, graphs, and tables, are often used in math classrooms because they are thought to be useful for helping students communicate and reason about mathematical concepts (Greeno & Hall, 1997), and the National Council of Teachers of Mathematics

recommends that teachers include multiple forms of representations when teaching mathematical concepts (NCTM, 2000).

Indeed, evidence abounds on the cognitive benefits of external representations, including diagrams. For example, students learn better when a diagram is added to text than if they are studying the text alone (Mayer, 1989; 2009), likely because learners are able to build two mental representations of multimedia material, a verbal representation and a visual one, and build connections between them (Mayer, 2005). Diagrams may also be beneficial because the spatial organization and grouping of related components that are characteristic of diagrams better enables users to search, recognize relevant pieces in, and draw inferences about the represented information (Larkin & Simon, 1987). Diagrams may also be beneficial because they promote users to engage in self-explanation, which is in itself beneficial for learning (Ainsworth & Loizou, 2003).

Are diagrams universally helpful?

Despite the intention of these tools to help students succeed, the use of diagrams is not always beneficial. Larkin and Simon (1987) posited that diagrammatic representations of any sort are only useful if they are constructed in a way that groups information and facilitates inference in a better way than is possible with text. Further, even a well-constructed diagram will not be useful unless the user knows the computational processes that are necessary for taking advantage of them. Ainsworth (2006) also cautions that the usefulness of diagrams is influenced by characteristics of the user such as expertise in the content domain and familiarity with the structure and components of the representation, as well as characteristics of the diagram and interactions between the two.

Consistent with these assertions, recent research on using diagrams with algebraic story problems suggests that not all students benefit from the addition of diagrams. Booth & Koedinger (2007) found that older and higher-achieving middle school students do benefit from the diagrams as intended—they solve more diagram problems correctly than problems without a diagram. However, low-achieving students do not benefit from the diagrams; they perform better on story problems that do not have accompanying diagrams. In fact, the diagrams may actually hurt their performance—they perform just as poorly on the diagram problems as they do when solving the problems as symbolic equations.

For students that do experience a diagrammatic advantage, results suggested that the benefit comes from protecting those students from making common conceptual errors in interpreting the problem (Booth & Koedinger, 2007). For example, for a problem where students are given a sale price and asked to determine the original price if the buyer purchased it at 1/5 off, having a diagram showing the pieces of the equation makes it less likely that higher-achieving students solve the problem by multiplying the original price by 5, which is a common strategy for students solving the problem in story format. Of course, this benefit can only be realized when students are able to effectively use diagrams to understand the problem.

For lower-achieving students, there appear to be two barriers to successful diagram use. One is that they are less likely than higher-achieving peers to attempt diagram problems. This is perhaps unsurprising, as low-ability students generally perceive problems to be more difficult than high or average ability students, and are more likely to shut down and not attempt the problems as a result (Ericsson & Simon, 1980). The real or perceived need to attend to more than one representation at a time causes split attention demands on working memory (Chandler & Sweller, 1991), making the problem seem overwhelming, and these students' limited diagram comprehension skills preclude the realization that the problem could be solved by simply ignoring the diagram and working from the story alone.

The other barrier to success with diagrams was the failure to glean a correct conceptual understanding of the problem from looking at the diagram. Young and low-achieving students were *more* likely to make conceptual errors in problems that included diagrams than ones with stories alone. This is likely due to either misinterpretation of the diagram itself or, more crucially, failure to accurately map the story problem to the diagram. How can we help low-achieving students to better comprehend the diagrams?

Using instruction to improve diagram use

Research from the fields of cognitive development and mathematics education suggests that effective instruction on external representations is necessary for correct student use (Sowell, 1989; Fueyo & Bushell, 1998; Uttal, Scudder, & DeLoache, 1997). Brief instruction on a particular visual representation may not suffice (Rittle-Johnson & Koedinger, 2001), but more involved representation-specific instruction could consume a significant amount of precious classroom time, and may not transfer well to other representations.

An alternative to instruction on utilizing particular types of diagrams is having students construct diagrams to represent story problems themselves. Middle school students can use self-created representations to successfully solve algebraic story problems they wouldn't ordinarily be able to solve (Koedinger & Terao, 2002), and both constructing diagrams from scratch or filling in partially completed diagrams have yielded increases in student

learning in a variety of domains (Lewis & Mayer, 1987; see Van Meter & Garner, 2005 for a review). Constructing diagrams has the potential to help students learn to coordinate and integrate text with visual representations (Ainsworth, 2006; Easterday, Aleven, & Scheines, 2007).

In the present study, we directly target low-achieving pre-algebra students to determine whether guided experience constructing one type of diagram from simple story problems facilitates broader use of diagrams for more complex problems. We also aim to investigate the mechanism underlying any resulting benefit by testing students on more than one type of diagram. If improvement is due to increased familiarity with the type of diagram used during instruction, benefits should manifest as increased willingness to attempt familiar-looking problems and improved performance on those items. However, if, as intended, the instruction provides students with the necessary tools for mapping between story problems and diagrams, benefits should be more likely to transfer to the other type of diagram as well.

Methods

Participants

Participating in this study were four classrooms of non-honors Pre-Algebra students ($N = 73$ eighth grade students; typically age 13) from a school in which only 8.5% of students reach the required state level of math proficiency. Eighty-nine percent of students at the participating school were economically disadvantaged; the ethnic breakdown of the school was approximately 95% Hispanic, 5% African-American, and < 1% Caucasian or other. Three additional students participated in the study, but were excluded because they were not given the correct version of the posttest.

All four classrooms used the Bridge to Algebra Cognitive Tutor curriculum. The Cognitive Tutor is a computer-based intelligent tutoring system which provides on-demand, step-specific help at any point in the problem-solving process and feedback on errors (Koedinger, Anderson, Hadley, & Mark, 1997).

Procedure

Prior to beginning the first Tutor unit in the curriculum (approximately three weeks after the beginning of the school year), participants completed a written pretest on which they were asked to solve algebraic story problems in three presentation formats: story alone, story with a vertical diagram, or story with a horizontal diagram. The test included six problem situations, each representing one of two underlying algebraic equations: 1) $ax + b = c$, and 2) $x + (x + a) + (x + b) = c$. Both equation types were represented in each of the three presentation formats on every test (See Figure 1 for examples of each presentation format for the second equation). There were three counterbalanced forms of the test, such that each problem

Horizontal Diagram

The sixth, seventh, and eighth grade classes brought in canned goods for the needy. They collected 227 cans between the grades. Sixth grade collected 9 more cans than eighth grade, and seventh grade collected 17 more cans than the eighth grade. How many cans did each grade collect? (You can use the picture below to help you solve the problem.)

situation appeared in each of the three presentation formats on one of the three test versions. After completing the pretest, students began the interactive Tutor unit on Picture Algebra, in which they created, labeled, and used vertical diagrams to solve simple story problems using multiplication, addition, or subtraction. The vertical training problems were simpler than those included in the test, in that they required the student to manipulate only two components compared with three or more components in test problems; thus, all test problems were transfer problems (see Figure 2 for examples of a problem in the Picture Algebra unit). Each student completed the unit at his or her own pace. As each student completed the unit, he or she was given a posttest by the classroom teacher; students were given the same version of the test that they had taken at pretest.
