

# **Building Bridges Across Cognitive Sciences Around the World**

## **Proceedings of the 34<sup>th</sup> Annual Meeting of the Cognitive Science Society**

Sapporo, Japan, August 1-4, 2012

*Edited by*

Naomi Miyake  
*University of Tokyo*

David Peebles  
*University of  
Huddersfield*

Richard P. Cooper  
*Birkbeck,  
University of London*

Austin, TX: Cognitive Science Society

ISBN: 978-0-9768318-8-4

*How to cite a paper in these Proceedings:*

**APA formatted citation for a 6-page paper:**

Author, A. & Author, B. (2012). This is the title of the paper. In N. Miyake, D. Peebles, & R. P. Cooper (Eds.), *Proceedings of the 34th Annual Conference of the Cognitive Science Society* (pp. NUMBERS). Austin, TX: Cognitive Science Society.

**APA formatted citation for a published abstract:**

Author, A. & Author, B. (2012). This is the title of the abstract [Abstract]. In N. Miyake, D. Peebles, & R. P. Cooper (Eds.), *Proceedings of the 34th Annual Conference of the Cognitive Science Society* (p. NUMBER). Austin, TX: Cognitive Science Society.

**APA formatted citation for a talk (or poster) presentation:**

Author, A. & Author, B. (2012, August). This is the title of the talk or poster. Paper (or Poster) presented at the 34th Annual Conference of the Cognitive Science Society. Sapporo, Japan.

# Table of Contents

<b>Introduction</b>	1
<b>Organizing Committee</b>	3
<b>Program Committee</b>	4
<b>Sponsors</b>	5
<b>Conference Awards</b>	6
<b>Glusko Dissertation Prizes and NSF Fellowships</b>	8
<b>Invited Plenary Presentations</b>	9
<b>Workshops</b>	
<i>Women in Cognitive Science sponsored interactive panel discussion: Professional advancement, leadership and international collaboration</i>	10
Laurie Beth Feldman, Janet van Hell, Judith Kroll, Suparna Rajaram	
<i>Teleoperated Android as a Tool for Cognitive Studies, Communication and Art</i>	12
Shuichi Nishio, Hiroshi Ishiguro	
<i>Modeling the Perception of Intentions</i>	14
Barbara Tversky, Shimon Ullman, Dare Baldwin, Frank E. Pollick, Joshua Tenenbaum, Tao Gao, Peter Pantelis, David Pautler	
<b>Tutorials</b>	
<i>And Now for Something Completely Different: Python in Cognitive Science</i>	16
Mark Andrews, Jesse Diaz	
<i>Full day tutorial on Quantum models of cognition and decision</i>	18
Jerome Busemeyer, Peter Bruza, Taiki Takahashi, Jennifer Trueblood	
<i>Using Bayes to Interpret Non-significant Results</i>	20
Zoltan Dienes	
<i>Nengo and the Neural Engineering Framework: From Spikes to Cognition</i>	22
Chris Eliasmith, Terrence Stewart	
<i>Probability, programs, and the mind: Building structured Bayesian models of cognition</i>	24
Noah Goodman, Joshua Tenenbaum	
<i>Using Machine Learning for Exploratory Data Analysis</i>	26
Joshua Lewis, Virginia de Sa	
<i>Practical Advice on How to Run Human Behavioral Studies</i>	28
Frank Ritter, Jong kim	

## Symposia

<i>Robotics and Emotion</i> .....	30
Rolf Pfeifer, Hiroshi Ishiguro, Yuichiro Anzai, Naomi Miyake	
<i>Computational Models of Intuitive Physics</i> .....	32
Peter Battaglia, Tomer Ullman, Joshua Tenenbaum, Adam Sanborn, Kenneth Forbus, Tobias Gerstenberg, David Lagnado	
<i>The role of comparison in structure learning: Developmental, learning science, and computational perspectives</i> .....	34
Stella Christie, Dedre Gentner, Mutsumi Imai, Etsuko Haryu, Hiroyuki Okada, Ji Y. Son, James Stigler, Leonidas Doumas, Robert G. Morrison, Lindsey E. Richland	
<i>Neural Computations Supporting Cognition: Rumelhart Prize Symposium in Honor of Peter Dayan</i>	36
Kenji Doya, John O'Doherty, Alexandre Pouget, Peter Bossaerts, Nathaniel Daw, Yael Niv	
<i>Thirty years of Marr's Vision: Levels of Analysis in Cognitive Science</i> .....	38
Chris Eliasmith, Tom Griffiths, Valerie Gray Hardcastle, Brad Love, William Bechtel, Richard P. Cooper, David Peebles	
<i>New Frontiers in Computational Models of Grammatical Development</i> .....	40
Micah Goldwater, Scott Friedman, Dedre Gentner, Kenneth Forbus, Cynthia Fisher, Michael Connor, Dan Roth, Franklin Chang, Gary Dell	
<i>Computational, Cognitive, and Neural Models of Decision-making Biases</i> .....	42
Jonathan Malmaud, Joshua Tenenbaum, Peter Dayan, Laurence Maloney, Edward Vul, Nick Chater	
<i>Governing Board Symposium: Cognitive Science and the Learning Sciences</i> .....	44
Naomi Miyake, Roy Pea, Reinhart Pekrun, Kurt Van Lehn, Richard Catrambone, Stella Vosniadou	
<i>How Vertical Spaces Are Perceived and Represented</i> .....	46
Daniele Nardi, Frank Durgin, Kate Jeffery, Steven Weisberg	
<i>What Can Cognitive Science Say or Learn about Economic Crises?</i> .....	48
Magda Osman, Björn Meder, Gerd Gigerenzer, Nick Chater, Daniel Read, Hansjörg Neth	
<i>Dynamic decision making: neuronal, computational, and cognitive underpinnings</i> .....	50
Magda Osman, Maarten Speekenbrink, Peter Dayan, Masataka Watanabe, Nigel Harvey	
<i>Grammatical Approaches to Written and Graphical Communication</i> .....	52
Colin Wilson, Neil Cohn, James Myers, Stephen Goldberg, Ariel Cohen-Goldberg	

## Papers

<i>Constructing a hypothesis space from the Web for large-scale Bayesian word learning</i> .....	54
Joshua Abbott, Joseph Austerweil, Tom Griffiths	
<i>Predicting focal colors with a rational model of representativeness</i> .....	60
Joshua Abbott, Terry Regier, Tom Griffiths	
<i>Gestures in Communication through Line Graphs</i> .....	66
Cengiz Acarturk, Ozge Alacam	

<i>Distributional Learning of Vowel Categories Is Supported by Prosody in Infant-Directed Speech</i> . . . .	72
Frans Adriaans, Daniel Swingley	
<i>Emotion-Based Reinforcement Learning</i> . . . . .	78
Woo-Young Ahn, Olga Rass, Yong-Wook Shin, Jerome R. Busemeyer, Joshua W. Brown, Brian F. O'Donnell	
<i>Cooperation in risky environments: Decisions from experience in a stochastic social dilemma</i> . . . . .	84
Florian Artinger, Nadine Fleischhut, Vittoria Levati, Jeffrey R. Stevens	
<i>Modeling individual differences in socioeconomic game playing</i> . . . . .	90
Derrik Asher, Shunan Zhang, Andrew Zaldivar, Michael Lee, Jeffrey Krichmar	
<i>Lexical Access Across Languages: A Multinomial Model of Auditory Distraction</i> . . . . .	96
Philip Beaman	
<i>Diagramming Phenomena for Mechanistic Explanation</i> . . . . .	102
William Bechtel, Adele Abrahamsen	
<i>Route choice in individuals—semantic network navigation</i> . . . . .	108
Nicole Beckage, Mark Steyvers, Carter Butts	
<i>Competent Deontic Reasoning: The Abstract Deontic Selection Task Revisited</i> . . . . .	114
Sieghard Beller, Andrea Bender	
<i>That's what she (could have) said: How alternative utterances affect language use</i> . . . . .	120
Leon Bergen, Noah Goodman, Roger Levy	
<i>Word predictability and frequency effects in a rational model of reading</i> . . . . .	126
Klinton Bicknell, Roger Levy	
<i>The retriever-connector model: Matching Classroom Data and Agent-Based Computer Models to Simulate Students' Use of Multiple Epistemological Resources</i> . . . . .	132
Paulo Blikstein	
<i>Inducing Mathematical Concepts from Specific Examples: The Role of Schema-Level Variation</i> . . .	138
David Braithwaite, Robert Goldstone	
<i>Learning to recognize unfamiliar voices: the role of language familiarity and music experience</i> . . . .	144
Micah Bregman, Sarah Creel	
<i>Misconceptions Regarding Emergent Phenomena Vary By Domain</i> . . . . .	150
Sarah Brem, Glenda Stump, Gale Sinatra, Raymond Reichenberg, Benjamin Heddy	
<i>Do I know that you know what you know? Modeling testimony in causal inference</i> . . . . .	156
Daphna Buchsbaum, Sophie Bridgers, Andrew Whalen, Elizabeth Seiver, Tom Griffiths, Alison Gopnik	
<i>Revisiting the Relationship between Allocentric-Heading Recall and Self-Reported Sense of Direction</i> . . . . .	162
Heather Burte, Mary Hegarty	
<i>Space-Time Interdependence and Sensory Modalities: Time Affects Space in the Hand But Not in the Eye</i> . . . . .	168
Zhenguang Cai, Louise Connell	

<i>Sentic Panalogy: Swapping Affective Common Sense Reasoning Strategies and Foci</i> .....	174
Erik Cambria, Daniel Olsher, Kenneth Kwok	
<i>Object discovery and inverse physical reasoning</i> .....	180
Christopher Carroll, Charles Kemp	
<i>Category structure modulates interleaving and blocking advantage in inductive category acquisition</i>	186
Paulo Carvalho, Robert Goldstone	
<i>Implicit Learning of L2 word stress rules</i> .....	192
Ricky Chan, Janny Leung	
<i>Generating Realistic Semantic Codes for Use in Neural Network Models</i> .....	198
Ya-Ning Chang, Steve Furber, Stephen Welbourne	
<i>Word Form Encoding in Mandarin Chinese Typewritten Word Production</i> .....	204
Jenn-Yeu Chen, Train-Min Chen	
<i>What Counts in Mandarin Chinese: A Study of Individuation and Quantification</i> .....	210
Pierina Cheung, Peggy Li, David Barner	
<i>The Role of Preview and Incremental Delivery on Visual Search</i> .....	216
Eric Chiu, Michael Spivey	
<i>Determining Relevance: Close Enough is Good Enough</i> .....	222
Sheldon Chow	
<i>Subject Relative Production in SLI Children during Syntactic Priming and Sentence Repetition</i> ..	228
Moreno Coco, Maria Garraffa, Holly Branigan	
<i>Segmenting Visual Narratives: Evidence for Constituent Structure in Comics</i> .....	234
Neil Cohn, Phillip Holcomb, Ray Jackendoff, Gina Kuperberg	
<i>Framing attention in American and Japanese comics</i> .....	240
Neil Cohn, Amaro Taylor-Weiner, Suzanne Grossman	
<i>Early-Talker and Late-Talker Toddlers and Networks Show Different Word Learning Biases</i> .....	246
Eliana Colunga, Clare Sims	
<i>Do you see what I'm singing? Visuospatial movement biases pitch perception</i> .....	252
Louise Connell, Zhenguang Cai, Judith Holler	
<i>Flexible Shortcuts: Linguistic Distributional Information Affects both Shallow and Deep</i>	
<i>Conceptual Processing</i> .....	258
Louise Connell, Dermot Lynott	
<i>Exploring Decision Rules and Sampling Dynamics in Recognition Memory</i> .....	264
Gregory Cox, Richard Shiffrin	
<i>Reverse appraisal: The importance of appraisals for the effect of emotion displays on people's</i>	
<i>decision making in a social dilemma</i> .....	270
Celso de Melo, Jonathan Gratch, Peter Carnevale, Stephen Read	
<i>Neural correlates of social perception: The posterior superior temporal sulcus is modulated by</i>	
<i>action rationality, but not animacy</i> .....	276
Ben Deen, Rebecca Saxe	

<i>The Role of Linguistic Labels in Infants' Categorization: An Eye Tracking Study</i> .....	282
Sophia Deng, Vladimir Sloutsky	
<i>Learning Deterministic Causal Networks from Observational Data</i> .....	288
Ben Devereitt, Charles Kemp	
<i>Enhanced Performance for Recognition of Irrelevant Target-Aligned Auditory Stimuli: Unimodal and Cross-modal Considerations</i> .....	294
Andrew Dewald, Scott Sinnett	
<i>The semantic structure of sensory vocabulary in an African language</i> .....	300
Mark Dingemanse, Asifa Majid	
<i>The Sound of Thickness: Prelinguistic Infants' Associations of Space and Pitch</i> .....	306
Sarah Dolscheid, Sabine Hunnius, Daniel Casasanto, Asifa Majid	
<i>What explains variability in brain regions associate with Theory of Mind in a large sample of neurotypical adults and adults with ASD?</i> .....	312
Nicholas Dufour, Elizabeth Redcay, Liane Young, Penelope Mavros, Joseph Moran, Christina Triantafyllou, John Gabrieli, Rebecca Saxe	
<i>Explanations of Counterfactual Inferences</i> .....	318
Brian Edwards, Lance Rips	
<i>Learning Conceptual Hierarchies by Iterated Relational Consolidation</i> .....	324
James Foster, Fabian Canas, Matt Jones	
<i>"Eyes Closed" and "Eyes Open" Expectations Guide Fixations in Real-World Search</i> .....	330
Tom Foulsham	
<i>Maximum utility unitary coherent perception vs. the Bayesian brain</i> .....	336
Charles Fox, Tom Stafford	
<i>Measuring children's visual access to social information using face detection</i> .....	342
Michael Frank	
<i>The Effects of Feedback During Exploration Depend on Prior Knowledge</i> .....	348
Emily Fyfe, Bethany Rittle-Johnson	
<i>Children's Inferences in Generalizing Novel Nouns and Adjectives</i> .....	354
Annie Gagliardi, Erin Bennett, Jeffrey Lidz, Naomi H. Feldman	
<i>When Suboptimal Behavior is Optimal and Why: Modeling the Acquisition of Noun Classes in Tsez</i> .....	360
Annie Gagliardi, Naomi H. Feldman, Jeffrey Lidz	
<i>Verbal Satiation of Chinese Bisyllabic Words: A Semantic Locus and its Time Course</i> .....	366
Bruno Galmar, Jenn-Yeu Chen	
<i>Online learning of causal structure in a dynamic game situation</i> .....	372
Yue Gao, Eyal Nitzany, Shimon Edelman	
<i>Noisy Newtons: Unifying process and dependency accounts of causal attribution</i> .....	378
Tobias Gerstenberg, Noah Goodman, David Lagnado, Joshua Tenenbaum	
<i>Explaining children's failure in analogy making tasks: A problem of focus of attention?</i> .....	384
Yannick Glady, Jean-Pierre Thibaut, Bob French, Agnes Blaye	

<i>Knowledge and implicature: Modeling language understanding as social cognition</i> .....	390
Noah Goodman, Andreas Stuhlmüller	
<i>Analogical Problem Solving: Insights from Verbal Reports</i> .....	396
Linn Gralla, Thora Tenbrink, Michael Siebers, Ute Schmid	
<i>Comparing the inductive biases of simple neural networks and Bayesian models</i> .....	402
Thomas Griffiths, Joseph Austerweil, Vincent Berthiaume	
<i>Cooperation in Prisoner's Dilemma Game: Influence of Social Relations</i> .....	408
Maurice Grinberg, Evgenia Hristova, Milena Borisova	
<i>Evaluating the Relationship Between Neuropsychological Function and Cognitive Performance</i> ....	414
Glenn Gunzelmann, L. Richard Moore	
<i>The Interplay between Feature-Saliency and Feedback Information in Visual Category Learning Tasks</i> .....	420
Rubi Hammer, Vladimir Sloutsky, Kalanit Grill-Spector	
<i>Self-Terminated vs. Experimenter-Terminated Memory Search</i> .....	426
J. Isaiah Harbison, Erika Hussey, Michael Dougherty, Eddy Davelaar	
<i>The use of ACT-R to develop an attention model for simple driving tasks</i> .....	432
Kerstin Sophie Haring, Marco Ragni, Lars Konieczny, Katsumi Watanabe	
<i>Testing the Split Attention Effect on Learning in a Natural Educational Setting Using an Intelligent Tutoring System for Geometry</i> .....	438
Robert Hausmann, Annalies Vuong	
<i>The effect of "Maverick": A study of Group Dynamics on Breakthrough in Collaborative Problem solving</i> .....	444
Yugo Hayashi	
<i>Tightening up Joke Structure: Not by Length Alone</i> .....	450
Christian F. Hempelmann, Julia M. Taylor, Victor Raskin	
<i>Logical or Pragmatic, as Long as it Suits our Convenience: Scalar Inferences in a Pro-and Contra-attitudinal Context</i> .....	456
Tom Heyman, Walter Schaeken, Katrijn Pipijn	
<i>Do repeated references result in sign reduction?</i> .....	461
Marieke Hoetjes, Emiel Krahmer, Marc Swerts	
<i>When gestures catch the eye: The influence of gaze direction on co-speech gesture comprehension in triadic communication</i> .....	467
Judith Holler, Spencer Kelly, Peter Hagoort, Asli Ozyurek	
<i>Learning from speaker word choice by assuming adjectives are informative</i> .....	473
Alexandra Horowitz, Michael Frank	
<i>Finishing each other's . . . Responding to incomplete contributions in dialogue</i> .....	479
ChrIstine Howes, Patrick G. T. Healey, Matthew Purver, Arash Eshghi	
<i>Identifying representations of categories of discrete items using Markov chain Monte Carlo with People</i> .....	485
Anne Hsu, Jay Martin, Adam Sanborn, Tom Griffiths

<i>An fMRI Investigation of Feature-Emergence-related Activation within Metaphor Comprehension</i>	2405
Asuka Terai, Naoko Kuriyama, Masanori Nakagawa, Kimihiko Yamagishi, Takashi Kusumi, Koji Jimura	
<i>Explanation Reconstruction through Reinterpretation of Key Facts</i> .....	2411
Hitoshi Terai, Kazuhisa Miwa, Shota Matsubayashi	
<i>Automatic Detection of Metonymies using Associative Relations between Words</i> .....	2417
Takehiro Teraoka, Ryuichiro Higashinaka, Jun Okamoto, Shun Ishizaki	
<i>Flexible sequence learning in a SOM model of the mirror system</i> .....	2423
Serge Thill, Josef Behr, Tom Ziemke	
<i>Fuzzy Memory Theory and its Use in Cognitive Science</i> .....	2429
Chris Thornton	
<i>From Head to Toe: Embodiment Through Statistical Linguistic Frequencies</i> .....	2434
Richard Tillman, Vivek Datla, Sterling Hutchinson, Max Louwerse	
<i>Evidence for Modality-Specific Processes in Approximate Numerical Comparison</i> .....	2440
Midori Tokita, Akira Ishiguchi	
<i>Embodied Communication Practices in Instructive Interaction between Musicians</i> .....	2446
Jackson Tolins	
<i>Viewing and performing actions can change what you see</i> .....	2451
Alexia Toskos Dils, Stephen Flusberg, Lera Boroditsky	
<i>Honoring Different Ontological Boundaries: The Role of Language in Category Formation</i> .....	2457
Duc Tran, Hanako Yoshida	
<i>Writing facilitates learning to read in Chinese through reduction of holistic processing: A developmental study</i> .....	2463
Ricky Van Yip Tso, Terry Kit-fong Au, Janet Hui-wen Hsiao	
<i>Temporal Dynamics of Action Perception: The Role of Biological Appearance and Motion Kinematics</i> .....	2469
Burcu Aysen Urgan, Markus Plank, Hiroshi Ishiguro, Howard Poizner, Ayse Pinar Saygin	
<i>Effects of Discourse Goals on the Process of Metaphor Production</i> .....	2475
Akira Utsumi, Kota Nakamura, Maki Sakamoto	
<i>Modeling Efficient Serial Visual Search</i> .....	2481
Bella Veksler, Wayne Gray	
<i>A Conceptual Network-Based Approach to Inferring the Cultural Evolutionary History of the Baltic Psaltery</i> .....	2487
Tomas Veloz, Ilya Tëmkin, Liane Gabora	

<i>Factors influencing children's display of surprise</i> .....	2493
Mandy Visser, Emiel Krahmer, Marc Swerts	
<i>Estimating Semantic Transparency of Constituents of English Compounds and Two-Character Chinese Words using Latent Semantic Analysis</i> .....	2499
Hsueh-Cheng Wang, Li-Chuan Hsu, Yi-Min Tien, Marc Pomplun	
<i>Visual Attention is Attracted by Text Features Even in Scenes without Text</i> .....	2505
Hsueh-Cheng Wang, Shijian Lu, Joo-Hwee Lim, Marc Pomplun	
<i>Implicit theories of the causes of weight gain in adults</i> .....	2511
Nicole Ware, Rachel Dryer	
<i>Relationship between Phonemes and Tactile-emotional Evaluations in Japanese Sound Symbolic Words</i> .....	2517
Junji Watanabe, Yuuka Utsunomiya, Hiroya Tsukurimichi, Maki Sakamoto	
<i>Actor-Observer Asymmetries in Judgments of Intentional Actions</i> .....	2523
Sarah Wellen, David Danks	
<i>Learning Causal Structure through Local Prediction-error Learning</i> .....	2529
Sarah Wellen, David Danks	
<i>Understanding each other: Defining a conceptual space for cognitive modeling</i> .....	2535
Robert West, David Pierre Leibovitz	
<i>Reading direction is sufficient to account for the optimal viewing position in reading: The case of music reading</i> .....	2540
Yetta Kwailing Wong, Janet Hui-wen Hsiao	
<i>Effects of Learning Order and Previous Language Experience in Novel Word Learning</i> .....	2546
Elizabeth Woods, Hanako Yoshida	
<i>Inference and culture : The distinction between low context culture and high context culture as a possible explanation for cultural differences in cognition</i> .....	2552
Hiroshi Yama, Norhayati Zakaria	
<i>"What" versus "How" in Nonvisual Whole-Body Movement</i> .....	2558
Naohide Yamamoto, Dale A. Hirsch	
<i>The Influence of Risk Aversion on Visual Decision Making</i> .....	2564
Ruixin Yang, Garrison Cottrell	
<i>Splitting Visual Focal Attention? It Probably Depends on Who You Are</i> .....	2570
Jit Yong Yap, Stephen Wee Hun Lim	
<i>Roles of Adult's Gestures and Eye Gaze in Whole or Object Part Presenting</i> .....	2576
Tetsuya Yasuda, Harumi Kobayashi	
<i>State-Trace Analysis of Sequence Learning by Simple Recurrent Networks</i> .....	2581
Fayme Yeates, Fergal Jones, Andy Wills, Ian P. L. McLaren	
<i>The Role of Attention in Three-way binding in Episodic Memory</i> .....	2587
Hyungwook Yim, Simon Dennis, Vladimir Sloutsky	

<i>Visual Context Effects on Thematic Role Assignment in Children versus Adults: Evidence from Eye Tracking in German</i> .....	2593
Lu Zhang, Pia Knoeferle	
<i>Argument Homogeneous and Structure Simplicity</i> .....	2599
Niina Ning Zhang	
<i>Modeling a Cognitively Limited Network in an Agent-Based Simulation</i> .....	2603
Changkun Zhao, Ryan Kaulakis, Jonathan Morgan, Jeremiah Hiam, Frank Ritter	
<i>Attention Modeling for Face Recognition via Deep Learning</i> .....	2609
Sheng-hua Zhong, Yan Liu, Yao Zhang, Fu-lai Chung	
<i>Cohesion Grading Decisions in a Summary Evaluation Environment: A Machine Learning Approach</i> .....	2615
Iraide Zipitria, Basilio Sierra, Ana Arruarte, Jon A. Elorriaga	

## Member's Abstracts

<i>The Effects of an Incubation Period on the Metaphor Creation Process</i> .....	2621
Keiga Abe	
<i>Trial Measurement of Implicit Attitude toward Violations in Nursing by the use of Implicit Association Test</i> .....	2622
Yuko Adachi, Shinnosuke Usui, Etsuko Nakagami-Yamaguchi, Akiko Yamada, Keun sik Park, Tatsuya Nakatani	
<i>Frame Augmented Language Model</i> .....	2623
Kisuh Ahn, Eunsuk Lim	
<i>Multi-Voxel Pattern Analysis Applied to the Language Switch in the Bilingual Brain—An fMRI Study</i> .....	2624
Hiroyuki Akama, Miao Mei Lei, Na Li, Brian Murphy	
<i>Visual prosody: The relationships between head movements and the verbs</i> .....	2625
Haruka Amatani	
<i>Determining the effect of ego-involvement on causal reasoning by using contingencies in causal situations</i> .....	2626
Yoshiko Arai	
<i>Which is Stronger? : Discriminative Learning of Sound Symbolism</i> .....	2627
Eiji Aramaki, Sachi Yasuda, Mai Miyabe, Satoshi Miura, Masaki Murata	
<i>The model comparison through orthography, phonology, and semantics</i> .....	2628
Shin-ichi Asakawa	
<i>Age-related Differences in Implicit Memory for Distractor Kanji Characters</i> .....	2629
Akihiro Asano, Etsuko T. Harada, Shoko Saito	
<i>Robots as learning partners in collaborative learning research</i> .....	2630
Jun Ashikaga, Takahiro Nakayama, Sho Inaba, Kenta Iyoki, Naomi Miyake	
<i>What do children hear? Japanese parents' use of numeral classifiers</i> .....	2631
Natsuki Atagi, Catherine Sandhofer	

<i>Comparison and contrast in novel objects categorization: the role of executive functions</i> .....	2632
Luc Augier, Jean-Pierre Thibaut	
<i>Comparison of the brain regions activated during comprehension of action sentences referring to unimanual or bimanual actions: An fMRI study</i> .....	2633
Shunji Awazu, Fumihiko Taya, Sayako Masuda, Shigeru Watanabe	
<i>Effectiveness of Transcranial Direct Current Stimulation on Medial Prefrontal Cortex in Aesthetic Judgement</i> .....	2634
Leila Azari Pishkenari, Hamed Ekhtiari, Mohammad Javad Hatami	
<i>Learning novel words with the help of morphological information</i> .....	2635
Sungbong Bae, Kwangoh Yi	
<i>Distant Border Color Is More Preferred In a Triple Color Combination</i> .....	2636
Ziba Bashardanesh, Ali Yoonessi	
<i>To peek and to peer: "visual" verb meanings are largely unaffected by congenital blindness</i> .....	2637
Marina Bedny, Jorie Koster-Hale, William Johnston, Lindsay Yazzolino, Rebecca Saxe	
<i>Cognitive typology</i> .....	2638
Chuluundorj Begz	
<i>Expert Memory in Blindfold Chess960 - An Interpretation in the light of LIDA</i> .....	2639
Eduardo Bermudez, David Dahmen, Henry Gonzalez	
<i>Vague Linguistic Expressions and the Problem of Equidistance in Verbal Response Scales</i> .....	2640
Franziska Bocklisch, Josef Krems	
<i>Going beyond the headlines: Narratives mitigate intergroup empathy bias</i> .....	2641
Emile Bruneau, Mina Cikara, Rebecca Saxe	
<i>Ordered Information and Word Learning: An Associative Learning Perspective</i> .....	2642
Joseph Burling, Hanako Yoshida	
<i>The Hierarchical Structure of Word Senses</i> .....	2643
Hee-Rahk Chae, Do-Il Hong	
<i>Word Segmentation Difficulty in Fourth Graders with Low Reading Achievement</i> .....	2644
Sau-chin Chen, Jenn-Yeu Chen	
<i>Is the Proximate Unit in Chinese Word Production Motivated by the Visual Prompt of the Task?</i>	2645
Train-Min Chen, Jenn-Yeu Chen	
<i>The Impact of Contextual Cues on Infant Categorization</i> .....	2646
I-Chen Chen, Marin Huang, I-Wen Yu, Pei-Ling Wang, Jon-Fan Hu	
<i>Knowing where to look: Conceptual knowledge guides fixation in an object categorization task</i> ...	2647
Lang Chen, Timothy Rogers	
<i>Mindset interacts with subjective knowledge but not fluency when affecting preferential judgment</i>	2648
Rongjuan Chen, Yasuaki Sakamoto	
<i>A Study of the Syntactic Category of Rhetorical Questions</i> .....	2649
Hongbo Chen	

<i>Eye Movement Patterns Reveal How Oriental People Group Objects</i> .....	2650
Fan-Ning Cheng, Yi-Rong Wu, Jo Pan, Gert Westermann, Hsueh-Chih Chen, Jon-Fan Hu	
<i>Reading and Writing Performance in School-aged Children with Specific Language Impairment or/and with Developmental Coordination Disorder Identified at Preschool Age</i> .....	2651
Rong-Ju Cherng, Hsiang-Chun Cheng, Jenn-Yeu Chen, Chia-Liang Tsai, Miao-Lin Shen	
<i>The development of numerical comparison in 2- to 4-year-old children</i> .....	2652
Pierina Cheung, Mathieu Le Corre	
<i>The examination of physiological factor on two context effects in multi-attribute decision making</i>	2653
Itsuki Chiba, Takashi Tsuzuki, Masashi Soma	
<i>A Classroom Study of Learning to Evaluate Scientific Evidence</i> .....	2654
Clark Chinn	
<i>Impact of Modified Cognitive Behavior Therapy on Children with Autism Spectrum Disorders</i> ...	2655
Suvarna Chinta, Bipin Indurkha	
<i>Can Articulating Aloud Offset Effects of Listening to L1 in a Foreign Accent?</i> .....	2656
Kit Cho, Laurie Beth Feldman	
<i>Blending Narrative Spaces of the Flashback Scenes in the Joint Security Area</i> .....	2657
Hye Rhang Cho, Seung Suk Nam, Sook Whan Cho	
<i>Blending Narrative Spaces of the Reenactment Scenes in the Thin Blue Line</i> .....	2658
Sook Whan Cho, Seung Suk Nam, Hye Rhang Cho	
<i>Ten-month-old Infants Prefer Comforters, not Helpers</i> .....	2659
Hui-Mei Chow, Stephanie Jui-chi Chen, Geroldene H. T. Tsui, Ping-Hui Chiu, Chia-Huei Tseng	
<i>Comprehension of Representational Gestures</i> .....	2660
Kawai Chui	
<i>Task-specific conflict monitoring and cognitive control in the prefrontal cortex</i> .....	2661
Chongwook Chung, Chobok Kim, Jeounghoon Kim	
<i>The Development of Orthographic Awareness for Radical Properties of Chinese Characters in Young Children</i> .....	2662
Yi-Ling Chung, Pei-Yu Luo, Hsueh-Chih Chen, Li-Yun Chang, Jon-Fan Hu	
<i>The Dynamics of Sentence (In)comprehension</i> .....	2663
Gregory Cox, Melody Dye, Seth Frey	
<i>Aquisition of multipliers: learning a new class of number</i> .....	2664
Meghan Dale, Mathieu Le Corre	
<i>Describing faces: conventionalizing ontologies through dialogic interaction</i> .....	2665
Nicolas Davidenko, Gregory Mills	
<i>The effect of speaker's identity on syntactic processing: Evidence from verb-gender agreement in Slovak</i> .....	2666
Doug J. Davidson, Adriana Hanulíková, Manuel Carreiras	

<i>Joint Evaluation and Trend Information Mitigates the Disposition Effect</i> .....	2667
Kyung Soo Do, Hee-Yeon Kim, Rae-yeop Park	
<i>Effects of Scaffolded Feedback and Confidence of Incorrect Answers on Retention</i> .....	2668
Kyung Soo Do, Hanna Kim	
<i>Computing Humorous Metaphors</i> .....	2669
Pawel Dybala, Kohichi Sayama	
<i>Expanding the Transformation Paths in a Mutual Transformation Mechanism of Music and Narrative</i> .....	2670
Jun Endo, Taisuke Akimoto, Takashi Ogata	
<i>Eye tracking differences in respondent behaviour across multiple survey modes</i> .....	2671
Tom Foulsham, Olena Kaminska	
<i>Automatic facilitation of social behavior by implicit inferring of social intention</i> .....	2672
Haruaki Fukuda, Hiroaki Suzuki, Ayumi Yamada	
<i>Quantifying linguistic coordination</i> .....	2673
Riccardo Fusaroli, Kristian Tylén	
<i>How a Quantum Approach to Memory Incorporates Contextuality and Potentiality</i> .....	2674
Liane Gabora, Kirsty Kitto	
<i>The Naturalization of Concepts between Computational Intractability and Cognitive Theories</i> ...	2675
Francesco Gagliardi	
<i>Selection of decision rules in dynamic decision making</i> .....	2676
Jean-François Gagnon, Marie-Ève St-Louis, Sebastien Tremblay	
<i>Annual Cognitive Modeling Competition</i> .....	2677
Kevin Gluck	
<i>Do Young Children Habituate to their Classroom Environment?</i> .....	2678
Karrie Godwin, Anna Fisher	
<i>Phonological neighbourhood clustering effects on verbal short-term memory</i> .....	2679
Winston Goh	
<i>Children's sensitivity to informant's inductive efficiency and learner's epistemic states in pedagogical contexts</i> .....	2680
Hyowon Gweon, Patrick Shafto, Joshua Tenenbaum, Laura Schulz	
<i>The End is Near: Anticipating the end of a sentence</i> .....	2681
Lance Hahn	
<i>Individual differences and phonetic aptitude in the earliest stages of L2 acquisition</i> .....	2682
Adriana Hanulikova, Dan Dediu, Zhou Fang, Jana Basnakova, Falk Huettig

<b>Author Index</b> .....	2923
<b>Reviewers List</b> .....	2943

## **Building Bridges across Cognitive Sciences around the World**

Welcome to Sapporo and CogSci 2012, the 34th Annual Conference of the Cognitive Science Society. We hope you enjoy the conference and find the program of workshops, tutorials, talks, symposia, and poster presentations that we have assembled to be both fascinating and inspiring.

CogSci 2012 represents a significant milestone in the history of the conference as it is the first to be located outside of Europe and North America. It is the culmination of several years of planning and the clearest example to date of the desire of the Cognitive Science Society to strengthen its connections with similar organizations in the Asia-Pacific region and elsewhere around the world.

As you browse this program, you will see that CogSci has evolved into a truly international conference with a total of 37 countries being represented. Of the 798 accepted talks and posters, approximately 40% are from East Asia, 37% come from the Americas, and 20% originate from Europe, with the rest coming from Australia, North Africa and other regions of Asia. We hope you will be impressed by the high quality of the research presented and the diverse range of questions being addressed.

In addition to this strong collection of talks and posters, we are delighted to have three world leaders in their fields as plenary speakers – Gerd Gigerenzer, Nancy Nersessian, and Lawrence Barsalou –, not to mention a broad set of symposia exploring the breadth of cognitive science.

As chairs, we organized two symposia to allow distinguished researchers an opportunity to discuss two important contemporary issues in cognitive science. The first takes the thirtieth anniversary of David Marr's landmark posthumous book, *Vision*, to address the question whether his tripartite formulation of levels of analysis is still relevant in the age of reductionist neuroscience and Bayesian analysis. Our second symposium reflects on and explores historical origins and recent developments in robotics research (an area of considerable activity and expertise in Japan) that seek new ways of understanding cognition via the mechanisms and processes of embodiment and emotion.

The Governing Board of the Cognitive Science Society has also organized a symposium to bring together leading thinkers from Asia, Europe and the US to discuss real world implementations of educational innovations based on cognitive and learning science principles and research.

This conference is the result of the hard work of many people. Firstly, we would like to thank the members of the Organizing Committee, the Program Committee, the prize judges, and all the many reviewers for their time and effort. Secondly, we would like to thank the Society's Business Manager, Deborah Gruber, for her work in administering prizes, visas, etc., James Stewart of Precision Conference Solutions for his rapid responses to our questions, and those at Scarritt Group for their organization of the venue and local arrangements. Thirdly, we would in

particular like to thank the Society's Conference Officer, Andy Stull, for his advice and help in coordinating the whole conference, getting the program together, and keeping us on schedule.

We would also like to thank members of The International Association of Cognitive Science (Asia-Pacific) and Japan Cognitive Science Society for their many contributions to this conference and to their progressive drive to strengthen ties between cognitive scientists throughout the Asia-Pacific region and beyond.

CogSci is renowned for the high quality and diversity of the research presented as well as for being a crucial annual opportunity to meet like-minded individuals from across the globe. As you attend the conference we hope you agree with us that this year is no exception. We hope also that the connections you make here bear fruit through new productive collaborations so that the conference can truly achieve its aim of building bridges across cognitive sciences around the world.

Naomi Miyake, David Peebles, Richard P. Cooper

Co-chairs, CogSci 2012

# Organizing Committee CogSci 2012

<b>Program Chairs:</b>	Naomi Miyake, University of Tokyo David Peebles, University of Huddersfield Richard P. Cooper, Birkbeck, University of London
<b>Sponsors Chairs:</b>	Hajime Shirouzu, Chukyo University Christopher T. Kello, University of California, Merced Holger Schultheis, University of Bremen
<b>Awards Chairs:</b>	Michael Pauen, Humboldt University Natalie Sebanz, Central European University Markus Knauff, University of Giessen Ipke Wachsmuth, University of Bielefeld
<b>Member Abstracts Chairs:</b>	Natalie Sebanz, Central European University Sachiko Kiyokawa, Chubu University
<b>Publicity Chair:</b>	Mitchell J. Nathan, University of Wisconsin-Madison
<b>Student Volunteer Chairs:</b>	Christopher Myers, Air Force Research Laboratory Toshihiko Matsuka, Chiba University
<b>Tutorials &amp; Workshops Chair:</b>	Glenn Gunzelmann, Air Force Research Laboratory
<b>Symposia Chair:</b>	Kai-Florian Richter, University of Melbourne
<b>Publication-based Talks Chair:</b>	Kai-Florian Richter, University of Melbourne
<b>Web Chair:</b>	Dongkyu Choi, University of Kansas

## **CogSci2012 Program Committee**

We thank the following people for their generous contribution of time and effort to CogSci 2012.

Altmann, Erik	Fu, Wai-Tat	Myers, Christopher
Aslin, Richard	Fum, Danilo	Navarro, Daniel
Ball, Jerry	Garrod, Simon	Neth, Hansjoerg
Barkowsky, Thomas	Gentner, Dedre	Noelle, David
Barley, Mike	Giudice, Nicholas	Nokes-Malach, Timothy
Beaman, Philip	Goel, Ashok	Oaksford, Mike
Bertel, Sven	Goldstone, Rob	Olivetti, Marta
Best, Brad	Gonnerman, Laura	Pani, John
Billman, Dorrit	Gonzalez, Cleotilde	Papafragou, Anna
Blessing, Stephen	Gunzelmann, Glenn	Peebles, David
Bonnefon, Jean-Francois	Hahn, Ulrike	Pleskac, Timothy
Brighton, Henry	Hampton, James	Ragni, Marco
Brook, Andrew	Hegarty, Mary	Reed, Stephen
Brumby, Duncan	Heit, Evan	Richter, Kai-Florian
Burns, Bruce	Helie, Sebastien	van Rijn, Hedderik
Busemeyer, Jerome	Jacobson, Michael	Scheutz, Matthias
Byrne, Ruth	Jones, Gary	Schmalhofer, Franz
Cacciari, Cristina	Kaschak, Michael	Schmid, Ute
Cangelosi, Angelo	Katz, Irvin	Schoelles, Mike
Casasanto, Daniel	Kemp, Charles	Schultheis, Holger
Cassimatis, Nicholas	Kennedy, William	Sebanz, Natalie
Clancey, Bill	Kintsch, Walter	Shah, Priti
Clement, Catherine	Kiyokawa, Sachiko	Shirouzu, Hajime
Cooper, Rick	Klenk, Matthew	Shultz, Thomas
Cottrell, Gary	Klippel, Alexander	Sloutsky, Vladimir
Cox, Anna	Knauff, Markus	Stracuzzi, David
Dale, Rick	Koedinger, Ken	Sun, Ron
Danks, David	Kokinov, Boicho	Tenenbaum, Josh
DMello, Sidney	Landy, David	Trafton, Greg
Douglass, Scott	Langley, Patrick	Treur, Jan
Estes, Zachary	Love, Brad	Tversky, Barbara
Feeney, Aidan	Luger, George	Upal, M. Afzal
Ferstl, Evelyn	Magnani, Lorenzo	Verguts, Tom
Forbus, Ken	Markman, Art	Waldmann, Michael
Frank, Mike	Matessa, Michael	Wood, Sharon
French, Bob	Miller, Craig	Youmans, Robert
Freudenthal, Daniel	Monaghan, Padraic	Young, Richard

# **CogSci 2012 Sponsors**

*We sincerely thank the sponsors of the 34<sup>th</sup> Annual Meeting of the Cognitive Science Society for their support of the conference awards and the tutorials, and for supporting student participation through reduced registration fees and coverage of travel costs.*

# CogSci 2012 Awards

## Marr Prize

The Marr Prize, named in honor of the late David Marr, is awarded to the best student paper at the conference. All student first authors were eligible for the Marr Prize for the best student paper. The Marr Prize includes an honorarium of \$1,000 and is sponsored by The Cognitive Science Society. The winner of the 2012 Marr Prize for Best Student Paper is:

**George Kachergis, Chen Yu, and Richard M. Shiffrin:** *Actively learning nouns across ambiguous situations* (Friday, 13:00, Track 1)

## Computational Modeling Prizes

Four prizes worth \$1,000 each are awarded for the best full paper submissions to CogSci 2012 that involve computational cognitive modeling. The four prizes represent the best modeling work in the areas of perception/action, language, higher-level cognition, and applied cognition. These prizes are all sponsored by The Cognitive Science Society. The winners of the 2012 Computational Modeling Prizes are:

### Applied Cognition

**Yugo Hayashi:** *The effect of “Maverick”: A study of group dynamics on breakthrough in collaborative problem solving* (Saturday, 14:10, Track 3)

### Perception/Action

**Kevin A. Smith & Edward Vul:** *Sources of uncertainty in intuitive physics* (Friday, 12:40, Track 5)

### Language

**Noah D. Goodman & Andreas Stuhlmüller:** *Knowledge and implicature: Modeling language understanding as social cognition* (Friday, 15:20, Track 1)

### Higher-Level Cognition

**Doug Markant & Todd M. Gureckis:** *Does the utility of information influence sampling behavior?* (Saturday, 12:20, Track 4)

## Cognition and Student Learning (CaSL) Prize

The Cognition and Student Learning (CaSL) Prize is an honorarium of \$1,000 that is awarded to the best paper on research conducted on a topic directly related to cognitive science, educational practice, and subject matter learning. This prize is sponsored by the Institute of Education Sciences (IES). The winner of the 2012 Cognition and Student Learning Prize is:

**Azadeh Jamalian & Barbara Tversky:** *Gestures alter thinking about time* (Thursday, 14:10, Track 4)

## **Student Travel Awards**

Travel awards have been provided to students whose papers were accepted as oral presentations with the highest reviewer rankings, and who indicated a need for travel funding. The Robert J. Glushko and Pamela Samuelson Foundation generously sponsored \$10,000 for student travel awards for these papers. The 2012 Travel Awards went to:

Ricky Chan (Department of English, The University of Hong Kong, Hong Kong)

Gregory Cox (Department of Psychological and Brain Sciences, Indiana University)

Sarah Dolscheid (Max Planck Institute for Psycholinguistics, Nijmegen)

Annie Gagliardi (Department of Linguistics, University of Maryland)

Linn Gralla (Department of Linguistics and Literary Sciences, Universität Bremen)

George Kachergis (Department of Psychological and Brain Sciences, Indiana University)

Jorie Koster-Hale (Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology)

Yakov Kronrod (Department of Linguistics, University of Maryland)

Andrew Lovett (EECS Department, Northwestern University, Illinois)

Doug Markant (Department of Psychology, New York University)

Long Ouyang (Department of Psychology, Stanford University)

Michael Pacer (Department of Psychology, University of California, Berkeley)

Patrick Plummer (Department of Psychology, University of California, San Diego)

Anna Rafferty (Computer Science Division, University of California, Berkeley)

Felix G. Rebitschek (Department of Psychology, University of Greifswald)

Kevin Smith (Department of Psychology, University of California, San Diego)

Sergiu Tcaci Popescu (Laboratoire Psychologie de la Perception, CNRS & Université Paris Descartes)

Tomoki Tsuchida (Department of Computer Science and Engineering, University of California, San Diego)

Joseph Jay Williams (Department of Psychology, University of California, Berkeley)

Ewelina Wnuk (Max Planck Institute for Psycholinguistics, Nijmegen)

Daniel Yurovsky (Department of Psychological and Brain Sciences, Indiana University)

## **Awards Committee**

Markus Knauff (co-chair), Michael Pauen (co-chair), Natalie Sebanz (co-chair), Ipke Wachsmuth (co-chair), Jennifer Wiley (CaSL award coordinator), Felice Bedford, Gary S. Dell, Morton Ann Gernsbacher, Ulrike Hahn, Bernhard Hommel, Boicho Kokinov, Stefan Kopp, Klaus Oberauer, Colleen Seifert, Leon Urbas, David Uttal, Eldad Yechiam.

## **Robert J. Glushko Dissertation Prizes**

The **Cognitive Science Society** and the **Glushko-Samuelson Foundation** will award up to five outstanding dissertation prizes in cognitive science each year. The goals of these prizes are to increase the prominence of cognitive science, and encourage students to engage in interdisciplinary efforts to understand minds and intelligent systems. The hope is that the prizes will recognize and honor young researchers conducting ground-breaking research in cognitive science. The eventual goal is to aid in efforts to bridge between the areas of cognitive science and create theories of general interest to the multiple fields concerned with scientifically understanding the nature of minds and intelligent systems. Promoting a unified cognitive science is consistent with the belief that understanding how minds work will require the synthesis of many different empirical methods, formal tools, and analytic theories. 2011 was the inaugural year of this prize, and a new competition is held annually.

### **Robert J. Glushko Dissertation Prize Recipients**

The 2012 recipients of the Robert J. Glushko Prizes for Outstanding Doctoral Dissertations / theses in Cognitive Science are:

**Dr. Timothy F. Brady** - 2011 PhD thesis "Structured Representations in Visual Working Memory"

Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology

**Dr. Jennifer L. Culbertson** - 2010 PhD thesis "Learning Biases, Regularization, and the Emergence of Typological Universals in Syntax"

Department of Cognitive Science, Johns Hopkins University

**Dr. Nazbanou Nozari** - 2011 PhD thesis "Is Comprehension Necessary for Error Detection? A Conflict-based Account of Monitoring in Speech Production"

Department of Psychology, University of Illinois at Urbana-Champaign

**Dr. Steven T. Piantadosi** - 2011 PhD thesis "Learning and the language of thought"

Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology

**Dr. Rachel Wu** - 2011 PhD thesis "Learning (to Learn) from Spatial Attention Cues During Infancy"

Birkbeck, University of London

## **NSF Funded Joint Conference Grant & Research Fellowships**

In association with the Cognitive Science Society, the US National Science Foundation has funded eight conference grants/research fellowships to US citizens who are enrolled as students at a US institution. The funds support students both to attend the 34<sup>th</sup> Annual Conference of the Cognitive Science Society (CogSci2012) and to participate in a collaborative research project with a sponsoring institution in Japan. The awardees are:

Deanne Adams, David Braithwaite, Heather Burte, Seth Frey, Drew Hendrickson, Laura Morett, Cybelle Smith and Richard Veale.

## Invited Plenary Presentations

### Rumelhart Prize Lecture

Reinforcement Learning in the Mind and Brain: Cinderella at the Cognitive Science Ball

*Peter Dayan*

*Thursday August 2<sup>nd</sup>, 16:30*

### Keynote Talks

Simple Heuristics that Make Us Smart

*Gerd Gigerenzer*

*Thursday August 2<sup>nd</sup>, 09:00*

Building Scientific Cognition: Conceptual Innovation on the Frontiers of Science

*Nancy J. Nersessian*

*Friday August 3<sup>rd</sup>, 09:00*

Situated Conceptualization

*Lawrence W. Barsalou*

*Saturday August 4<sup>th</sup>, 09:00*

**Keywords:** cross cultural diversity; networking; participation; professional development; research collaboration.

Women in Cognitive Science conducts panels at yearly meetings of several professional societies. Their goal is to increase attention to the situation of women cognitive scientists, to better understand the reasons for existing problems of under representation in key positions, and to provide a forum for professional development that encourages both junior and senior scientists to consider the ways in which they might work with their own home institutions to effect change. Specific topics have addressed networking and collaboration, best practices for institutional transformation, and issues of family and academic careers. Speakers and panelists have included both women and men who represented senior and junior scientists and topics have focused on the experience of both faculty and administration in negotiating these issues and in developing policies that are likely to support women's success. Its history demonstrates that WICS is in a unique position to address the concerns of junior as well as senior scientists in their professional careers.

The goal of a small "Connections" conference sponsored by the US National Science Foundation in Japan and the Japan Science and Technology Agency of Japan in 2010 was to establish networking connections between researchers and to strengthen international partnerships for collaboration. American and Japanese participants represented a variety of STEM disciplines. The primary goal of that meeting was to foster the research agendas of the participants. A secondary goal was to "help develop future leaders in science and engineering by encouraging discussion on the institutional environment and culture that are conducive to nurturing women STEM leaders."

The **Interactive Panel Discussion: Professional advancement, leadership and international collaboration** seeks to build on this momentum by bringing together American and Japanese researchers in Cognitive Science at

the 2012 meeting of the Cognitive Science Society in Sapporo, Japan. Speakers include Sanae Ariga (Hokkaido U), Mutsumi Imai (Keio U), Noriko Hoshino (Kobe U Foreign Studies), Naomi Miyake (U Tokyo), Hanako Yoshida (Houston), Laurie Feldman (U Albany & Haskins Labs) and Betty Tuller (NSF). These scientists represent American and Japanese junior and senior researchers, university administrators and program officers/directors of NSF.

Speakers will discuss cross-cultural solutions to foster research productivity and visibility for women scientists. One major theme will be leadership, both how to identify and assume positions that help to develop leadership skills for professional advancement. A related theme is how those experiences do and do not differ across cultures. A second major theme will be how to develop new research collaborations outside of one's primary institution, including international collaborations. All acknowledge that this is not a simple process and often evolves slowly, out of more social networking connections. While such solutions generally occur on an ad hoc basis and vary across individuals, the aim of the WICS workshop is to enable discussion of possible solutions so as to enhance the productivity and visibility for women scientists in cognitive science.

Social Hour and refreshments to follow.

### **Acknowledgments**

Women in Cognitive Science (WICS) was founded in 2001 by Judith Kroll (Penn State), Randi Martin (Rice University), and Suparna Rajaram (Stony Brook) with NSF ADVANCE Funds. From 2007 onwards, Laurie Feldman (Albany) and Janet van Hell (Penn State) have assumed a leadership role within the group. In 2012, Natasha Tokowitz joined the group.

Partial funding for this event comes from NSF Award BCS-1049764 and is organized in conjunction with the Tokyo office of the NSF Office of International Science and

Engineering. Funds were also contributed by the Office of Support for Female Researchers at Hokkaido University.

# **Full-day Workshop proposal: Teleoperated Android as a Tool for Cognitive Studies, Communication and Art**

**Shuichi NISHIO (nishio@ieee.org)**

Hiroshi Ishiguro Laboratory, Advanced Telecommunications Research Institute International (ATR)  
2-2 Hikaridai, Keihanna Science City, Kyoto 619-0288, Japan

**Hiroshi ISHIGURO (ishiguro@sys.es.osaka-u.ac.jp)**

Department of Systems Innovation, Graduate School of Engineering Science, Osaka University  
1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan

## **Theme and Goals**

Following the successful workshops in 2005 and 2006 on *Android Science*, the aim of this full-day workshop is to introduce and discuss on current insights and future usage of teleoperated androids.

Teleoperated androids, robots owning humanlike appearance equipped with semi-autonomous teleoperation facility, was first introduced to the world in 2007 with the public release of Geminoid HI-1. *Geminoid* is a teleoperated android robot that resembles existing human being. While androids were designed for studying human nature in general, *geminoids* was made to study individual aspects as presence or personality traits, tracing their origins and implementation into robots. Both its appearance that resembles the source person and its teleoperation functionality serves in making Geminoid as a research tool. After the release of Geminoid HI-1, several types of teleoperated androids have been produced: Geminoid F, Geminoid DK, Telenoid R1/R2 and Elfoid P1. While the Geminoids are after real existing persons, Telenoid and Elfoid are attempts to represent human beings in their minimalistic forms; a challenge to see to what extent elements that forms us can be omitted but still able to transfer presence of the teleoperating person.

Since their birth, Geminoids and Telenoids have been used in a variety of domains throughout the world, from studies in various fields such as in cognitive psychology / neuroscience, social psychiatry, developmental psychology, robotics, and human-machine interface to philosophy and art. One example is the *android drama* which showed new possibilities on not only on usage for teleoperated android robots but for artistic representations as well as seeking purity in the natures of human beings.

The past workshops that concentrated on autonomous humanlike robots and androids laid a foundation for android science research, a field that integrates the synthetic approach from robotics with the empirical methodologies of the social sciences. Participants, coming from engineering and the social, cognitive, and biological sciences sought fundamental principles underlying cognition and communication between individuals.

In this workshop, we will focus on the further enhanced and broadened usage of teleoperated androids that can provide new means for cognitive science studies, and can bridge

the gap between cognitive neuroscience and the behavioral sciences, as well as philosophy, social science and arts, leading to a new way of understanding human beings.

## **Topics**

- Using teleoperated androids as a controllable mankind for psychological experiments
- The role of affect and motivation in social development or communication
- Empathic relationships among people and/or robots
- How people become adapted to teleoperated androids
- The evolution, development, and nature of agency, intentionality, or social intelligence
- Models of personal, interindividual, group, or cultural norms
- Cross-modal synchronization or stabilized plasticity in speech and/or gesture
- Teleoperated androids in the society
- Androids working alongside people as peers
- Applications in human environments
- Ethical issues concerning teleoperated androids
- Perception of naturalness, attractiveness, or charisma of teleoperated androids
- Minimal elements required to show human likeness
- The relationship between appearance and perceived behavior
- The Total Turing Test
- Teleoperated androids as communication device
- Elderly care with teleoperated androids
- Using teleoperated androids for artistic expression

## **Importance and Relevance for the conference**

This workshop focuses on and discusses about cross-disciplinary studies under the current usage and future possibilities of teleoperated android robot which can provide new means for cognitive science studies, and can bridge the gap between cognitive neuroscience and the behavioral sciences, as well as philosophy, social science and arts, leading to a new way of understanding human beings. Thus, this will provide opportunities for conference participants to see latest

advances in this area as well as to discuss and find research seeds with researchers of different disciplines.

The organizers has been involved in making and conducting studies on teleoperated androids. Prof. Hiroshi Ishiguro is the inventor of both the notion of android science as well as various teleoperated androids, Geminoid, Telenoid and Elfoid. Dr. Shuichi Nishio has been with Prof. Ishiguro in constructing teleoperated android systems and have conducted various laboratory / field studies with them up to now.

### **Audience**

- Robotics engineers and computer scientists with an interest in cognitive psychology, robotics, human-robot interaction, as well as artificial intelligence, machine learning, pattern recognition and control theory.
- Psychologists and sociologists who are concerned and/or interested with embodied communication or social development
- cognitive scientists who are concerned with the relationship between brain processes and social dynamics; social and comparative biologists;
- Philosophers who are interested in human nature issues such as mind/body separation and interaction;
- Artists and dramatists who are interested in new possibilities of art on human nature;

The workshop is of interest to the target participants because teleoperated androids can work as a test tool for social and cognitive theories. Research in this domain depends on interdisciplinary collaboration between engineers and natural and social scientists.

### **Possible presenters**

- Christian Becker-Asano (University of Freiburg, Germany)
- Thierry Chaminade (University College of London, UK)
- Kazuo Hiraki (Tokyo University, Japan)
- Hiroshi Ishiguro (Osaka University, Japan)
- Shoji Itakura (Kyoto University, Japan)
- Karl MacDorman (Indiana University, US)
- Takashi Minato (ATR, Japan)
- Hideyuki Nakanishi (Osaka University, Japan)
- Shuichi Nishio (ATR, Japan)
- Hideaki Ogawa (Ars Electronica, Austria)
- Kohei Ogawa (ATR, Japan)
- Hirata Oriza (Theater company Seinendan)
- Ayse Saygin (University of California, US)
- Henrik Scharfe (Aalborg University, Denmark)
- Hidenobu Sumioka (ATR, Japan)

### **Estimate of the number of participants**

Thirty participants including organizers and presenters.

### **Publication**

The publication of the workshop will be done in four ways.

1. To our research collaborators:  
We have research collaboration with many laboratory in the world, especially in Japan, Europe and US. We will ask these collaborators to submit papers and to participate in the workshop.
2. Via grant agency:  
This workshop theme, teleoperated android, is now studied under several grants in Japan and Europe. We will ask the grant agency to promote the workshop.
3. To the cognitive science and robotics society:  
This will be done via mailing lists and web pages.
4. To the press people: Our laboratory is accepting more than 50 requests for interviews and shooting from various press in the world. We will advertise the workshop to the press who visited us in the past.

After the workshop has been accepted, we will ask several journals for a special issue so that the fine presentations will appear gathered in much details. Also, we are planning to publish a book that collects the findings and activities related with teleoperated android robots.

### **Special requirements**

If the space allows, we would like to bring our robots and run them throughout the workshop so that people who cannot attend the conference may be able to teleoperate the androids from remote and pseudo-join the conference. In this way, people can see the actual teleoperated androids in use and participants can discuss the real effects of using the robots in the workshop.

This will require: power supplies (100V), a separate room not far away for placing air compressor (because this is noisy) and an Internet connection.

# Workshop on Modeling the Perception of Intentions

**David Pautler (pautlerd@ihpc.a-star.edu.sg)**

Programme in Computational Social Cognition, Institute of High Performance Computing  
1 Fusionopolis Way, 16-16 Connexis  
Singapore 138632

**Keywords:** intention recognition; action understanding; theory of mind; event perception; social cognition; computational modeling; probabilistic inference.

exploring a complex cognitive activity from different disciplinary perspectives.

## Abstract

Attributing intentions to others based on observations of their behavior is a core cognitive ability. It is also a necessary precursor to social judgments such as judgments about responsibility and morality. The seminal work of Heider and Simmel (1944) highlighted the spontaneity, richness, and range of intention attributions that can be elicited by a stimulus as impoverished as moving geometric figures. Subsequent research has revealed a wide range of visuospatial cues that suggest specific intentions as well as observer attributes that influence judgments. How are such cues and observer attributes integrated into an inferred specific intention? A handful of processing models have used frameworks such as schema-matching or probabilistic inference to integrate such cues. This workshop will address two questions: 1) How have different fundamental paradigms fared in the quest for a model of human intention perception? and 2) What questions about this topic are most in need of answers?

## Goals

- To foster on-going communication, and perhaps coordinated research, across disciplines among researchers on this topic.
- To provide an overview for the audience of how different disciplines have approached this topic.

## Why a workshop?

Perception of intentions has been studied by cognitive, social, and developmental psychologists, philosophers, anthropologists, artificial intelligence researchers, and computer vision researchers. Apart from its intrinsic interest, there is the prospect of different approaches informing each other. Because there are several lines of research to cover, and because we want to encourage speakers not just to cover their own lab's work but propose ways of linking with others, a symposium or half-day workshop would not afford enough time.

## How it is relevant?

The topic has drawn much interest across disciplines, and the confirmed speakers represent many of those disciplines. The event could provide a useful example the value of

## The Organizer

While trained as a computer scientist myself, I have led a project on this topic for two years, collaborating closely with cognitive and social psychologists. Together we have completed a literature review spanning the disciplines listed above, designed and built a computational simulation furthering the schema-matching line of research, and published that work in a journal article last year:

Pautler, D., Koenig, B.L., Quek, B.K., Ortony, A. (2011). [Using modified incremental chart parsing to ascribe intentions](#). *Behavior Research Methods* 43(3), 643-665, DOI: 10.3758/s13428-011-0128-2.

## Target Audience

The workshop will be most relevant to those working in high-level perception, theory of mind, and plan recognition, but we expect it to be of general interest to many researchers in cognitive, developmental, and social psychology, as well as artificial intelligence, anthropology, and philosophy. It is hard to predict the number of early arrivals at the first CogSci conference to be held in Asia, but we expect approximately 30 people in the audience.

## Archiving and Special Requirements

If videotaping will be available at the conference site, we would like to use the workshop budget of US\$1200 to cover that cost. Videos might be hosted by the organizer's institutional website, <http://cogsys.ihpc.a-star.edu.sg/>.

## Publicity

The most relevant mailing lists we know of are: [Plan Rec Psychonomics](#), and [ACT-R](#). All of those listservs are commonly used for announcements of such events. Furthermore, [CASA](#) (conference on Computer Animation and Social Agents) will be held here in Singapore in May, and we will advertise there.

# And Now for Something Completely Different: Python in Cognitive Science

Mark Andrews ([m.andrews@ntu.ac.uk](mailto:m.andrews@ntu.ac.uk))

Jesse Diaz ([jesse.diaz@ntu.ac.uk](mailto:jesse.diaz@ntu.ac.uk))

Division of Psychology,  
Nottingham Trent University  
Nottingham  
NG1 4B,UK

**Keywords:** Python; Programming; Scientific Computing; Numerical Computing; Computational Modelling; Experimental Design; Stimuli Presentation Software; Data Analysis;

## Objectives and Scope

The objective of this tutorial is to introduce and motivate the use of the Python programming language in cognitive science research. Within the last 10 years, the development of scientific and numerical libraries in Python has grown to the point where Python can now be used as a scientific and numerical computing environment comparable to products like Matlab and Mathematica. As of yet, however, it appears that knowledge of the potential applications of Python to research in cognitive science is still rather limited. The aim of this tutorial, therefore, is to describe these areas of application and to advocate the advantages and appeals of using Python as the principal programming language in cognitive science research. Given the generality of the tools being discussed, it is hoped that this tutorial will have widespread appeal and relevance.

## Outline of Tutorial

The tutorial will be divided into three main parts. The first part introduces the Python language generally. The second introduces numerical and scientific programming in Python. The third part introduces how to develop computer-based psychology and psychophysics experiments using Python.

The tutorial will involve both classroom style lectures with slides and workshop style computer-based worked examples and exercises. The audience are encouraged to bring their own laptop, and all necessary software will be provided in advance.

## General Introduction

In order to introduce Python, we will begin by describing the fundamentals of the Python language. We will also demonstrate how to start an interactive Python session using the ipython environment. The audience will be encouraged to follow the examples themselves using their own computers.

As part of this introduction, we will also compare Python to its alternatives, paying particular attention to comparison with Matlab. This comparison is inevitable, given that Matlab has traditionally been the principal scientific computing tool in cognitive science. Notable points of similarity between Python and Matlab are that both offer an interactive array-processing and visualization environment using high-level dynamic programming languages. Both are designed

for rapid prototyping and development. Both allow for seamless extension using external modules written in compiled languages like C/C++ and Fortran. Notable advantages of Python, however, include that it is a general-purpose language whose application goes far beyond numerical array processing. Python is one of the top five programming language currently in use throughout the world. Python is a remarkably well-designed object-oriented language whose standard library is large and comprehensive. Finally, Python is non-commercial open-source software distributed according to an unrestricted software license. Likewise, its large set of third-party extension modules and libraries are, almost without exception, also distributed using unrestricted or public open-source software licenses.

## Numerical and Scientific Python

The basic Python language as introduced in the previous section lacks n-dimensional numerical arrays and the ability to easily plot and visualize data. These capabilities, in addition to a large number of more special-purpose scientific libraries are provided by the Scipy/Numpy suite of modules. These libraries are seamlessly integrated with ipython to create a rich interactive array-processing and visualization environment, comparable in functionality to Matlab and Mathematica.

We will begin this section by describing ipython's capabilities more extensively than done in the previous section. These include: Interactive high-performance parallel computing for clusters and multicore architectures, an online interactive Notebook comparable to that used in Mathematica, sql-based searchable command histories, in-line graphics, and symbolic mathematics with T<sub>E</sub>X-based output.

Having established how to use ipython, the audience will be encouraged to follow the examples as we discuss the the following topics:

Arrays: General n-dimensional arrays and their operations (e.g. element-wise function application, summing, slicing, indexing, searching) are provided by numpy.

2d visualization: Plotting and visualization, especially of 2d data, are provided by matplotlib, amongst others.

3d visualization: Complex 3d graphics are provided by mayavi.

Parallel computing: Interactive high-performance and parallel programming is a built-in functionality of python.

Integration with C/C++ and Fortran: Interfaces to programs written in compiled languages like C/C++ or Fortran are pro-

vided through the use of interface generators like `swig` and `f2py`.

## Computer-based Experiments

Computer-based cognitive psychology and psychophysics experiments are now almost ubiquitous in cognitive science. While these tasks have been traditionally handled by GUI-based programs like *e-prime* and *superlab*, these programs do not allow for the flexibility and control that is often demanded by researchers. While high-level languages like Matlab are being used as an alternatives to GUI-based programs, Matlab's special-purpose nature is not well suited to the non-numerical programming necessary for experimental stimuli presentation and recording. By contrast, due to the generality of its language, its extensive of widget toolkits (e.g. `wxpython`, `pyGTK`, `pyQt`), and video-game libraries (`pyGame`, `pyglet`), Python allows for considerable flexibility and sophistication in the design experiment software.

Currently, there are at least 4 Python-based stimulus-presentation programs: `Psychopy`, `open-sesame`, `vision-egg`, and `pyepl`. This final section will describe each in brief, but concentrate primarily on `psychopy`.

The aim of this section will be to discuss the principles and functionality of `psychopy` and then to work through examples of simple experiments (e.g. the stroop task, the lexical-decision task). `Psychopy`'s basic object-oriented stimuli and events will be described in order to understand its extensibility. We will, however, also make extensive use of its *builder* interface that can allow from rapid development of code templates. Finally, we will discuss how to interface `psychopy` and Python generally with external devices such as serial response boxes that allow for precise timing of responses.

## The Presenters

The main presenter for this tutorial will be Mark Andrews. Mark Andrews is a Lecturer (Assistant Professor in North American Terminology) in the Division of Psychology, Nottingham Trent University, and has a research affiliate position in the Division of Psychology and Language Sciences, University College London. His teaching primarily involves advanced statistics and experimentation methods. In this capacity, for the past two years, he has taught programming using R and Python to undergraduate and postgraduate students, with student evaluations being overwhelming costive. He has been a Python user for over 10 years, and has extensive experience with all the topics that will be covered in this tutorial. He also is very familiar with the Cognitive Science community, having presented at past conferences often, and being awarded the Computational Language Modelling prize in 2009. Jesse Diaz is a research assistant in Nottingham Trent University, with extensive experience with general Python programming and especially with the use of Python in psychology experiments, both using tools like `psychopy` and by using Python web-application frameworks for online experiments.

## Materials

The use of Python in science is backed by a vibrant community of developers and advocates. We have been in direct contact with principal individuals in this community and they have generously offered their support, both by providing their presentation slides and other teaching materials and by providing their general advice on how to promote Python in settings such as the Cognitive Science tutorials. For example, we have been contact with Dr. Fernando Perez who is a research scientist in neuroscience at UC Berkeley. Dr. Perez is the creator and principal developer of `ipython`. He has kindly offered the extensive teaching materials on the `ipython` computing environment that are at his disposal. Likewise, we have been in contact with Dr. Jonathan Peirce who is an Associate Professor in Psychology in the University of Nottingham. Dr. Peirce is the creator and principal developer of `psychopy`, and has had extensive experience both teaching `psychopy` to students and promoting its use in psychology and cognitive neuroscience. As a result, we have a considerable body of relevant teaching materials to draw upon. Examples are available at sites like following, and elsewhere:

<http://scipy-lectures.github.com>

<http://ipython.org/presentation.html>

**Keywords:** classical information processing; quantum information processing; logic and mathematical foundation; Bayesian probability, quantum probability; Markov and quantum processes; quantum entanglement; quantum game theory; conceptual combinations; decision making, memory.

causal reasoning, decision making, conceptual combinations, memory recognition, and associative memory. This tutorial is needed to introduce and train cognitive scientists on this promising new theoretical approach to cognitive science.

## General Purpose

This *full day* tutorial is an exposition of a rapidly growing new alternative approach to building computational models of cognition and decision based on quantum theory. The cognitive revolution that occurred in the 1960's was based on classical computational logic, and the connectionist/neural network movements of the 1970's were based on classical dynamical systems. These classical assumptions remain at the heart of both cognitive architecture and neural network theories, and they are so commonly and widely applied that we take them for granted and presume them to be obviously true. What are these critical but hidden assumptions upon which all traditional theories rely? Quantum theory provides a fundamentally different approach to logic, reasoning, probabilistic inference, and dynamical systems. For example, quantum logic does not follow the distributive axiom of Boolean logic; quantum probabilities do not obey the disjunctive axiom of Kolmogorov probability; quantum reasoning does not obey the principle of monotonic reasoning. It turns out that humans do not obey these restrictions either, which is why we consider a quantum approach. This tutorial will provide an exposition of the basic assumptions of classic versus quantum information processing theories. These basic assumptions will be examined, side by side, in a parallel and elementary manner. The logic and mathematical foundation of classic and quantum theory will be laid out in a simple and elementary manner that uncovers the mysteries of both theories. Our main point will be to show that quantum theory provides a unified and powerful explanation for a wide variety of paradoxes found in human cognition and decision ranging across findings from attitudes, inference,

## Presenters

Jerome Busemeyer is a professor of Cognitive Science at Indiana University. He was editor of the *Journal of Mathematical Psychology* and he is now *Associate Editor of Psychological Review*. His research interests include decision making and dynamic modeling. Peter Bruza is a professor of information science and he is a pioneer in the field of quantum interaction (QI). He also serves on the editorial boards of *Information Retrieval*, *Journal of Applied Logic*, *The Logic Journal of the IGPL*. Jerome and Peter are co-authors of a new book "*Quantum models of cognition and decision*" Cambridge University Press, 2012. Taiki Takahashi is a professor at Hokkaido University working in the field of neuroeconomics, but also with expertise in quantum decision theory, and he has published articles on this topic in *Physical Letters A*. Jennifer Trueblood is a PhD student at Indiana University with several publications on the topic of quantum cognition including one in *Cognitive Science*.

## Previous Tutorials and Symposia

This tutorial was presented for a full day at the Cognitive Science meetings in Nashville, 2007, Washington DC 2008, and Amsterdam, 2009, which included around 30 people each time. The ratings obtained from participants after the tutorial were all very good. Also this tutorial follows a symposium on quantum cognition presented at the Cognitive Science meeting 2011, and these papers will appear as a special issue in *Topics in Cognitive Science*. A similar tutorial was presented at the 3<sup>rd</sup> and 4<sup>th</sup> Annual Meetings on Quantum Interaction held

at Saarbruecken, Germany, 2009, and Aberdeen Scotland, 2010 with about 40 participants.

### Participant Background

This tutorial will introduce participants to an entirely new area and no previous experience or background with quantum theory will be assumed. **No background in physics is required.** In fact, except for a few simple examples to motivate the idea, little or no reference to physics will be made during main part of the tutorial. What is required is an elementary background in classic logic and probability. During the tutorial, we will review basic concepts of linear algebra needed for quantum theory. (e.g., vectors, projectors, unitary transformations).

### Material to be Covered

1. The first topic will examine the major differences between classic versus quantum theories of probability. The concept of superposition is introduced and distinguished from classic probability mixtures. The important issue of measurement in classical and quantum systems will be compared and examined. The key to this section will be several dramatic empirical examples illustrating empirical violations of the classic laws of probability (e.g., conjunction, disjunction, total probability) and the parsimonious explanation of all these violations by quantum theory. (1 hr).
2. Next we examine the differences between classical and quantum dynamical systems. The basic idea of a Markov processes will be introduced and compared with quantum processes. (Cognitive architectures and many neural networks can be represented as Markov processes). A parallel development of Markov and quantum processes will be shown. The concept of a state will be distinguished for Markov and quantum systems. The effects of measurement on the state of the system are compared for Markov and quantum systems. A key feature of this section is to show when and how quantum processes depart from Markov processes. (1 hr)
3. The third part will present the details of Matlab and R programs used to compute the choice probability and response time predictions of a dynamic quantum model that has been developed to explain three ongoing research programs in cognitive and decision making: violations of the “sure thing principle” of rational decision theory, violations of dynamic consistency in decisions, and interference of categorization on decisions. (45 min)
4. The fourth part will introduce quantum computing and information processing ideas. The concepts of a bit and a qubit will be contrasted. The concept of a conjunction of properties used in classic information processing theory will be related to the concept of a tensor product space used in quantum theory. The controlled U-gate will be introduced and compared with a production rule. The linear transformation of states used by quantum theories will be related to the distributed representation and content addressable properties of connectionist/neural networks.

The concept of fuzzy representation and probabilistic representation will be discussed and compared for fuzzy set, Bayesian, and quantum theories. The idea of an entangled state will be described. Bell’s inequality will be introduced, and violations found in conceptual combinations are reviewed. The dramatic implications of violations of this inequality for classical theories will be discussed. (45 min)

5. This part will present the details of Matlab programs used to perform quantum computing for some complex information processing tasks. This includes pattern recognition and planning event dependent action sequences under uncertainty. Basic tools of quantum computing will be used including Kronecker products to perform U-gate operations, and partial traces for measurement of components of a complex system. (45 min).
6. This part will detail how quantum theory is being used to model the human mental lexicon. In particular, quantum entanglement will be described as a means of modeling cognitive phenomena in non-reductionist way, e.g., conceptual combinations. A key feature of this section is to introduce formal tools and experimental methods which can determine whether cognitive phenomena can be validly modeled in a decompositional way. (1.0 hr)
7. Review and future directions (30 min).

# Proposal for a tutorial on Using Bayes to Interpret Non-significant Results

**Zoltan Dienes (dienes@sussex.ac.uk)**

School of Psychology, University of Sussex, Brighton, BN1 9QH

**Keywords:** Bayesian inference; Bayes Factors; confidence intervals; likelihood intervals; non-significant results; evidence.

## 1. Outline the objectives and scope of the tutorial.

The purpose of the tutorial is to present simple tools for dealing with non-significant results, an area which cognitive scientists have consistently found problematic. In particular, people will be taught how to apply Bayes Factors and likelihood intervals to draw meaningful inferences from non-significant data, using free easy-to-use on-line software: Software which allows one to determine whether there is strong evidence for the null and against one's theory, or if the data are just insensitive, a distinction  $p$ -values cannot make. These tools have greater flexibility than power calculations and allow null results to be interpreted over a wider range of situations. Such tools should allow the publication of null results to become easier.

The online software for Bayes Factors (with instructions) is here:

[http://www.lifesci.sussex.ac.uk/home/Zoltan\\_Dienes/inference/Bayes.htm](http://www.lifesci.sussex.ac.uk/home/Zoltan_Dienes/inference/Bayes.htm)

And the online software for likelihood intervals here:

[http://www.lifesci.sussex.ac.uk/home/Zoltan\\_Dienes/inference/Likelihood.htm](http://www.lifesci.sussex.ac.uk/home/Zoltan_Dienes/inference/Likelihood.htm)

## 2. Explain how the tutorial will be delivered giving a detailed description of the material that will be covered.

The tutorial will consist of lectures by me; after the second hour people will be able to use their internetted laptops to work through examples on the software, and thereby interactively follow the points I make, and also explore the tools for themselves.

Schedule:

9:30 – 10:30 Basics: The different aims of significance testing and Bayesian inference (including the three moral and inferential paradoxes of significance testing and their solution)

10:45 – 11:45 Bayes Factors

12- 1 Examples with Bayes Factors, to illustrate appropriate and inappropriate use, and robustness checks (Bayesian analysis can of course be misused in ways we will clarify)

2-3 Confidence intervals, likelihood intervals, credibility intervals with examples, including the (little discussed) four principles for using intervals inferentially in theory testing

3:30 – 4:30 Examples showing the complementary strengths and weaknesses of Bayes factors and interval methods for interpreting null results

4:45 – 5:30 Discussion of e.g. any particular data people wish to bring, and free questions

The tutorial will emphasize how statistics, both Bayes factors and interval estimates, can be brought into more intimate contact with theory than has typically been the case, and appropriate ways of doing this. (Interpreting null results requires making contact with theory.)

My emphasis will be practical rather than ideological, though conceptual arguments will be important.

## 3. Justify why it is important to have a tutorial in the proposed area at the conference.

Users of statistics have been criticised for decades for their interpretation of non-significant results. Users have either used null results to count against a theory that predicted a difference (without establishing that the results actually counted against the theory) or ignored the results as uninformative (without establishing that they were). One only need pick up any recent issue of almost any journal to see this. (I don't exclude many of my own papers from this criticism!) In that sense the topic has been important to clarify for a long time. Recently, however there was been a resurgence of interest in Bayesian and likelihood methods, and the recent developments are particularly useful for users of statistics. Little can be more important than that we as a community draw appropriate inferences from data, and get the most from our data. The issues are applicable to the whole community of cognitive scientists, and hence appropriate for a meeting of the Cognitive Science Society. Several strategies for dealing with null results will be taught, as well as reasons why the most common strategies, orthodox as well as Bayesian, can be problematic.

## 4. Specify how relevant the topic is for the conference (i.e., does it focus on an emerging or cross-disciplinary research topic?)

Bayes has been making a resurgence for getting on 10 years now in cognitive science. Part of the interest has been in Bayes as a model for how the mind works. While the workshop has nothing to say on what the best theory of the mind is, theories of how we should analyse data are clearly relevant to theories of how the mind works. More importantly, part of the recent interest in Bayes is precisely on the topic of the workshop – principles and methods for drawing statistical inferences. Indeed, at the meeting of the Society last year Kruschke held a very successful workshop on Bayesian inference based on his book. I will be teaching a slightly different philosophy and different methods (but which complement Kruschke's approach). Kruschke

covered Markov Chain Monte Carlo methods and hierarchical modelling; the workshop will not cover these topics. This workshop offers different tools to the researcher, simple tools for dealing with a t-test (i.e. 1-df contrasts – which is all we are normally really interested in), tools which a researcher could directly use straight after walking out of the workshop (without learning R, BUGS, or anything else). I will make most use of the notion of strength of evidence rather than posterior probabilities. In terms of data, the Bayesian analyses taught just require the sort of summary statistics SPSS or other packages produce. I believe that a majority of people will leave transformed in how they conceive of non-significant results, however they then choose to deal with them.

### **5. State why you are well suited to organize a workshop in the proposed area.**

Dienes (2008) is an introduction to orthodox, Bayesian and likelihood inference which has an associated website with free online software. Dienes (2011) discusses the arguments for Bayes, and also provides practical advice for using Bayes. I have been teaching students to use Bayes at the University of Sussex since 2005 on the undergraduate course Philosophy of Psychology, and the masters course Philosophy of Science, thereby coaching hundreds of students on applying Bayes to over a hundred different papers of their choice. This experience has helped me both pedagogically and in seeing how to apply Bayes in a practical way. I have now submitted (and had reviewed) more than half a dozen standard research papers with Bayesian analyses in them (using the same software that I will be teaching). The Bayesian analyses have not been queried, so my arguments for their use and interpretation seem unproblematic to the community so far! Four of the papers are now published (see

[http://www.lifesci.sussex.ac.uk/home/Zoltan\\_Dienes/inference/Bayes.htm](http://www.lifesci.sussex.ac.uk/home/Zoltan_Dienes/inference/Bayes.htm)

and scroll to bottom for examples of published papers using Bayes as a tool). I have also lectured on using Bayes in China, Norway, Greece and around the UK.

In January I ran the proposed workshop as a one-day national workshop for the Economic and Social Research Council (ESRC) National Centre for Research Methods. Some feedback:

“Thank you again for an extremely informative day that was very well delivered. Sussex students must be very pleased about having such a clear and articulate statistics tutor,” from a UK Professor of Psychology and Research Director of Department. “I’d like to thank you for a very enjoyable and stimulating workshop last Tuesday. Your web page is also extremely helpful,” from a lecturer in Genetics. “I came to the workshop not sure about how useful it would be or how easy to understand – Zoltan made it really interesting and clear with examples. I will definitely use this in my research,” from a psychology postgraduate.

### **6. Identify the likely audience for the tutorial.**

**Specifically, state whether the tutorial will introduce participants to an area, or whether it will cover an advanced topic for participants who already have knowledge in a particular area.**

The audience is anyone who uses statistical inference – i.e. just about everybody attending the Meeting could be interested. I will assume the audience is familiar with a t-test; I will not assume more detailed knowledge. But those with more extensive knowledge will also appreciate the material (I have lectured on the material to undergraduates as well as to statisticians; it has been well received in all contexts).

### **8. Specify any special requirements for the tutorial - particularly, any specialist equipment or software required by participants..**

A laptop per participant, or one laptop between two. Ideally the laptops should be connected to the net.

### **9. Provide full contact details: name of contact person, affiliation, address (including post code/zip and country), telephone, fax, e-mail, names and affiliation of additional author(s).**

# Nengo and the Neural Engineering Framework: From Spikes to Cognition

Chris Eliasmith ([celiasmith@uwaterloo.ca](mailto:celiasmith@uwaterloo.ca))

Terrence C. Stewart ([tcstewar@uwaterloo.ca](mailto:tcstewar@uwaterloo.ca))

Center for Theoretical Neuroscience, University of Waterloo  
200 University Ave West, Waterloo, ON, N2L 3G1, Canada

**Keywords:** cognitive modeling; neural engineering; representation; decision making; working memory; cognitive architecture; cognitive control

## Tutorial Objectives

As we learn more about the neural activity underlying cognitive function, there is an increasing demand to explicitly and quantitatively connect cognitive theories to neurological details. Bridging these levels provides benefits in both directions; aspects of the cognitive theory can predict and be constrained by neurological details, and the neurological details can in turn identify important modifications to the overall cognitive theory.

This tutorial introduces the Neural Engineering Framework (NEF; Eliasmith and Anderson, 2003) and the associated open-source toolkit Nengo (<http://nengo.ca>), which offer a general method for implementing high-level cognitive theories using biologically realistic spiking neurons. This approach takes a high-level description of a cognitive theory (in terms of information being represented and transformed) and combines it with relevant anatomical and neurophysiological constraints, producing a detailed mechanistic model of how interacting neurons can efficiently produce the desired behaviour. The resulting models can be run to produce predictions of spike patterns, firing rates, fMRI time-courses, accuracy, reaction times, and overall behaviour. Complete details can be found in the book *How to Build a Brain* (Eliasmith, 2012; to be released by OUP at CogSci 2012).

These methods have been made more accessible by the construction of the software package Nengo, which provides a graphical interface suitable for network construction. This tutorial introduces the NEF theory explaining how high-level function can be systematically related to single cell activity, and provides extensive hands-on experience building these neural models using Nengo. Our central objective is to allow participants to leave the tutorial with a method for constructing cognitive models with spiking neurons, and experience using that method in an intuitive software environment.

## Tutorial Structure

This full-day tutorial combines the theoretical bases of the Neural Engineering Framework with hands-on examples of practically applying these concepts using Nengo. For example, the presentation of the theory for how a scalar value can be represented by the spiking pattern in a group of neurons is paired with a tutorial on using Nengo to generate such a neural group and simulate its behavior over time.

Participants are expected to bring a laptop to follow along with these tutorials (Windows, OS X, and Linux are all supported, and software is provided).

In particular, the tutorial covers using the NEF to represent scalars and vectors, perform linear and nonlinear transformations on these values, and store information over time. These are the basic mechanisms required for a wide range of algorithms, and form the basis for our models of sensorimotor systems, working memory, and cognitive control. This provides participants with basic building blocks for constructing novel neural implementations of a wide variety of cognitive models.

To supplement this, we more closely examine how cognitive theories can be expressed in terms of vectors and transformations. The basic approach of employing *semantic pointers* (vectors that combine the benefits of semantic similarity measures with the compositionality of symbol structures) is described. We show how this method provides a unified approach to many types of cognitive models, including perceptual, symbolic reasoning, and motor control models. For example, we show how to construct a non-classical symbol system, capable of performing the operations required for symbolic cognition. The result is a scalable and efficient neural cognitive architecture, constructed from the basic approaches described in the first half of the tutorial.

Finally, we explore recent results in building whole-brain models using the NEF. This involves a fully integrative model spanning vision, object recognition, working memory, cognitive control, and motor control to produce a neural cognitive architecture. This ~3 million neuron model is built in Nengo, uses images for input, draws digits using a 2-joint arm as its output, and is performs a variety of tasks, including list memory, mental addition, inductive reasoning over symbols, and reinforcement learning. The tutorial covers this model and its behavioural and neurobiological constraints, including the dopaminergic learning system.

Variants of this tutorial were presented at ICCM 2009, CogSci 2010, Telluride 2011, and CogSci 2011. An on-line tutorial is available at <http://nengo.ca>, and significant changes have been made in terms of scaling Nengo models up to larger neuron counts and more complex behaviour.

## Tutorial Justification

The Neural Engineering Framework provides a method to bridge the gap between cognitive and neural theories. Its earlier applications have been to sensory and motor systems, including the barn owl auditory system, rodent navigation, swimming control in zebrafish, and the vestibular ocular

reflex in monkeys. However, these same principles are now being applied to cognitive models. This includes models of serial-order recall (Choo & Eliasmith, 2010), action selection in the basal ganglia (Stewart, Choo, & Eliasmith, 2010), visual working memory (Singh & Eliasmith, 2006), deep belief networks for visual recognition (Tang & Eliasmith, 2010), the Wason card task (Eliasmith, 2005), the Tower of Hanoi task (Stewart & Eliasmith, 2011), and a model of inductive rule generation that received the computational modelling prize in higher-level cognition at CogSci 2010 (Rasmussen & Eliasmith, 2010).

While we find that the Neural Engineering Framework produces extensive new insights into the neural grounding of cognitive function, we also find that the underlying mathematics and a lack of familiarity with biologically realistic neural modeling have been a significant barrier to entry for new researchers. As a result, we feel that a full-day tutorial is most appropriate for introducing the necessary concepts from control theory, signal theory, and theoretical neuroscience. Feedback from previous tutorials has been extremely positive, with participants now using Nengo for their own research and in the classroom at the University of Manchester, Rensselaer, Yale, Franklin & Marshall College, and Stanford.

The NEF provides an exciting new tool for cognitive science, as it provides a technique for producing direct neural predictions from cognitive theory. Furthermore, it leads to important theoretical results as to the relationships between neural properties and the high-level algorithms they are capable of implementing (e.g. the relationship between neurotransmitter re-uptake rate and the 50ms cognitive cycle time; Stewart, Choo, & Eliasmith, 2010).

These consequences are also very general, as the NEF provides techniques that can be applied to a wide variety of cognitive theories. It provides a structure for organizing a high-level description such that it can be implemented by realistic spiking neurons, providing meaningful data in terms of the expected spike patterns, time course, and behavioural accuracy. We have made use of it in a variety of contexts, and have developed tools that support the creation and analysis of these models. Tutorial participants will gain hands-on experience with a tool that helps generate new models and can be applied to existing models. In both cases, these tools will help participants incorporate ever-more-abundant neural data into their research.

Figure 1: The Nengo interface. Network construction (left) is done either by point-and-click or by Python scripting. Visualization (right) provides on-the-fly control of inputs with plots of spiking activity, decoded representations, etc.

## Audience

Participants are not expected to have any previous experience with neural modeling. All participants are encouraged to bring a laptop for installing Nengo (Linux, OS X, and Windows versions are provided), allowing for hands-on interactions with the models discussed.

## Presenters

Chris Eliasmith holds a Canada Research Chair in Theoretical Neuroscience, and is director of the Centre for Theoretical Neuroscience at the University of Waterloo. He has over 50 publications spanning neuroscience, psychology, philosophy, computer science, and engineering, on topics including working memory, mental representation, population coding, neural dynamics, computation, automatic text classification, and cognitive architectures. His recent book, *How to Build a Brain*, and his earlier book, *Neural Engineering*, form the basis for this tutorial.

Terry Stewart is a postdoc in the Centre for Theoretical Neuroscience, and has developed large-scale models with the NEF, including the Tower of Hanoi task, focussing on problems of cognitive control.

# Probability, programs, and the mind: Building structured Bayesian models of cognition

Noah D. Goodman (ngoodman@stanford.edu)

Department of Psychology,  
Stanford University, Stanford CA 94305 USA

Joshua B. Tenenbaum (jbt@mit.edu)

Department of Brain and Cognitive Sciences,  
Massachusetts Institute of Technology, Cambridge MA 02139 USA

## Objectives and scope

Human thought is remarkably flexible: we can think about infinitely many different situations despite uncertainty and novelty. Probabilistic models of cognition (Chater, Tenenbaum, & Yuille, 2006) have been successful at explaining a wide variety of learning and reasoning under uncertainty. They have borrowed tools from statistics and machine learning to explain phenomena from perception (Yuille & Kersten, 2006) to language (Chater & Manning, 2006). Traditional symbolic models (e.g. Newell, Shaw, & Simon, 1958; Anderson & Lebiere, 1998), by contrast, excel at explaining the productivity of thought, which follows from compositionality of symbolic representations. Indeed, there has been a gradual move toward more structured probabilistic models (Tenenbaum, Kemp, Griffiths, & Goodman, 2011) that incorporate aspects of symbolic methods into probabilistic modeling. Unfortunately this movement has resulted in a complex “zoo” of Bayesian models. We have recently introduced the idea that using programs, and particularly *probabilistic programs*, as the representational substrate for probabilistic modeling tames this unruly zoo, fully unifies probabilistic with symbolic approaches, and opens new possibilities in cognitive modeling. The goal of this tutorial is to introduce probabilistic models of cognition from the point of view of probabilistic programming, both as a unifying idea for cognitive modeling and as a practical tool.

The probabilistic programming language Church (Goodman, Mansinghka, Roy, Bonawitz, & Tenenbaum, 2008), mathematically grounded on the stochastic  $\lambda$ -calculus, provides a universal language for representing probabilistic models. We will use Church to introduce key ideas and examples of probabilistic modeling. A Church program represents a probabilistic model, and hence inferences that can be drawn from this model, without committing to a process level implementation of inference. This will allow us to focus the tutorial on structured representations and probabilistic inference phenomena without worrying about the details of inference algorithms (such as Markov chain Monte Carlo) that tutorials on Bayesian modeling often become bogged down in. On the other hand, because there are existing inference tools for Church (e.g. Wingate, Stuhlmüller, & Goodman, 2011), students will get hands-on experience with performing inference over different probabilistic models.

The tutorial will include several in-depth case studies where the probabilistic programming viewpoint is particularly useful. These include intuitive theories, such as naive physics and theory of mind, and models of inductive learning that exhibit learning-to-learn and structured abstraction.

## Tutorial format

This full-day tutorial aims to introduce students to key ideas of, and new tools for constructing, structured probabilistic models. We will assume only basic familiarity with probability and with programming (i.e. minimal mathematical or statistical background). The tutorial will thus be appropriate for a general Cognitive Science audience, as well for practitioners of bayesian modeling who want to learn about probabilistic programming.

We will teach this tutorial drawing on a combination of infrastructure and materials that we’ve have used to teach graduate-level classes at Stanford and MIT (and which has been used by others at UCSD and University College Dublin). In particular, students will use the on-line ChurchServ interface to Church, in order to explore these tools without the need to install special software. This interface has been integrated into a Wiki document on Probabilistic Models of Cognition ([http://projects.csail.mit.edu/church/wiki/Probabilistic\\_Models\\_of\\_Cognition](http://projects.csail.mit.edu/church/wiki/Probabilistic_Models_of_Cognition)) that we will use for portions of the tutorial.

In addition, we will create new examples focussed on aspects of the approach that we expect to be both new and interesting to a Cognitive Science audience. These include models of physics and vision, based on forward-simulation with standard graphics and vision simulators, and models of language understanding that predict detailed, quantitative human data.

We will use the morning session to introduce the ideas of probabilistic modeling and the Church language, to illustrate basic ideas (such as explaining away, and hierarchical models), and to provide hands-on exercises using Church to create models. The afternoon session will be devoted to case studies of more sophisticated applications of these ideas to cognition, including studies from vision, language, and reasoning.

We, the instructors, have extensive experience in probabilistic modeling of cognition and extensive experience teaching courses and tutorials on these techniques. In addition we are active at the forefront of developing probabilistic programming languages, both conceptually and as practical

tools. Both of the instructors have extensive experience teaching tutorials on probabilistic models of cognition specifically from the viewpoint of Church, including courses to graduate students, high-school students, linguists, and psychologists.

Tutorials on Bayesian Models of Inductive Learning have been taught at the Annual Conference of the Cognitive Science Society in 2006, 2008, and 2010 (all co-taught by JBT). This tutorial will be similar in covering the ideas of recent work in Bayesian modeling, but will do so from a different viewpoint and will introduce a different skill set (Church and probabilistic programming). We have presented similar tutorials at the European Summer School For Logic Language and Information 2010 (NDG), the Institute for Pure and Applied Mathematics (NDG and JBT), and several other venues. We will adjust the tutorial based on feedback from those experience as well as the particular audience we expect at Cognitive Science.

## Abstract

This tutorial will introduce attendees to fundamental concepts in the clustering and dimensionality reduction fields of unsupervised machine learning. Attendees will learn about the assumptions algorithms make and how those assumptions can cause the algorithms to be more or less suited to particular datasets. Hands-on interaction with machine learning algorithms on real and synthetic data are a central component of this tutorial. Students will use the software platform Divvy (freely available from the Mac App Store or [divvy.ucsd.edu](http://divvy.ucsd.edu)) to visualize and analyze data in real time while testing the concepts learned during formal instruction. We encourage attendees to bring their Mac laptops and their own datasets for the hands-on portion of the tutorial, and if possible to email their datasets ahead of time to [josh@cogsci.ucsd.edu](mailto:josh@cogsci.ucsd.edu).

Attendees will leave the tutorial with a much better understanding of basic concepts in unsupervised machine learning. Pragmatically they will understand when to apply, e.g., k-means to a dataset versus single linkage clustering. Attendees will also learn how to integrate Divvy into their existing research workflow so that they can quickly test and compare machine learning algorithms on their data.

## Objectives and Scope

This tutorial will introduce attendees to fundamental concepts in the clustering and dimensionality reduction fields of unsupervised machine learning. Attendees will learn about the assumptions algorithms make and how those assumptions can cause the algorithms to be more or less suited to particular datasets. Hands-on interaction with machine learning algorithms on real and synthetic data are a central component of this tutorial. Students will use the software platform Divvy to visualize and analyze data in real time while testing the concepts learned during formal instruction. We will encourage attendees to bring their own datasets for analysis in the hands-on portion of the tutorial.

Attendees will leave the tutorial with a much better understanding of basic concepts in unsupervised machine learning. Pragmatically they will understand when to apply, e.g., k-means to a dataset versus single linkage clustering. Attendees will also learn how to integrate Divvy into their existing research workflow so that they can quickly test and compare machine learning algorithms on their data.

## Topics

We will split the tutorial into two sections, a morning section focused on clustering and an afternoon section focused on dimensionality reduction. Both sections will start with a brief (approximately 1.5 hours) formal introduction to mathematical and conceptual underpinnings of the topic, followed by a hands-on lab session applying the concepts learned directly

before. The lab sessions will start with synthetic datasets designed to reinforce conceptual lessons, and then move to real datasets provided by ourselves and the attendees.

The clustering section will cover centroid-based methods (such as k-means), hierarchical methods (such as single linkage), spectral clustering, and probabilistic modeling (such as Gaussian mixture models). The dimensionality reduction section will cover linear methods (such as PCA and projection pursuit) and that nonlinear methods (such as Isomap, tSNE, and Kernel PCA).

Though we will provide formal mathematical characterizations, our focus will be on conceptual differences between techniques, specifically related to choosing the correct technique based on known structure in a dataset. Additionally, we will emphasize that there is no single best clustering or embedding for any given dataset (in other words, there is no universally agreed upon objective function for clustering and dimensionality reduction). One's own analysis goals can play a significant role in, e.g., determining the number of clusters to search for. Finally, on the topic of evaluation we will cover the visualization and interpretation of algorithmic output as well as formal quality measures such as Silhouette for clusterings and Trustworthiness for embeddings.

We will transact our lab sections in Divvy, a free and open-source software platform for performing unsupervised machine learning (see <http://divvy.ucsd.edu> where there is a video of Divvy in action). Divvy will allow attendees to rapidly cluster, reduce and visualize a wide variety of datasets without having to write any code. Divvy can concurrently visualize several perspectives on a dataset and can switch between datasets with one click, even when algorithms are computing in the background. Divvy integrates well with existing research workflows—it can import data from Matlab and R and it exports data and visualizations in standard formats for further analysis.

## Qualifications

Joshua Lewis recently completed his PhD thesis, *Anthropocentric Data Analysis*, on the topic of reintegrating humans into the data analysis process. He is the lead software architect behind Divvy, and has done several studies on the relationship between human reasoning and machine learning. He is a postdoc in UCSD's Natural Computation Lab under the supervision of Virginia de Sa. He has attended CogSci and presented papers every year starting in 2009. Joshua will lead the tutorial.

Virginia de Sa is an associate professor at UCSD in the Cognitive Science department. She has done extensive re-

Figure 1: The full Divvy UI. Each visualization represents a different view of the same dataset (generated by combining a dimensionality reduction technique, a clustering technique and a dataset visualizer) and users can set the properties of each view using the tools to the right. A list of datasets resides in the bottom right, allowing the user to switch between them at any time, even while results are computing in the background.

search in the fields of machine learning and human perception and has ten years of experience in teaching undergraduate and graduate courses in data analysis and machine learning to people with both weak and strong mathematical backgrounds. She is the PI on NSF Grant #SES-0963071, which funds Divvy's development. Virginia will assist in developing the tutorial curriculum.

For detailed CVs, please see our websites (listed in the Contact Us section below).

### Relevance to CogSci

Data analysis is a fundamental part of most scientific endeavors, and the judicious application of machine learning techniques to the analysis process is often quite profitable. Further, in the field of Cognitive Science in particular, a basic understanding of machine learning techniques is valuable for interpreting the work done in computer science-focused subfields such as artificial intelligence and computational neuroscience. Clustering and dimensionality reduction are established methodologies for performing data analysis, and this tutorial presents them from the unique perspective of enabling the human researcher to use them wisely.

### Audience

This tutorial will introduce attendees to the area of unsupervised machine learning for data analysis. It does not presuppose any machine learning background and thus will be

appropriate for any graduate student or faculty member interested in integrating machine learning techniques into their research process. On the other hand, it will be less valuable to those researchers who already have extensive experience applying machine learning techniques.

### Attendee Requirements

Divvy a Mac OS X 10.6/10.7 application, and the hands-on portions of the lab will require a Mac laptop with a 64-bit Intel processor (basically any Mac made in the last three years). Attendees will be able to easily download and install the software at the conference or ahead of time. Those who do not have or do not wish to bring a laptop will be grouped with those who do. Hopefully enough attendees can bring laptops to have groups of about 2 to 4 people per analysis team. Last year's conference was suffused with glowing white Apple logos, so we don't think this will be an onerous requirement. Additionally, attendees can submit datasets to us ahead of time that we can integrate into the instruction as examples of real-life data analysis problems.

# Practical Advice on How to Run Human Behavioral Studies

**Frank E. Ritter (frank.ritter@psu.edu)**

++1 (814) 865-4453

College of IST, Penn State

University Park, PA 16802 USA

**Keywords:** Psychology experimental method; HCI usability studies.

## (I) Objectives and scope of the tutorial

The lack of materials on the details of running human experiments can lead to a gap between theory and practice, which is particularly acute in cognitive science done outside of psychology departments. Consequently, labs frequently must not only impart these practical skills to students informally but also must address misunderstandings arising from this divorce of theory and practice in their formal education. Researchers in psychology often end up appalled by the lack of this common but undocumented sense when behavioral research is reported by researchers outside of psychology. This tutorial provides practical advice on how to run studies for beginning students and researchers coming starting to run studies.

The details about how to run the studies themselves, how to interact with subjects and so on, are often learned solely through apprenticeship in a psychology or HCI lab. However, many researchers who are running or want to run studies do not have access to learning this tacit knowledge.

This half-day or full-day tutorial will provide participants with an overview of how to run studies with human participants, that is, not how to design or analyze studies but the practicalities of how to setup, debug, and run studies. It will help people running experiments to run them more effectively safely, and comfortably. Our purpose is to provide hands-on knowledge about experimental procedure.

The tutorial will cover the major topics noted in Figure 1. In particular, the tutorial will cover the role of identifying the research problem and reading in the general area; preparation for running a study, including piloting and IRB proposals; preparing to run a formal study, including advertising and recruiting subjects; running study sessions; and wrapping up a study.

## (II) How the tutorial will be delivered

The tutorial will cover the topics in Figure 1 using a lecture/discussion format. The topics will be introduced using a presentation and discussion will follow each section using scenarios and questions included in the book and developed for the Cognitive Science Conference. An early draft (approximately half the current length) of the material is available at [acs.ist.psu.edu/reports/ritterKM09.pdf](http://acs.ist.psu.edu/reports/ritterKM09.pdf), and published copies will be available in the future from Sage.

**Jong W. Kim (Jong.Kim@ucf.edu)**

++1 (814) 865-4453

Psychology, U. of Central Florida

Orlando, FL 32816 USA

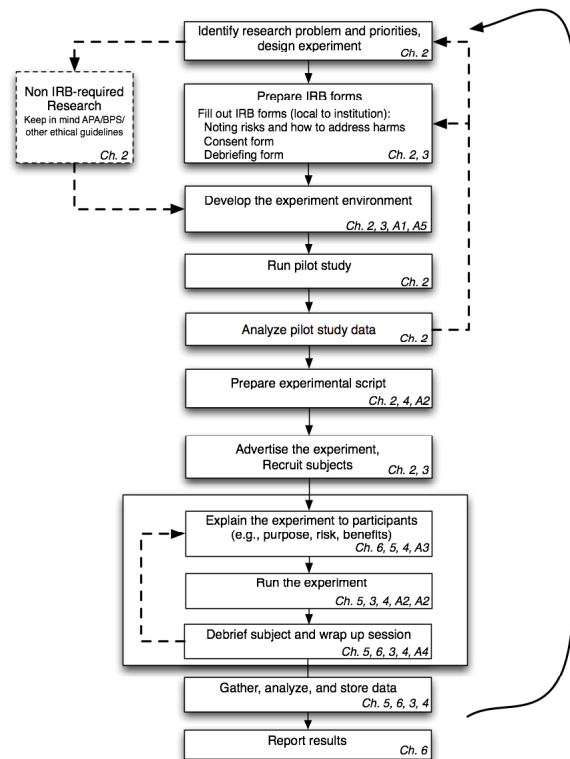

Figure 1. A pictorial summary of the research process with respect to running a human behavioral study. This is similar to, but developed separately from Bethel and Murphy's (2010) figure for human-robotic studies

A copy of the 121 page book as a printout will be provided (assuming that participant numbers can be specified well enough in advance or copied by the conference locally).

## (III) Why the presenter and authors are well suited to give a tutorial in the proposed area

The presenter is well qualified to prepare and present a tutorial in this area. Along with colleagues, Ritter has recently written a book for Sage on this topic (Ritter, Kim, Morgan, & Carlson, in press).

Ritter has also run and directed studies with human participants (e.g., Klein, Bennett, Whetzel, Granger, & Ritter, 2010; Reder & Ritter, 1992; Ritter, Freed, & Haskett, 2005; St. Amant, Horton, & Ritter, 2004; Yeh, Gregory, & Ritter, 2010). His collaborators on this tutorial and book include an industrial engineer (Kim), a research assistant who helps run studies (Morgan), and a professor of psychology who has been a member of an IRB board and

director of a psychology department subject pool (Carlson). While these co-authors will not be presenting, they will help prepare the slides and are co-authors of the book that will be given to attendees.

Ritter is also familiar with tutorials in general because he served as the first co-chair of tutorials at the Cognitive Science Conference in 1999. Since then he has served as tutorial chair or co-chair at the Cognitive Science Conference (2001, 2002, 2004, 2005), and at the International Conference on Cognitive Modeling (2004, 2006, 2007, 2009, 2010, 2012), and was the co-chair of the 2011 HCI Consortium Workshop, which was made up exclusively of tutorials on ways of knowing in HCI. In addition, he gave a tutorial on Soar at HCI International when it was in Japan and two invited lectures in Japan, has hosted a Japanese visitor, and published a paper in Japanese (Ritter, 2009).

This tutorial has been given at the *Behavior Representation in Modeling and Simulation (BRIMS 2012)* conference. The tutorial will be slightly modified for attendees at the Cognitive Science Conference by making it less practitioner/industry oriented, and making it more oriented for Asian and European researchers and for computer scientists. This will mean changing a few slides to represent problems more frequently found in academia than in industry, and assuming slightly different research questions are being asked, for example, a greater emphasis on cognitive science studies and less on controlled observation for product design.

#### **(IV) Why it is appropriate to have a tutorial in the proposed area?**

Practical skills on how to run studies are well known and well taught skills in psychology departments, but often not well known outside of psychology departments. Yet, in cognitive science, if the field believes in building computational models and gathering data to test those models (or starting the other way 'round, or having non-psychologists gather data), for example, work by Morita and colleagues (Morita, Miwa, Kojima, & Ritter, 2011), then how to gather that data is an important skill for every cognitive scientist, no matter their home discipline or outlook.

There are few teaching materials on the practical details on how to run studies, which this tutorial starts to address. So, this tutorial covers an established but not well documented or often formally taught common technique. The tutorial and related book will show that there are important aspects of this technique, and we would argue that without training these aspects are not well known to researchers outside of psychology, and put the resulting researchers and research done by those not trained at risk for failure, interpretable results, or incorrect results.

#### **(V) The likely audience for the tutorial.**

Earlier versions of the material have been used in teaching graduate courses at Carleton University (cognitive science, Canada), U. of Connecticut (human factors, US), Florida Institute of Technology (HCI), U. of Texas at Houston

(medical informatics), Middlesex U. (HCI, UK), Georgia Tech (industrial engineering), and at Penn State (information sciences and HCI). So, we believe that is accessible and useful to undergraduate and graduate students who are working with human participant studies, but are outside of psychology departments.

So, the likely audience for the tutorial are students and researchers outside of psychology departments who are running studies with humans in cognitive science, HCI, and related disciplines. It will also be useful to researchers in industry who are interested in running safer, more efficient, more controlled experiments.

**Keywords:** Fungus-eater robots, Emotional fungus-eaters,  
Urge theory.

Robotics studies have developed at many places across the globe and explored many different approaches. Among others, Japan has been one of the leading countries promoting robotics studies, breaking new ground with establishing Human Robot Interaction as an international society and leading the world with very human-like Geminoids. In the 1940's, Masanao Toda, a founder of cognitive science in Japan, proposed a visionary robotic system to explore and understand the function of emotion as a trigger of cognitive mechanisms for survival. For example, when a human was exploring in the ancient wilderness, fear must have worked as a switch between the exploratory mode and the find-an-escape mode to promote survival. The thought-experimental robot, the Fungus Eater, seeded some of the early AI research when it was introduced to psychologists in the U.S. and the Netherlands (Toda, 2000, 1982).

In this symposium, we will look to a few of the starting points of robotics research, like that of Toda's, and explore how this has expanded to include AI and robotics researchers in Europe, particularly with emphasis on embodiment and emotion, and how this has influenced new developments of robotics research in Japan. Our aim is to explore how to extend our understandings of human cognition through the eye of robotics, allowing us to reflect upon ourselves more directly than carefully scripted experiments.

The first speaker, Rolf Pfeifer, who has once connected his work on robot's emotion to Toda's fungus eater robots, will reflect on his own and Toda's work, to foresee the future of cognitive sciences, through the development of robotics studies. The second speaker, Yuichiro Anzai, has witnessed the beginning of the raise of active cognitive sciences in the U.S. in Herb Simon's lab during the late

1970's, and actually worked with Toda at Hokkaido University, to implement Toda's ideas into robotics reality. Reflecting on his own trajectory as a cognitive scientist, reflects on Toda's work to push open new research topics under the theme of robotics and emotion. The third speaker, Hiroshi Ishiguro, as a leading robotics engineer studying human cognition through the eyes of most human-like robots like his own Geminoid, will push him further to integrate neuro-scientific studies, to gain further insights. Putting all three together, we hope to see how the topics of robotics and emotion would re-open a new research field for cognitive sciences.

## Do robots need emotions? An embodied perspective

Rolf Pfeifer (University of Zurich)

Traditionally, in robotics, artificial intelligence, and neuroscience, there has been a focus on the study of the control or the neural system itself. Recently there has been an increasing interest into the notion of embodiment in all disciplines dealing with intelligent behavior, including cognitive science, psychology, philosophy, and linguistics. In an embodied perspective, cognition and emotion are conceived as emergent from the interaction of brain, body, and environment, or more generally from the relation between physical (including physiological) and information (neural, control) processes. It can be shown that through the embodied interaction with the environment, in particular through sensory-motor coordination, information structure is induced in the sensory data, thus facilitating categorization, perception and learning. The patterns thus induced depend jointly on the morphology, the material characteristics, the action and the environment. Because biological systems are mostly "soft", a new engineering discipline, "soft robotics", has taken shape over the last few

years. This is of particular interest to the fields of developmental, social and service robotics, where robots will share their living space with humans and safe and pleasant interaction is at center stage. I will analyze the different roles that emotion can play in this process. Moreover, I will discuss the far-reaching implications of embodiment, in particular of having a soft body, on our view of the mind and human behavior in general: Cognition and emotion are no longer centralized in the brain, but distributed throughout the organism. Because in "soft" systems part of the functionality is in the morphology, the physiology, and the materials, there is no longer a clear separation between control and the to-be-controlled, which implies that we need to fundamentally re-think the notion of control. These ideas will all be illustrated with case studies from biology -- humans and animals -- and robotics. Finally, I will try to establish the relation between these thoughts, Toda's "Fungus Eaters", and his theory of emotion.

### **From fungus-eater robots to emotional, socially interact-able robots**

Yuichiro Anzai (JSPS)

Toda had been trained as a theoretical physicist before he changed his research fields into psychology. This shift contributed to free him from the burden of stereotypic academic psychological thinking, venturing into under-researched topics of emotion, not in isolated fashion but in a more integrated, general-systemic perspectives of his own. Toda's combination of the two fields has given him some unique insights on the nature of man and time. Toda believed that a system of emotions is an evolutionally organized survival mechanism with nearly optimal operating characteristics, which would explain the complexities of our social interaction, altruism, social coalition, as well as the structures of the society. As one of the closest younger colleagues with him, I will develop my own interpretation of his work, to foresee the research only possible with an engineering orientation like robotics.

### **Cognitive Neuroscience Robotics**

Hiroshi Ishiguro (Osaka University/ATR)

Robotics is not just engineering but also human science. The current robotics focuses on *interaction* in addition to *navigation* and *manipulation* that were major topics in previous robotics. Researchers are developing interactive humanoids and androids with humans by using technologies developed in robotics and knowledge found in cognitive science and neuroscience. On the other hand, the developed robots, humanoids and androids, are important research platforms for cognitive science and neuroscience.

Thus, robotics is tightly coupled with the human sciences. For example, we can studies effects of human-like

appearance in inter-personal and social situations by using androids mimicking human appearances. We can study social relationships and the dynamics among humans and robots by using multiple interactive humanoids.

We call this new robotics *cognitive robotics* or *cognitive neuroscience robotics*. This talk will introduce a series of robots developed in Osaka University and ATR and discuss cognitive experiments using them. Especially, the androids give us various insights on human-human and human-robot interactions in inter-personal and social situations.

Researchers joining to the Center Of Excellence program titled *cognitive neuroscience robotics* in Osaka University are sharing this new interdisciplinary research area and working together. This talk also introduces several topics from the program, some of which are related to the topics on studies of emotion.

**Keywords:** Intuitive physics; qualitative reasoning; probabilistic programming; Bayesian models; psychophysics.

People have a powerful “physical intelligence” – an ability to infer physical properties of objects and predict future states in complex, dynamic scenes – which they use to interpret their surroundings, plan safe and effective actions, build and understand devices and machines, and communicate efficiently. For instance, you can choose where to place your coffee to prevent it from spilling, arrange books in a stable stack, judge the relative weights of objects after watching them collide, and construct systems of levers and pulleys to manipulate heavy objects. These behaviors suggest that the mind relies on a sophisticated physical reasoning system, and for decades cognitive scientists have been interested in the content of this knowledge, how it is used and how it is acquired. In the last few years, there has been exciting progress in answering these questions in formal computational terms, with the maturation of several different traditions of cognitive modeling that have independently come to take intuitive physics as a central object of study. The goals of this symposium are to: 1) highlight these recent computational developments, focusing chiefly on qualitative reasoning (QR) models and Bayesian perceptual and cognitive models; 2) begin a dialog between leading proponents of these different approaches, discussing a number of dimensions along which the approaches appear to differ and working towards bridging those differences; 3) enrich these models with perspectives from empirical work in cognitive science.

**Background.** The research to be discussed builds on several decades of prior work from multiple traditions in cognitive science. Cognitive psychologists since the 1970s have studied the role that human intuitive physics plays in development, perception, education, and reasoning. Behavioral research with adults focused on identifying errors and biases in people's general understanding and theories about physical rules (McCloskey, 1983), as well as psychophysical studies of how sensory cues drive specific judgments in dynamic displays (Todd & Warren, 1982). Early and ongoing developmental work has identified milestones in cognitive sensitivity and expectations about core physical principles (Baillargeon, 2007). Though these efforts have made significant progress, they did not frame

their results as computational models with sufficient clarity and power to explain people's physical reasoning in complex and varied scenes.

Crucial computational progress has come from the fields of human and computer vision, artificial intelligence (AI), and machine learning. Human and machine vision researchers have recently developed computational models of natural scene understanding (Oliva & Torralba, 2007), but their focus has been on knowledge about the geometry and semantics of scene layouts, not the role of physical constraints and how physical properties are represented and exploited for prediction, reasoning and planning. AI researchers have been developing frameworks for qualitative reasoning (QR) and applying them to physical domains for over 30 years, and these approaches have now matured to the point that they can both solve challenging real-world inference problems and engage directly with behavioral experiments, giving state-of-the-art accounts of people's intuitive reasoning in a wide range of science and engineering domains (Forbus, 2011). The framework of Bayesian reasoning in probabilistic generative models has revolutionized AI and machine learning, and in the last decade has also come to provide a lingua franca for sophisticated reverse-engineering models of human perception, action and cognition (Chater et al, 2006; Tenenbaum et al, 2011). But only in the last few years have Bayesian models been applied to challenging physical reasoning problems, and been shown to give strong quantitative accounts of human physical judgments (Sanborn et al, 2009; Hamrick et al, 2011).

This symposium brings together leading researchers modeling intuitive physics from the QR, Bayesian cognition and perceptual modeling traditions, to discuss highlights of recent models and points of contact and contrast between different modeling approaches. The talks and discussion will explore several axes in the space of possible models, including the following: rational reverse-engineering vs. descriptive or heuristic accounts; qualitative vs. quantitative reasoning; probabilistic vs. deterministic inference; lower-level perceptual vs. higher-level cognitive inferences; implicit vs. explicit reasoning; analog simulation vs. symbolic rule-based representations; the role of memory-, experience- and learning-dependent reasoning; the role of

causal, counterfactual and explanatory reasoning; reasoning about simple rigid bodies vs. complex physical entities and concepts, like non-rigid objects, non-solid substances, fluids, gasses, heat; simple scenarios with few objects moving in simple ways vs. compound scenes of many objects interacting and moving according to complex dynamics.

The speakers come from various avenues of artificial intelligence and cognitive science: Sanborn studies computational models of memory and cognition; Battaglia, computational perception and motor control; Forbus, AI and qualitative reasoning; Tenenbaum, learning and inference in humans and machines.

#### **Sanborn: Reconciling intuitive and Newtonian mechanics for colliding objects**

People have strong intuitions about the masses of objects and the causal forces that they exert upon one another when they collide. These intuitions appear to deviate from Newtonian physics, leading researchers to conclude that people use a set of heuristics to make judgments about collisions. We show that people's judgments about mass are indeed consistent with Newtonian physics, provided uncertainty about the velocities of the objects is taken into account. The resulting rational model of intuitive dynamics easily extends to accommodate other aspects of people's inferences about physical causation, such as judgments of whether one object caused another to move. We argue that intuition and physics need not be divorced, and that a simple psychological process - stochastically approximating Bayesian inference by recalling previous collisions - can bring them together.

#### **Battaglia: Intuitive mechanics in physical reasoning**

I will explore the idea that the brain has an "intuitive mechanics", a realistic model of physics that can estimate physical properties and predict probable futures. This intuitive mechanics is surprisingly faithful to the laws of classical mechanics, it captures statics, dynamics, forces, collisions, and friction. It is fundamentally probabilistic, it supports Bayesian inferences that robustly handle uncertainty, and, like people, its predictions can deviate from objective reality. And, it is resource-bounded, supporting only judgments that can be made based on a few low-precision, short-lived simulations. We conducted a series of psychophysical experiments in which participants made physical judgments about various complex, 3D scenes, and found that this formal model of intuitive mechanics well-predicts people's responses by accounting for their accuracy and several systematic biases. These results suggest that an approximate, probabilistic model of physics forms the basis of human physical reasoning. More generally, this principled computational approach provides a unifying framework for analyzing and understanding this crucial part of human cognition.

#### **Forbus: Qualitative modeling: Capturing human reasoning about the physical world**

There is ample evidence that qualitative representations of space, quantity, and causality capture important regularities of human reasoning about physical situations and systems

(Forbus, 2011). Qualitative reasoning has been used to model intuitive phenomena, such as motion, liquids, and heat. It has also been used to model aspects of the reasoning of scientists and engineers, such as guiding the solution of quantitative problems and extracting insights about complex dynamical systems from visual data. Qualitative representations of space provide a bridge between perception and conceptual knowledge, and can be used to model visual problem solving. When combined with analogical reasoning, qualitative models can provide explanations for aspects of conceptual change (eg. Friedman & Forbus, 2010). This talk will summarize recent work on modeling conceptual change concerning intuitive notions of force, the human circulatory system, and how the seasons change. There is great potential for synthesis between qualitative and Bayesian modeling: Qualitative modeling provides formal languages for hypotheses, while statistical information (in our case, computed automatically via analogical generalization over examples) provides criteria for accepting hypotheses.

#### **Tenenbaum: Integrative perspectives**

I will discuss the prospects for building computational models of intuitive physical reasoning that integrate features of qualitative and probabilistic approaches introduced earlier in the symposium, and present preliminary results on several lines of work exploring this integration. Specific points will include (1) using qualitative reasoning to generate efficient proposals for Monte Carlo-based approximate inference in probabilistic models; (2) using dynamic probabilistic models as the basis for linguistic ascriptions of causal responsibility and explanatory reasoning (joint work with Gerstenberg and Langado); (3) modeling conceptual change in intuitive physics via hierarchical Bayesian inference over symbolic expressions for physical laws (joint work with Ullman).

**Keywords:** relational thinking, analogy, comparison, cognitive development, computational modeling

The ability to perceive, comprehend and reason about relations (i.e., *relational thinking*) is central in human cognition. Relational thinking is powerful because it is structured. Specifically, relational thought allows inferences and generalizations that are constrained by the *roles* that elements play, rather than strictly the properties of the elements themselves.

The role of relational comparisons in learning is emerging as an important area of developmental and learning science research. Relational comparisons allow learners to derive symbolic, abstract, and conceptual knowledge representations that are generative, in that children and adults can then use them broadly in new contexts to reason about new elements. Indeed, comparison seems to underlie the very development of the structured relational representations that underlie relational cognition.

This symposium aims to bring to together research on the role of comparison in developmental and adult learning. Specifically, we present research on the role of comparison in the development of spatial reasoning, language learning, adult mathematics learning, and computational approaches to learning structured (i.e., symbolic) representations.

## Christie & Gentner: Domain Specific vs Abstract Language in Spatial Learning

Many studies have suggested that language provides important tools for learning and thinking in cognitive development. In this work we test one specific claim concerning the cognitive effects of language learning: namely, that systematic semantic structure in language can invite correspondingly systematic conceptual structure (Gentner, 2010; Gentner & Christie, 2011). Evidence for this claim comes from prior studies by Loewenstein and Gentner (2005) in which children performed better on a difficult spatial mapping task involving three-tiered structures when they were given the monotonic set of spatial terms *top, middle, bottom*

than when they were given the less systematic set of terms *on, in, under*. To discover the generality of these effects, in this series of studies we asked whether children given *nonspatial* (but systematic) language would still show an advantage in the spatial mapping task. We presented children with a spatial mapping task as in Loewenstein & Gentner (2005). There were three groups: one heard a systematic set of spatial terms (*top/middle/bottom*); one heard a systematic set of nonspatial terms (*one/two/three*); and a third heard a nonsystematic set of nonspatial terms (*dog/pig/cat*). In addition to the standard three-tiered mapping task, we also conducted a vertical-to-horizontal mapping task. The results suggest that (1) children benefit from systematic language; (2) domain-specificity benefits early learning; and (3) at older ages, abstract language can have a larger advantage in a difficult transfer task.

## Imai, Haryu, & Okada: Progressive alignment in verb learning

Verbs should be extended by the sameness of action, whereas nouns should be extended attending to similarity of objects. Children under four years of age easily generalize a novel noun to other objects of like kinds, whereas even 4-year-olds tend to fail extending a novel verb to the same action performed by a different agent or with a different object (Imai et al., 2005, 2008). Children fail to segregate the action from the objects constituting it. In other words, children fail to structurally align action events. Previous research suggests that object similarity between objects in corresponding relational roles can promote structural alignment and help children notice higher-order relational similarity (e.g., Gentner & Toupin, 1986). Borrowing this idea, two experiments examined whether young children's verb generalization would be fostered by similarities between corresponding objects in the two events.

In the first experiment 4 year-old children were shown a video in which a woman was doing a novel action with a novel object, and heard a novel verb. Children were then asked to extend the verb to either a

situation where the action from the video was performed on a novel object (AS), or a novel action was performed on the object from the video (OS). In the AS video, the object was either similar in shape to the object in the original action event (*same object condition*), or dissimilar to the original object (*dissimilar object condition*). Children performed better in the similar object condition, suggesting that object similarity enhanced overall similarity across events and helped children map a novel verb to the same action.

The second study tested whether verb generalization with the help of object similarity can bootstrap 4-year-olds into verb generalization even with perceptually dissimilar objects. Indeed, four-year-olds succeeded in verb generalization across dissimilar objects after having experienced a verb generalization task with similar objects; but they failed when they had experienced verb generalization with dissimilar objects from the beginning.

### **Son & Stigler: Fragmented analogies from procedural understanding of mathematics**

Cross-national comparisons of math pedagogy (e.g., Stevenson & Stigler, 1994) indicate that US classrooms are highly focused on procedures without explanation of their conceptual foundations. The long-term consequences of such pedagogy are dire. Even though the domain of mathematics fundamentally requires an understanding of quantitative relations, students may merely amass a collection of seemingly arbitrary rules along with fragments of relational knowledge. Although analogical processes are typically powerful for reasoning across domains, when rules and procedures are not grounded in relational concepts, students may exhibit fragile or incorrect mappings across contexts thus resulting in inconsistent quantitative reasoning. We examined this hypothesis in a sample of college students (mostly Psychology majors) enrolled in a statistics course. In two studies, students were asked to reason about the results of dividing a positive value,  $a$ , with integers (e.g.,  $a/5$  vs.  $a/9$ ), decimals (e.g.,  $a/.1$  vs.  $a/.05$ ), and variables (e.g.,  $a/n$  vs.  $a/(n-1)$ , given that  $n > 1$ ). Students were asked to indicate which of two given values was larger and why. The integer problem was presented first because it could serve as a potential source for analogical transfer. The first study was conducted with individual interviews where students often chose not to use a pen and paper that was available to them. In study 2, students were asked to write down their choices and rationale. Judgments of quantity in the context of decimals and variables were reliably worse than with integers. Examinations of the rationale given for their choices showed that different numerical contexts yielded distinctly different reasoning strategies. Strategies used for reasoning about integers were either

abandoned or misapplied when reasoning about decimals or variables. Research on analogical reasoning may help educators remedy such fragmented understanding.

### **Doumas: Developing structure**

DORA (Discovery Of Relations by Analogy; Doumas, Hummel, & Sanhofer, 2008) is a symbolic connectionist network that uses time as a signal to dynamically bind distributed (i.e., connectionist) representations of relational roles and objects into explicitly relational (i.e., symbolic) structures. DORA relies on the processes of analogical mapping and intersection discovery to highlight shared abstract properties between separate systems and subsequently predicates these similarities as explicit (i.e., symbolic) representations that can be bound to arguments. Subsequently, DORA can exploit the pattern of activation that emerges between mapped role-filler pairs as a cue to combine these sets of role-filler pairs into a single multi-place relational structure. These processes permit the discovery and predication of shared properties and relations across otherwise different systems and thus allow DORA to learn structured representations from unstructured examples. The DORA model has been used to simulate more than 20 phenomena from child and adult relation learning (e.g., Doumas & Hummel, 2010; Doumas et al., 2008). We propose that DORA's learning mechanism provides an account of how humans learn relational representations and the development of analogical reasoning.

inference; uncertainty

## Motivation

Principles of sound statistical inference underpin prominent accounts for a variety of cognitive phenomena, including perception, learning, and decision-making. Linking these building blocks of cognition to the biological substrate that supports them, recent work has investigated how the brain implements probabilistic inference and learning under uncertainty. The interplay between the psychological and biological levels of analysis has shed light on the structure of cognition and computation at both levels.

This symposium builds on Peter Dayan's seminal contributions to linking psychological, neural and computational phenomena. In particular, speakers will discuss recent work growing out of two areas where Dayan made early and fundamental contributions: the brain's mechanisms for reinforcement learning, and neural representations supporting probabilistic inference under uncertainty.

## Reinforcement learning and the basal ganglia

**Authors:** Kenji Doya and Makoto Ito

**Abstract:** The discovery of the parallel between the firing of dopamine neurons and the temporal difference error signal of the reinforcement theory in the 1990s brought a breakthrough in understanding the function of the basal ganglia. Previously the most enigmatic part of the brain is now considered as the center for linking perception, action,

and reward. After more than a decade from the discovery, however, there still remain questions to be answered, such as what striatal neuron firing represents, how and where an action is selected, and how negative reinforcement is realized. Here we review Peter Dayan's seminal contributions and recent developments.

## Fractionating model-based reinforcement-learning its component neural processes

**Author:** John P. O'Doherty

**Abstract:** It has recently been proposed that action-selection in the mammalian brain depends on at least two distinct mechanisms: a model-free reinforcement learning (RL) mechanism in which actions are selected on the basis of cached values acquired through trial and error, and a model-based RL system in which actions are chosen using values computed on-line by means of a rich cognitive model of the decision problem and knowledge of the current incentive value of goals. While much is now known about the putative neural substrates of the model-free RL system and its concomitant temporal difference prediction error, much less is known about how model-based RL is implemented at the neural level. In this talk I will review recent evidence from a series of functional neuroimaging studies in humans supporting the presence of neural signals within a wide expanse of cortex that are relevant to model-based RL. These include, a state-action based prediction error signal within a fronto-parietal network that could mediate learning of the cognitive model, a goal-value signal encoding the value of putative goal-outcomes within the

ventromedial prefrontal cortex, computations corresponding to action-contingency within inferior parietal cortex, and the representation of the effort costs of an action within the dorsomedial frontal cortex. These different computations then need to be integrated in order to construct an overall model-based action-value. Taken together, this evidence suggests that model-based reinforcement-learning theory provides a scaffold upon which a deeper understanding of the functions of a large extent of cortical territory within the mammalian brain can be built.

### **Probabilistic inferences in neural circuits using probabilistic population codes**

**Author:** Alexandre Pouget

**Abstract:** A wide range of seemingly unrelated behaviors can be formalized as instances of probabilistic inferences. This includes odor recognition, sensorimotor transformations, decision making, simple arithmetics and visual search, to name just a few. We will present a neural theory of probabilistic inference in which neurons encode probability distributions using a basis function decomposition of the log probability or log likelihood. This approach makes very specific predictions about the form of the variability in neural responses, as well as about the neural implementation of various probabilistic inferences such as product of distributions, marginalization and sampling. We will discuss several experimental tests of these predictions in the context of arithmetics, visual search and bistable perception.

### **The neural process of subjective belief formation in humans**

**Author:** Peter Bossaerts

**Abstract:** We present a general experimental paradigm with which to study human belief formation from experience. We first establish that human learning proceeds along Bayesian principles, but from subjective albeit robust priors rather than the true prior. Second, properly dissociating neural encoding of values and beliefs, we identify the default mode network as the locus of beliefs learned from frequencies. Third, we study the neural basis for combining objective frequentist information with prior beliefs and discover that Bayesian posterior beliefs are encoded bilaterally in the lateral prefrontal cortex.

**Keywords:** Marr; levels of description and explanation;  
computational level; algorithmic and representational level;  
implementational level.

## Introduction

Thirty years after Marr's landmark posthumous book, *Vision* (Marr, 1982), the argument for which he is most cited remains the distinction between computational, algorithmic and representational, and the implementation levels. In the interim, many reformulations of this basic distinction have been proposed, but is it still relevant? This symposium will discuss whether there is still a place for the algorithmic and representational level, with its cognitive-level concepts, given the rise in reductionist neuroscience from below and Bayesian analysis from above.

### Marr's Attacks: A Gentle Reminder Chris Eliasmith

Marr's (1982) three levels can be seen as the result of two deep concerns he had about how brain theories were being constructed in his day. We can see these concerns giving rise to 1) an attack on reductionism; and 2) an attack on vagueness.

With respect to reductionism, Marr was interested in ensuring the centrality of not only mechanisms, but also of their function to our generation of brain theories (Marr and Poggio, 1977). With respect to vagueness, Marr wanted to ensure that our high-level descriptions of neural phenomena could be tested against empirical data (Marr, 1975).

Unfortunately, many researchers after Marr seem to have taken his purpose to be a divisive one. Some, such as Pylyshyn (1984), refer to the "three autonomous levels of

description" (p. 259). In contrast, Marr (1982) seems to be suggesting that the intermediate, representational level, is a *bridge* between our more abstract characterizations, and more detailed characterizations (pp. 23-24).

I argue that Marr's levels should be understood in an integrative sense. I show that adopting this perspective provides critical constraints for building Marr-type brain models. I provide the details of one such model: a large-scale simulation of spiking neurons that reproduces detailed neural and behavioral results across a wide array of cognitive and non-cognitive tasks.

In short, adopting Marr's perspective on levels helps pave the way for the kind of unified models of brain function for which he, himself, was striving.

### Bridging Levels of Analysis for Probabilistic Models of Cognition Tom Griffiths

Most probabilistic models of cognition are intended to explain human behavior at the computational level, linking how people act to the solution to an abstract computational problem. This focus is quite different from that of other approaches to cognitive modeling, which tend to emphasize the algorithmic and implementational levels. This raises a number of important questions: When are theories at these different levels incompatible with one another? What are the implications of a computational-level analysis for theories at the other levels? How can we begin to draw connections across levels of analysis, for an integrated account of cognition? I will argue that we can only answer these questions by explicitly taking on the challenge of building a bridge between levels of analysis, considering how

computational-level models can be translated to the algorithmic and implementational levels and how algorithmic- and implementational-level accounts might be cast at the computational level. I will illustrate this argument with examples drawn from recent work looking at Monte Carlo methods as a source of “rational process models” and analyses of the computational-level commitments of artificial neural networks.

## **A New Appreciation for Marr’s Levels:**

### **Understanding How Brains Break**

**Valerie Gray Hardcastle and Kiah Hardcastle**

Much work in the cognitive sciences, including computational neuroscience, now focuses on brains performing less than optimally. That is, while the original programs in artificial intelligence and the like aimed to articulate what thought was in ideal terms, much research now looks at how and why brains or other cognitive engines fail to function as they should. This focus on impairment affects how one can understand Marr’s three levels. In this presentation, we use a method of exploring impulsivity and behavioral inhibition based on a neural network/ population activity model of the cortico-striatal circuitry as a case study to refine Marr’s distinctions. In particular, we will show that the computational level should be redefined, for simply knowing the goal of a computation may not tell us much about why something has gone wrong and why the information-processing device is exhibiting abnormal behavior. We will also argue, as have many others, that the distinction between algorithm and hardware largely collapses when considering the brain.

## **The Primacy of Mechanism in Cognitive Science**

**Brad Love**

Cognitive science is primarily concerned with the “how” questions of brain and behavior. These questions address mechanism, and therefore make contact with Marr’s algorithmic level. From below, mechanistic accounts can be informed, constrained, and inspired by neuroscience. Rather than being reduced by neuroscience, cognitive models are proving valuable in interpreting fMRI data because these mechanisms help neuroscientists understand the function of brain regions. From above, despite many cognitive scientists professing a devotion to the computational level, very few are trained or focus their research on characterizing evolutionary environments, niches, and histories. I will argue that explanations formulated purely at the computational level are not sufficiently constrained, because rational Bayesian models are uninformed by a wide range of process-level data and their assumptions about the environment are generally not grounded in empirical measurement.

Given the recent surge of interest in computational-level theories of cognition, one question is whether integration across algorithmic and computational levels would be

beneficial. One promising avenue for integration is to evaluate the representations on which Bayesian inference operates and the algorithms and heuristics that carry it out as psychological mechanisms. In other words, one means of integration is to evaluate Bayesian models at the algorithmic level. A number of researchers have adopted this strategy and have concluded that humans engage in forms of approximate Bayesian inference that are intended to reflect human capacity limitations. Although an improvement over purely rational approaches, approximate Bayesian models face significant challenges. One challenge is that people are suboptimal for reasons other than capacity limitations. In domains where people’s behavior falls far short of that predicted by rational accounts, the layering of capacity limitations and suboptimality onto the rational account may only serve as a lengthy detour to the algorithmic level.

## **Differentiating While Integrating Levels**

**William Bechtel**

Are all three of Marr’s levels needed? Should they be kept distinct? Symposiasts emphasize how cognitive science is or should integrate Marr’s levels. This is important, but it is also important to emphasize the distinct contributions and methodologies of each level of inquiry. They represent three different perspectives required to understand mechanisms generally, but especially information processing mechanisms. Marr viewed neuroscience of his day as emphasizing the material implementation at the expense of the algorithmic-representational and computational levels, and that has been true of mechanistic science generally. But mechanisms only work insofar as they are organized, and this is especially true of information processing mechanisms that must insure that information is encoded appropriately within the mechanism and made available to the operations that require it. Moreover, it is crucial to understand how a mechanism functions in broader environments that determine the computations it needs to perform (and may fail to perform). Different modes of inquiry are required to examine each of these. This is especially true of the computational perspective, which requires looking outside the mechanism to the environment in which it operates and engaging in appropriate experimental and theoretical studies to understand what those demands really are.

## Introduction

How children acquire the grammar of their native language has been a central topic in cognitive science since its outset, and has been the focus of much debate. One view assumed an innate Universal Grammar which genetically endowed the child with highly structured knowledge of language (Chomsky, 1965). An opposing position argued against both the assumptions of innate knowledge and structured representations, instead using connectionist architectures with distributed representations to learn grammatical patterns (e.g., Rumelhart & McClelland, 1986).

The field has progressed. There have been many years of rigorous empirical work, detailing the developmental pattern in children. In parallel, AI and cognitive science have made many advances in sophisticated learning algorithms. This symposium brings together models on the forefront of such empirical and computational research. Each model has roots in both sides of the early debate, positing (at least some) structured representations and specifying learning mechanisms. However, the models differ in many crucial ways. They use different computational architectures, learning algorithms, and differ in the knowledge built into the system. These differences in the models reflect and build on different current theories of grammatical development. The models focus on simulating empirical phenomena critical in distinguishing such theories. This symposium presents a unique opportunity to compare these new approaches and invite an open discussion.

## Symposium Structure

This symposium will present three computational models of grammatical development. The first talk, by Cindy Fisher, presents a model rooted in *early abstraction* theories of language development (e.g., Fisher, 2002). The model is implemented in a machine learning architecture that uses its

innate biases linking syntax and semantics and learned grammatical categories to semantically parse sentences and guide word learning. The second talk, by Franklin Chang will describe a connectionist model that does not require explicit thematic roles or innate linking rules to learn syntax, but instead can acquire language from visual-spatial input. The third talk, by Micah Goldwater, presents a third approach—a usage-based model that uses structured symbolic representations and learns abstract thematic roles via analogical abstraction

The symposium begins with a brief introduction, followed by three presentations of computational models, and concludes with a discussion exploring the issues.

**Dedre Gentner** will introduce the symposium. She is the Alice Gabrielle Twight Professor of Psychology and Education at Northwestern University.

**Gary S. Dell** will serve as the discussant. He is Professor of Psychology and Linguistics at University of Illinois at Urbana-Champaign.

We now summarize each talk in turn.

## The Origin of Syntactic Bootstrapping: A Computational Model

Syntactic bootstrapping proposes that children use knowledge of sentence structure in sentence interpretation and verb learning. We present a computational model of the origins of syntactic bootstrapping, based on systems for automatic semantic-role labeling (SRL). SRL models learn to identify sentence constituents that fill semantic roles, and to determine their roles, such as agent, patient, or goal. The present 'BabySRL' instantiates the structure-mapping account of syntactic bootstrapping (Fisher et al., 2010). We assume a structure-mapping process between the nouns in a sentence and the core semantic arguments of the verbs, in which children are biased to create one-to-one mappings. Given this one-to-one mapping bias, the number of nouns in the sentence becomes intrinsically meaningful to toddlers. Second, this account proposes that children's representations of sentences, though partially specified, are couched in

abstract terms, permitting generalization of new syntactic learning to new verbs. We used the BabySRL to investigate the consequences of these assumptions for learning from natural corpora of child-directed speech. The results yield strong evidence that partial sentence representations grounded in a set of nouns are useful as a foundation for further learning. We show (1) that such representations support new learning about English word order (e.g., the first of two nouns is typically an agent), and (2) permit children to learn which words are verbs by tracking their argument-taking behavior in sentences.

**Cynthia L. Fisher** is Professor of Psychology and Linguistics at University of Illinois at Urbana-Champaign.

### The Dual-Path Model

A theory of language should unite acquisition, production, and comprehension. To link acquisition to production, Chang (2002) proposed a connectionist model called the Dual-path model. The model used the same learning mechanism for acquiring abstract English syntactic representations to explain structural priming in adult production (Chang, et al., 2006). The model could learn English and Japanese to similar levels (Chang, 2009). Importantly, the model's incremental planning mechanism could also account for the different direction of heavy NP shift in each language. That is, English speakers tend to postpone long noun phrases (NPs) to the end of sentences, while Japanese speakers tend to place these NPs earlier. Finally, a new version of the model has been developed where thematic roles in the message are replaced with arbitrary spatial pointers. The production or comprehension of words depends on the activation of these pointers, and hence they can simulate eye-tracking in scenes. The model can account for different types of anticipation in English and Japanese during eye-tracking in the visual world (e.g., Kamide et al., 2003). The model highlights the role of non-linguistic processes such as implicit learning and spatial binding in language acquisition and use.

**Franklin Chang** is Lecturer of Psychology at the University of Liverpool.

### An Analogical Learning Model of the Development of Thematic Roles & Structural Priming

This model explores the hypothesis that analogical learning processes can account for the abstraction of thematic roles (Goldwater et al., 2011). We use SME (Falkenhainer et al., 1989) and SAGE (Kuehne et al., 2000) to model analogical mapping and generalization. Learning proceeds via incremental comparison of specific examples to reveal their common structure and create generalizations. This allows the model to evolve abstract roles from verb-specific ones. We assess the abstractness of the model's semantic roles by simulating structural priming in sentence production. To construct an utterance for a new event, it first uses analogical retrieval to find utterances with similar semantic structure in memory. It then creates an analogical mapping between events and transfers the previous sentence structure to construct the new utterance. Hence, structural priming is

shown when a new utterance has analogous structure to a prime utterance.

We assume a usage-based learning trajectory in which children's initial semantic representations are verb-specific (e.g., Tomasello, 2003). Because shared semantic structure is necessary to show priming, early in training priming occurs only across sentences that share verbs. As the model learns, across-verb priming occurs. For example, initially the model can align *giving* events only with other *giving* events, because the roles do not match those of other verbs. By gradual re-representation and generalization, the model develops a hierarchy of more abstract roles.

**Micah B. Goldwater** is a postdoctoral fellow in the Department of Psychology at Northwestern University.

## Summary

The question for the symposium is how best to understand biases in decision-making, going beyond traditional judgment and decision-making (JDM) accounts such as prospect theory to take a more modern reverse-engineering perspective bridging rational computational, algorithmic, and neural levels of explanation, and viewing decision-making under risk and uncertainty not just as a simple matter of evaluating lotteries but in the context of cognition more broadly, taking seriously learning, perception, motor control, memory, and action planning.

The dominant normative approach to studying decision-making under risk is axiomatic expected utility theory, which argues that any agent obeying seemingly reasonable axioms of choice consistency can be modeled as maximizing the expected utility of its decisions. From decades of research that analyzes people's choices between simple gambles in the lab, it is known that humans routinely violate these axioms. This has forced decision theorists to adopt descriptive models of choice that lack a normative rational in order to account for observed patterns of choice, the most prominent of which is Kahneman's and Tversky's prospect theory for one-shot decisions under risk with immediate outcomes and hyperbolic discounting for decisions involving delayed outcomes.

There are several challenges not addressed by prospect theory and its variants. First, they are silent on the issue of the cognitive mechanisms that are actually responsible for human choice behavior. Second, they do not seem as a practical matter to scale to real-world decision problems, where the space of possible outcomes and actions is not sharply defined, the effects of actions are highly uncertain, and the explicit calculation of expected values is impractical. Third, they do not strongly constrain or give an underlying rationale for the probability weighting function, temporal discounting function, or utility function featured in prospect theory. Thus these models cannot explain why these functions' estimated

forms and parameters seem to be greatly affected by seemingly irrelevant factors of the task framing and setup, such as whether the outcome probabilities are presented numerically in tables or learned through experience and why the evaluation of individual gambles seems to be highly effected by the properties of other gambles in the choice set. More broadly, these theories fail to explain why in day-to-day life human decision-making seems to generally be highly robust and effective while sharply contrasting with normative predictions in the simple, stylized decision tasks commonly used in JDM experiments.

This symposium brings together researchers who represent a variety of perspectives on ways cognitive science can inform our understanding of decision biases to address these challenges, with relevance at all three Marr levels of analysis. Malmaud and Tenenbaum, and Dayan both offer computational-level Bayesian accounts that explain decision-making biases as resulting from reasoning with priors that are adapted for real-world or evolutionary-relevant decision tasks. Malmaud and Tenenbaum explain choices in terms of advanced models from the AI planning literature and animal foraging theory. Dayan offers a neurobiological implementation of inference that spans the Marr levels.

Other approaches relate to algorithms levels of the Marr hierarchy with links to lower and higher levels. Vul offers an algorithmic description of biases as resulting from cognitive limitations associated with reasoning using only a limited number of samples from a posterior over decision parameters. Maloney and Chater link high-level decision-making to known properties of perception and cognition, such as scale-invariance. Maloney gives a unifying account of the probability weighting function as arising from the same principles as perception of continuous quantities in psychophysics. Chater explores the origin of subjective utility and temporal discounting through connections to broader cognitive processes.

One general idea that cuts across all these approaches is that human decision-making can be modeled in a unified way as the result of general cognitive principles that offer prin-

ciplined explanatory accounts of biases in decision-making, rather than via a series of descriptive utility-maximizing models that have undergone ad hoc adjustments to account for a mélange of deviations from a narrow normative standard.

### **Malmaud and Tenenbaum: Prospect theory as rational response**

We will open the symposium by presenting a brief review of the traditions of axiomatic decision theory and descriptive prospect theory, including how sophisticated computational models are beginning to fill in some of prospect theory's known shortcomings as a model of high-level decision-making at the individual level. We will briefly discuss our position that human decision-making is adapted for solving rich, sequential decision problems with structured goals and highly uncertain action-outcome contingencies and as such should not be expected to perform optimally according to narrow normative standards in simple one-shot decision tasks with known contingencies. We will show how modeling human choices as the result of employing state-of-the-art AI methods for planning under uncertainty to a specific class of 'survival' goals commonly studied in the animal foraging literature naturally implies a sequential decision strategy that is compatible with the descriptive predictions of prospect theory. Our approach is also able to make predictions about human behavior for a wide class of tasks for which prospect theory is not applicable. We will present preliminary empirical evidence that these predictions are supported on a specific set of ecologically relevant sequential decision tasks.

### **Dayan: Pavlovian choice illusions**

One useful interpretation of many perceptual illusions is in terms of biases resulting when the mechanisms of inference reflect genetically encoded or learned priors that are inconsistent with a given scene. We will consider how some of the biases of decision-making on which this symposium focuses can be seen as illusions of choice arising from forms of Pavlovian influences that reflect evolutionarily appropriate dispositions. These influences are exerted by various neural systems, notably the neuromodulators dopamine and serotonin and regions of the amygdala, acting on areas such as the striatum that are involved in decision-making. As an example, we will discuss the case of behavioral inhibition, which is one very general response to potential threats, and is closely associated with serotonin. We will show how such inhibition can lead to a particular form of bias in the on-line evaluation of complex options, and show how problems with this bias might even have deleterious psychiatric consequences.

### **Maloney: Ubiquitous log odds**

Similar patterns of distortion are found in visual frequency estimation, frequency estimation based on memory, and in the use of probability in decision-making under risk. Based on joint work with Zhang et al., I will show that probability distortions in all cases (so far) can be approximated by a lin-

ear transformation of the log-odds of probability or relative frequency. The slope and intercept of the linear transformation control probability distortion. Researchers have not been able to predict or explain the values of slope and intercept observed in experiments across tasks or across participants.

In Zhang & Maloney (2012) we focused on one method for presenting probability, the relative frequency of items of one kind in a visual array of  $N$  items. We developed a model of human distortion of relative frequency and demonstrated in two experiments that we can separately control slope and intercept with high accuracy. Our results support the conjecture that probability is systematically adapted to particular tasks much as perceptual information concerning lightness or loudness is transformed. We shown how a simple model based on chunking of information can explain the results we observe with a high degree of precision.

### **Vul: Decision biases and heuristics arising from inference by sampling**

Across many domains, people integrate sophisticated world knowledge with prior expectations nearly optimally, yet when making conscious cognitive judgments, they seem to be grossly irrational. I will explore a potential explanation: that conscious cognitive judgments reflect sample-based approximate inference under constrained cognitive resources. Experiments measuring multiple judgments from individuals with no new information yield evidence for this sampling proposal: any one decision appears to reflect only a small fraction of the information the participant has available, suggesting that each decision is based on only a small number of samples. Here, I will talk about the tradeoffs inherent in using a small number of samples for a decision: why we might want to use few samples, the consequences of using a few samples for judgments, the risks associated with using a few samples when rewards are asymmetric, and how these consequences relate to biases seen in judgment and decision-making.

### **Chater: From cognitive principles to JDM**

This talk will consider how far candidate cognitive principles (such as scale-invariance, relative coding of magnitudes, and incommensurability between distinct dimensions) can provide quantitative and qualitative explanations of results in decision-making. I will illustrate how widespread patterns in JDM (such as constant relative risk-aversion and hyperbolic time-discounting) can be derived; and consider how basic cognitive processes can explain when and in what way, such regularities break down. The aim is to build a theory of JDM built on cognitive principles, rather than rational axiomatic foundations.

**Keywords:** Learning science, learning tools, constructive interaction, coordinated learning, test anxiety, tutoring system efficacy.

### **Introduction**

The focus of the symposium is on real world implementations of educational innovations based on cognitive and learning science principles and research. These real world implementations can be in physical classrooms, on-line courses, informal educational settings, as well as other learning environments. The innovations can include new ways of conceptualizing and presenting a domain, computer-based multimedia learning tools, and other innovations. The common thread though is that these innovations are beyond lab-testing and are guided by principles and research from the cognitive and learning sciences. The governing board symposium will bring to the conference educational innovation found in different parts of the world (US, Asia, Europe) from distinguished researchers representing a variety of theoretical orientations and focusing on different aspects of the learning process (e.g., cognitive, social, emotional/ motivational).

### **Can intelligent tutoring systems become even more effective than human tutors?**

**Kurt VanLehn**

This talk will start by reviewing reasons why human tutoring should be more effective than computer tutoring. Studies indicate that human tutors do not actually use some of the techniques that they are assumed to use. Moreover, the techniques that they do use are also used by step-based tutoring systems, which are a type of intelligent tutoring system. Thus, it comes as no surprise that step-based tutoring systems and human tutoring are equally effective, as shown in a meta-analysis of content-controlled experiments. This raises the question: what if step-based tutoring systems started using some of the techniques that human tutors

were supposed to use? Would they even become more effective than human tutors?

### **Social foundations of coordinated learning across environments**

**Roy Pea**

A persistent challenge in the learning sciences is accounting for coordinated learning across the socio-cultural environments in which people participate. K-12 aged children have been a special focus of these inquiries, given the preponderance of their awake time for learning outside of school, the recalcitrant problems of transfer of school learning to life, the underuse of funds of knowledge children have from life in school learning, and persistent achievement gaps. Contemporary accounts of K-12 learning over environments, while still attentive to cognitive issues of learning and reasoning in the disciplines, have been making substantive progress on the coordinated learning challenge in their attention to associated learner developments in identity, interests, social networks (and affiliated social learning capital), and examining social learning mechanisms such as imitation, joint visual attention, formative feedback, positioning in discourse, and accountable reasoning and talk in communities of practice. Highlights of recent work on these issues are also imbued with significance for socio-technical design of engaging learning environments that can mediate learning using new social media and mobile technologies. Our NSF-funded LIFE Center (Learning in Informal and Formal Environments) has been pursuing these issues as it seeks to develop and test principles about the social foundations of human learning from infancy to adulthood. Select findings will illustrate these developments towards understanding and designing connected human learning.

## **Bridging cognitive and learning sciences by engineering constructive interaction in Asian classrooms**

**Naomi Miyake**

Real-world learning situations provide us with test fields for our cognitive science theories of how people learn. In this presentation, I report a case where a fundamental framework about how people constructively interact to learn could guide some policy making and practices in classrooms, which could influence the course of change in Japanese school education. The framework is named “constructive interaction,” (Miyake, 1986) which states that two person, when engaged in solving a shared problem, exchange roles of a task-doer who proposes possibilities for solutions and a monitor who reflects upon such proposals, and such role exchange potentially promote each participating individual’s understanding of the problem.

Though group work has been common in Japanese classrooms, such practice has not been guided nor assessed via lenses of cognitive and learning sciences. In the pursuit of acquiring the 21<sup>st</sup> century skills, current classrooms have been trying to shift their practice from teacher-centric, fact-oriented training to learner-centric, knowledge-building learning. In such classes the learners’ activities are often socially interactive, or collaborative. There are many different ways to make a classroom collaborative, sometimes with confusion about which leads to which outcome. In my recent research in promoting collaborative classrooms based on the above framework, I have identified three research questions related to such confusion, created a testable classroom design to answer the questions. The three questions are to confirm that (1) outcomes of constructive interaction are individualistic, not easily shared by other members of the same group (or class), (2) a learner who mostly listens and monitors can still learn as much as more active learners, and (3) for a constructive interaction to lead productive learning, there is no need to socially organize the group, but it is essential for the members to share the desire to solve an apparently shared problem, or understand it. During 2010 and 2011, one hundred and four teachers from elementary to high school devised and delivered such classes in major subject areas, which resulted in higher performance than regular classes, with higher motivation to learn more after the class (<http://coref.u-tokyo.ac.jp/en>). The findings so far show that the answers to the above three questions are positive, as predicted by the basic framework of constructive interaction, making it possible to create design principles for designing more productive collaborative classes around cognitive science frameworks. It has also been shown that this type of cognitive-science-based design principles could guide real learning in real classrooms, and when some basic cognitive science is shared by the practitioners, the outcomes of such classrooms can lead them to develop better practices on their own.

## **Emotions are important for students’ learning and achievement** **Reinhard Pekrun**

Emotions are ubiquitous in academic settings. Students frequently experience emotions such as enjoyment, hope,

pride, anger, anxiety, shame, hopelessness, and boredom in these settings. Moreover, these emotions are likely to influence students’ learning, achievement, and health. Traditionally, they have not received much attention by empirical research, test anxiety studies and attributional research being notable exceptions. During the past ten years, however, there has been growing recognition that emotions are central to students’ learning. In this presentation, I will address the functional relevance of emotions for student learning. Subsequently, I will discuss the origins of these emotions and related educational intervention aiming to promote adaptive emotions that facilitate academic learning. Pekrun’s (2006) control-value theory of achievement emotions will be used as a conceptual framework.

Test anxiety research has shown that anxiety can exert profound effects on academic performance; is this true for other emotions as well? I will discuss five cognitive and motivational mechanisms that can mediate effects on learning: (1) availability of working memory resources; (2) long-term storage of information in terms of retrieval-induced forgetting and facilitation; (3) intrinsic and extrinsic motivation to learn; (4) use of learning strategies; and (5) self-versus external regulation of learning. As a consequence of effects on these processes, emotions can profoundly influence students’ competence development. I will present experimental evidence and findings from two longitudinal studies on upper elementary and university students’ emotions documenting these effects.

Given that students’ emotions are functionally important, their origins and related educational tools to modify these emotions should be considered. Using the control-value theory, I will argue that appraisals of control over achievement activities and outcomes, and of the value of these activities and outcomes, are fundamentally important for emotion arousal in academic settings. By implication, teachers, tasks, and learning environments influence students’ emotions by shaping their perceived control and values, and ways to influence these emotions can be developed by considering these appraisals. One especially important variable shaping students’ appraisals and emotions likely is the cognitive quality of tasks. I will present exemplary evidence from an intervention study which examined the impact of cognitively activating tasks involving mental modeling on students’ emotions in mathematics. The findings suggest that it is possible to promote students’ appraisals and adaptive emotions by shaping tasks and learning environments in cognitively and emotionally activating ways.

## Introduction

The purpose of this symposium is to highlight how the vertical dimension is perceived and represented differently from the horizontal dimensions, and the role of this dimension in spatial learning. This is a new and important issue because literature on spatial cognition has hitherto neglected the study of the vertical dimension, under the assumption that space can identically be investigated in the horizontal plane. This notion, while untested, ignores a crucial, unique property of the vertical dimension – that of being parallel to the force of gravity, which poses constraints on affordances and energetic potential. Additionally, the ability to move freely in three dimensions imposes computational complexities not present in two. New research impetus is trying to clarify the role of the vertical dimension in space. The present symposium will try to tie together different perspectives (psychophysics, cognition, neurophysiology), using different animal models (human and non-human), and different experimental methods (real and virtual environments), in order to provide a synthetic view on this issue, and to establish future goals of common interest. We focus here on two aspects of three-dimensional space: surface properties (e.g., hills and valleys) and volumetric properties.

## Surface Properties

A major constraint to terrestrial movement is represented by the inclination of the terrain. While a moderate hill can be a challenge to walk, a steep one can be dangerous and energetically depleting. Therefore, it is ecologically adaptive for our perceptual system to be extremely sensitive in estimating geographical slants. Recent research by Durgin's lab has indeed shown that the coding of slant, and

other angular variables, is exaggerated by the introduction of perceptual biases, such that the range of inclinations relevant to locomotion is more densely coded (Durgin & Li, 2011). This angular scale expansion enables us to more precisely represent small differences in inclinations, and thus may improve the precision of action control. Furthermore, the theory quantitatively predicts the well-reported overestimation of hill slant, suggesting that this phenomenon may not be directly due to a role of effort or physical potential, but to a more general angular coding scheme that is useful for action control as well as route planning and spatial orientation.

Beyond perceptual encoding of slope for action, recent research has demonstrated large individual differences in the ability to rely on slope cues for cognitive spatial tasks, including navigation (Weisberg & Newcombe, 2011). Given that slope is a stable and salient part of the lay of the land, a fundamental question explored in a line of research by Weisberg is whether people are able to take slope into account when building a mental map of the environment – and what makes slope difficult to use for some people. Using a navigation task in a virtual environment, it was found that individual's navigation ability is a crucial factor in determining whether terrain slope facilitated a more accurate representation: in a complex environment, only good navigators were able to take advantage of the information. This result is very important because it can explain previously reported sex-specific difficulties with slope in light of individual differences in broad spatial abilities.

Given the theoretical distinctiveness of the vertical component of space, due to its link with the gravity axis, an important question to investigate is the salience of vertical information in spatial learning tasks. Studies on non-human animal models have indicated that vertical information dominates over horizontal information. Recently, a line of research by Nardi has investigated if the same occurs in humans. Reorientation was tested in a real-world

environment with two different strategies available: one based on directional cues (the slope gradient of the tilted floor) and one based on positional cues (landmarks). Interestingly, slope information did not dominate the reorientation process, as people were equally likely to rely upon either cue. Furthermore, men and women did not significantly differ in their reliance on slope or landmarks, suggesting that in a real environment there is not a sexually dimorphic preference for spatial strategies. However, men exhibited greater overall confidence in solving the task. These findings suggest that the female disadvantage with slope cues, shown in Nardi, Newcombe, and Shipley (2011), could be due – at least partially – to a general difficulty in reorienting, namely lower spatial confidence.

### **Volumetric Properties**

Our evolutionary ancestors, being aquatic, moved freely in all three dimensions, and many animals still do. It is therefore likely that the brain has evolved a method for representing volumetric space in a cognitive map, but the properties of this map are not yet understood. Studies of the representation of space at the single neuron level are providing clues, however. In ordinary, horizontal environments, place cells in the hippocampus encode location while grid cells, in the neighbouring entorhinal cortex, encode an integrated signal of distance and direction. Jeffery's lab has studied for the first time how place and grid cells respond to travel in the vertical dimension. Using rodents as an animal model, it was found that while grid cells are highly insensitive to vertical distances, place cells do show some responsiveness, though at a coarser scale than for horizontal distances (Hayman, Verriotis, Jovalekic, Fenton & Jeffery, 2011). The findings suggest that the representation of vertical space, or perhaps space in the dimension normal to the body plane of the animal, is represented differently, and maybe non-metrically. Preliminary behavioral studies support this notion, finding that rats and mice can encode goal locations in three dimensions but prefer to organize their search behavior in horizontal bands.

From the above findings, it seems that the so-called “cognitive map” of space may perhaps not be uniform in all dimensions, despite our subjective experience to the contrary, a finding that has implications for those navigating in volumetric spaces (astronauts, pilots, deep sea divers, virtual reality explorers etc).

**Keywords:** Cognitive Science, Economics, Decision making, Uncertainty, Behavioral Economics, Rationality, Heuristics

## The issue

Economic crises bring to the fore deep issues for the economic profession: why are such crises often not foreseen, and what does this entail for economic theory? In this symposium we also adopt a self-critical analysis, by asking the following: what can the cognitive science community say or learn about cognition and behavior in the context of economic crises? After all, cognitive science shares one of its principle objectives with economics: to investigate and model the principles that underlie and govern human behavior.

## Challenges

The current financial crisis presents us with a real-world example of decision making under uncertainty. Cognitive science offers a variety of theories and models, from probabilistic models of cognition (Chater & Oaksford, 2008) to heuristic approaches (Gigerenzer & Gaissmaier, 2011), each designed to describe decision making under uncertainty. Empirically, the extant methods used to examine this question in both economics and psychology involve simple choice tasks (e.g., lotteries and games with well-defined probabilities and outcomes). *But, are the models sufficient to accurately represent uncertainty, and are the tools adequate for the job of capturing decision making under uncertainty?*

Uncertainty can permeate all aspects of a decision problem, from constructing the action space, to inferring probabilities of outcomes and the behavior of other agents in the situation. For instance, politicians need to decide whether to bail out fragile banks and countries under time pressure, with incomplete information about the problem space, and the necessity to manage conflicting goals (e.g., also considering the needs of their won electorate). Turning situations of this kind into lottery type tasks may in fact be a way of translating the unmanageable (uncertainty) into something manageable (risk), but at the same time the evidence may be giving answers to the wrong kind of questions.

Additionally, there is an issue of scalability. Neoclassical economics assumes that macro-level behavior can be deduced from modeling agents as rational, utility-maximizing individuals. While this oversimplification is often recognized by economists, scaling up to the aggregate level is a necessity when having to inform policy decision. The crucial challenge in revising the microfoundations of economic behavior is how we can build more realistic models, which nevertheless can be scaled up to the aggregate level.

## Goals of the Symposium

The symposium is themed around the target questions: *What can our community say or learn about cognition and behavior in economic crises?*

For instance, could rational or heuristic models help predicting or preventing crises? Or could the psychology of crowds help to explain economic crises? By bringing together researchers with different research perspectives and methodologies, the key objective is to discuss the challenges that real-world problems such as economic crises present us with, and ways in which cognitive science could possibly inform economic theory and policy making. The symposium will consist of a general introduction (Osman, Meder), four talks (Chater, Gigerenzer, Neth, Read) and a discussion (Meder, Osman) involving all participants.

### **Nick Chater**

Chater's work has explored the fundamental principles of cognition, in particular in contexts in which the cognitive system is faced with uncertain inferences (e.g., learning, decision making, reasoning, perception). Recently, his work also concerns applications to policy making.

Chater, N., & Oaksford, M. (2008). *The probabilistic mind: Prospects for Bayesian cognitive science*. Oxford: OUP.

### **Gerd Gigerenzer**

Gigerenzer's core research approach has been to understand decision making from the perspective of bounded rationality. This includes heuristic decision making and the development of effective tools for risk communication, with the goal of helping people to make better decisions in an uncertain world.

Gigerenzer, G., & Selten, R. (Eds.). (2001). *Bounded rationality: The adaptive toolbox*. Cambridge, MA: MIT Press.

### **Björn Meder**

Much of Meder's work has been concerned with the connections between causal induction and decision making. His recent research focuses on information search, economic psychology, and alternative frameworks of rationality.

### **Hansjörg Neth**

Do people allocate their resources (time, information processing effort) adaptively when facing tasks that vary in their demands and complexity? Neth's empirical work has examined task switching behavior and simple satisficing strategies in cognitive foraging tasks, consumer choice, and financial decision making.

## Challenging Issues

As complexity in our everyday environment increases (e.g., mobile applications for monitoring energy consumption), how do we adapt and react to the changing demands placed on us? In dynamic decision making (DDM) problems, the environment changes over time due to previous decisions made and/or factors outside the control of the decision-maker. To maximize his/her reward, an agent effectively needs to control a complex dynamic system. This often involves planning in the face of uncertainty about how decisions change the state of the system and the rewards that can be obtained. Thus, DDM refers to a process by which an agent selects a course of action in a manner that achieves or maintains a desired state in a dynamic environment. This includes balancing exploration and exploitation, distinguishing between different sources of variability within the environment, and tracking the current state of the environment (i.e., filtering).

Thus far there has been little attempt at a synthesis of the amassing research from different areas of cognitive science directed towards understanding DDM. The objective of this symposium is to bring together the latest theoretical approaches and empirical research investigating DDM. The speakers range in expertise from comparative (Prof Watanabe), applied (Prof Harvey) and cognitive psychology

(Dr Osman), computational neuroscience (Prof Dayan), and computational learning theory (Dr Speekenbrink). By bringing these diverse approaches together, the aim is to generate discussion around the following critical question: *What are the processes/mechanisms that enable us to adapt to changes in uncertain environments in terms of the information we process, the decisions we make, and the intrinsic and extrinsic goals that we pursue?* The symposium will consist of a general introduction (Osman), three talks (Dayan, Harvey, Watanabe) and an extended discussion (moderated by Speekenbrink) involving all participants.

## Peter Dayan

Peter Dayan's work in computational and experimental neuroscience has contributed significantly to our understanding of the neural mechanisms underlying DDM and the learning of reward structures therein. Dayan is an expert on reinforcement learning and in recent work, has elucidated the distinction between "model-based" and "model-free" learning and the neural circuits supporting these.

Model-based learning, usually associated with declarative task-knowledge, can support complex planning. Model-free learning, due to its more procedural nature, supports quick and habitual decisions, but will not cope well in an environment that undergoes rapid, abrupt changes. Dayan's recent work has shown how both processes work concurrently to support effective DDM.

Dayan P., & Daw, N.D. (2008). Decision theory, reinforcement learning, and the brain. *Cognitive, Affective & Behavioral Neuroscience*, 8, 429-453.

### **Nigel Harvey**

How effective are judgments, and what role do they play in using evidence to plan actions in complex decision making environments? Nigel Harvey's work in cognitive and applied decision making has developed cognitive models of judgments and decisions, and the confidence placed therein, in a variety of domains including economic (e.g., consumer choice behavior), financial and medical (e.g., comparisons of clinical and actuarial judgment). More recently, Harvey has shown that in a variety of decision making situations people decide whether to focus their efforts on acquiring new information from feedback, or whether to implement their extant knowledge.

Harvey, N. (2011). Learning judgment and decision making from feedback: An exploration-exploitation trade-off? In M.K. Dhami, A. Schlottmann and M. Waldmann (Eds.) *Judgment and decision making as a skill: Learning, development, and evolution*. Cambridge: Cambridge University Press.

Reimers, S., Harvey, N. (2011). Sensitivity to autocorrelation in judgmental time series forecasting. *International Journal of Forecasting*, 27, 1196-1214.

### **Magda Osman**

Magda Osman's recent work has advanced the proposal that successful learning in DDM environments can be achieved indirectly via prediction or directly via control processes. In two reviews of DDM, Osman brings together theoretical and empirical research from disparate disciplines spanning engineering, machine learning, management, social and cognitive psychology, and neuroscience, and shows that each has contributed to answering the question: *How do we isolate the effects of our actions from those generated independently in order to achieve desirable outcomes?*

Osman, M. (2011). The role of feedback in decision making. In *Parkinson's Disease* (Chapter 3), InTech Publishers.

### **Maarten Speekenbrink**

In DDM environments, the potential consequences of actions can change over time, either due to previous actions or external factors. How do people adapt their representations of a task to such abrupt or gradual changes? In contrast with popular beliefs, the findings from Speekenbrink's research suggest that people are generally able to rapidly adapt their predictions to different types of changes in multiple cue environments.

### **Masataka Watanabe**

Adaptive goal-directed behaviours can be acquired by neuronal mechanisms that can learn and anticipate the possible outcomes of actions, and determine the actions that might be successful for achieving desirable outcomes. Having close anatomical connections with high-order cortical and subcortical limbic areas, the prefrontal cortex (PFC) play the most important role in this process. In several primate studies, Masataka Watanabe has shown that neurons in the lateral PFC integrate cognitive (outcome probabilities) and motivational (rewards) representations that enable adaptive decision making in complex circumstances.

## Introduction

The notion of mental grammar has been at the heart of linguistic theorizing for much of the past century. The arguments for the existence of grammar, a set of mental rules/constraints governing the well-formedness of linguistic structures, are vast and varied, however the central argument that has been made in its favor is that speakers are capable of producing (and understanding) an infinite set of systematically structured words (phonology, morphology) and utterances (syntax).

Within the cognitive sciences, the notion of mental grammar has been reserved to describe competence in spoken language, signed language, and on occasion, narrative structure. This symposium explores the possibility that the notion of grammar should be extended to other cognitive domains, specifically the domain of written and graphical communication. Four different domains representing a broad swath of written communication are considered: letter combinations in spelling (orthotactics), sequential images in comics, the internal structure of individual Chinese characters, and the formal structure of calligraphic scripts. Although these domains all integrate elements of spoken language (e.g., phoneme-grapheme mappings, thought bubbles in comics, etc.), this symposium focuses exclusively on those aspects that are distinct from spoken language: abstract orthography-specific spelling knowledge, the system by which narratives are constructed with sequential graphical panels, the internal formal structure of Chinese characters, and the constraints governing the articulation of brushstrokes in a calligraphic manuscript.

The papers presented here provide theoretical and experimental evidence that the move to extend the notion of

grammar to these domains is substantive and is not simply a metaphor or an analogical borrowing of terminology. These domains are shown to have complex internal structure that is subject to specific constraints on well-formedness. In some cases acceptability judgments and electrophysiological data indicate that speakers have online, synchronic knowledge of these structural constraints. The similarities and differences between the grammars of natural languages and the written/graphical domains presented here will be discussed. Regardless of whether term ‘grammar’ is ultimately applied in these cases, the complexity and systematicity of the cognitive processes underlying these domains must be recognized.

## Modeling the statistical structure of orthographic representations

The study of positional and sequential restrictions on speech sounds (phonotactics) is a traditional subfield of linguistics that has been the subject of much recent experimental and computational research (e.g., Vitevitch et al., 2004; Hayes & Wilson 2008). The possibility that there are analogous, independent restrictions on graphemic representations -- orthotactic constraints on letter or grapheme sequences that are formally similar to those found in spoken language but not reducible to phonotactics or other phonological regularities -- has not been extensively investigated (but see Jespersen 1909-1949; Venezky 1970). In this talk, Wilson evaluates the evidence for an independent orthotactic component by combining a number of methodologies: computational modeling of the mapping from phonology to orthography in spelling, which is plausibly constrained to construct letter strings that are orthotactically acceptable; experimentally elicited judgments of stimuli that differ in spelling but not pronunciation; and prediction of spelling errors made by normal and impaired individuals, which may

similarly respect orthotactic restrictions despite deviating from the intended outputs. The talk also discusses the reciprocal issue, namely how grammatical knowledge of phonotactics can constrain and simplify the mapping from orthography to phonology in reading aloud. The resulting model is one in which individual grammars of sound, spelling, and the mapping between them combine to explain the joint statistical structure of the spoken and written forms of words. (This talk is based on joint work with Mike McCloskey, Simon Fischer-Baum, and Don Mathis).

### **The grammar of visual narratives: Structure and processing of sequential images in comics**

Comics are a ubiquitous form of visual narrative in contemporary society, and nowhere is this more prevalent than Japan, where comics occupy over one-third of all printed material (Gravett, 2004). In this talk, Cohn argues that, just as syntax allows us to differentiate coherent sentences from scrambled strings of words, the comprehension of sequential images in comics also uses a grammatical system to distinguish coherent narrative sequences from random strings of images. First, Cohn will present a theoretical model of the narrative grammar underlying comics—a hierarchic system of constituency structure that constrains the sequences of images. He then will provide an overview of recent research that supports the psychological validity of this grammar, using methods from psycholinguistics and cognitive neuroscience. In particular, Cohn will emphasize that the same neurophysiological responses that appear to violations of syntax and semantics in sentences appear to violations of narrative and semantics in the sequential images of comics. Finally, Cohn considers what ramifications a narrative grammar of sequential images has on theories of verbal narrative and language in general.

### **Levels of analysis in the generalization of Chinese character regularities**

Regardless of calligraphic style, Chinese characters obey strict shape regularities, including restrictions on reduplicated elements and on the location and shape of semantic radicals. In this talk, Myers argues that these regularities should be ascribed to a true grammar. Experimentally collected well-formedness judgments of nonce characters show that the regularities are psychologically active and readily generalize to non-radicals and lexically non-reduplicating character elements (Myers, 2011). New reanalyses show just how far beyond lexical analogy these generalizations can go. Intriguingly, the superficially distinct regularities are derivable from a single abstract structural template that, like metrical feet, shows asymmetric binary branching (Myers, 1996). New cross-regularity priming experiments test whether this template is itself active in character judgments. Together the findings suggest that high-level character grammar is not only real, but akin to prosody in spoken and signed languages.

## **Constraint interaction in the analysis of Chinese calligraphic scripts**

The field of Art History has traditionally treated its object of study—art, in its various physical manifestations—as a phenomenon “out in the world”. Yet, art, like language, is fundamentally a product of the human mind. Goldberg and Cohen-Goldberg argue that the field of Art History can benefit from a mentalist perspective where art is considered the product of artistic/esthetic cognition. Goldberg and Cohen-Goldberg provide a theoretical account of Chinese calligraphy that views calligraphic scripts (seal, clerical, and standard scripts) as the product of a grammar that must simultaneously balance the needs of scriptural well-formedness and legibility (Goldberg, 2004). Borrowing notions from work in theoretical phonology, they argue that calligraphic grammars consist of “markedness” constraints that assure that the calligraphic inscription possess script-typical qualities while “faithfulness” constraints ensure the recoverability of the underlying character. Utilizing this framework, they report novel results concerning 1) the various types of scope that are active within a calligraphic script and 2) the formal relationships that exist between scripts.

# Constructing a hypothesis space from the Web for large-scale Bayesian word learning

Joshua T. Abbott (joshua.abbott@berkeley.edu)

Joseph L. Austerweil (joseph.austerweil@gmail.com)

Thomas L. Griffiths (tom\_griffiths@berkeley.edu)

Department of Psychology, University of California, Berkeley, CA 94720 USA

## Abstract

The Bayesian generalization framework has been successful in explaining how people generalize a property from a few observed stimuli to novel stimuli, across several different domains. To create a successful Bayesian generalization model, modelers typically specify a hypothesis space and prior probability distribution for each specific domain. However, this raises two problems: the models do not scale beyond the (typically small-scale) domain that they were designed for, and the explanatory power of the models is reduced by their reliance on a hand-coded hypothesis space and prior. To solve these two problems, we propose a method for deriving hypothesis spaces and priors from large online databases. We evaluate our method by constructing a hypothesis space and prior for a Bayesian word learning model from WordNet, a large online database that encodes the semantic relationships between words as a network. After validating our approach by replicating a previous word learning study, we apply the same model to a new experiment featuring three additional taxonomic domains (clothing, containers, and seats). In both experiments, we found that the same automatically constructed hypothesis space explains the complex pattern of generalization behavior, producing accurate predictions across a total of six different domains.

**Keywords:** generalization; concept learning; word learning; Bayesian modeling; online databases

## Introduction

Many problems solved by the mind conform to the same abstract computational formulation: How should a property be generalized to novel stimuli from a set of stimuli observed to have the property? As there are many ways to extend the property that are consistent with some observed evidence, these are problems of *induction*, where the evidence constrains, but does not determine, the solution to a problem. The Bayesian generalization framework (Shepard, 1987; Tenenbaum & Griffiths, 2001) has been remarkably successful at explaining human generalization behavior in a wide range of domains. However, its success is largely dependent on the choice of a hypothesis space and a prior probability distribution on hypotheses, which are usually hand constructed by the researcher for each specific problem. This is unsatisfying practically, because the models do not scale beyond the originally modeled problem, and theoretically, as it is unclear whether their success is due to the cleverness of the modeler and not because of a deep mathematical property of the computational problem that people solve.

One possible solution is to use existing sources of information about the organization of a domain as the basis for specifying a hypothesis space and prior. This helps address both the practical and the theoretical concerns raised by the

Bayesian generalization model. In this paper, we use this approach to show how a hypothesis space and prior can be constructed automatically from a large online database, making it possible to apply the Bayesian generalization framework to a wide range of naturalistic stimuli. We focus on one specific generalization problem, word learning, where people learn new words from observing a few objects that can be labeled with that word. Given that the number of possible extensions of a word is essentially infinite, learning the objects referred to by a word is a very difficult inductive problem (Quine, 1975). Xu and Tenenbaum (2007) showed how the Bayesian generalization framework could be used to explain how people learn new words. However, to construct the hypothesis space of their Bayesian model, Xu and Tenenbaum (2007) elicited approximately 400 similarity judgments from their participants. Clearly this is not practical to extend into every domain where people learn words. Thus, word learning is an appropriate setting for exploring novel methods of constructing hypothesis spaces and prior distributions.

We propose a method for automatically constructing the hypothesis space and prior distribution of a Bayesian word learning model using freely available online resources. In particular, we use WordNet (Fellbaum, 2010; Miller, 1995) as an initial source for automatically creating the hypothesis space, and ImageNet (Deng et al., 2009) as a source of naturalistic images that can be used as stimuli to test the resulting model in behavioral experiments. WordNet is a popular lexical database of English comprised of over 100,000 relational sets of synonyms. ImageNet is a large ontology of images conforming to the hierarchical structure of WordNet, with the aim of providing over 500 high-quality images per noun in WordNet. These resources allow us to construct hypothesis spaces and prior distributions for word learning without eliciting a single judgment from participants and test the resulting model on a much larger scale than was previously possible. We demonstrate that the Bayesian model formulated from WordNet captures participant judgments in two behavioral experiments, addressing the practical and theoretical issues with Bayesian models discussed earlier.

The plan of the rest of the paper is as follows. In the next sections we review the Bayesian generalization model and then examine how Xu and Tenenbaum (2007) constructed the hypothesis space for their Bayesian word learning model. We then show how to build a hypothesis space from WordNet that can be used to evaluate word learning models on a large scale. Afterwards, we present two experiments utilizing this hypoth-

esis space: one that replicates a previous study of adult word learning, and one that investigates word learning for a set of complex concepts in novel domains. Finally, we discuss the implications of our work and future directions for research.

## The Bayesian Generalization Framework

The Bayesian word learning model is a special case of the Bayesian generalization framework. This framework has been used to model generalization in a number of domains including dimensional concepts (Austerweil & Griffiths, 2010; Shepard, 1987; Tenenbaum, 1999), word learning (Xu & Tenenbaum, 2007), numerical concepts (Tenenbaum, 2000), sequential rules (Austerweil & Griffiths, 2011) and rule-based categorical concepts (Goodman, Tenenbaum, Feldman, & Griffiths, 2008). Typically, problems are formulated in this framework as follows: Assume we observe  $n$  positive examples  $\mathbf{x} = \{x_1, \dots, x_n\}$  of concept  $C$  and want to compute  $P(y \in C|\mathbf{x})$ , the probability that some new object  $y$  belongs to  $C$  given the observations  $\mathbf{x}$ . We compute this probability by using a hypothesis space  $\mathcal{H}$ , which is a set of hypothetical concepts, where each hypothesis is defined by the objects that would be members of the concept if the hypothesis were true,  $P(\mathbf{x}|h)$ .

Defining a Bayesian generalization model amounts to defining a hypothesis space  $\mathcal{H}$ , a prior probability distribution over hypotheses,  $P(h)$ , and for each hypothesis, a likelihood function,  $P(\mathbf{x}|h)$ , indicating the probability of observing a set of objects  $\mathbf{x}$  given that the hypothesis is true. A typical definition of the likelihood follows from assuming strong sampling, where objects are generated uniformly at random from the true hypothesis (Tenenbaum & Griffiths, 2001)

$$P(\mathbf{x}|h) = \begin{cases} 1/|h|^n & \text{if } \mathbf{x} \subset h \\ 0 & \text{otherwise} \end{cases}. \quad (1)$$

This likelihood function instantiates the *size principle* for scoring hypotheses: hypotheses containing a smaller number of objects assign greater likelihood than hypotheses with more objects to the same set of objects (Tenenbaum, 1999; Tenenbaum & Griffiths, 2001). The prior distribution over hypotheses,  $P(h)$  depends on the domain and in previous literature has ranged from a simple uniform distribution over the hypothesis space (Shepard, 1987) to a stochastic process over tree structures (Kemp & Tenenbaum, 2009). Given the prior and likelihood, the posterior probability that a hypothesis is true given a set of objects belonging to a novel concept,  $P(h|\mathbf{x})$ , follows from Bayes' rule:  $P(h|\mathbf{x}) \propto P(\mathbf{x}|h)P(h)$ . From this, we can compute the probability that a new object  $y$  is also a member of the concept  $C$  by averaging the predictions of all hypotheses weighted by their posterior probabilities:

$$P(y \in C|\mathbf{x}) = \sum_{h \in \mathcal{H}} P(y \in C|h)P(h|\mathbf{x}), \quad (2)$$

where  $P(y \in C|h) = 1$  if the new object  $y$  is in hypothesis  $h$ , and 0 otherwise.

## Word Learning as Bayesian Inference

Xu and Tenenbaum (2007) derived the hypothesis space for their Bayesian word learning model by applying hierarchical clustering (see Duda & Hart, 1973) to the perceived similarity of every pair of objects. The hypothesis space, prior and likelihood are defined by the tree resulting from hierarchical clustering. Using a tree is well justified from a psychological perspective as children assume the possible referents of novel nouns are tree-structured (Markman, 1991). Nodes in the tree represent potential words (hypotheses) which extend to all the leaves they cover, where the leaves of the tree correspond to the domain of possible objects. The height of a node  $h$  (minimal distance from the node to a leaf) is a measure of the average pairwise dissimilarity of objects covered by node  $h$  and approximates the heterogeneity of the objects that can be called that word. The intuition that more distinctive clusters are more likely to have distinguishing names, was incorporated by defining the prior  $P(h)$  to be proportional to the branch length separating node  $h$  from its parent:

$$P(h) \propto \text{height}(\text{parent}(h)) - \text{height}(h), \quad (3)$$

where  $\text{parent}(h)$  returns the parent of node  $h$ . To incorporate a *basic-level* bias (Markman, 1991; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976) in which new words tend to refer more often to a word at an intermediate level in a taxonomy, the prior probability of hypotheses at the basic level were 10 times the value given by Equation 3 (see below for examples). As the height of node  $h$  also approximates the number of objects in the extension of the possible word  $h$ , the likelihood of observing  $n$  objects called word  $h$  is defined as

$$P(\mathbf{x}|h) \propto \left[ \frac{1}{\text{height}(h) + \epsilon} \right]^n, \quad (4)$$

where  $\epsilon$  is a small constant so that the leaf hypotheses (those that refer to only a single object) do not have infinite likelihood (as their height is zero).

Using this framework, Xu and Tenenbaum (2007) accurately predicted how people extend words to new objects depending on the diversity and number of objects labeled with that word. In a set of experiments on both adults and children, they showed participants one or more positive examples of a novel word while manipulating the taxonomic relationship of the objects the word referred to. For example, participants might observe one Dalmatian, three Dalmatians (exemplars at the subordinate-level), a Dalmatian, terrier, and mutt (exemplars at the basic-level), or a Dalmatian, pig, and toucan (exemplars at the superordinate-level) being labeled with a novel word (e.g. “fep”). After observing a word refer to one or three example objects at the subordinate, basic, or superordinate-level, they were asked whether the word referred to novel subordinate, basic, superordinate, and out-of-domain objects.

When participants were given one example of an object that refers to a word (e.g. one Dalmatian), they tended

to select the subordinate-level matches (e.g. the two other Dalmatians) and the basic-level matches (e.g. the two non-Dalmatian dogs). However, when they were shown three subordinate-level examples of a concept (e.g. three Dalmatians), the participants tended to choose only the subordinate-level matches (e.g. they only believed the word referred to the two other Dalmatians). The Bayesian word learning model captured this phenomenon because the prior favors words at the basic-level, but the likelihood favors words at the subordinate-level, and the likelihood's weight increases exponentially in the number of objects.

Unfortunately, the manner in which the hypothesis space was constructed (through hierarchical clustering on pairs of similarity judgments) poses a serious constraint to assessing the model's validity. To construct the hypothesis space in the three domains tested by Xu and Tenenbaum (2007), where there are 15 images per concept, each participant had to provide roughly 400 similarity judgments. To test how well this framework extends to new concepts and domains using their method for constructing the hypothesis space, an impractically large quantity of human judgments would need to be elicited. In the following section, we introduce an alternative method of constructing a hypothesis space for the Bayesian word learning model, which allows for testing the framework without eliciting any judgments from participants.

## Large-Scale Word Learning

Using an online word ontology, we can automatically construct the hypothesis space of a Bayesian word learning model. WordNet is a large lexical database of English represented as a network of words linked by directed edges denoting semantic relatedness (Fellbaum, 2010; Miller, 1995). Its structure was manually designed to group lexical concepts in an "is-a" hierarchy based on the many-to-one mapping of synonyms. For example, a Poodle "is-a" type of dog, thus WordNet has a directed edge from the node for *dog* to the node for *Poodle*. As WordNet is hierarchically structured like the hypothesis space used by Xu and Tenenbaum (2007), it is an ideal candidate for constructing our hypothesis space.

Using a hypothesis space derived from WordNet, we can better test the predictions of different generalization theories for word learning by examining their predictions for a large range of concepts. In the rest of this section, we present the method used to construct a hypothesis space from WordNet and outline the implementations of three generalization models using this hypothesis space for large-scale word learning.

### Constructing a Hypothesis Space

In the context of the Bayesian generalization framework, the hypotheses correspond to subsets of the universe of objects that are psychologically plausible candidates as extensions of concepts (Tenenbaum & Griffiths, 2001). Using WordNet as the basis of our hypothesis space, the set of objects is the set of leaf nodes from the noun-space of the directed graph and the hypotheses correspond to both the inner nodes of the directed graph and the leaf nodes, which distinguish between

objects at the subordinate-level. To construct a hypothesis space from WordNet, we first extracted a tree from the 82,115 noun nodes of WordNet.<sup>1</sup> The nodes are hypotheses, which represent possible words, and form the hypothesis space for the model. From this graph we create a hypothesis space that is a binary matrix,  $\mathcal{H}$ , whose rows are the objects (64,958 leaf nodes from the graph) and columns are the hypotheses (82,115 nodes, 17,157 of which are inner nodes and 64,958 are leaf nodes). Each entry  $(i, j)$  of the matrix  $\mathcal{H}$  denotes whether or not hypothesis node  $j$  is an ancestor of leaf node  $i$  in the WordNet graph (with a 1 indicating it is). The leaf nodes are included as hypotheses so that the model distinguishes between subordinate objects.

### Generalization Models

With a hypothesis space derived from WordNet, we now have the ability to test the Bayesian model of word learning on a much larger scale. In addition, we can use the hypothesis matrix as a feature space for testing alternative models. We compare the Bayesian model against two similarity models: a prototype model and an exemplar model. Given a set of examples  $\mathbf{x} = \{x_1, \dots, x_n\}$  representing some concept  $C$  (where the elements of  $\mathbf{x}$  correspond to rows in the hypothesis matrix  $\mathcal{H}$ ), we can compute a score for each row  $y \in \mathcal{H}$  denoting the probability that  $y$  is also a member of  $C$ . We present the different ways to compute this score below.

**Bayesian model.** This is the Bayesian generalization framework that we discussed earlier. We used strong sampling for the likelihood,  $P(\mathbf{x}|h)$ , which is computed via Equation 1, where the size of  $h$  is the number of nodes that can be reached by a directed path from  $h$ . This simply corresponds to the sum of the elements in the column corresponding to  $h$ .

The prior  $P(h)$  was defined to be Erlang distributed in the size of the hypothesis (a standard prior over sizes in Bayesian models; Shepard, 1987; Tenenbaum, 2000)

$$P(h) \propto (|h|/\sigma^2) \exp\{-|h|/\sigma\}, \quad (5)$$

where the  $\sigma$  parameter was set to 200 by hand fitting the model predictions to all human responses (the same value was used in both experiments). This value favors medium sized hypotheses, which is roughly equivalent to a basic-level bias. The probability that word  $C$  extends to object  $y$  after observing a set of objects called  $C$  is

$$\text{Bscore}(y) = P(y \in C|\mathbf{x}) = \sum_{h \in \mathcal{H}} P(y \in C|h)P(h|\mathbf{x}), \quad (6)$$

where  $P(y \in C) = 1$  if  $y \in h$  and 0 otherwise, and  $P(h|\mathbf{x})$  is the posterior distribution over hypotheses.

**Prototype model.** In this model, we define the prototype of a set of objects,  $x_{\text{proto}}$ , to have those features owned by a majority of the objects in the set. The generalization measure for

<sup>1</sup>Technically WordNet is a directed acyclic graph because some nodes have multiple parents (the method still works in these cases).

an object  $y$  is

$$\text{Pscore}(y) = \exp\{-\lambda_p \text{dist}(y, x_{\text{proto}})\}, \quad (7)$$

where  $\text{dist}(\cdot, \cdot)$  is the Hamming distance between the two vectors and  $\lambda_p$  is a free parameter (for all of the results presented here,  $\lambda_p = 0.15$ , optimized by hand using half-interval search). Pscore was then normalized over all objects  $y$  in the hypothesis space (all leaf nodes).

**Exemplar model.** We define the exemplar model using a similar scoring metric as the prototype model, except rather than computing the distance of object  $y$  to a single prototype vector, we compute a distance for each item  $x_j$  in the set of observations  $\mathbf{x}$ . The exemplar generalization measure is thus computed as

$$\text{Escore}(y) = \sum_{x_j \in \mathbf{x}} \exp\{-\lambda_e \text{dist}(y, x_j)\}, \quad (8)$$

where  $\text{dist}(\cdot, \cdot)$  is the Hamming distance between two vectors and  $\lambda_e$  is a free parameter (for all of the results presented here,  $\lambda_e = 0.20$ , optimized by hand using half-interval search). Escore was then normalized over all objects  $y$  in the hypothesis space (all leaf nodes).

## Behavioral Experiments

To evaluate the performance of our models using the WordNet-based hypothesis space, we conducted two experiments using the paradigm of Xu and Tenenbaum (2007). The first experiment replicates Xu and Tenenbaum (2007) on their three object taxonomies (animals, vehicles, and vegetables), which validates our approach for constructing a hypothesis space from WordNet and using images from ImageNet as stimuli. The second experiment extends the paradigm into three previously unexplored domains (clothing, containers, and seats), which have hierarchical structure, but it is not as clear how well they conform to a natural basic-level taxonomy (Rosch et al., 1976).

### Experiment 1: Validating Our Approach

**Participants.** Thirty four participants were recruited via Amazon Mechanical Turk and compensated \$0.05 for each trial (training set) completed out of twelve possible. Each participant completed as many trials as he or she wished, and twenty unique participants completed each trial. All participant responses were used.

**Stimuli and Procedure.** Within each taxonomy, the stimuli consisted of the images of objects distributed across the superordinate, basic and subordinate-levels, and subsequently split into training and test sets. The training sets were the labeled objects given to participants of which there were four conditions: a single subordinate-level example (e.g. a Dalmatian); three examples of the same subordinate-level object (e.g. three Dalmatians); the subordinate-level object and

two basic-level objects (e.g. a Dalmatian, a Shih Tzu, and a Beagle); and the subordinate object and two superordinate-level objects (e.g. a Dalmatian, a hippopotamus, and a toucan). This corresponds to twelve trials total (four conditions for each of the three object taxonomies).

The test sets were the same regardless of the training set and consisted of eight objects matching the currently tested taxonomy: two subordinate examples (e.g. two other Dalmatians); two basic-level examples (e.g. a Cocker Spaniel and a Corgi); and four superordinate examples (e.g. a cat, a bear, a sea lion, and a horse). There were also sixteen non-matching objects in the test set corresponding to the objects that match the two other taxonomies.

For each trial, participants were instructed that they needed to help a cartoon frog who speaks a different language from us, pick out objects that he wants. The frog shows one or more examples of a novel word (e.g. “dak”) and the participant is instructed to select other items that are a “dak” from the objects comprising the test set. A unique novel word was associated with each of the twelve trials.

**Results.** Figure 1 shows the results of this experiment, along with the predictions of the different generalization models. For each training set condition, the data for each test item has been averaged over participants and domains. The generalization judgments of participants (left-most panel of Figure 1) follows the same qualitative trend as those reported in Xu and Tenenbaum (2007). There is a sharp drop in generalization to basic-level objects when seeing only a single subordinate example compared to the condition when seeing three subordinate examples.

The Bayesian model predictions (second panel from the left) exhibits this same generalization pattern ( $r^2 = 0.98$ ), while the prototype and exemplar models do not ( $r^2 = 0.66$  and  $r^2 = 0.84$ , respectively). This validates our method of automatically creating hypothesis spaces with WordNet.

### Experiment 2: Novel Domains

**Participants.** Thirty six participants were recruited via Amazon Mechanical Turk and compensated \$0.05 for each trial completed out of twelve possible. As in Experiment 1, each participant completed as many trials as he or she wished, and twenty unique participants completed each trial. All participant responses were used.

**Stimuli and Procedure.** Table 1 contains the objects we used for training in the three hierarchical domains (clothing, containers, and seats).<sup>2</sup> As in Experiment 1, the same test objects were used for every training set, and the “non-match” test objects were the objects in the test set which match the two other taxonomies that are not contained in the training set. As before, this corresponds to twelve trials total. The procedure was identical to Experiment 1.

<sup>2</sup>The additional subordinate-level training image and the test images were omitted from Table 1 for brevity.

Figure 1: Participant generalization judgments and predictions of the Bayesian, prototype, and exemplar models averaged across the three domains in Experiment 1. The generalizations for non-matching items are omitted for brevity (neither the participants chose nor the Bayesian model predicted non-matching objects, while the prototype and exemplar models predicted non-matches less than 4% of the time for each condition).

**Results.** Figure 2 presents the averaged results of how participants<sup>3</sup> and the Bayesian model generalized the learned words to the test objects based on the observed training set across the different domains in Experiment 2.<sup>4</sup> Across the three domains, the generalization probabilities of the participants and Bayesian model with the same parameters are extremely similar. This is exemplified in the very good quantitative model fit on the averaged data ( $r^2 = 0.95$ ). Furthermore, the hypothesis space constructed automatically from WordNet explains the idiosyncrasies of participant generalization behavior in each domain ( $r^2 = 0.97, 0.88$ , and  $0.91$ , for clothing, containers, and seats respectively). For example, the model accurately predicts that participants would generalize most broadly in the seats domain for the single exemplar and three basic-level exemplar training sets. Additionally, the model captures that people generalized the least in the containers domain for the three subordinate-level exemplar training sets. This would not have been possible if the hypothesis space for each domain had the same structure.

Note that there is a larger amount of variance between model predictions and human performance in Experiment 2 than Experiment 1. We believe that this is due to the domains not conforming to a natural taxonomy. For example, it is unclear if box should be the basic-level category for a mail box and a cigar box; however, this is the basic level of these objects provided by WordNet. Regardless, the good quantitative fit of the Bayesian model’s predictions provides evidence that using WordNet as a hypothesis space for word learning can capture people’s generalizations even for hierarchies without clearly defined basic-level concepts.

## Discussion

Although the Bayesian generalization framework has been extremely successful in explaining human generalization behavior, the hypothesis spaces are typically hand-constructed, which is unsatisfying. In this paper, we explored automatically constructing the hypothesis space using an online re-

source as a potential solution to the methodological challenges posed by this problem. In the first behavioral experiment, we validated that the Bayesian model using this hypothesis space can capture previously found word learning phenomena. In the second behavioral experiment, we showed that the same Bayesian model explains how participants learned words in three novel domains. Using the automatically constructed hypothesis space, the model predicted the subtle changes in participants’ word learning behavior across three domains, thus demonstrating the practical and theoretical benefits of our approach.

In the future, we hope to perform a large scale empirical test of the Bayesian word learning model using more heterogeneous training sets (e.g. one subordinate-level and one basic-level object) and more domains with varied conceptual structure. The larger set of empirical results would enable us to perform a more detailed investigation of the prior knowledge over the types of conceptual structures that people use when they learn words (e.g. do people prefer shallow or deep taxonomies?). Additionally, we hope to incorporate how participant behavior is affected by the visual similarity of the images in the training and tests sets (and its interaction with conceptual structure), which at the moment would not be possible to explore with the Bayesian word learning model.

As word learning is a special case of the more general problem of generalization, our approach potentially could be applied to automatically construct hypothesis spaces for generalization problems in other domains. For example, a Bayesian model of commonsense reasoning could be formulated by automatically deriving hypothesis spaces from ConceptNet (Liu & Singh, 2004) or OpenCyc (Matuszek, Cabral, Witbrock, & DeOliveira, 2006). This follows a development in modern machine learning, which has leveraged online resources to make more successful learning algorithms (Medelyan, Legg, Milne, & Witten, 2009; Ponzetto & Strube, 2006). We hope that this draws a closer connection between computer science and cognitive science, which can lead to more psychologically valid, yet still scalable, artificial intelligence systems.

**Acknowledgments.** This work was supported by the DARPA BOLT contract HR0011-11-2-0009 and grant number IIS-0845410 from the National Science Foundation.

<sup>3</sup>Non-matching objects were only chosen twice (both in the containers domain) and so, they were omitted from Figure 2.

<sup>4</sup>The prototype and exemplar models were omitted from Figure 2 for brevity ( $r^2 = 0.80$  and  $r^2 = 0.90$  averaged over domains, respectively).

## Abstract

Best examples of categories lie at the heart of two major debates in cognitive science, one concerning universal focal colors across languages, and the other concerning the role of representativeness in inference. Here we link these two debates. We show that best examples of named color categories across 110 languages are well-predicted by a rational model of representativeness, and that this model outperforms several natural competitors. We conclude that categorization in the contested semantic domain of color may be governed by general principles that apply more broadly in cognition, and that these principles clarify the interplay of universal and language-specific forces in color naming.

**Keywords:** Language and perception; semantic universals; color naming; representativeness; Bayesian inference.

## Introduction

Do the world's languages reflect a universal repertoire of cognitive and perceptual categories? Or do different languages partition the experienced world in fundamentally different ways? These questions have been pursued in depth in the domain of color naming and cognition (e.g. Berlin & Kay, 1969; Kay & McDaniel, 1978; Lindsey & Brown, 2006; Roberson, Davidoff, Davies, & Shapiro, 2005; Roberson, Davies, & Davidoff, 2000), and current findings suggest an interestingly mixed picture. There are clear universal tendencies of color naming across languages, but there is also substantial cross-language variation (e.g. Regier, Kay, & Khetarpal, 2007), more than is suggested by traditional universalist accounts. At the center of this debate is the disputed role of *focal colors*, or the best examples of named color categories.

It has long been claimed that color naming across languages is constrained by six universal privileged points, or foci, in color space, corresponding to the best examples of what would be described in English as *white*, *black*, *red*, *yellow*, *green*, and *blue*. This view has received empirical support: the best examples of color terms across languages tend to cluster near these six points (Berlin & Kay, 1969; Regier, Kay, & Cook, 2005), and these colors have also been found to be cognitively privileged (Heider, 1972; but see Roberson et al., 2000). A natural and influential proposal (Kay & McDaniel, 1978) is that these privileged colors constitute a universal foundation for color naming, such that languages differ in their color naming systems primarily by grouping these universal foci together into categories in different ways.

Roberson et al. (2000) advanced a diametrically opposed view of color naming, and of the role of best examples in it.

They argued that color categories are not defined around universal foci, but are instead defined at their boundaries by local linguistic convention, which varies across languages. They proposed: "Once a category has been delineated at the boundaries, exposure to exemplars may lead to the abstraction of a central tendency so that observers behave as if their categories have prototypes" (p. 395). On this view, best examples do not reflect a universal cognitive or perceptual substrate, but are merely an after-effect of category construction by language: best examples are derived from language-specific boundaries, rather than boundaries from universal best examples.

A proposal by Jameson and D'Andrade (1997) has the potential to reconcile these two opposed stances. This proposal holds that there are genuine universals of color naming, but they do not stem from a small set of focal colors. Instead, universals of color naming may stem from irregularities in the overall shape of perceptual color space, which is partitioned into categories by language in a near-optimally informative way. This proposal has been shown to explain universal tendencies in the *boundaries* of color categories (Regier et al., 2007). However it has not yet provided an account of *best examples* of these categories, which lie at the heart of the debate.

Here, we address this open issue, completing the reconciliation of the two standardly opposed views. We suggest that best examples are largely universal (in line with the universal-foci view), but nonetheless derived from category boundaries (in line with the relativist view). Specifically, given the independent explanation of category boundaries in terms of the shape of color space, we propose that universal tendencies of best examples are derived from those of boundaries, rather than the other way around as has been traditionally assumed. Moreover, we propose that best examples are derived from category boundaries in an optimal manner, echoing the optimal or near-optimal partition of color space into categories. To pursue this idea, we draw on previous work on a rational model of representativeness, and ask whether the best examples of color categories can be well-predicted as those colors that are most representative of a given category.

The remainder of the paper proceeds as follows. In the next section, we discuss the previous work on representativeness on which we draw, and contrast it with other approaches to that problem. We then describe the color naming data we consider, and a set of competing models that predict the foci

of color categories from the extensions of those categories. We first test these models broadly against data from 110 languages, and then test them in a targeted fashion against the data of a language with an unusual color naming system. In both cases, we find that the rational model of representativeness provides a good fit to the empirical data, and outperforms competing models. We close by discussing the implications of our findings.

## Representativeness

Why do people believe that the sequence of coin flips HHTHT (where H=heads, T=tails) is more likely than the sequence HHHHH to be produced by a fair coin? Using simple probability theory, it is easy to show that the two sequences are in fact equally likely. Cognitive psychologists have proposed that people use a heuristic of “representativeness” instead of performing probabilistic computations in such scenarios (Kahneman & Tversky, 1972). We might then explain why people believe HHTHT is more likely than HHHHH to be produced by a fair coin by arguing that the former is more representative of the output produced by a fair coin than the latter. If this heuristic is a correct account of such inferences, how do we define it? Numerous proposals have been made, connecting representativeness to existing quantities such as similarity (Kahneman & Tversky, 1972), and likelihood (Gigerenzer, 1996). Tenenbaum and Griffiths (2001) took a different approach to this question, providing a *rational analysis* (Anderson, 1990) of representativeness by trying to identify the problem that such a quantity solves. They noted that one sense of representativeness is being a good example of a concept, and showed how this could be quantified in the context of Bayesian inference.

Formally, given some observed data  $d$  and a set of of hypothetical sources,  $\mathcal{H}$ , we assume that a learner uses Bayesian inference to infer which  $h \in \mathcal{H}$  generated  $d$ . Tenenbaum and Griffiths (2001) defined the representativeness of  $d$  for hypothesis  $h$  to be the evidence that  $d$  provides in favor of a specific  $h$  relative to its alternatives:

$$R(d, h) = \log \frac{p(d|h)}{\sum_{h' \neq h} p(d|h')p(h')} \quad (1)$$

where  $p(h')$  in the denominator is the prior distribution on hypotheses, re-normalized over  $h' \neq h$ . This measure was shown to outperform similarity and likelihood in predicting human representativeness judgments for a number of simple stimuli. We propose this measure can also be used to determine focal colors from the set of colors named with a particular color term - that is, the extension of that named color category.

## Representativeness and color foci

Evaluating formal models of representativeness as an account of color foci requires a good source of color naming data. The data we considered were those of the World Color Survey (WCS), which collected color naming data from native speakers of 110 unwritten languages worldwide (Cook,

Figure 1: The WCS stimulus array. The rows correspond to 10 levels of Munsell value (lightness), and the columns correspond to 40 equally spaced Munsell hues. The color in each cell corresponds approximately to the maximum available Munsell chroma for that hue-value combination.

Kay, & Regier, 2005). Participants in the WCS were shown each of the 330 color chips from the stimulus array in Figure 1, and were asked to name each chip with a color term from their native language; we refer to the resulting data as “naming data”. Afterwards, participants were asked to pick out those cells in the stimulus array that were the best examples (foci) of each color term they used; we refer to these as “focus data”. The WCS dataset is available at <http://www.icsi.berkeley.edu/wcs/data.html>.

We applied Tenenbaum and Griffiths’ (2001) representativeness model, and a set of natural competitor models, to the problem of predicting best examples of color categories from the extension of those categories. Thus, the models we consider are different formalizations of our central proposal that best examples may be derived from category boundaries. Following Kay and Regier (2003), we represented each color in the stimulus array as a point in 3-dimensional CIELAB color space. For short distances at least, Euclidean distance between two colors in CIELAB is roughly proportional to the perceptual dissimilarity of those colors. For each named color category used by each speaker in each language of the WCS, we modeled that category as a 3-dimensional Gaussian distribution in CIELAB space, and estimated the parameters of that distribution using a normal-inverse-Wishart prior, a standard estimation method for multivariate Gaussian distributions of unknown mean and unknown variance (Gelman, Carlin, Stern, & Rubin, 2004). Specifically, given a set of  $M$  chips  $\mathbf{x}_i$  in color category  $t$  we obtain the estimates:

$$\mu_t = \frac{1}{M} \sum_i^M \mathbf{x}_i$$

$$\Sigma_t = \frac{SS_t + \lambda_0}{n_t + \nu_0}$$

where  $SS_t$  is the sum of squares for category  $t$ :  $\sum_i^M (\mathbf{x}_i - \mu_t)(\mathbf{x}_i - \mu_t)^\top$ ,  $n_t$  is the number of chips in category  $t$  for the current speaker, and  $\lambda_0$  and  $\nu_0$  are the parameters of the prior.  $\lambda_0$  was set by taking an empirical estimate of the variance in CIELAB coordinates over all chips in the stimulus array, and  $\nu_0$  was set to 1. We chose this Bayesian formulation of parameter estimation over standard Maximum Likelihood Es-

timization (MLE) since MLE will result in singular covariance matrices for color categories containing few color chips.

With an estimate of the distribution characterizing the category named by color term  $t$ , we can now adopt the representativeness measure given in Equation 1 to determine how good an example each color chip  $x$  is of a color term  $t$ . Substituting  $x$  in for the observed data  $d$  and  $t$  for hypothesis  $h$  we obtain the expression:

$$R(x, t) = \frac{p(x|t)}{\sum_{t' \neq t} p(x|t')p(t')} \quad (2)$$

where  $p(x|t)$  is computed from the density function of the estimated Gaussian described above and the priors  $p(t')$  are proportional to  $n_{t'}$ , the number of chips in named color category  $t'$ . We test this Bayesian measure against the alternative proposals of representativeness mentioned above (Gigerenzer, 1996; Kahneman & Tversky, 1972): a likelihood model and two similarity models (a prototype model and an exemplar model). In addition, we explore a model that selects as the focus for category  $t$  that chip in the extension of  $t$  that has the highest chroma. Chroma, or saturation, corresponds loosely to how colorful or “un-gray” a given color is, and in exploring this model we follow the suggestion (Jameson & D’Andrade, 1997; Regier et al., 2007) that focal colors tend to be those with high chroma. We note that each of these models captures some variant of the category *central tendency* idea promoted by Roberson et al. (2000), as described above. We present the details of the competing models below. As with the representativeness model, for a given color  $x$  and color term  $t$ , each model assigns a score indicating how good  $x$  is as an example of  $t$ .

**Likelihood model.** In this model, the goodness score of color  $x$  as an example of color category  $t$  is given by the density function of the Gaussian distribution that was fit to the naming data for  $t$ . Thus,

$$L(x, t) = p(x|t) \quad (3)$$

Note that this model is similar to the representativeness model, but without the denominator which captures competition among categories in that model.

**Prototype model.** In this model we define the focus, or prototype, of color category  $t$  to be the mean  $\mu_t$  of the distribution characterizing  $t$ . The score for this measure then becomes the similarity of  $x$  to that prototype:

$$P(x, t) = \exp\{-\text{dist}(x, \mu_t)\} \quad (4)$$

where  $\text{dist}(\cdot, \cdot)$  is the Euclidean distance between two colors in CIELAB color space.

**Exemplar model.** We define the exemplar model using a scoring metric similar to that in the prototype model, except rather than computing the similarity of color  $x$  to a single prototype, we compute its similarity to each color chip that falls

in the extension of category  $t$ , and sum the results. This similarity measure is thus computed as

$$E(x, t) = \sum_{x_j \in \mathbb{X}_t} \exp\{-\lambda \text{dist}(x, x_j)\} \quad (5)$$

where  $\mathbb{X}_t$  is the set of color chips that fall in the extension of category  $t$ ,  $\text{dist}(\cdot, \cdot)$  is the Euclidean distance between two colors in CIELAB space, and  $\lambda$  is a free parameter. For the results presented below,  $\lambda$  was set to the value that yielded the best performance overall, which was 0.25.

**Chroma model.** The score for this model is computed similarly to that for the prototype model, but rather than computing the similarity of color  $x$  to the mean of a distribution characterizing category  $t$ , we compute its similarity to that color chip  $c_t$  which has the highest chroma (saturation) value within the extension of category  $t$ . The chroma values for each chip in the stimulus array are provided with the WCS data. Thus we compute

$$C(x, t) = \exp\{-\text{dist}(x, c_t)\} \quad (6)$$

where  $\text{dist}(\cdot, \cdot)$  is the Euclidean distance between two colors in CIELAB space, and  $c_t$  is the chip within the extension of  $t$  that has the highest chroma value. In the case of ties for  $c_t$  - that is, several chips with the same maximum value for chroma - we randomly select a chip from the set of ties.

## Predicting foci from category extensions

We assessed these models as follows. For each speaker of each language in the WCS, we first considered that speaker’s naming data, and modeled the categories in those data as a set of Gaussians in the manner described above. Then, for each such category, we determined how representative of that category each of the 330 chips in the stimulus array is, according to each model. This yielded, for each model, a ranking of chips in the array by predicted representativeness, and we then compared this model prediction with empirical focus data from the WCS. In the following sections we present both qualitative and quantitative evaluations of the models.

## Distribution of foci

A simple means of assessing the models is to generate predicted focal choices from each model’s ranking of chips, and to then compare those predicted focal choices with the actual focus data of the WCS. Some speakers in the WCS provided more than one focus (best example) for some categories; if a speaker provided  $n$  foci for a given category, we selected the  $n$  top-ranked chips as a given model’s predicted focal choices for that category and speaker. In this manner we obtained, for each model, one predicted focal choice for each empirical focal choice in the data. We then counted the number of times each of the 330 color chips in the stimulus array was selected as a focal choice, yielding a distribution of focal choices over the stimulus array. We then compared the

empirical distribution of foci across the array with the distribution predicted by each of the models. Following Regier et al.'s (2005) empirical analysis of WCS focus data, we plotted these distributions over the chromatic portion of the array, where the 2-dimensional layout makes contours easily interpretable. Accordingly, we did not plot the focal choices for the terms a speaker used to name A0 and J0, corresponding to English focal *white* and *black*. The resulting contour plots, of the empirical WCS focus distribution and the five models' predicted focus distributions, are shown in Figure 2.

The empirical distribution is shown in panel (a), and replicates the findings of Regier et al. (2005). The distribution predicted by the Bayesian representativeness model (panel b) matches this empirical distribution qualitatively fairly well. Moreover, at least on informal inspection, the Bayesian model appears to approximate the empirical distribution more closely than do the competing models. The chroma model (panel f) at first appears to also approximate the empirical distribution fairly well, but closer inspection reveals that several of the peaks of the model distribution do not align correctly with those of the empirical distribution.

This qualitative assessment is reinforced by a quantitative one. The Jensen-Shannon divergence (JSD) is a measure of the dissimilarity between two probability distributions,  $P$  and  $Q$ , defined as

$$\text{JSD}(P||Q) = \frac{1}{2}KL(P||M) + \frac{1}{2}KL(Q||M) \quad (7)$$

where  $M = \frac{1}{2}(P + Q)$ , and  $KL(\cdot)$  is the more commonly-known Kullback-Leibler divergence. JSD is closely related to Kullback-Leibler divergence, with the important difference that JSD is always a finite value, ranging from a value of 0 when the two distributions are identical, to a value of 1 when they are maximally different.

We computed the JSD between the WCS empirical focus distribution (normalized so that it may be considered a probability distribution, taken to be  $P$  in Equation 7), and each of the model distributions (similarly normalized, taken to be  $Q$  in Equation 7). The results are shown below in Table 1. The Bayesian model outperforms the other models, diverging less from the empirical distribution than its competitors.

### Rank position of foci

Each model produces as output a ranking of the stimulus chips, where rank is assigned in descending order. Thus, another natural way to assess the models is to note the position of the true empirical focal choice in this ranked list. For example, if a model correctly ranked the true focal chip as the single most representative example of a given color category, it would receive a score of 1/330. As noted previously, sometimes a speaker provided multiple foci for a given color term. To accommodate this we averaged the positional ranking of each focus empirically provided and took the resulting quantity as the model performance for a given color term. In turn, we averaged this performance over the number of color terms a speaker used, then averaged over the number of speakers in

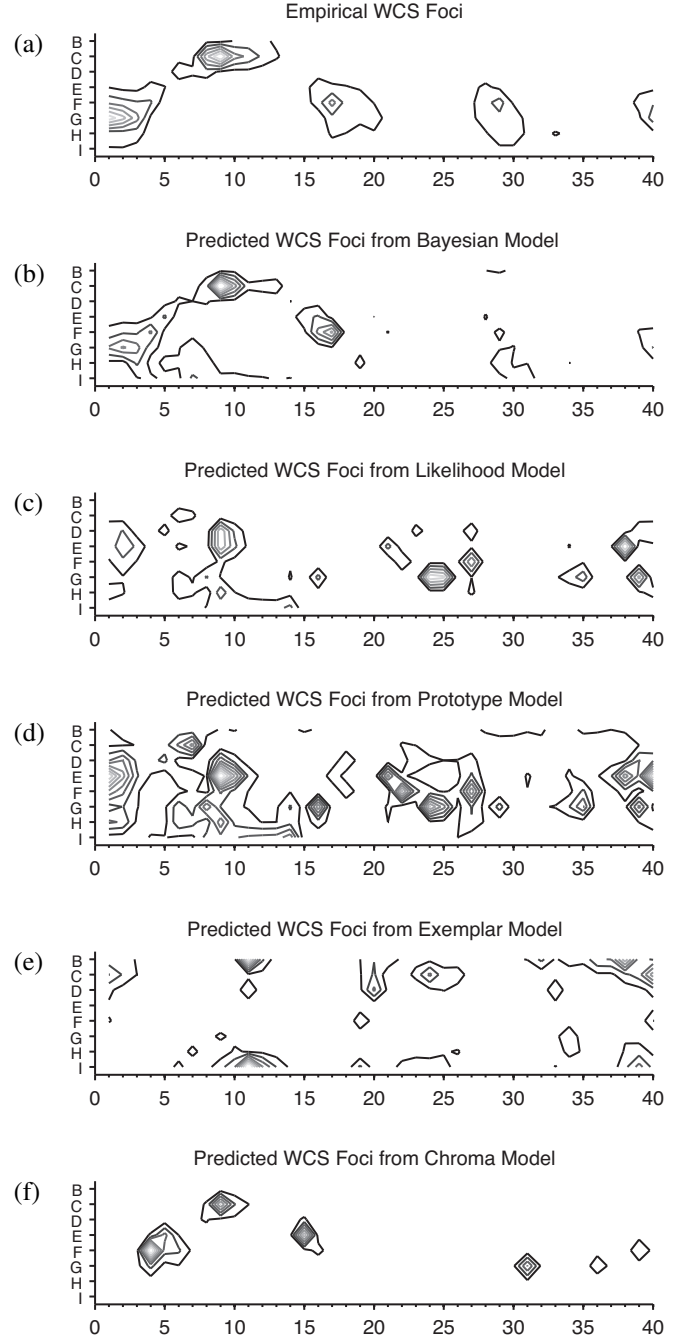

Figure 2: Contour plots of the focus distributions in (a) the WCS, and as predicted by (b) the representativeness model, (c) the likelihood model, (d) the prototype model, (e) the exemplar model, and (f) the chroma model. Each contour line corresponds to 100 focal choices.

a language, and finally computed an average overall model performance for all 110 WCS languages. The average rank position of empirical WCS foci for each model is presented in Table 2.

As before, we find that the Bayesian measure of representativeness outperforms the other models, ranking the true

Table 1: Divergence between empirical WCS focus distribution and model prediction

Model	Jensen-Shannon Divergence
Bayesian	0.0368
Likelihood	0.1977
Prototype	0.1750
Exemplar	0.1760
Chroma	0.1698

Table 2: Average rank position of empirical WCS foci for each model

Model	Average Rank Position

Exemplar	0.1457
Chroma	0.2306

foci within the top 11% of chips on average. In comparison, the likelihood model, which has the second highest average, ranks the true foci in the top 14% of chips on average. It is noteworthy that the chroma model, which captures the natural idea that best examples correspond to chroma maxima, performs most poorly, ranking the true foci only within the top 24% of chips.

### A final test: Karajá

So far, we have suggested that color foci may be derived from category boundaries as representative members of a category - and we have shown that this idea accounts well for universal tendencies in focal colors. Thus, foci may inherit their universal tendencies from category boundaries, rather than projecting their universal tendencies to those boundaries. Note, however, that the demonstrations we have seen so far do not discriminate between these two hypotheses. For languages with common color-naming systems, the two hypotheses make the same prediction: foci should tend to fall in the canonical positions shown in Figure 2(a). This is predicted on the traditional universal-foci account, because these are the proposed locations of the universal foci. Roughly the same outcome is predicted by our account, as seen in Figure 2(b).

In a final investigation, then, we attempt to discriminate between these two hypotheses. The hypotheses diverge in their predictions for languages with color categories that have unusual extensions. If foci are a universal groundwork for color naming, then in such unusual cases, foci will fall in the universal (canonical) positions, despite the non-canonicity of the category boundaries. In contrast, our account predicts that in such cases, foci should follow the category boundaries, and fall in non-canonical positions. We test these predictions against a language that is known (Regier, Kay, & Khetarpal, 2009) to have color categories with unusual extensions: Karajá, a language of Brazil.

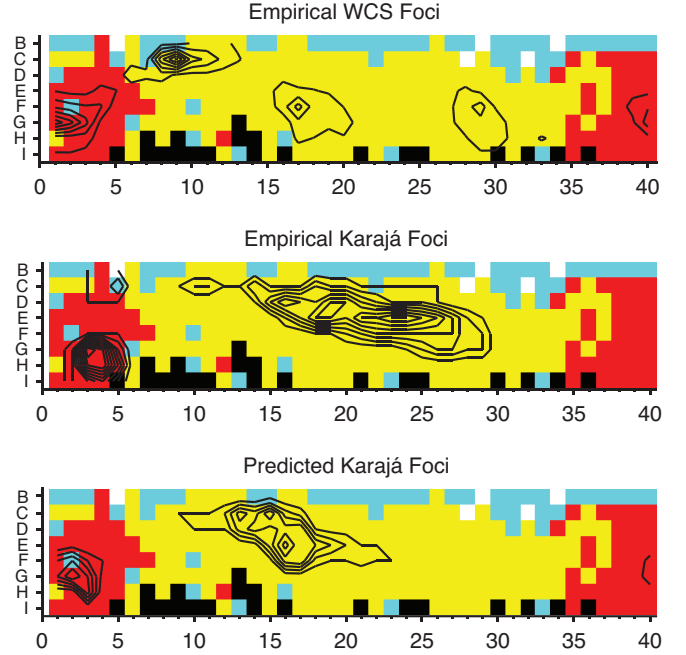

Figure 3: Naming data for the Karajá language, overlaid with contour plots of three different focus distributions: the empirical focus distribution for all languages in the WCS (upper panel), the empirical focus distribution for Karajá itself (middle panel), and the focus distribution predicted by the Bayesian model of representativeness (lower panel).

Figure 3 presents WCS color naming data for Karajá. Here, chips displayed in the same color were named with the same color term by a plurality of participants. These modal naming maps are overlaid with three different focus distributions: the full empirical focus distribution of the WCS (upper panel), the empirical focus distribution from Karajá only (middle panel), and the focus distribution for Karajá predicted by the Bayesian representativeness model (lower panel). The difference between the focus distributions in the top two panels is clearly seen, demonstrating that the foci of Karajá follow the language’s color boundaries and are not in line with the universal foci found across the WCS. Additionally, the focus predictions from the Bayesian model of representativeness follow the empirical Karajá focus distribution relatively closely. As before, these qualitative results are confirmed by a quantitative analysis that measures the Jensen-Shannon divergence between the empirical Karajá focus distribution and the distribution predicted by each of the models. As can be seen in Table 3 below, the Bayesian model outperforms the other models on Karajá considered by itself, not just on the entire WCS dataset. We also examined the rank position of the empirical Karajá foci in the ranking produced by each model, and by this measure as well, the Bayesian model fits the data more closely than the competitors, as shown in Table 4 below.

In sum, when boundaries fall in non-canonical positions,

Table 3: Divergence between empirical Karajá focus distribution and model prediction

Model	Jensen-Shannon Divergence
Bayesian	0.3272
Likelihood	0.4430
Prototype	0.5524
Exemplar	0.5137
Chroma	0.5848

Table 4: Average rank position of empirical Karajá foci for each model

Model	Average Rank Position
Bayesian	0.2064
Likelihood	0.2298
Prototype	0.2877
Exemplar	0.3023
Chroma	0.3199

foci do as well - suggesting that foci may in fact be derived from boundaries. This conclusion is reinforced by the observation that the Bayesian representativeness model predicts foci from boundaries fairly well in this non-canonical case, as well as more generally across the WCS.

## Conclusion

Focal colors, or best examples of color terms, lie at the center of the debate over color naming. These foci have traditionally been viewed either as the underlying source of color naming universals, or as derived from category boundaries that vary with local linguistic convention. In contrast, we have argued for a novel account of this disputed construct, in which focal colors show strong universal tendencies, but are nonetheless derived from category boundaries, as the most representative members of categories. In support of this proposal, we have shown that an existing Bayesian model of representativeness can predict the distribution of focal colors in the world's languages, from category extensions. This account synthesizes traditionally opposed views of color naming (Kay & McDaniel, 1978; Roberson et al., 2000), and accounts for data that challenge the traditional views.

Our proposal also coheres naturally with a recent theoretical account that explains universal tendencies in color naming in terms of optimally informative partitions of an irregularly shaped perceptual color space (Jameson & D'Andrade, 1997; Regier et al., 2007). Significantly, that view explains universal tendencies in color category boundaries without reference to a small set of focal colors, and it leaves the nature of focal colors unexplained. Our proposal fills that gap. Taken together, the two proposals suggest a single overall account of color naming: foci are optimally representative members of categories that are defined at their boundaries - and the boundaries themselves result from near-optimally informative partitions of color space.

## Abstract

Line graphs are widely used in communication settings, for conveying information about states and processes that unfold in time. The communication is achieved by the contribution of other modalities than graphs, such as language and gestures. In a set of experimental investigations, we analyzed the production and comprehension of gestures during communication through line graphs. The findings reveal a systematic use of gestures as well as the limitations of cognitive resources due to the split of attention between the modalities.

**Keywords:** Gesture production; gesture comprehension; graph comprehension; line graphs.

## Line Graphs in Time Domain

Line graphs represent statistical data, most often the relationship between two domain variables. In line graphs, line segments are used for representing the mapping between the values. When used in time domain, line graphs represent the mapping between the values of the domain variable and time. From the perspective of human comprehension, line graphs in time domain have a peculiar characteristic: they represent not only statistical data but also *states* and *processes* that unfold in time, by providing perceptual cues for continuation (Figure 1).

Figure 1: Sample population graph from PRBO (2012); redrawn based on the original.

Accordingly, the population graph in Figure 1 does not only represent the mapping between years and the population of the bird species but also leads to a conceptualization of how population *increases*, *decreases* or *remains stable* in certain periods of time.<sup>1</sup>

<sup>1</sup> Line graphs are generated based on a set of assumptions that specify the way the data points are represented by lines. For instance, according to the original source (PRBO, 2012), the line

Human conceptualization through statistical graphs has been a topic of interdisciplinary research since the past 30 years. The research on graph comprehension has covered a broad range of analyses including the investigations on perceptual processes of graph comprehension (e.g., Cleveland & McGill, 1985), analysis from the perspective of psychology and usability (e.g., Kosslyn, 1989), cognitive models (Lohse, 1993; Peebles & Cheng, 2002), educational psychology and instructional design (Winn, 1987; Mautone & Mayer, 2007). On the other hand, the research on modalities that accompany graphs, such as language and gesture in communication through graphs, has been scarce except for a few studies (e.g., Gerofsky, 2011, on gestures in graphs of polynomial functions). Concerning the relationship between language and gestures, gestures have been considered as having a key role in organizing, conveying spatial information, and preventing decay in visuospatial working memory (Hostetter & Alibali, 2010), thus having the potential to promote learning in educational contexts (Goldin-Meadow, 2010). Analyzing the relationship between graphical cues, language and gestures, the present study investigates communication through line graphs from the perspective of multimodal interaction.

## Communication through Line Graphs

Graphs are abundant both in spoken communication settings (e.g., classroom settings) and in written communication settings (e.g., newspaper articles). Communication through graphs is achieved by means of the contribution of several modalities: language (both in written form and in spoken form), graphical cues in written communication settings, and gestures in spoken communication settings. The previous research on multimodal comprehension reveals a frequent use of spatial terms that convey spatial information in communication through line graphs (Habel & Acartürk, 2007). Moreover, in spoken communication, people tend to produce more gestures when they perform tasks that involve spatial information, compared to tasks with no spatial information (Alibali et al., 2001; Trafton et al., 2006; Hostetter & Sullivan, 2011). Consequently, in communication through line graphs, humans frequently produce gestures that accompany spoken language.

graph in Figure 1 was generated by applying a local regression method called Loess smoothing on data points. The resulting spatial aspects of line graphs, such as smoothness, influence humans' interpretation of the states and processes (Acartürk et al., 2008), a topic beyond the scope of the present study.

Gestures in communication are of different types: the most commonly used ones are deictic (or pointing) gestures and iconic (or representational) gestures. Deictic gestures show objects, people and places, whereas iconic gestures are representations of shape of an object or an action (Özçalışkan & Goldin-Meadow, 2005). In communication settings, deictic gestures facilitate achieving joint attention on objects, whereas iconic gestures overlap with spatial tasks (Alibali et al., 2001; Trafton, et al., 2006). In communication through line graphs, humans may produce both deictic gestures and iconic gestures. It is also not unusual that humans emphasize certain aspects of processes and states represented by line graphs, such as a specific increase, a peak or a stable period of the domain value, in addition to emphasizing an overall pattern. Graphical annotations (also called graphical cues) on graph lines are generally used for this purpose.

The major focus of the present study is to investigate gestures in communication through line graphs, both from a production perspective and a comprehension perspective. For a systematic analysis, we limited the domain of investigation to the relationship between gestures and graphical cues in line graphs (rather than the overall pattern of the graph line). In the first step of the analysis, one group of participants produced gestures during a verbal description task (Experiment 1). We considered the produced gestures as human interpretations of the structural aspects of the states and processes represented by the graphs. The gestures produced by the participants of Experiment 1 were used for designing the stimuli for a comprehension experiment (Experiment 2). This approach resembles what has been termed the “3Ps (Preference-Production-Performance) program” as an empirical method for selecting appropriate representations for abstractions (Kessell & Tversky, 2011). The two approaches are similar; in that, both aim to perform an empirical investigation of the representations rather than leaving the decision for selecting the appropriate representation to intuitions of the graphic designer. Instead of graphic representations, however, we investigated gestures in communication through graphs in a set of consecutive analyses (i.e., the outcome of Experiment 1 was used for preparing the stimuli set in Experiment 2).

## Experiment 1

In Experiment 1, the participants presented verbal descriptions of annotated graphs. Spontaneous gestures of the participants were analyzed in terms of the relationship between the type of the graphical cue and the gesture type.

### Participants, Materials and Design

A total of seven participants (*Mean age* = 25.4, *SD* = 3.78) who were graduate students or teaching assistants from the Faculty of Education, Middle East Technical University (METU) participated in the experiment, five of which reported having teaching experience. The experiment language was Turkish, which was the native language of the

participants. The participants were asked to imagine themselves in an online meeting, in which their task was to present single-sentence summaries of annotated graphs to the audience. According to the scenario, the audience was able to see the participant (i.e., the presenter) but not the graphs. Therefore, the presenter first investigated the graph displayed on a computer screen, then s/he turned towards the audience (an audience picture displayed on another computer screen), and then presented a single-sentence summary of the graph. The participants were not informed that their gestures were in the focus of the experiment. Each participant presented the single-sentence summaries for 14 annotated graphs, thus generating 14 video recordings per participant. The graphs represented populations of bird species in a lagoon. Each graph involved a graphical annotation that emphasized a certain aspect of the information represented, such as a specific increase or a peak. In particular, three types of annotations were used.

- Process annotation: A diagonal arrow that emphasized a specific increase or a decrease.
- Durative state annotation: A horizontal arrow that emphasized a specific period of constant value.
- Punctual state annotation: A point-like circle that emphasized a specific value such as a peak value.

The 14 stimuli involved 2 graphs for familiarization of the participant to the task. The remaining 12 stimuli involved 6 punctual state annotations (2 for the start point of the lines, 2 for middle and 2 for the endpoint of the lines), 4 (diagonal) process annotations and 2 (horizontal) durative state annotations (Figure 2).

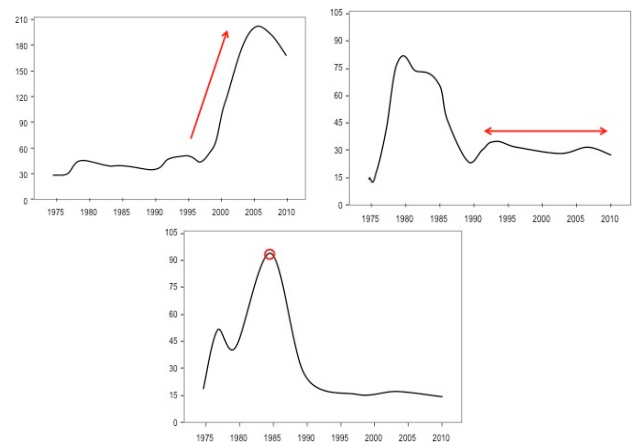

Figure 2: Sample annotated graphs with a process annotation (upper left), a durative state annotation (upper right), and a punctual state annotation (bottom).

Following Gerofsky (2011), we employed the coding scheme proposed by Creswell (2007) for the analysis of (14 graphs x 7 participants) 98 experiment protocols. The Noldus Observer XT event logging software was used for coding. Two coders analyzed the protocols according to the following criteria: For each gesture in the video recording, the coder first classified the gesture in terms of its directionality: having no gesture, no direction, being

vertical, horizontal, diagonal or other.<sup>2</sup> Then the coder identified the following features of each gesture: size (small or big), palm direction (up, down or front), speed (slow or fast) and start position (low, middle or high). In the present study, we focus on the directionality of gestures by leaving the analysis of other features to an extended study. One coder initially coded the entire data, and a second coder, who was blind to the hypothesis, carried out 57% of the dataset. Interrater reliability between coders was calculated by Cohen's kappa. The results revealed an agreement value of .78. According to Landis and Koch (1977), a value above .61 indicates substantial interrater agreement.

## Results

The participants gestured in 86% of the protocols. This number is close to what Hegarty et al. (2005) reported: the participants gestured when they described solutions to mental animation problems in 90% of the cases.<sup>3</sup> Pearson's chi square test and follow-up McNemar tests were conducted to investigate the relationship between the annotation type and the gestures produced by the participants. The test showed a significant effect of annotation type on gesture,  $\chi^2 = 48.1$ ,  $p < .05$ . In particular, for the graphs with process annotations, the participants produced more vertical and diagonal gestures compared to both horizontal gestures,  $\chi^2 = 15.7$ ,  $p < .05$ , and gestures with no direction,  $\chi^2 = 5.88$ ,  $p < .05$ . On the other hand, they produced more horizontal gestures compared to other types of gestures for durative states,  $\chi^2 = 4.08$ ,  $p < .05$ . Finally, for punctual annotations, more non-directed pointing gestures were produced compared to vertical gestures,  $\chi^2 = 16.5$ ,  $p < .05$ , to horizontal gestures,  $\chi^2 = 26.0$ ,  $p < .05$ , and to diagonal gestures,  $\chi^2 = 20.8$ ,  $p < .05$ .

These findings show that, in terms of the categorization of the gestures (cf. McNeill, 2005; Özçalışkan & Goldin-Meadow, 2005) the participants produced iconic gestures for process annotations and durative state annotations. On the other hand, for punctual state annotations, they produced pointing gestures that were ambiguous between iconic (because the pointing gesture was representational) and deictic (by definition).

## Experiment 2

The findings obtained in Experiment 1 suggest that humans produce a specific type of gesture depending on the emphasized aspect of the information represented in the graph. Based on the results obtained in Experiment 1, we investigated comprehension of gestures by humans in

<sup>2</sup> The 'other' category involved beat gestures (simple up-and-down movements without semantic information) or more complex gestures like the combination of vertical, horizontal or diagonal movements.

<sup>3</sup> A further investigation revealed that the five participants who reported teaching experience gestured in 93% of the protocols whereas the two participants who reported no experience in teaching gestured in 68% of the protocols. The finding suggests a potential correlation between teaching experience and gesturing.

Experiment 2. For this, we prepared 14 video recordings in which a narrator presented a single-sentence summary of annotated graphs by producing a relevant gesture concurrently with the spoken description. The verbal description was a single-sentence summary for a graph with process annotation, a graph with durative state annotation or a graph with punctual state annotation. For example, for a graph with a process annotation, the narrator uttered the sentence "[t]he population of coot in the lagoon increased between 1980 and 1985" while producing an upward diagonal gesture that showed an increase. She uttered the sentence "[t]he sanderling population in the lagoon remained stable between 1975 and 1985" accompanied by a horizontal gesture for a graph with a durative state annotation. Finally, for a graph with a punctual state annotation, the narrator uttered the sentence "[t]here exists about 120 terns in the lagoon in the year 2010" accompanied by a pointing gesture (Figure 3). The duration of the video recordings was between 5.3 seconds and 8.6 seconds ( $M = 6.24$ ,  $SD = 0.95$ ).

Figure 3: Snapshots from the video recordings with a diagonal gesture for a process annotation (left), a horizontal gesture for a durative state annotation (middle), a pointing gesture for a punctual state annotation (right).

Experiment 2 was conducted in three different conditions. In the first condition, the participants played the videos on the screen one by one and they listened to a single-sentence summary for each graph concurrently. In the second condition, the participants played the same video recordings but the sound was muted, therefore they interpreted what was presented on the screen only. In both the first condition and the second condition, we noted that participants' gaze shifted between the gesture and the face of the narrator. We interpreted this finding as a potential source of attention split. Therefore, in the third condition, we provided the participants with only gestures not the face of the narrator. In all conditions, the participants were asked to predict the described graph among a set of three alternative graphs.

### Condition 1: Concurrent Interpretation of Gestures and Language

**Participants, Material and Design.** Eleven participants ( $Mean\ age = 31.8$ ,  $SD = 5.1$ ), who were either graduate or undergraduate students of METU, participated in the experiment. Each participant was presented 14 video recordings (2 trials and 12 tests). After playing each recording, the participant was asked to choose the described

graph among three alternatives (the alternate graphs were the same except for the graphical annotation). After submitting each choice, the participant reported a subjective evaluation for confidence (“*How confident are you about your judgment?*”) by using a 1 to 3 scale (1 showing a low confidence, 3 showing a high confidence; Beattie and Shovelton, 1999). The stimuli were displayed on a Tobii non-intrusive 120 Hz eye tracker, integrated into a 17” TFT monitor with a resolution of 1024x768 pixels. The spatial resolution and the accuracy of the eye tracker were 0.25° and 0.50° respectively. No time limit was set for the answers. The order of presentation of the stimuli was randomized.

**Results.** The participants exhibited high success rates in predicting the annotated graphs, for all three types of gestures, i.e. the process gesture ( $M = 1.0$ , i.e. 100%), the durative state gesture ( $M = 1.0$ ) and the punctual state gesture ( $M = .93$ ,  $SD = 0.01$ ). The results of an ANOVA test revealed a significant difference between the gesture types,  $F(2, 20) = 5.17$ ,  $\eta^2 = .36$ ,  $p < .05$ : the success rate in punctual states was lower than the other two gesture types. A comparison of the confidence scores reported by the participants, however, revealed no significant difference between the gesture types  $F(2, 20) = 1.86$ ,  $\eta^2 = .16$ ,  $p > .05$ . Finally, the participants spent the longest time to answer punctual state questions ( $M = 7.03$  seconds,  $SD = 2.97$ ), which was longer than both processes ( $M = 5.27$  seconds,  $SD = 1.69$ ) and durative states ( $M = 6.65$  seconds,  $SD = 2.97$ ),  $F(2, 20) = 3.61$ ,  $\eta^2 = .27$ ,  $p < .05$ , without a significant difference between the last two.

### Condition 2: Interpretation of Gestures

The first condition of the experimental investigation employed the most naturalistic setting for an online communication environment: the participants listened to the narrator when she produced the gestures concurrently. In other words, both modalities (i.e., language and gesture) were available to the participants. Therefore, it is not possible to analyze the role of language and gestures separately in comprehension of the presented stimuli. The participants might have used the linguistic information to predict the graph without taking the gestures into account. In the second condition of the study, we asked the participants to predict the described graphs by displaying the video recordings with the sound muted.

**Participants, Material and Design.** Eighteen participants, from METU participated in the experiment ( $Mean\ age = 21.1$ ,  $SD = 1.37$ ). They were presented the same video recordings but they did not hear the narrator. The same experimental procedure was applied as in the previous condition.

**Results.** The participants in Condition 2 exhibited high success rates for processes ( $M = .93$ ,  $SD = .11$ ) and durative states ( $M = .91$ ,  $SD = .19$ ) but a significantly lower success

rate for punctual states ( $M = .55$ ,  $SD = .22$ ),  $F(2, 34) = 25.4$ ,  $\eta^2 = .60$ ,  $p < .05$ . The difference between processes and durative states was not significant. The lack of the language modality resulted in significant differences between the three gesture types in confidence scores,  $F(2, 34) = 18.1$ ,  $\eta^2 = .51$ ,  $p < .05$ . The participants reported lower confidence scores for punctual states ( $M = 2.01$ ,  $SD = 0.42$ ) compared to both processes ( $M = 2.61$ ,  $SD = 0.33$ ) and durative states ( $M = 2.61$ ,  $SD = 0.47$ ). As in Condition 1, the mean response time of the participants in punctual states ( $M = 4.34$  seconds,  $SD = 1.74$ ) was longer than both processes ( $M = 2.66$  seconds,  $SD = 0.80$ ) and durative states ( $M = 2.88$  seconds,  $SD = 1.44$ ),  $F(2, 34) = 10.5$ ,  $\eta^2 = .38$ ,  $p < .05$ , without a significant difference between the last two.

### Condition 3: Attention Split between Gestures and Face

The findings obtained in Condition 1 and Condition 2 show that the lack of linguistic information results in lower success rates in predicting the answers; in particular, in punctual states. The analysis of the eye movements of participants revealed another finding about inspection patterns on the video recordings: the participants shifted their gaze between narrator’s gestures and face both in Condition 1 ( $M = 2.55$ ,  $SD = 0.28$ ) and in Condition 2 ( $M = 2.68$ ,  $SD = 0.35$ ), without a significant difference between the two groups of participants,  $F(1, 26) = 0.83$ ,  $p > .05$ , thus suggesting a potential source of attention split during comprehension. Therefore, a third group of participants were presented narrator’s gestures only, without face and sound.

**Participants, Material and Design.** Twenty-one participants ( $Mean\ age = 21.2$ ,  $SD = 2.37$ ) from METU participated in the experiment. The participants were presented the same stimuli except that the video recordings were cut from the top, so that only the gestures (but not the face) of the narrator were displayed. The same experimental procedure was applied as in the previous conditions.

**Results.** The participants showed high success rates for processes ( $M = .96$ ,  $SD = .10$ ) and durative states ( $M = 1.0$ ) but a relatively lower success rate for punctual states ( $M = .70$ ,  $SD = .19$ ),  $F(2, 40) = 32.0$ ,  $\eta^2 = .61$ ,  $p < .05$ , without a significant difference between processes and durative states. Confidence scores for punctual states ( $M = 2.31$ ,  $SD = 0.40$ ) were also significantly lower than both processes ( $M = 2.69$ ,  $SD = 0.30$ ) and durative states ( $M = 2.76$ ,  $SD = 0.37$ ),  $F(2, 40) = 14.7$ ,  $\eta^2 = .42$ ,  $p < .05$ . Finally, they spent the longest time to answer punctual state questions ( $M = 3.52$  seconds,  $SD = 1.18$ ), significantly different than both processes ( $M = 2.60$  seconds,  $SD = 1.04$ ) and durative states ( $M = 2.41$  seconds,  $SD = 1.02$ ),  $F(2, 40) = 8.84$ ,  $\eta^2 = .31$ ,  $p < .05$ , without a significant difference between the last two.

A comparison between the three groups of participants in the three conditions of Experiment 2 showed that the highest success rate (in predicting the correct annotated

graph that was described in the video recording) was obtained when the participants listened to the single-sentence description of the graphs while playing the video recording. The lack of the language modality, however, resulted in a decrease in success rates. On the other hand, helping the participants to focus on gestures only (by removing narrator's face from the view) resulted in an increase in the success rates (Figure 4).

Figure 4: Mean success rates (left) and mean confidence scores (right) in Experiment 2.

For the comparison of the results obtained in the three conditions of Experiment 2, a Games-Howell test was applied since the number of samples for the three groups was not equal and the population variances were significantly different. The test returned a significant difference between the three groups of participants in their overall success rates,  $F(2, 47) = 17.2$ ,  $\eta^2 = .42$ ,  $p < .05$ . Finally, a comparison of the confidence scores between the participant groups showed that the lack of the language modality resulted in lower self-confidence of the participants about their predictions,  $F(2, 47) = 10.3$ ,  $\eta^2 = .30$ ,  $p < .05$  (Figure 4).

## Discussion

In two experiments, we investigated how humans produce gestures (Experiment 1) and comprehend gestures (Experiment 2) when they communicate through graphically annotated line graphs. In Experiment 1, the participants produced more frequent vertical and diagonal gestures to emphasize processes (e.g., *increase*, *decrease*) whereas they produced more horizontal gestures to emphasize durative states (e.g., *remain stable*). Those two types of gesture are known as *iconic gestures* and they overlap with representation of spatial information (Alibali et al., 2001; Trafton et al., 2006). For emphasizing punctual states (e.g., a *peak*), the participants produced *pointing gestures*. In Experiment 2, three groups of participants were presented video recordings and they were asked to predict the described graphs: the video recordings were designed based on the correspondence between diagonal gestures and processes, between horizontal gestures and durative states, and between pointing gestures and punctual states. When gestures were displayed concurrently with linguistic information (Condition 1), the participants showed a high success rate in all gesture types. When language modality was absent, however, they showed a lower success rate and lower self-confidence, in particular in punctual states. These

findings suggest a low efficiency of the pointing gesture (in the form of a deictic pointing gesture) in conveying information about punctual states. On the other hand, vertical and diagonal gestures were efficient in conveying information about processes. Horizontal gestures were efficient in conveying information about durative states. An explanation to these findings may be related to the major roles of iconic gestures and deictic gestures in communication. In contrast to iconic gestures that convey spatial information, the major role of pointing gestures is to attract the attention of the communication partner (McNeill, 2005; Özçalışkan & Goldin-Meadow, 2005). Consequently, further research is needed to identify more appropriate candidates for emphasizing punctual states in graphs. For instance, a circular movement of the index finger might be more appropriate for representing punctual states.

Another finding obtained in Experiment 2 was that participants' back and forth movement of their gazes between the gestures and the face of the narrator is a potential source of attention split during the course of comprehension. Although speech sound was absent (Condition 2) and therefore no linguistically useful information was provided by the narrator (except for the possibility of lip reading), the participants shifted their gaze several times between the narrator's face and the gestures. When the narrator's face was removed from the video recordings (Condition 3), an increase in success rates was observed compared to Condition 2, though the success rates were still lower than the ones obtained when the linguistic information was available (Condition 1). Although this is far from being a naturalistic setting for communication through graphs, the analysis of such boundary cases is necessary for understanding the contribution of separate factors in comprehension. In fact, the findings support the likelihood of the split of attention. A possible explanation may be sought in the domain of the intersection between cognitive science and instructional science, in which the previous studies show that the split of attention between information sources leads to degraded learning outcomes due to limited cognitive resources that are available for understanding the instructional material (Sweller et al., 1998; Mayer & Moreno, 1998). Consequently, the findings suggest that tasks demands may be high in communication through graphs; therefore, attention split should be avoided by, for instance, using small window sizes so that the communication partner is able to attend to both gestures and face in a single fixation.

## Conclusion and Future Work

In communication settings, humans produce gestures when they convey spatial information. As a consequence, in communication through line graphs, gestures are an indispensable part of communication. In this study we investigated how humans produce and comprehend gestures in communication through line graphs. We found that vertical and diagonal gestures efficiently convey information about processes such as increase and decrease,

and horizontal gestures efficiently convey information about durative states. However, pointing gestures are not efficient in conveying information about punctual states, possibly due to their concurrent role as deictic gestures in communication. Our future research will address finding more appropriate gesture candidates for punctual states. The future research will also address the investigation of the interaction between gestures and gradable (scalar) adjectives, gradable adverbs and spatial prepositional phrases and adverbials, e.g. *from*, *to*, and *between*, which are part of the vocabulary in communication through line graphs, in addition to state verbs and verbs of change.

# Distributional Learning of Vowel Categories is Supported by Prosody in Infant-Directed Speech

Frans Adriaans (adriaans@psych.upenn.edu) and Daniel Swingley (swingley@psych.upenn.edu)

## Abstract

Infants' acquisition of phonetic categories involves a distributional learning mechanism that operates on acoustic dimensions of the input. However, natural infant-directed speech shows large degrees of phonetic variability, and the resulting overlap between categories suggests that category learning based on distributional clustering may not be feasible without constraints on the learning process, or exploitation of other sources of information. The present study examines whether mothers' prosodic modifications within infant-directed speech help the distributional learning of vowel categories. Specifically, we hypothesize that 'motherese' provides the infant with a subset of high-quality learning tokens that improve category learning. In an analysis of vowel tokens taken from natural mother-infant interactions, we found that prosody can be used to distinguish high-quality tokens (with expanded formant frequencies) from low-quality tokens in the input. Moreover, in simulations of distributional learning we found that models trained on this small set of high-quality tokens provide better classification than models trained on the complete set of tokens. Taken together, these findings show that distributional learning of vowel categories can be improved by attributing importance to tokens that are prosodically prominent in the input. The prosodic properties of motherese might thus be a helpful cue for infants in supporting phonetic category learning.

**Keywords:** Infant-directed speech; phonetic category learning; prosody; computational modeling.

## Introduction

Infants in the first year of life develop knowledge of the phonetic categories that make up the consonants and vowels of their native language (e.g., Werker & Tees, 1984). The early age at which this takes place rules out learning accounts in which semantic contrast in phonologically similar words drives most category learning. As a result, it is assumed that infants learn phonetic categories using an implicit statistical clustering process that relies on separation of the categories in perceptual space. Indeed, 6- and 8-month-old infants have been found to form representations of two distinct categories (e.g., /d/ and /t/) when exposed to an artificially generated bimodal distribution on a distinguishing acoustic dimension, but not when exposed to a unimodal distribution (Maye, Werker, & Gerken, 2002; Maye, Weiss, & Aslin, 2008; see also Cristià, McGuire, Seidl, & Francis, 2011). Further evidence for the plausibility of distributional learning of phonetic category structure comes from analyses of infant-directed speech. Mothers appear to provide their infants with acoustic cues that support distributional learning of phonetic categories (Werker et al., 2007). In particular, infant-directed speech is characterized by expansion of the F1-F2 vowel formant space, which could enhance the separability of vowel categories (Kuhl et al., 1997). Several studies

have used approximations of infant-directed speech tokens as input to computational procedures (such as multivariate Gaussian mixture models) that succeed in learning vowel categories, suggesting that distributional learning could be feasible for infants (de Boer & Kuhl, 2003; McMurray, Aslin, & Toscano, 2009; Vallabha, McClelland, Pons, Werker, & Amano, 2007).

Some caution is appropriate in interpreting these findings. Studies that show the usefulness of distributional cues for category learning have, in large part, been based on analyses (and simulations) of vowel tokens that were elicited in a laboratory setting, and that occurred in a small number of words or nonwords. It is possible that maternal speech under these conditions is different from maternal speech in quotidian home contexts. Analyses of natural, unscripted infant-directed speech recordings show that vowel distributions are highly variable, and that overlap between categories poses a substantial problem for distributional category learning (Swingley, 2009). One possibility suggested by this result is that infants' learning of phonetic categories is guided by additional sources of information, such as the emerging lexicon (Feldman, Griffiths, & Morgan, 2009; Swingley, 2009).

Another possibility, explored here, is that infants are able to succeed in category learning because they have a bias to attend to some tokens more than to others, and that these salient tokens are clearer instances of their categories. If so, the difficulty of distributional category learning is overestimated by considering the whole mass of experienced speech sounds. This notion is indirectly supported by studies showing that infants prefer "motherese" speech over adult-directed speech. Across different languages motherese is characterized by acoustic exaggeration, including higher overall pitch, greater intonation contours, and longer durations (Fernald et al., 1989; Grieser & Kuhl, 1988; Kuhl et al., 1997). These properties have been found to modulate infants' attention, and possibly facilitate language learning by enhancing infants' speech discrimination skills (Fernald & Kuhl, 1987; Karzon, 1985; Liu, Kuhl, & Tsao, 2003; Trainor & Desjardins, 2002).

It remains to be demonstrated that motherese effectively guides the infant's attention to those vowel tokens that are most useful for category learning. Computational models that aim to explain category learning are typically fit to isolated, equally weighted vowel tokens (de Boer & Kuhl, 2003; Vallabha et al., 2007). Such models overlook prosodic context which might make certain vowel tokens more attractive than others, and which thus potentially affects the learnability of vowel categories.

The current study examines the relation between prosodic exaggeration and vowel learning from infant-directed speech. Specifically, we hypothesize that motherese provides the infant with a subset of high-quality learning tokens that improves distributional category learning. First, we analyze prosodic determinants of vowel expansion within infant-directed speech, thereby attempting to predict which vowel tokens in the infant's speech input could be particularly beneficial for phonetic category learning. Second, we simulate the distributional learning of phonetic categories in order to examine whether prosodic focus helps in discovering category structure in cases of large overlap between categories. Importantly, analyses and simulations are done on realistic data, using vowel tokens taken from recordings of natural mother-infant interactions. We thus provide a test of distributional learning in a setting that acknowledges the variability and complexities that are found in real everyday speech.

### Vowel Expansion in Infant-Directed Speech

Earlier studies on vowel expansion compared speech directed to adult listeners and speech directed to infant listeners (Kuhl et al., 1997). While infant-directed speech is often hyperarticulated compared to adult-directed speech, the mechanisms underlying vowel expansion in infant-directed speech are not yet fully understood. It seems likely that the prosodic exaggeration notable in infant-directed speech has an effect on vowel expansion. Here we explore this possibility by asking whether prosodically prominent vowels in infant-directed speech are hyperarticulated relative to parts that are not prosodically highlighted. In analyses of recordings of natural mother-infant interactions, we examine whether prosodic focus predicts vowel expansion (see also Mo, Cole, & Hasegawa-Johnson, 2009). We examine expansion in tokens that were labeled to have focus by human assessors (what we define as "annotated focus"), and also in tokens that were defined as exaggerated on acoustic grounds (higher pitch, greater pitch change, and longer duration; what we define as "acoustic focus"), to determine whether such vowels are more differentiable. Evidence of vowel expansion at prosodically predictable locations in infant-directed speech would indicate that attention to prosody could aid in vowel category learning.

### Methods

Vowel expansion was examined by analyzing vowel productions by one mother ('f1') in the Brent corpus (Brent & Siskind, 2001), available through CHILDES (MacWhinney, 2000). These recordings consist of natural, unscripted infant-directed speech and therefore have no restrictions on the words or vowel types that may occur. Formant (F1, F2) measurements were obtained and hand-checked for 1,166 vowel tokens. Tokens covered the monophthongs of American English (/i/, /ɪ/, /e/, /æ/, /ɑ/, /ʌ/, /ɔ/, /ʊ/, /u/). Measurements taken at 33% and 50% of the vowel's duration were averaged and transformed into *z* scores to neutralize scale differences. Vowel expansion was measured by calculating the

Euclidean distance of each token to the center of the mother's vowel space (Bradlow, Torretta, & Pisoni, 1996). In order to measure prosodic prominence in infant-directed speech each vowel token was judged by a human assessor who indicated whether the vowel occurred in a syllable that the mother was trying to emphasize (*focus* vs. *no focus*). Potential acoustic correlates of focus that were considered were: duration (logarithm of the absolute duration in ms.), pitch (F0 averaged over 33% and 50% measurements), and pitch change (the absolute value of the difference in F0 between measurements at 33% and 50%). The label of "acoustic focus" was assigned to vowels that exceeded the *z*-score of 0.5 for at least one of the three dimensions.

### Results

Table 1 shows the number of focused and unfocused tokens for each vowel. The annotated-focus set contained 336 vowel tokens (28.8% of the total set). The acoustic-focus set had 543 tokens (46.6% of the total set). Figure 1 shows the mean formant frequencies of vowels in focused and unfocused position. Vowels in focused position were further away from the center of the vowel space than vowels in unfocused position.<sup>1</sup>

Stepwise linear regression analyses revealed that annotated focus is a significant predictor of the vowel's distance from the center of the vowel space, independent of vowel type (adjusted  $R^2 = 0.4221$ ; vowel\*\*\*, focus\*\*, vowel:focus *ns*). Vowels in syllables with annotated focus were thus hyperarticulated relative to vowels in unfocused syllables. This confirms the intuition that in natural infant-directed speech mothers exaggerate certain vowels by marking them with sentence focus. Interestingly, vowel expansion did not manifest itself through stretching of the triangle defined by the "point vowels" (/i/, /a/, /u/), but rather followed a consistent pattern of expansion throughout the entire set of monophthongs.

The tokens that had acoustic focus showed very similar results. Stepwise regression revealed that acoustic focus is a significant predictor of vowel expansion (adjusted  $R^2 = 0.4300$ ; vowel\*\*\*, focus\*\*\*, vowel:focus\*). These results indicate that whether infants are able to judge focus (as our annotators did), or whether they simply pay attention to tokens that have extreme values on prosodic dimensions (i.e., "acoustic focus"), the tokens that have focus show expansion, and are thus possibly particularly helpful for the learning of phonetic categories.

In sum, vowels that are prosodically exaggerated might be particularly useful for phonetic learning because they have distributional properties that enhance the separability of vowel categories. The overlap between categories, however, is still substantial. It thus remains to be demonstrated that prosodic highlighting makes a meaningfully large difference in the learnability of vowel categories.

<sup>1</sup>The exception was /ɔ/ and /ʊ/ in the acoustic-focus set. The means of these vowels are unreliable due to their low frequency of occurrence in the data set. (See Table 1.)

Table 1: Frequency of occurrence of vowels in focused and unfocused position.

	/i/	/ɪ/	/ɛ/	/æ/	/ɑ/	/ʌ/	/ɔ/	/ʊ/	/u/	Total:
	(182)	(320)	(163)	(139)	(112)	(130)	(21)	(22)	(77)	(1,166)
Focus (annotated)	41	72	51	67	32	36	12	5	20	336
No focus (annotated)	141	248	112	72	80	94	9	17	57	830
Focus (acoustic)	105	112	65	95	55	45	16	10	40	543
No focus (acoustic)	77	208	98	44	57	85	5	12	37	623

## The Learnability of Vowel Categories

In order to see if prosodically highlighted vowels would be beneficial to infant language learners, we simulate the distributional learning of vowel categories from infant-directed speech. In particular, we examine whether prosodic focus helps in discovering category structure in cases of large overlap between categories. If distributional models of vowel learning show improved performance when trained on prosodically defined subsets of vowel data, then this would constitute evidence that the prosodic properties of motherese support phonetic category learning.

## Methods

The learnability of vowel categories is simulated for two different sets of vowels: /i/, /ɪ/, /ɛ/ and /ɛ/, /æ/, /ɑ/. These sets were chosen because they each contain three vowels that are close in the F1-F2 formant space. As a consequence, the overlap between categories is large, and the learning of these categories poses a substantial problem for distributional learning models. In line with earlier work on computational modeling of phonetic category learning (e.g., de Boer & Kuhl, 2003; McMurray et al., 2009; Vallabha et al.,

2007), we treat categories as multivariate Gaussian distributions. The learning problem is characterized as estimating the parameters (means, covariances and mixing proportions) for these distributions. In our case, categories are defined as 2-dimensional distributions (the  $z$  scores of the first and second formants). Data points are assigned to the category that has the maximum likelihood for that point. Parameters of the Gaussian distributions are estimated using the EM algorithm (Dempster, Laird, & Rubin, 1977) as implemented in the *MCLUST for R* software package (Fraley & Raftery, 2006). All models reported below were trained to discover three ellipse categories. Since vowel ellipses are known to vary in volume, shape, and orientation (e.g., Hillenbrand, Getty, Clark, & Wheeler, 1995), the models were given no information or constraints with respect to volume, shape, or orientation.

In order to assess whether focused tokens were helpful for category learning, models were trained on a subset of the data (either the annotated-focus set or the acoustic-focus set). The Gaussian distributions that were estimated from these subsets were subsequently used to classify all vowel tokens in the data set. We predicted that Gaussian mixture models trained

on a relatively small set of prosodically prominent vowel tokens would provide a better classification of the data than Gaussian mixture models that were trained on the complete set of vowel tokens. Performance of the unsupervised clustering models was assessed by comparing their classification accuracy to a supervised learner that learned three Gaussian categories based on actual vowel category labels. The supervised learner represented an upper bound on the classification accuracy that can be obtained given the maximum likelihood classification criterion that is imposed on the overlapping Gaussian distributions.

## Results

Table 2 shows the classification accuracy for models trained using all tokens, annotated-focus tokens, acoustic-focus tokens, and all tokens’ category labels (this last being the supervised “ideal”). The first thing to note is that the classification accuracy of the supervised learners was below 80%, confirming that overlap between categories was substantial. Considering the unsupervised “All tokens” model, the 12- to 15-percentage-point decline relative to the supervised model shows that the categories are not trivially detectable in the distributions.<sup>2</sup> Using vowel tokens annotated as focused aided accuracy to a small degree in the i-ɪ-ε data set, a result that nevertheless reveals some utility to focus marking given that this model was trained on only 164 data points rather than the entire dataset (which consisted of a total of 665 i-ɪ-ε tokens). However, for the ε-æ-ɑ data set the clustering algorithm was unable to fit a model to the annotated-focus tokens. We believe that this is due to the small size of the annotated-focus data set for ε-æ-ɑ ( $n = 150$ , with only 32 tokens for /ɑ/, see Table 1). Thus, focused vowels are, in at least some cases, variable enough that category solutions are difficult to determine when the quantity of data is very small.

Training on the bigger set of acoustic-focus tokens helped learning substantially, bringing the model within 3 percentage points of the supervised model in the i-ɪ-ε data set, and within 6 percentage points in the ε-æ-ɑ data set. Models that were trained on tokens that were acoustically prominent (long duration, high pitch, greater pitch movement) thus showed substantial classification improvement as compared to models that were prosodically uninformed. To illustrate the performance of different learning models, we display the i-ɪ-ε data along with the classifications that are predicted by different models in Figure 2. Figure 2 shows that only the acoustic-focus training set is able to predict three clearly distinct categories.

As it turns out, tokens that have focus or show acoustic exaggeration have a positive effect on the unsupervised learning of vowel categories. Importantly, these high-quality tokens are easily identifiable based on their prosodic properties. It is thus likely that these tokens are identifiable for infant language learners, and contribute to language learning.

<sup>2</sup>Such a decline is not found in models of the point vowels (i-ɑ-u) alone, for which we found accuracy > 90% for both the supervised

Table 2: Classification accuracy on two different sets of overlapping vowel categories.

Model	Accuracy	
	i-ɪ-ε	ε-æ-ɑ
All tokens	0.6060	0.6449
Annotated focus	0.6331	-
Acoustic focus	0.7008	0.7343
Supervised	0.7278	0.7947

## Discussion

In learning the phonetic categories of their native language, infants face large amounts of variability in the acoustic realizations of different vowel tokens. This poses a substantial problem for the purely bottom-up distributional learning of vowels. Here we presented one possible source of information that may guide phonetic category learning. If infants are able to detect high-quality learning tokens in the input, then they could make considerable progress in category learning. Motherese may play an important role in this process, by bringing such “high-quality” tokens to the infant’s attention through prosodic modifications of the speech stream.

In our clustering experiments, focus as annotated by human listeners was not as effective as “focus” estimated using simple, one-dimensional acoustic measures. It is possible that this difference derived from sample-specific gaps in the number or quality of human-annotated focus tokens for some vowel types; this cannot be ruled out without examining other samples. Furthermore, it is likely that annotators’ judgments of focus were, in some cases, based on their interpretation of the speaker’s intentions: an adult listener might judge a word as being the one the speaker wished to emphasize even if the phonetics were not particularly marked. Still, the superior performance of the model that learned from the tokens that were simply more extreme on at least one of the acoustic dimensions shows that the benefits of “motherese” prosodic highlighting do not depend on possession of a mature capacity for interpreting focus. Sensitivity to simple dimensions like duration or pitch goes a long way.

Infant-directed speech prosody, with its exaggerated prosodic variation, certainly captures infants’ attention, and this may be important for learning. Earlier studies have shown that pitch contours enhance infants’ discrimination skills, since contours increase the acoustic salience of formant frequencies (Trainor & Desjardins, 2002). Such perceptual salience is not taken into account by our model. Our results show that prosody has additional benefits. We find that acoustically exaggerated tokens show a different distribution in the F1-F2 space, with greater distances from the center and enhanced separability of categories. The picture that emerges from earlier studies, combined with the current findings, is

and unsupervised learner.

Figure 2: The i-i-ε data set with (a) actual categories, (b) predicted categories based on all tokens, (c) predicted categories based on focused tokens, and (d) predicted categories based on acoustically exaggerated tokens. The means are plotted for each (predicted) category.

that the exaggerated prosody of infant-directed speech may capture infants' attention to speech in a general fashion, and at the same time provide an enhanced speech signal that supports language learning – if infants' category learning favors attention to the most salient instances.

## Abstract

Studies have shown that counterfactual reasoning can shape human decisions. However, there is a gap in the literature between counterfactual choices in description-based and experience-based paradigms. While studies using description-based paradigms suggest participants maximize expected subjective emotion, studies using experience-based paradigms assume that participants learn the values of options and select what maximizes expected utility. In this study, we used computational modeling to test 1) whether participants make emotion-based decisions in experience-based paradigms, and 2) whether the impact of regret depends on its degree of unexpectedness as suggested by the current regret theory. The results suggest that 1) participants make emotion-based choices even in experience-based paradigms, and 2) the impact of regret is greater when it is expected than when it is unexpected. These results challenge the current theory of regret and suggest that reinforcement learning models may need to use counterfactual value functions when full information is provided.

**Keywords:** Decision making; Bayesian modeling; mathematical modeling; regret; reinforcement learning.

## Introduction

In our daily lives, we constantly face decisions to make and assess the costs and benefits of possible options (e.g., “Should I buy a lottery or just buy a snack with this money?”, “Should I buy Apple or Google stock?”). Usually we know only the outcome of our choices. On rare occasions, we also know what would have happened if we had made different choices (e.g., stock market). Having ‘complete feedback’ (or *full information*) under risk or uncertainty can evoke strong emotions such as regret or disappointment that are triggered by our capacity to reason counterfactually.

The effects of counterfactual reasoning have received much attention, and several theories have been proposed. A growing consensus suggests that disappointment and elation are elicited by comparison between different states (e.g., “my grant was not funded...”) whereas regret and rejoice come from comparison between different choices (e.g., “I should have married another person...”). Also, the unique aspect of regret is a feeling of *responsibility* that comes with negative outcomes from choices.

Among several theories of counterfactual decision-making, *decision affect theory* is regarded as one of the leading models (Mellers, Schwartz, & Ritov, 1999). Decision affect theory assumes that individuals make emotion-based choices and want to maximize subjective expected *pleasure* (or emotion)

rather than to maximize expected return. In decision affect theory, our emotional responses ( $R$ ) are based on obtained outcomes, relevant comparisons, and beliefs about the likelihood of the outcomes:

$$R \propto \text{Chosen Outcome Utility} + \text{Regret / Rejoice} + \text{Disappointment / Elation} \quad (1)$$

All counterfactual terms (regret, rejoice, disappointment, and elation) are weighted by their unexpectedness. Decision affect theory effectively explained various experimental results (Mellers et al., 1999) and Coricelli et al. (2005) used a modified version of the theory to examine the neural correlates of regret using description-based paradigms.<sup>1</sup>

Several studies have examined counterfactual decision-making using experience-based paradigms as well (Lohrenz, McCabe, Camerer, & Montague, 2007; Boorman, Behrens, & Rushworth, 2011; Hayden, Pearson, & Platt, 2009; Yechiam & Rakow, 2011). Although models used in the studies differ slightly from each other, all previous studies used reinforcement learning models, which assume that participants learn about chosen and foregone outcomes from trial-by-trial experience and then choose an option that has the highest expected value.

This study was developed from this gap in the literature: to explain choice behaviors in description-based paradigms with full information, researchers have assumed participants would make emotion-based choices. To explain choice behaviors in experience-based paradigms, researchers have assumed that participants learn the obtained and foregone payoffs and do not make emotion-based choices. We tested whether individuals make emotion-based choices in experience-based paradigms by building computational models for all competing hypotheses. This approach allowed us to quantitatively compare hypotheses in a rigorous way.

Another aim of the study was to test whether regret would be weighted by its unexpectedness (i.e., surprisingness). Mellers et al. (1999) claimed that “...unexpected out-

<sup>1</sup>In description-based paradigms, the outcomes of all options and their probabilities are provided to participants and participants rarely receive feedback. In experience-based paradigms, participants must learn the outcomes or their probabilities from their personal experience (Hertwig, Barren, Weber, & Erev, 2004).

comes have greater emotional impact than expected outcomes.” However, how would you feel given the following scenarios? In scenario 1, an Apple employee told you some inside information about Apple, which would increase its stock price. You believed that this was 80% reliable, but you did not buy the stock whose price sky-rocketed. In scenario 2, an untrustworthy looking stranger told you the same information. You believed he was 20% reliable, but you did not buy the stock, whose price sky-rocketed. According to Mellers et al. (1999), you would experience more regret in scenario 2. However, we hypothesized that scenario 1 would generate more regret because of the unique aspect of regret: a feeling of responsibility. Therefore, we predicted that regret would be weighted by its *expectedness* rather than its unexpectedness. Mellers, Schwartz, Ho, and Ritov (1997) showed that a smaller probabilities of disappointment/elation were associated with greater emotional response. Although Mellers et al. (1999) claimed that the effect of probability would be the same with regret/rejoice, no experiment has directly tested it to our knowledge.

In sum, we designed our experiment to test the following hypotheses. The first hypothesis proposes that participants will learn the chosen and fictive outcomes, compare all available options, and try to maximize their expected return (“Fictive Learning Alone”). The second hypothesis proposes that participants will make emotion-based decisions (i.e., maximize their expected subjective emotion) and their regret will be weighted by its unexpectedness (“Original Regret”). The third hypothesis proposes that participants will make emotion-based decisions and will weight their regret by its expectedness (“Modified Regret”). We designed our experiment to test these hypotheses.

## Method

### Participants

Nineteen healthy individuals (7 men, mean age = 23.0, SD=4.9) participated in the study. Electroencephalography (EEG) was continuously recorded from the scalp, but EEG findings are not reported in this paper. Participants were paid \$10/hr for participation and told that they would earn performance bonuses based on total points earned during the task. In reality, all participants received a fixed amount (\$5) as their bonus money (Lejuez et al., 2003). Study procedures were approved by the Indiana University’s Human Subjects Institutional Review Board.

### Task

All participants completed four separate gambling games, the order of which was randomly mixed for each participant. At the start of each game, participants were told that each game was independent of the previous game(s). In each game (90 trials/game), participants were asked to choose one of two options. One option was a safe option in which participants always won a fixed amount of points (e.g., 11). The other was a risky option in which participants won either larger (e.g., 26)

or smaller points (e.g., 1). The probability of winning larger points was fixed but unknown, and had to be learned from experience. The payoffs of both chosen and unchosen options were revealed on every trial (“full information”). The locations of the options were fixed within games, but randomized across games. Participants were encouraged to choose an option that would maximize their gain. Payoffs were distributed so that the long-term expected values of two options were the same (see Table 1).

Table 1: The payoff distributions of games 1-4. Note that the (long-term) expected values of the safe option (M) and the risky option are the same. M: points of the safe option, L: low (smaller) points, H: high (larger) points, %H: the probability of winning larger points. SD: standard deviation.

Game	M	Risky Option				
		L	H	%H	Mean	SD
1	12	1	56	0.2	12	22.0
2	11	1	26	0.4	11	12.3
3	10	1	16	0.6	10	7.4
4	9	1	11	0.8	9	4.0

The timing and presentation of a trial is illustrated in Figure 1. Each trial started with a message (“WAIT”), which was presented for 1-1.5s. After two options were presented, the participant had 2s to select an option by pressing buttons corresponding in a spatially compatible way to the options. The color of the chosen option remained changed for .6s, and the payoffs of both options appeared for 1s.

Figure 1: Time course of the gambling task.

### Computational Modeling

Three hypotheses (1. Fictive Learning Alone, 2. Original Regret model, 3. Modified Regret model) were implemented as three distinct reinforcement learning models. They utilized identical learning (probability learning) and choice rules (softmax), but used different value functions. Due to the specific design of the task (only 2 possible payoffs of the risky option in each game), it was assumed that participants would learn the probability of a larger payoff of the risky option (probability learning). In the delta rule (Rescorla & Wagner,

1972), the probability of a larger payoff (H) (the risky option) on the next trial  $t + 1$ ,  $Pr_H(t + 1)$ , is updated as follows:

$$Pr_H(t + 1) = Pr_H(t) + \gamma \cdot [Y(t) - Pr_H(t)] \quad (2)$$

Here  $\gamma$  is the learning rate ( $0 < \gamma < 1$ ) and  $Y(t)$  is the outcome (1 if H, 0 if L) of the current trial  $t$ . We assumed no learning occurred about the safe option because its payoff was always the same (e.g., 11) in a given game. We assumed that the choice of a risky or safe option did not affect the learning rate.<sup>2</sup>

Action selection was implemented via the Luce choice rule (a.k.a. softmax) (Luce, 1959). The inverse temperature parameter ( $\theta$ ) determines the sensitivity of the choice probabilities to the action values. We employed a trial-independent choice rule (Yechiam & Ert, 2007), where  $\theta = 3^c - 1$  ( $0 < c < 5$ ). When  $c$  approaches zero, choices become completely random (exploratory). When  $c$  becomes large, choices become deterministic (exploitive).

$$Pr_R(t + 1) = \frac{e^{\theta \cdot Q_R(t+1)}}{e^{\theta \cdot Q_R(t+1)} + e^{\theta \cdot Q_S(t+1)}} \quad (3)$$

Here  $Q_R(t + 1)$  and  $Q_S(t + 1)$  are action values of choosing the risky (R) and safe (S) options on trial  $t + 1$ , respectively.  $Pr_R(t + 1)$  is the probability of choosing the risky option on trial  $t + 1$ . Next, we describe differences between three competing models (1. Fictive Learning Alone (FLA), 2. Original Regret model, 3. Modified Regret model).

**Fictive Learning Alone (FLA)** The FLA model assumes that participants compute action values of each option separately, then select an option that would maximize their expected return. The action value for the safe option is always the same on each game,  $Q_S(t + 1) = M^\alpha$  ( $0 < \alpha < 1.5$ ). In other words, the chosen outcome utility of  $X$  points ( $u_X$ ) was set to  $X^\alpha$ .  $\alpha$  is a parameter that governs the shape of the utility function. As  $\alpha$  goes to zero, the reward sensitivity diminishes. The action value of the risky option is the sum of two possible utilities, weighted by their probabilities. In other words,  $Q_R(t + 1) = u_H \cdot Pr_H(t + 1) + u_L \cdot Pr_L(t + 1)$ .<sup>3</sup> These action values are entered into Equation 3 to compute the probability of choosing each action on the next trial.

**Original Regret Model** In Regret models (both Original and Modified versions), it is assumed that participants choose an option that maximizes their *subjective expected pleasure* or *emotion* (Mellers et al., 1999). Thus, action values are the weighted sum of expected *emotional responses* ( $R$  in Equation 1), rather than expected *utilities*.

Here we used the notation that  $R_{A(B)}(t + 1)$  is the expected emotional response on trial  $(t + 1)$  when chosen and unchosen

payoffs are  $A$  and  $B$ , respectively. We used Equation 1 to calculate  $R_{M(L)}(t + 1)$ ,  $R_{M(H)}(t + 1)$ ,  $R_{L(M)}(t + 1)$ , and  $R_{H(M)}(t + 1)$ .<sup>4</sup> Following Mellers et al. (1999), we set regret/rejoice and disappointment/elation terms to  $sgn(A - B) \cdot |A - B|^\alpha$  when chosen and unchosen payoffs were  $A$  and  $B$ .<sup>5</sup> We assumed that  $\alpha$  is identical for both counterfactual functions and the chosen outcome utility. Importantly, regret/rejoice or disappointment/elation will be weighted by its surprisingness. We used 1 minus its probability as an index of surprisingness (e.g.,  $1 - Pr_H(t + 1)$ ) (Mellers et al., 1999). For example, suppose a participant chooses the safe option (chosen payoff =  $M$  and the foregone payoff =  $H$ ). Then, the expected emotional response can be expressed as  $R_{M(H)}(t + 1)$  from Equation 1, which is equal to  $M^\alpha + (-1) \cdot |M - H|^\alpha \cdot (1 - Pr_H(t + 1))$ .<sup>6</sup> If the participant chooses the risky option and the chosen payoff is  $L$ , the expected emotional response is  $R_{L(M)}(t + 1)$ .  $R_{L(M)}(t + 1)$  is equal to  $L^\alpha + (-1) \cdot |L - M|^\alpha \cdot (1 - Pr_L(t + 1)) + (-1) \cdot |L - H|^\alpha \cdot (1 - Pr_L(t + 1))$ . Note that the disappointment term was included in this case.  $R_{M(L)}(t + 1)$  and  $R_{H(M)}(t + 1)$  can be calculated in the same way and these terms can be used to calculate action values in Equation 4:

$$\begin{aligned} Q_S(t + 1) &= R_{M(H)}(t + 1) \cdot Pr_H(t + 1) + R_{M(L)}(t + 1) \cdot Pr_L(t + 1) \\ Q_R(t + 1) &= R_{H(M)}(t + 1) \cdot Pr_H(t + 1) + R_{L(M)}(t + 1) \cdot Pr_L(t + 1) \end{aligned} \quad (4)$$

The computed action values are entered into the softmax choice rule in Equation 3 to calculate trial-by-trial probability of choosing a risky (or safe) option.

**Modified Regret Model** This model is identical to the Original Regret model except that regret (but not any other counterfactual comparisons) is weighted by Regret's expectedness. We used regret's probability as its expectedness (e.g.,  $Pr_H(t + 1)$ ). Thus, only  $R_{M(H)}(t + 1)$  and  $R_{L(M)}(t + 1)$  are different between two Regret models because participants experience rejoice, but no regret for  $R_{M(L)}(t + 1)$  and  $R_{H(M)}(t + 1)$ .

**Summary of Three Competing Models** In sum, we compared three different models (specifically, value functions). The FLA model assumes that participants evaluate two options separately and choose the option that maximizes their expected return. The two Regret models assume that participants evaluate anticipated emotional responses and maximize their subjective pleasure. The Regret models, however, make different assumptions about the role of surprisingness when processing regretful outcomes. All three models have three free parameters: learning rate ( $\gamma$ ), utility shape ( $\alpha$ ), and choice consistency ( $c$ ). We used hierarchical Bayesian approach to estimate them, which is useful for reliably estimating group and individual parameters (for a review see Lee, 2011).

<sup>2</sup>We tried several other versions of learning rules (e.g., separate learning rates for chosen and unchosen options) and choice rules (e.g., trial-dependent inverse temperature parameter) that are not reported here, but they did not improve model-fits.

<sup>3</sup> $Pr_L(t + 1) = 1 - Pr_H(t + 1)$ ,  $u_H = H^\alpha$ , and  $u_L = L^\alpha$ .

<sup>4</sup>In all settings,  $L < M < H$  (e.g.,  $L=1$ ,  $M=11$ ,  $H=26$ ).

<sup>5</sup> $sgn(x) = 1$  if  $x > 0$ ,  $-1$  if  $x < 0$ .

<sup>6</sup>The disappointment/elation term is present only for risky choices. The disappointment/elation term is missing in  $R_{M(H)}(t + 1)$  because the safe option was chosen, in which there is only one state.

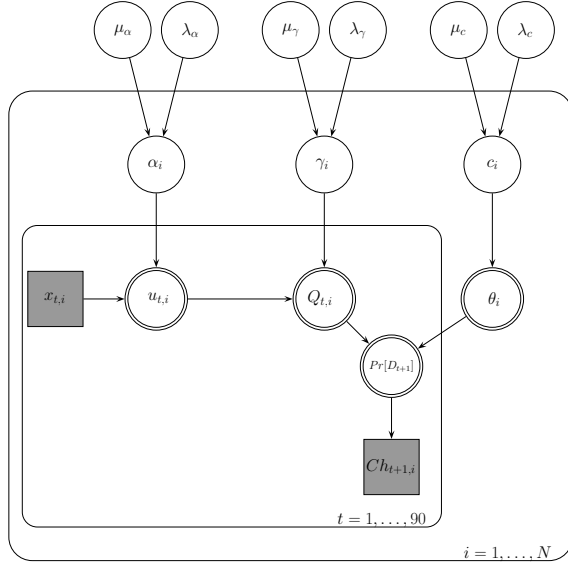

Figure 2: Graphical depiction of the hierarchical Bayesian analysis for three reinforcement learning model.  $R_{A(B)t,i}$  replaces  $u_{t,i}$  for Regret models.

### Graphical Model Implementation - Hierarchical Bayesian Parameter Estimation

Figure 2 shows the graphical representation of all three models. We modeled the variation in  $\gamma_i$ ,  $\alpha_i$ , and  $c_i$  parameters by assuming they have censored Gaussian distributions across participants. (e.g.,  $\gamma_i \sim \text{Normal}(\mu_\gamma, \lambda_\gamma)I(0, 1)$ , where  $\mu_\gamma$  and  $\lambda_\gamma$  are the mean and precision variables of the Gaussian distribution). Mean variables had uniform priors and precision variables had Gamma priors (e.g.,  $\lambda_\gamma \sim \text{Gamma}(.001, .001)$ ). In Figure 2, clear and shaded shapes indicate latent variables and observed variables, respectively. Single and double outlines indicate probabilistic and deterministic functions of input, respectively. Circles and squares indicate continuous and discrete variables, respectively (Lee, 2008). Vectors  $x_{t,i}$  (payoffs) and  $Ch_{t+1,i}$  (choices) were observed and individual ( $\gamma_i$ ,  $\alpha_i$ ,  $c_i$ ) and group parameters ( $\mu_\gamma$ ,  $\mu_\alpha$ ,  $\mu_c$ ,  $\lambda_\gamma$ ,  $\lambda_\alpha$ ,  $\lambda_c$ ) were estimated. We used OpenBUGS (Lunn, Spiegelhalter, Thomas, & Best, 2009) to perform Bayesian inference. We used 50,000 posterior samples collected following a total of 30,000 burn-in samples. Multiple chains were used to check convergence and  $\hat{R}$  values indicated that Markov chain Monte Carlo (MCMC) chains converged well with the target posterior distributions. Given that participants' choice behavior varied across games (see Figure 3), we estimated parameters separately for each game (but across all participants within each game). Ideally, model parameters should remain stable across games. Otherwise the model might simply mimic data without providing a coherent theoretical explanation of choice behavior.

Figure 3: The mean proportions of risky choices over trials on Games 1-4. The blue solid line indicates the group mean on each trial and shaded region indicates  $\pm$ s.e.m. (a moving-average filter was used).

## Results

### Behavioral Results

The proportions of risky choices in each game are plotted in Figure 3. As seen, participants' choice behavior varied across games although the expected values of two options were equated on all games. The mean proportions of risky choices on games 1-4 were .28, .40, .50, and .68 and the differences between games were all significant (games 1 vs 2:  $p < .003$ ; games 2 vs 3:  $p < .004$ ; games 3 vs 4:  $p < .001$ ).

Next, we examined the effect of chosen feedback, foregone feedback, and the magnitude of their difference (Coricelli et al., 2005). For this goal, we performed panel logic regression using the individual random-effects model. The dependent variable was 'switch' (1 if switched from the previous trial, 0 otherwise), and independent variables were the chosen pay-offs (or feedback) ( $fb$ ), the foregone payoffs ( $fgFb$ ), and the magnitude of their difference ( $|fb - fgFb|$ ) on the previous trial (T-1). Table 2 shows that participants were more likely to switch if the chosen feedback was lower ( $p < 3E-16$ ), the foregone feedback was higher ( $p < 2E-13$ ), and the magnitude of the difference was higher ( $p < .011$ ). These results suggest that participants take all three variables into account when making decisions.

To examine the effect of feedback on previous trials, another panel logistic regression analysis was performed, examining how many previous trials ( $fb - fgFb$ ) biased the switch behavior. Figure 4 shows that chosen-foregone pay-offs of up to two previous trials significantly influenced the switch behavior.

Table 2: Regression analysis (panel logit procedure with individual random effect). fb: the chosen payoff (feedback), fgFb: the foregone payoff (feedback).

Variable	Coefficient	Std. Error	$t$	$p$
Constant	.3902	.0186	21.00	<b>&lt;3E-16</b>
fb	-.0064	.0009	-7.44	<b>&lt;2E-13</b>
fgFb	.0027	.0007	3.71	<b>&lt;.001</b>
fb -fgFb	.0025	.0010	2.53	<b>.011</b>

Figure 4: Effects of past outcomes on current choice behavior. fb: the chosen payoff, fgFb: the foregone payoff. \*\*\*  $p < .0001$  \*\*  $p < .001$ .

## Modeling Results

To determine which model best fits our data, we used maximum likelihood estimation (MLE) methods to fit the model to each person and game separately, and then used the Bayesian information criterion (BIC) (Schwartz, 1978) to compare the Bernoulli baseline model, in which the probabilities of two options were equal to the individual's overall proportion of each option (the number of free parameters=1) against three models of interest.<sup>7</sup> The BIC score is a statistic that combines badness of fit with a penalty for the number of parameters. To evaluate the models, we used a BIC change score that measures the improvement of the computational model over the Bernoulli baseline model (BIC change equals the BIC from the baseline model minus the BIC from the cognitive model). Therefore positive BIC changes represent improvement over baseline, and the model with the highest BIC change is considered the best.

Figure 5 shows that the Modified Regret model has the best model fit. When tested across participants, the difference was significant (the Modified vs. Original Regret models:  $p < .005$ , the Modified Regret vs. FLA models:  $p < .05$ ). When the descriptive accuracy was assessed by posterior predictive analysis, the best-fitting model (the Modified Regret model) provided good individual-level model predictions. For example, Figure 6 illustrates a good match between the observed data (Figure 6A) and the model's predictions for a participant's choices (Figure 6B).

Next, we examined whether the parameter values of three models would remain stable across games. Again, ideally model parameters should be similar across different games or tasks. In Figure 7, all parameters of the models were plotted across games 1-4. Clearly, the parameters of the Modified Regret model, which had the best model fit, were the most stable across games. Note that the utility shape ( $\alpha$ ) and consistency ( $c$ ) parameters of FLA and Original Regret models

<sup>7</sup>We are currently working on comparing models by estimating their Bayes factors (Kruschke, 2011)

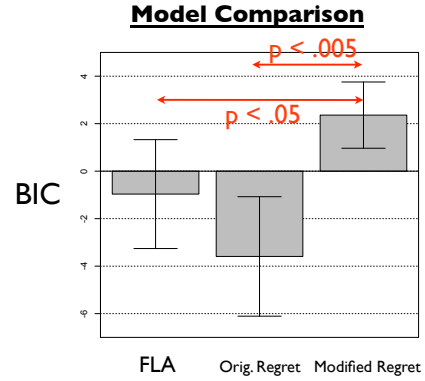

Figure 5: BIC (Bayesian information criterion) scores of three competing models compared to the baseline model. Note that higher BIC indicates a better model fit. Error bars indicate  $\pm$ s.e.m. FLA: Fictive Learning Alone.

varied greatly across games. In sum, the results of both model fit and parameter consistency indicate that the Modified Regret model explains participants' choice behavior best.

## Discussion

The goals of this study were to examine: (1) whether participants make emotion-based choices in experience-based paradigms; (2) whether regret would be weighted by its unexpectedness or expectedness. The modeling results provided strong support for the Modified Regret model: the model had the best model fit and its parameters were the most stable across games, suggesting it might provide a coherent theoretical account for choice behavior across games. The results provide strong support that participants make emotion-based choices and experience greater regret when it was expected rather than when it was unexpected.

We believe this study is the one of the first attempts to incorporate emotion-based decisions into reinforcement learning. Our findings are consistent with previous studies using description-based paradigms that found participants made emotion-based decisions. Our results suggest that reinforcement learning models may need to use value functions that can incorporate emotional components. The results are also consistent with the notion that emotions provide a common currency on how we make decisions under risk or uncertainty (Loewenstein, Weber, Hsee, & Welch, 2001; Weber & Johnson, 2009).

We also believe these results need to be tested in other experience-based paradigms and to determine their generalizability. Some studies found that Bayesian learning models outperformed the delta learning rule (Boorman et al., 2011). Although it is possible that using such a learning model can improve the model fit for all three models, we do not think it will change the main findings of the current study. In sum, we found strong support for the Modified Regret model, which challenges the current theory of regret.

## Abstract

Often in cooperative situations, many aspects of the decision-making environment are uncertain. We investigate how cooperation is shaped by the way information about risk is presented (from description or from experience) and by differences in risky environments. Drawing on research from risky choice, we compare choices in stochastic social dilemmas to those in lotteries with equivalent levels of risk. Cooperation rates in games vary with different levels of risk across decision situations with the same expected outcomes, thereby mimicking behavior in lotteries. Risk presentation, however, only affected choices in lotteries, not in stochastic games. Process data suggests that people respond less to probabilities in the stochastic social dilemmas than in the lotteries. The findings highlight how an uncertain environment shapes cooperation and call for models of the underlying decision processes.

**Keywords:** Decisions from Experience; Cooperation; Risky Choice; Public Good.

## Cooperation in Risky Environments

When people face an opportunity to cooperate, such as when opening a business together or pursuing a joint research project, the outcomes of these enterprises are frequently uncertain. On the one hand, joint enterprises often constitute a social dilemma, where it is in the collective interest of the group to cooperate, yet individually rational to free ride. Despite these incentives, there is overwhelming evidence that many people still engage in cooperation (e.g., Ostrom, 1990). On the other hand, even if people cooperate outcomes often are uncertain due to a risky environment. For instance, even if all business partners cooperate, a new start-up may fail due to external events, such as natural disasters disrupting supplier shipments. Laboratory experiments show that when social dilemmas are embedded in a stochastic environment, cooperation declines sharply (for a review see E. Van Dijk et al., 2004). What has not been addressed is how different levels of environmental risk and the format in which it is presented affect cooperation.

Studies on risky choice find a pronounced difference in behavior depending on how information in lotteries is

presented: whether people sample the distribution of outcomes (*decisions from experience*) or decide based on a summary description of outcomes and probabilities (*decision from description*) (for a review see Rakow & Newell, 2010). In conventional lotteries with described probabilities, people choose as-if they overweight small probabilities as reflected in Prospect Theory (Kahneman & Tversky, 1992). In contrast, people decide as-if they underweight small probabilities if they acquire risk information sequentially by sampling (Hertwig et al., 2004). The difference in choice patterns between decisions from description and experience has been labeled the *description-experience gap* (DE gap).

In lotteries, outcomes depend on environmental risk alone, whereas outcomes in social dilemmas also depend on the choices of other individuals. Stochastic social dilemmas thus combine social uncertainty and environmental risk. Yet our understanding of cooperation in stochastic environments is currently limited to situations in which environmental risk is described by outcomes and probabilities (e.g., Bereby-Meyer & Roth, 2006; Gong et al., 2009; Levati et al., 2009). We argue that real-world risky choices often involve experiencing the outcomes and probabilities of choices rather than receiving their summary statistics. Therefore, examining how risk presentation influences people's decisions is critical to understand how and when people cooperate in risky environments.

There is one important presupposition: risk presentation can influence cooperation only if people are responsive to differences in environmental risk. In lotteries, people's decisions have been found to vary with *different levels of risk*, i.e. for different combinations of outcomes and probabilities while keeping the expected value constant. Analogously, one can describe a stochastic social dilemma by the expected payoffs of cooperation. In a one-shot prisoner's dilemma, people not only cooperate but also respond to different outcomes (Guyer & Rapoport, 1972). Extending this finding to a stochastic setting, the second goal of this study is to establish whether and how different levels of risk affect behavior in one-shot social dilemmas with the same expected payoffs.

Like other types of choices, cooperation is a function of the match between decision processes and the decision-making environment, or what has been labeled ecological rationality. Besides social uncertainty, which has been studied extensively, the levels of environmental risk and uncertainty are critical components of real-world environments that researchers are only recently beginning to appreciate. For instance, cooperation unravels slower in a stochastic social dilemma than in a deterministic one (Bereby-Meyer & Roth, 2006), and groups cooperate more than individuals (Gong et al., 2009). None of the studies, however, addresses how differences in risky environments and the way risk is presented affects cooperation.

## Experiment

The goal of the study is to investigate how risk presentation and different levels of environmental risk affect cooperation in a social dilemma. Even if the outcomes of cooperation also depend on the action of others, the environmental risk affects all who cooperate equally. We thus expect both aspects to influence cooperation in risky environments in the same way as lottery choices with environmental risk alone. To facilitate understanding, we present the detailed hypotheses (see below) after the implementation.

We used a 2 x 2 between-subjects design in which we manipulated risk presentation (description vs. experience) and choice situation (social dilemma vs. lottery). In the *description* condition, subjects received information about how environmental risk influenced outcomes in a *social dilemma* as a probability statement, whereas in the *experience* condition participants sampled to infer the probabilities. To control whether the values and probabilities chosen to implement environmental risk replicated the DE gap, two further groups made decisions in *lotteries*, again either from description or experience. The environmental risk was identical between lotteries and games. To investigate how different levels of risk affect behavior in one-shot social dilemmas, we varied probabilities and outcomes within-subjects while keeping the expected outcomes constant.

## Methods

### Environmental Risk in Social Dilemmas and Lotteries

For the *social dilemma* conditions, we used a stochastic 2-person public goods game (PG) with binary choices. For each choice, participants receive an endowment  $e$  (10€) which they could contribute to a joint project with a randomly matched partner or keep for themselves. Contributions were multiplied by a value ( $msr$ ) and shared equally between both pair members. Denoting  $i$ 's contribution by  $c_i$ , where  $c_i \in \{0, e\}$  and  $i = 1, 2$ ,  $i$ 's payoff is given by

$$\pi_i = e - c_i + \frac{msr}{2}(c_1 + c_2). \quad (1)$$

We impose  $msr \in \{1, 2\}$ . An  $msr > 1$  made it socially optimal to contribute, whereas an  $msr < 2$  rendered free-

riding the dominant strategy for a selfish person, thus creating a social dilemma.

We manipulated environmental risk by assigning the  $msr$  to one of two possible values, representing either a good or a bad event, with a certain probability. In case the bad event occurred (with probability  $p$ ), contributions were multiplied by an  $msr < 1$ , decreasing the value of the public good. When the good event occurred, contributions were multiplied by an  $msr > 1$ , increasing the value of the contributions. The environmental risk only affected what was invested. Cooperation thus represents the risky and non-cooperation the sure option. We chose the two potential  $msr$ -values and corresponding probabilities such that the expected  $msr$ ,  $E[msr]$ , across good and bad event always yielded a social dilemma with  $1 < E[msr] < 2$ .

Table 1 illustrates the eight decision situations employed. Situations 1 to 4 contained *rare* ( $p < 0.25$ ) bad events, analogous to the DE gap studies with lotteries (e.g., Hertwig et al., 2004). Situations 5 and 6 contained more *common* ( $p > 0.25$ ) bad events to test whether the DE gap extends beyond rare events as found by Ludvig and Spetch (2011). We use two different expected  $msr$ , 1.2 and 1.4, to check the robustness of the results. Situations 1 – 6 were designed to extend the findings from the DE gap studies in risky choice to social dilemmas. At the same time, keeping the expected  $msr$  constant across different combinations of probabilities and potential returns allows us to test whether different levels of environmental risk affect choices in the PG in the same way in which they affect choices in lotteries.

Decision situation 7 and 8 explored boundary conditions of a social dilemma and provided a further control of participants' understanding of the incentives. In situation 7, the  $E[msr]$  equaled 1.1, which made it less attractive to cooperate compared to situations 1 – 6. In contrast to the other situations, here the rare event was the good state of the world. Different from situations 1 to 7, the expected  $msr$  of 2.1 in situation 8 did not generate a social dilemma and made it individually and socially optimal to cooperate.

In most studies on the DE gap, the risky option has an expected value that is only marginally higher than the sure option. To avoid floor effects in the social dilemma, we used relatively large expected  $msr$ . This should provide strong incentives to cooperate in the PG but results in a larger difference between the expected  $msr$ -value of the sure option and risky option. To control whether the parameters we chose for implementing environmental risk replicated the DE gap in more standard settings, we ran the same choices as lotteries with identical environmental risks. In the lottery conditions, participants also received an endowment  $e$  and had to decide whether to invest into a risky option. The risky option in each lottery used the same two possible  $msr$  with the same probabilities as the corresponding PG. Yet, while the payoffs in the games also depended on the action of another person, the payoffs in the lotteries only depended on the realized state of the world. The lotteries strip the strategic component away but retain the stochastic component that stems from the environment. We

randomized the order of decision situations in games as well as lotteries, and participants received no feedback about the realized *msr* (or decision of the other group member) after each decision.

### Decisions from Description vs. Decision from Experience

In the *description* conditions, participants received information about environmental risk as a summary statement about probabilities and associated *mrs*-values before they made their decision. In the *experience* conditions, participants sampled the distribution of *mrs*-values by drawing 25 cards from a deck. We used a matched-sampling design based on Ungemach et al. (2010), where people were forced to view a representative sample of the underlying distributions of outcomes. Each card contained a number corresponding to one of the two possible *msr*. For example, in situation 1 the deck had 2 cards with the *msr* 0 and 23 cards with the *msr* 1.30. The sequence of cards was randomized for each participant, yet the two possible *msr* and their frequencies matched exactly the objective probabilities given in the *description* condition. Thus, sampling error could not cause any differences observed between the two conditions.

In the *experience* conditions, we additionally collected time stamps that allowed us to evaluate how long participants viewed a certain card and whether this influenced their decision. To check the accuracy of risk estimates, we also asked participants after the last round how often they saw the two sampled *msr*-values. In the *description* conditions, participants translated the probability statement of the last round into a frequency statement to control whether participants accurately understood the risk.

**Further Tasks** In the *social dilemma* conditions, participants also faced two deterministic PGs with an *msr* of 1.2 and 1.4 (randomized order) after the stochastic situations. This allowed us to investigate how cooperation varies if the stochastic component is removed, since the deterministic games matched the expected *msr* of the stochastic PGs in situations 1, 2, and 5 ( $E[mrs] = 1.2$ ) as well as 3, 4, and 6 ( $E[mrs] = 1.4$ ).

At the end of the experimental session, participants indicated in a questionnaire which of six reasons best explains their decision to invest/not invest into the stochastic PGs: the probability of the *mrs* were (not) sufficiently high, the values of the *mrs* were (not) sufficiently high, conditional cooperation, social uncertainty, greed/opportunism, moral values, or none of these. A section on demographics concluded the experiment.

**Participants and Procedure** We randomly assigned 128 students in Jena, Germany, to one of four sessions. In the social dilemma conditions, participants had to pass control questions to ensure that they understood the impact of

environmental risk and of the other person's choice on their payoffs. All tasks were completed anonymously employing a perfect stranger design. At the end, one decision situation was randomly chosen to determine the payoff. Participants earned on average 14€.

### Hypotheses

**Risk sensitivity in social dilemmas and lotteries** Do different levels of environmental risk affect stochastic PGs in a similar way as they affect lotteries? To test this presupposition, we focus on decisions from description and employ the predictions of Prospect Theory (Kahneman & Tversky, 1992). Using a separate value and weighting function, Prospect Theory transforms the expected outcomes of a lottery into Prospect Theory Values (PTVs), analogous to expected values. When comparing the PTV of a lottery's risky option with a sure option (always 1 in our case), the conventional prediction is that the risky (sure) option is picked if the PTV is larger (smaller). Investment rates into the PG are expected to be lower than in lotteries due to a second source of uncertainty that stems from the other person. Thus, the PTVs based on environmental risk alone are unlikely to be useful. However, the PTVs also produce a ranking of the 8 decision situations in terms of proportion of risky choices. Such a ranking can be applied to both lotteries and stochastic PGs in the description condition. Table 1 lists the PTVs for the eight decision situations of this experiment based on the parameters used by Tversky and Kahneman (1992). From the PTVs, two predictions follow for PGs and lotteries with the same expected *msr*:

(1a) Situations 1 and 3 (bad event occurs with 8%) will lead to a higher number of risky choices than situations 2 and 4 (where the bad event occurs with 20%).

(1b) Situation 5 (6), where the bad event is more common, will lead to more risky choices than situations 1 and 2 (3 and 4).

**Decisions from Description and from Experience** Using lotteries, studies found that experienced small probabilities appear to be underweighted in choices compared to described ones (Hertwig et al., 2004). Extending this choice pattern to social dilemmas leads to the following hypothesis for stochastic PGs and lotteries:

(2) The risky option will be chosen more frequently in the experience condition than in the description condition if the bad event is less likely (situations 1 – 6 and 8), whereas this pattern should reverse for situation 7, in which the good event is less likely.

## Results

### Risk Sensitivity in Social Dilemmas and Lotteries

We would not expect risk presentation to matter unless people are sensitive to different levels of risk in games as they are in lotteries. For the results of hypothesis 1a and 1b,

Table 1: Percentage of subjects investing in PGs / lotteries and differences between description and experience conditions

Decision Situations				Stochastic PG			Lotteries

8	2.20, 0.96 0.30, 0.04	2.1	1.70	91	88	-3 ( $\chi^2(1) = 0.16$ , $p = 0.69$ )	100	97	-3 ( $p = 0.50$ , Fisher's exact test)

we focus on data from the *description* conditions for decision situations 1 to 6.

When comparing decision situations with an  $E[msr] = 1.2$  and  $E[msr] = 1.4$ , cooperation increases with the expected  $msr$ . The deterministic PGs yield a similar pattern: the rate of cooperation is 53% when  $msr = 1.2$  and, 81% when  $msr = 1.4$  ( $\chi^2(1) = 5.74$ ,  $p = 0.02$ ). In the stochastic PGs, the average rate of cooperation is 33% when  $E[msr] = 1.2$  and 48% when  $E[msr] = 1.4$  ( $\chi^2(1) = 4.23$ ,  $p = 0.04$ ). Thus, differences in expected  $msr$  affect behavior even though the social dilemma is maintained and the dominant strategy for a person is not to cooperate. This replicates Guyer & Rapoport (1972) findings and extends it to a stochastic setting. But, besides being sensitive to different expected outcomes, do people react to different levels of risk for constant expected outcomes?

To address this question, we pool our data across situations with expected  $msr$ -values of 1.2 and 1.4 to obtain more reliable results. The mean cooperation rate is 1.7 times higher in situations where the bad event occurs with 8% than in situations where the bad event is common ( $\chi^2(1) = 7.12$ ,  $p = 0.01$ ). Thus, changes in the stochastic environment have a large impact on cooperation. The difference in cooperation between deterministic and stochastic PG with

an 8% chance of a bad event is only 10.5% and not significant ( $\chi^2(1) = 1.62$ ,  $p = 0.20$ ).

To investigate hypotheses 1a and 1b – that situations with 8% receive more investment than situations with 20% –, one can also rely on the pooled data across the  $E[msr]$  of 1.2 and 1.4 because the rankings of PTVs are identical for both. The rate of investment in situations with a probability of 8% compared to 20% sharply drops both for stochastic PGs (from 56% to 33%,  $\chi^2(1) = 7.17$ ,  $p = 0.01$ ) and lotteries (from 80% to 53%,  $\chi^2(1) = 10.12$ ,  $p < 0.001$ ). Paralleling each other, stochastic PGs and lotteries thus are in line with prediction 1a based on Prospect Theory.

For prediction 1b, the data also suggests a decline in cooperation between situations with a probability of 20% and those with two common events. Statistically, however, there is no difference between these two situations, neither for the stochastic PGs (the investment rate is constant at 33%,  $\chi^2(1) = 0.00$ ,  $p = 1.00$ ), nor for lotteries (the investment rate declines from 53% to 39%,  $\chi^2(1) = 2.55$ ,  $p = 0.11$ ). Hypothesis 1b based on Prospect Theory – that the rate of investment is highest with a common event – is neither met in stochastic PGs nor in lotteries.

In summary, we find that different levels of environmental risk both influence choice in the PGs for

decisions from description and result in similar behavior in stochastic PGs and lotteries. Though the data confirm the predictions of Prospect Theory for hypothesis 1a, we did not obtain support for hypothesis 1b for either PGs or lotteries.

### Decisions from Description and from Experience

**Is there a DE gap in lotteries and games?** We initially focus on pooled data from the eight decision situations to start with more reliable results. Hypothesis 2 is directional and states that, except for situation 7, participants should choose the risky option more often in the experience condition. To test this hypothesis, we subtracted the percentage of people contributing in the experience condition from those in the description condition, except for situation 7 where we do the opposite. The results show a positive gap for lotteries ( $\chi^2(1) = 8.24, p = 0.003$ ), with a mean difference between experience and description of 12% (SD = 10%).

Table 1 lists percentage of people investing in experience and description separately for all eight decisions situations in lotteries and stochastic PGs. For lotteries, the predicted difference between the experience and description condition is observed in all situations (including the reversal for situation 7) – except for lottery 8. This lottery shows a ceiling effect because the expected outcome is twice as high as the sure option, so that in both conditions all participants but one invested.

Averaging across lotteries 1-4, which contain a rare event, shows a DE gap of 13% (Table 1). The same DE gap (13%) occurs with lotteries containing a more common bad event (5 and 6, Table 1). The results replicate Ludvig and Spetch (2011), who find the DE gap also for situations with common events. Overall, responses to decisions from description and experience differed in lotteries as predicted based on previous findings. Thus, the parameters we chose for environmental risk replicate the DE gap found in the risky choice literature.

Given that the parameters replicate the DE gap in lotteries and the previous result that people's decisions in games were similarly sensitive to differences in risk as in lotteries, we expected the risk presentation format to influence cooperation as well. The behavior in the stochastic PGs, however, does in this respect not match the behavior in lotteries: the DE gap completely disappears in games ( $\chi^2(1) = 0.38, p = 0.30$ ). The mean difference between experience and description in the stochastic PG is -3% (SD = 6%).

The stochastic PGs stand in stark contrast to the results in the lotteries. In games, 6 out of 8 decision situations show no or only minimal gaps. Experience and description conditions do not differ for any of the decision situations. In fact, situation 7, which is closest in spirit to the situations used in by Hertwig et al., (2004) and Ungemach et al., (2009), shows a strong DE gap in lotteries, but the gap disappears completely in the games.

**Why is there a DE gap in lotteries but not in games?** In the following, we explore reasoning processes in PGs and

lotteries that provide hints to why risk presentation affects lotteries but not stochastic PGs.

One possible explanation underlying this pattern is that participants spend different amounts of time sampling in lotteries and games, which may indicate different search processes. In lotteries, participants spent more time viewing the rare event ( $M = 0.91$  seconds,  $SD = 0.99$ ) compared to the frequent event ( $M = 0.67$  seconds,  $SD = 0.65, t(6400) = 10.01, p < 0.001$ ). Similarly, for the games, participants viewed the rare event ( $M = 0.51$  seconds,  $SD = 0.51$ ) longer than the frequent event ( $M = 0.43$  seconds,  $SD = 0.33, t(6400) = 6.38, p < 0.001$ ). In lotteries, however, participants spent more time sampling than in games for both rare events ( $t(2432) = 12.45, p < 0.001$ ) and frequent events ( $t(10368) = 24.02, p < 0.001$ ). These differences in sampling times thus provide evidence for potentially different search processes in games which appear to pay less attention to the actually observed probabilities compared to lotteries.

To control for the accuracy of risk perception, participants in the experience conditions stated the frequency of the two outcomes in the last situation after they had decided. The actual distribution of outcomes participants saw correlates with the stated frequencies for lotteries ( $r_s = 0.72, p < 0.001$ ) yet to a lesser extent for stochastic PGs ( $r_s = 0.43, p < 0.01$ ). In both conditions participants were calibrated to the actual probabilities and did not underestimate but rather, if anything, overestimated the probability of rare events.

Some researchers suggest that the larger influence of recent events in decisions from experience may drive the DE gap. Hertwig et al. (2004) and Rakow, Demes, & Newell (2008) found a recency effect in decisions from experience but Ungemach et al., (2010) and Hau, Pleskac, Kiefer, & Hertwig (2008) did not. To test for a recency effect, we divided the 25 samples participants draw before each decision into two sets: from 1 to 12 (initial) and from 13 to 25 (latter). Then we computed the expected  $msr$  from the initial samples,  $E[msr]_{1-12}$ , and from the latter samples,  $E[msr]_{13-25}$ . Finally, we compare the number of risky choices made when  $E[msr]_{13-25} > E[msr]_{1-12}$  to the number of risky choices made when  $E[msr]_{13-25} < E[msr]_{1-12}$ . When the  $E[msr]$  of the latter, more recent sample was larger, we find a higher number of risky choices in lotteries ( $\chi^2(1) = 3.77, p = 0.04$ ) but not in games ( $\chi^2(1) = 0.30, p = 0.34$ ). This also suggests that the actual observed probabilities may play a less important role in games than in lotteries.

Finally, for the stochastic PG in description and experience, participants indicated their most important reasons for cooperating as well as not cooperating. This resulted in two statements per participants. Aggregating across both statements, probabilities influenced cooperation decisions in the description condition for 59% of the participants, compared to 39% in the experience condition. In this condition, participants rather emphasized both the value of the  $msr$  they could obtain (20% in experience, and 3% in description) and their expectation whether the other will (not) cooperate, i.e. conditional cooperation (20% in

experience and 11% in description). This indicates that the importance of the probabilities for decisions is further reduced in the stochastic PG in experience.

In summary, participants sampled more quickly in the stochastic PG in the experience condition than in lotteries, as if they were paying less attention to the observed probabilities. In line with this, subjects' risk perception was less accurate in games than in lotteries, and recency – a potential cause of the DE gap – did not play a role in games, whereas we did find a recency effect in lotteries. The questionnaire also highlighted that probabilities were less important in the PG in experience than the size of the values and beliefs about others' behavior. This provides converging evidence that as the probabilities of the risky option lose importance in the games, the DE gap washes out.

### General Discussion

People often cooperate in social dilemmas. We examined how critical aspects of the stochastic environment shape cooperation. First, different levels of environmental risk influence cooperation. Investments in the stochastic PGs match those observed in lotteries, with people preferring an 8% chance of a bad event to a 20% chance for constant expected payoffs. Second, the *msr*-values and probabilities chosen to implement environmental risk replicate the DE gap within individual risky choices in lotteries. That is, people choose the risky option more often when experiencing the risky outcomes compared to when receiving summary descriptions. Our key finding is that, nevertheless, risk presentation matters in lotteries but not in games: no DE gap existed for the social dilemmas. Process data and subjects self-reported reasons for cooperation suggest that the disappearance of the DE gap in games may result from a decision process that emphasizes the size of the outcomes and expectations about others' behavior over outcome probabilities.

In our view, to include environmental risk and decisions from experience into the study of cooperation invites more realism into the laboratory. This study is only a small step to build on insights from research on risky choice for decision situations which combine environmental risk and social uncertainty. In particular, models that focus more on actual decision processes instead of choices alone may provide promising alternative starting points to Prospect Theory, which in our study could not account for the data in the description condition for either lotteries or games. In complex interactive environments, it seems rather likely that non-compensatory decision making emerges. For instance, a lexicographic strategy like the Priority Heuristic (Brandstatter et al. 2006), outlines a sequential decision process which considers outcomes in the first and probabilities only as a second step if no decisions has been made. In a similar fashion, other strategies that do not trade-off reasons may be valuable to model search and decisions processes in situations that combine environmental risk and social uncertainty – and thus also include expectations about

others and further social reasons besides mere outcomes and probabilities.

## Abstract

Game theory has been useful for understanding risk-taking and cooperative behavior. In the present study, subjects played the Hawk-Dove game with simulated and embodied (robotic) neural agents which used a neurobiologically plausible model of action selection and adaptive behaviors. Subjects had their serotonin levels temporarily altered through acute tryptophan depletion (ATD). The traditional assumption for subject data from Game-theory-ATD or human robot interaction (HRI) studies is that all participants come from the same underlying distribution or same group. We used probabilistic graphical models in order to determine potential sub-group affiliations based on the subjects' responses while playing the Hawk-Dove game. The results from the models indicate sub-groups within a subject population exist. We find that two-group, one that tends toward cooperation and the other that tends toward aggression, best describes the effect of subject behavior in response to ATD and embodiment.

## Introduction

Economic game theory has had a long, productive history of predicting and describing human behavior in cooperative and competitive situations (Maynard Smith, 1982 ; Nowak, Page, & Sigmund, 2000 ; Skyrms, 2001). The theory of games has also been used to illuminate the neural basis of economic and social decision-making (Lee, 2008 ; Rilling & Sanfey, 2011). However, these studies typically have people play against opponents with set strategies and predictable behavior. Moreover, in most of these studies, subjects are making decisions while sitting in front of an antiseptic computer screen. The present study addresses these issues by having subjects play a socioeconomic game, known as Hawk-Dove, against an autonomous robot with the ability to adapt its behavior to the game situation.

Neuromodulatory systems, such as dopamine and serotonin, appear to be applicable to decision-making in social situations. The serotonergic (5-HT) and dopaminergic (DA) systems oppose each other with respect to predicting punishment (5-HT) versus predicting reward (DA) (Boureau & Dayan, 2011).

We developed a computational model of neuromodulation and action selection based on the assumptions, that dopamine levels are related to the expected reward of an action, and serotonin levels are related to the expected cost or risk of an action (Asher, Zaldivar, & Krichmar, 2010 ; Zaldivar, Asher, & Krichmar, 2010). The model of neuromodulation and action selection demonstrated the ability to adapt to the game situation and its opponent's strategy. The model was embedded in both simulated and embodied neural agents to investigate reciprocal social interactions in games of cooperation

and conflict with people (Asher, Zaldivar, Barton, Brewer, & Krichmar, submitted).

Subjects played a series of Hawk-Dove games against robotic and simulated agents. The effects of serotonergic levels on adaptive behavior in these games were tested by simulating serotonergic lesions in the neural agent, which results in a more aggressive agent, or lowering the CNS serotonin levels of people through a dietary manipulation called acute tryptophan depletion (ATD), which has been shown to decrease cooperation and lower harm-aversion (Crockett, Clark, Tabibnia, Lieberman, & Robbins, 2008 ; Wood, Rilling, Sanfey, Bhagwagar, & Rogers, 2006).

A major finding of the study was that people changed their overall strategies in response to changes in the neural agents state. Subjects tended to deploy either Tit-For-Tat (T4T) or Win-Stay, Lose-Shift (WSLS) strategies during game play. In a T4T strategy, a subject copies the most recent move of the opposing player. In a WSLS strategy, a subject selects the same action that led to a positive payoff in the previous game (Win-Stay), or a different action from the previous game if that action led to zero or negative payoff (Lose-Shift). When playing against a more aggressive neural agent, which had a lesion to its serotonergic system, subjects switched from a Win-Stay, Lose-Shift (WSLS) strategy to a Tit-For-Tat (T4T) strategy. This change in strategy was independent of whether the neural agent was a robot or a computer simulation, and independent of subject tryptophan levels.

In the present study, we test whether embodiment and lowering serotonin has an effect on individual subject behavior during Hawk-Dove game playing by using hierarchical latent mixture models with Bayesian inference. This framework for developing and evaluating structured cognition offers a principled and comprehensive approach for modeling individual differences and their use of cognitive strategies (Lee, 2008 ; Lee, Zhang, Munro, & Steyvers, 2011). The hierarchical nature of the models allows variation in the parameters controlling cognitive processes across individuals to be accommodated. We find that two categories of subjects, one that tends to be more aggressive and one that tends to be more cooperative, best describes subject behavior in response to ATD and embodiment.

## Experiment

### Subjects

Eight subjects (three female; mean age: 26.6 years; standard deviation of age: 3.8 years) participated in this study.

## Hawk-Dove Game

The Hawk-Dove game consisted of a human and a neural agent choosing a single action in response to a territory of interest (TOI). The Hawk-Dove game, which is similar to Prisoner's Dilemma, was chosen because it is amenable to a physical instantiation with a robot. Moreover, it has an additional strategic element since choices are different depending on who arrives at the TOI first. At the start of the game, the TOI and the human subjects' location were randomly placed on a playing grid. The current location of the robot was used as a starting position. The player who arrived at the neutral TOI first had the opportunity to take one of two possible actions: Escalate (i.e. an aggressive, confrontational tactic) or Display (i.e. a nonviolent, cooperative tactic). The player who arrived second responded with one of the two aforementioned actions. After each game, a payoff was calculated. If both players chose Escalate, they received a penalty that is set before the game. If both players chose Display, they split the value of the TOI resource. If one player chose Escalate and the other chose Display, the player who chose Escalate received the entire value of the resource.

We also developed a simulated variant of the Hawk-Dove game, where subjects played against a robot icon on an interactive screen. The same neural model used for the real robot dictated the control of the robots icon and its decision-making. This simulated setup allowed us to judge whether physical embodiment had an effect on human behavior.

## Acute Tryptophan Depletion (ATD)

ATD was used to temporarily alter the levels of serotonin in the brain via a decrease in blood plasma tryptophan, the amino acid precursor to serotonin. Because free blood plasma tryptophan levels, and the corresponding serotonin levels in the brain, vary with the amount of dietary tryptophan and the rate of protein synthesis, these levels can be altered by a low protein diet in combination with a specially prepared 'protein shake'. This protein shake contains an amino acid load (lacking tryptophan), which has two effects. First, it stimulates protein synthesis in the liver, which uses up blood plasma tryptophan. Second, the amino acids that are given in the protein shake compete with tryptophan for transport across the blood-brain barrier, which restricts entry of tryptophan into the brain and leads to lower levels of serotonin in the brain (e.g. Bell, Hood, & Nutt, 2005 ; Hood, Bell, & Nutt, 2005).

## General Procedures

In a double-blind study, human subjects were randomly assigned on the first experimental day to receive either the control mixture (Tryp+) with tryptophan or the mixture without tryptophan (Tryp-). The mixtures were administered as a specially prepared protein shake. The Tryp+ and Tryp- shakes contained 16 and 15 amino acids respectively.

Each subject then returned to participate in the other condition at least seven days later to ensure the return to baseline blood plasma tryptophan levels between experimental days. On the morning of each experimental day, a blood sample

was drawn to determine baseline blood plasma tryptophan levels. Following the blood draw, subjects ingested one of the mixture drinks (either Tryp+ or Tryp-). A second blood sample was drawn approximately 5 hours after ingestion of the mixture to confirm reduction (Tryp- condition) or maintenance (Tryp+ condition) of blood plasma tryptophan levels. Roughly 5.5 hours after consumption of the mixture, human subjects then participated in a series of Hawk-Dove games against a neural agent.

## Experimental Conditions and Data

We were interested in two experimental conditions per subject. In the Simulation vs. Robot condition, subjects would play games against a computer agent or against the robot; In the Tryp+ vs. Tryp- condition, subjects would play games against a neural agent with an intact simulated neuromodulatory system or a simulated lesion of its serotonergic system.

The Escalate or Display decisions for each game were collected for both the subject and neural agent for all games in each condition. The dependent variables of interest are the percentage of games per condition a subject chose the Escalate tactic and the use of either the Tit-For-Tat (T4T) or Win-Stay, Lose-Shift (WSLS) strategies. Human subjects played 20 games of Hawk-Dove per condition. For detailed experimental conditions, see Asher et al. (submitted).

## Data Analysis

### Bayesian Hierarchical Model Approach

To investigate the influences of lowering serotonin levels and of agent embodiment on individual decision-making, we used hierarchical latent mixture models with Bayesian inference. Hierarchical Bayesian inference has been demonstrated as a flexible and interpretable way of extending simple models of cognitive processes (e.g. Lee, 2008 ; Rouder, Lu, Speckman, Sun, & Jiang, 2005 ; Wetzels, Vandekerckhove, Tuerlinckx, & Wagenmakers, 2010). The hierarchical nature of the models allows variation in the parameters controlling cognitive processes across individuals to be accommodated. The latent mixture nature of the models allows the use of entirely different cognitive strategies across individuals to be modeled.

Formally, we recast the cognitive models as probabilistic graphical models and used Markov Chain Monte Carlo (MCMC) methods for computational Bayesian inference. This approach to Bayesian inference over richly-structured cognitive models has been applied to data covering a diverse set of cognitive skills. For example, Bayesian graphical models have been used to make inferences about the use of strategies, such as WSLS or T4T, from sequences of choice data in bandit problems and other sequential decision-making tasks (e.g. Lee et al., 2011 ; Newell & Lee, 2011).

Using hierarchical latent mixture models, we addressed the question of how ATD and embodiment can affect subjects' decisions to compete (i.e., escalate) or cooperate (i.e., display). We modeled the probability of escalating through a logistic model. Specifically, the logit of the probability of es-

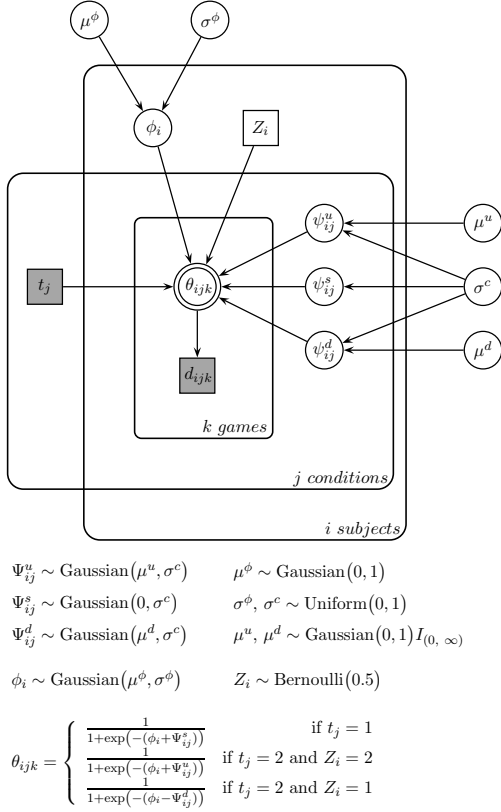

Figure 1: Generic process of escalation or strategy usage under the effect of ATD or embodiment.  $\phi$ : baseline tendency of escalation or strategy usage;  $\Psi^u$ ,  $\Psi^d$  and  $\Psi^s$ : additive effects of escalation or strategy usage associated with the experimental conditions;  $t$ : indicator of experimental condition;  $\theta$ : probability of escalation or strategy usage;  $d$ : observed escalation decision or strategy usage;  $Z$ : latent group indicator;  $\mu^\phi, \sigma^\phi, \mu^u, \mu^d, \sigma^c$ : hyper-parameters of prior distributions. Experimental conditions are either Tryp- vs. Tryp+, or Robot vs. Sim.

calating for each subject in each condition is assumed to follow a Gaussian distribution defined by its mean and variance (hyperparameters in the hierarchical model), with the mean modeled as the sum of the baseline level of escalating for the subject, and an additive effect associated with ATD. To give a full account of the data, the hierarchical model is designed to address individual differences at two levels, the baseline level, which depends on the subjects, and the additive level, which depends on the interaction between subjects and experimental conditions. Our justification is that it is possible that the effect of ATD or embodiment can vary across different individuals, resulting in either an increase or decrease in the likelihood of escalating a fight.

### The Graphical Model

We use graphical models to describe the relationship between subject decision-making (escalation, T4T and WSLs) and

predictors of interest (ATD and embodiment). In total we built six graphical models for every decision-making and predictor pair. In this section, we show a concrete example of how we model the relationship between escalation and ATD; all other models were built along a similar line.

As shown in Figure 1, nodes represent variables of interest, and the graph structure is used to indicate dependencies between the variables. Arrows run into nodes from their direct influences (parents). Formally, the model represents the assumption that, given its parent nodes, each node is independent of all other nodes in the graph except its descendants.

Each subject is assumed to produce data through the same generative model with different parameters. The plate with  $i$  subjects corresponds to independent replications for all subjects. Each subject is assumed to have their own baseline of escalation,  $\phi_i$ , independently drawn from a Gaussian distribution with mean  $\mu^\phi$  and variance  $\sigma^\phi$  (termed as hyper-parameters). Each subject  $i$  is also associated with a latent group identity,  $Z_i$ , with  $Z_i = 1$  indicating that the subject comes from a ‘down group’ that shows less escalation decisions with ATD, and  $Z_i = 2$  indicating that the subject comes from an ‘up group’ that shows more escalation decisions with ATD.

The plate with  $j$  conditions corresponds to independent replications for all experimental conditions.  $t_j$  is an observed variable, with  $t_j = 1$  indicating the control condition (Tryp+), and  $t_j = 2$  indicating the treatment condition where the subjects received ATD (Tryp-).

In the control condition, random fluctuations around the baseline are drawn from a Gaussian distribution with mean of 0 and a variance  $\sigma^c$ . In the ATD condition, the increment in escalation depends on which group the subject is from. For example, if subject  $i$  is from the ‘up group’, the increment of escalation, denoted by  $\Psi_{ij}^u$  in the graphical model, will be drawn from a Gaussian with a positive mean  $\mu^u$  and variance  $\sigma^c$  and added to the baseline  $\phi_i$ . If subject  $i$  is from the ‘down group’, however, the increment  $\Psi_{ij}^d$  will be drawn from a Gaussian with a different positive mean  $\mu^d$  and variance  $\sigma^c$  and deducted from the baseline<sup>1</sup>.

The probability of escalation for subject  $i$  on the  $k$ th game of day  $j$ , denoted by  $\theta_{ijk}$ , is determined through the logistic function by the overall level of escalation. The observed escalation decision of each subject on each game,  $d_{ijk}$ , is a binary variable which is assumed to be independent and identically generated by  $\theta_{ijk}$  through a Bernoulli distribution. Overall, one would determine the likelihood of the observed data for all subjects for each combination of the hyperparameters, and each choice of individual parameters.

We use the conventions of representing continuous variables with circular nodes and discrete variables with square nodes, and unobserved variables without shading and observed variables with shading, and stochastic variables with

<sup>1</sup>Even though in theory,  $\Psi_{ij}^u$  and  $\Psi_{ij}^d$  could flip in sign following the way this model is specified, this almost never happened in the sampling process when the MC chains have converged.

single borders and deterministic variables with double borders. In addition, the plate encloses subsets of the graph that have independent replications in the model. For example, the probability of escalation for each subject in each game is a continuous variable that is not directly observable, but is determined by the overall level of escalation, therefore it is represented by a circular, unshaded, double-bordered node. On the other hand, the binary escalation decision is generated with probability and directly observable, therefore it is represented by a square, shaded node with a single border.

We built another model that captures the relationship between escalation and the effect of embodiment (Robot vs. Simulation). There are only two differences from the graphical model shown in Figure 1. First,  $t_j$  represents embodiment with  $t_1$  indicating robot and  $t_2$  indicating simulation; secondly,  $Z_i = 1$  indicates the latent group that shows more escalation when playing against simulation, and  $Z_i = 2$  indicate the group that shows more escalation when playing against robot.

In addition to escalation decisions, we are also interested in whether general strategies that subjects employed for the Hawk-Dove game were related to ATD and embodiment. Similar to the generative model shown in Figure 1, the observed T4T-type (WSLS-type) decisions are Bernoulli variables generated by probabilities of T4T (WSLS) usage, which are determined by an overall level of T4T (WSLS) usage that is the sum of a baseline level of usage and additive effect from ATD or embodiment.

## Results

### Inferring Strategies

All the graphical models were implemented using WinBUGS which uses MCMC methods. We evaluated all six graphical models by drawing 1000 posterior samples after a ‘burn-in’ period (early steps of MCMC where samples are not recorded so that the Markov chain is allowed time to converge) of 100 samples.

The results showed that both serotonin levels and the embodiment of a robot were influential factors in individual subject decision-making (See Figure 2). For example, panel (a) provides evidence that there are at least two sub-groups within a subject population with respect to how escalation may be altered by ATD. Subject 2, 6 and 8 fall in the ‘down’ group, and subject 1, 3, 4, 5 and 7 fall in the ‘up’ group. Panel (b) shows two sub-groups within a subject population with respect to how escalation may be altered by embodiment. Subject 3, 5 and 6 fall in the ‘down’ group (less escalation when playing with a robot), while all other subjects fall in the ‘up’ group (more escalation when playing with a robot). Individual differences in strategy usage were also affected by ATD and embodiment, as shown in Figure 2c through f. For example, Figure 2c shows individual differences in the effect of ATD on the proportion of T4T-type decisions. The red (dark) dots are subjects who had more T4T-type decisions when tryptophan depleted and the green (light) dots are subjects

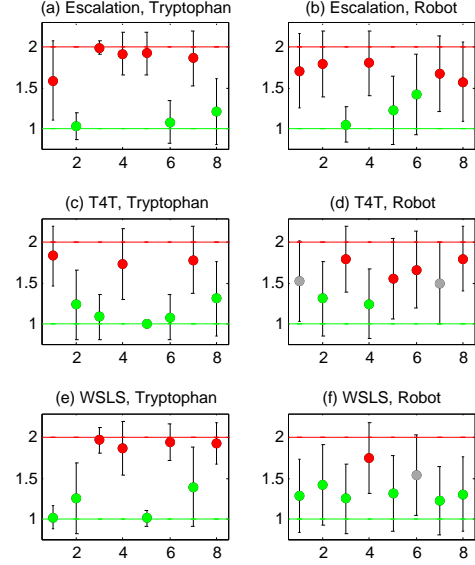

Figure 2: (a): Estimated group identities based on ATD’s effect on escalation. Horizontal axis shows subject indices. Vertical axis shows the posterior mean of the latent variable  $Z$ , with  $Z = 1$  indicating ‘down’ group and  $Z = 2$  indicating ‘up’ group based on the effect of tryptophan depletion. Red (dark) dots are subjects who were more likely to escalate when tryptophan depleted and green (light) dots are subjects who were less likely to escalate when tryptophan depleted. Error bars show the 95% Bayesian CI of the posterior mean. Gray dots imply ambiguous group identities. (b): Estimated group identities based on embodiment’s effect on escalation. Red dots are subjects who were more likely to escalate when playing against a robot. (c): Estimated group identities based on ATD’s effect on T4T usage. Red dots indicate more T4T-type decisions when tryptophan depleted. (d): Estimated group identities based on embodiment’s effect on T4T usage. Red dots indicate more T4T-type decisions when playing against a robot. (e)-(f): Estimated group identities on of the effect of ATD and embodiment on WSLS usage.

who had less T4T-type decisions when tryptophan depleted. In Figure 2d, red (dark) dots represent subjects who had more T4T-type decisions when playing against robot. Similarly, Figure 2e and 2f represent individual differences in how ATD and embodiment affect their usage of WSLS. All conditions show a tendency that subjects can be categorized into sub-groups with regard to how ATD or embodiment may affect strategy usage.

In general, subgroups are more clear when the effect of tryptophan depletion rather than the embodiment type is considered. Potential connections of subgroup identities across conditions for each subject is an interesting point raised here and will be addressed in future research.

## Predictions of Behavioral Patterns

To check the models' ability to describe the data accurately, we examined the posterior predictions of escalation decision and strategy usage for all subjects in all conditions. The posterior predictive is the prediction about observed data for each possible combination of parameter values under the model, where each combination is weighted according to its posterior probability. Our goal is not game-by-game prediction, rather, it is the prediction of overall rate of escalation decision and strategy usage in a specified condition, as captured in Figure 3. The x-axis shows experimental conditions, and the y-axis shows the proportion of escalation decisions or strategy usage. Each gray line is a subject. The colored (dark) lines are posterior predictives (summarized in the same way as the data) for each model, with filled vs. open circles representing whether subjects were inferred in the 'up' or 'down' groups corresponding to the condition (ATD or embodiment). It is clear that our models were able to capture individual differences and fit the data well, especially for the effect of ATD and embodiment on escalation and T4T usage. Predictions of proportions of WSLs-type decisions had larger fluctuations, but the general pattern of change in WSLs usage associated with ATD and embodiment were captured.

## Conclusions

In contrast to the results observed in our population analysis of subject behavior during Hawk-Dove game play (Asher et al., submitted), we found strong influences of lowering serotonin levels and of agent embodiment on individual decision-making by using hierarchical latent mixture models with Bayesian inference. The results from Figure 2 and Figure 3 show that individual differences likely exist within a subject population. Specifically, it appears that there are two groups of subjects within a given population. Our hypothesis is that within Game-theory-ATD and HRI studies, there exist two opposing subgroups within any given population of typical human subjects. These subgroups may exist due to inherent genetic variation. It is interesting to note that the results from Game-theory-ATD and HRI studies are mild when considering a single subject group. However, if one considers that there exist two groups with opposing affects, the results for these kinds of studies may be significantly more robust.

ATD had a strong effect on subject behavior and this behavior could be categorized in two groups: subjects who were more aggressive when tryptophan depleted and subjects who were less aggressive when tryptophan depleted. Aggressive, uncooperative behavior has been reported in behavioral studies in which serotonin levels were lowered through ATD (Schweighofer et al., 2008 ; Tanaka et al., 2007). However, individual variation both due to experience and genetic background can affect behavior. For example, there is widespread variation in the serotonin transporter gene 5-HTTLPR (Homberg & Lesch, 2011). Subjects carrying the short allele variant of the 5-HTTLPR outperform subjects with the long allele in an array of cognitive tasks and show

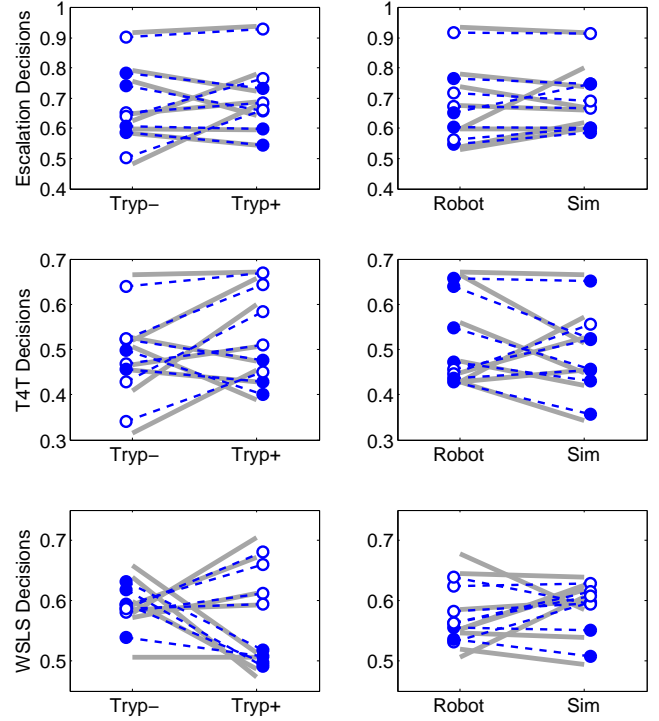

Figure 3: Predicted escalation rate by the model for all subjects with a comparison to the real data. Tryptophan depleted and non-depleted conditions labeled as 'Tryp-' and 'Tryp+'. The broken lines are predictions from the models, with filled vs. open circles representing subjects who show more escalation when tryptophan depleted vs. subjects who show less escalation when tryptophan depleted. The solid lines are the data. Labels of 'Robot' and 'Sim' indicate whether the game was played against the robot or the simulation.

increased social conformity under normal conditions. However, subjects carrying the long allele variant perform better under stressful conditions. The prevalence of these and other genetic polymorphisms in the human population suggests that there is an evolutionary advantage for this variability, such as optimizing competition or cooperation in different situations.

Embodiment had a strong effect on subject behavior and, similar to the ATD effect, this behavior could be categorized in two groups: subjects who were more aggressive when playing against a robot and subjects who were less aggressive when playing against a robot. Playing an opponent who is interactive and personified has previously been observed to evoke strong responses in subjects. For example, in the Ultimatum Game, subjects rejected more offers made by a human partner than those offers made by a computer, suggesting that participants had a stronger emotional reaction to unfair offers from humans than from a computer (Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003). Indeed, such embodied models have been shown to elicit strong reactions in humans (Breazeal & Scassellati, 2002 ; Kidd & Breazeal, 2004)

and to exhibit more natural and complex behavior than pure simulations (Krichmar & Edelman, 2002, 2005). However, it appears that individuals responded differently and idiosyncratically to the presence of a robot in the present study.

Our results highlight the following ideas: first, the hierarchical latent mixture model's ability to capture individual differences; secondly, serotonin levels have differing effects on subject decision-making, and lastly embodiment plays a role in how likely subjects are willing to cooperate with an agent. Our results suggest that there are at least two opposing subgroups with respect to Game-theory-ATD and HRI studies. We suggest the possibility that these subgroups may have emerged as a result of genetic variation. A next step towards investigating this hypothesis involves genetic testing of polymorphisms responsible for subject variance and their decision-making in competitive and cooperative games of Game theory along with human robot interactions.

# Lexical Access Across Languages: A Multinomial Model of Auditory Distraction.

C. Philip Beaman (c.p.beaman@reading.ac.uk)

School of Psychology & Clinical Language Sciences, University of Reading  
Earley Gate, Whiteknights, Reading RG6 6AL, UK

## Abstract

Recall in many types of verbal memory task is reliably disrupted by the presence of auditory distracters, with verbal distracters frequently proving the most disruptive (Beaman, 2005). A multinomial processing tree model (Schweickert, 1993) is applied to the effects on free recall of background speech from a known or an unknown language. The model reproduces the free recall curve and the impact on memory of verbal distracters for which a lexical entry exists (i.e., verbal items from a known language). The effects of semantic relatedness of distracters within a language is found to depend upon a redintegrative factor thought to reflect the contribution of the speech-production system. The differential impacts of known and unknown languages cannot be accounted for in this way, but the same effects of distraction are observed amongst bilinguals, regardless of distracter-language.

**Keywords:** Auditory distraction; bilingualism; memory; MPT models.

## Introduction

Auditory distraction is a simple and inevitable fact of everyday experience, stemming from the role of audition as the “sentinel of the sense” (Handel, 1989; Jones, Hughes & Macken, 2010). A considerable body of experimental data has been amassed, particularly with regard to immediate serial memory (e.g., Jones et al, 2010), indicating that – as a predictor of disruption experienced to the primary task – the lexical content of verbal auditory distracters is less important than the acoustic properties of the signal. For example, to reliably disturb immediate serial recall it is necessary for an auditory stream to consist of multiple, varying items – a single repeated item is much less disruptive (Jones & Macken, 1993). Nevertheless, given the verbal nature of most primary tasks shown to be vulnerable to interference from auditory distracters, it would be surprising if no effect of the lexical properties of the distracters was ever observed.

One task which reliably shows more disruption from meaningful verbal distracters that are semantically related to the material being studied than from semantically unrelated material is categorical free recall. In this task, participants are asked to recall, in any order that occurs to them, a series of items all drawn from the same semantic category (e.g., a fruit, a vegetable, or a four-footed animal) which are presented to them visually, one item at a time. Recall in this task is disrupted by the presence of auditory-verbal distracters but is disrupted more when these distracters are drawn from the same category as the to-be-recalled material. Participants are always asked to ignore anything they may hear, and are never tested on the content of the auditory stream. Results obtained within this task show the extent,

and nature, of the processing to which the auditory distracters are subjected. Similarities and differences between results obtained with category free-recall and with identical distracters applied during immediate serial recall also indicate the generality, and specificity, respectively, of both the auditory distraction effect and memory models which aim to account for this effect.

## The Schweickert (1993) model.

The model tested in this study is Schweickert’s (1993) multinomial model of immediate recall. This model has previously been applied to short-term memory for serial order, in which items must be recalled in the order in which they appeared and are scored as incorrect if an item appears in the wrong position in the serial recall protocol. This model was able to successfully account for the interaction in serial recall data between the frequency of words within the English language (the word frequency effect) and the point at which they were presented in a to-be-recalled list (Hulme, Roodenrys, Schweickert, Brown, Martin & Stuart, 1997). The same model also accounted for a distracter-word frequency effect, that is an effect on immediate serial recall of whether an auditory distracter – presented concurrently with the visual presentation of the to-be-recalled list – was of high or low frequency, with low frequency words causing the most distraction (Buchner & Erdfelder, 2005). As such, the model is a useful one for examining the effects of lexical properties of the auditory distracters, and how these might interact with lexical processing of the to-be-recalled items.

The multinomial model is conceptually straightforward, the structure of the model is given in Figure 1. An item is either directly recalled in an intact form, with probability  $i$ , or else the representation of the item exists only in a degraded form and it must be redintegrated, or reconstructed, which is only possible with probability  $r$ .

Figure 1. Diagrammatic representation of Schweickert’s (1993) multinomial processing tree model.

The form of the model thus allows for two means by which items can be correctly recalled – they may already exist in an “intact” form and be readily available, or they may require reconstruction. If both of these processes fail, the item cannot be recalled. The model has thus far been applied only to immediate serial recall – that is recall commonly considered to be from “short-term memory” but the existence of two distinct processes, each underlying recall in a different way, calls to mind earlier models previously applied to free recall (e.g., Atkinson & Shiffrin, 1968) which also assumed dual components to recall, so it is of interest to examine whether Schweickert’s model for serial recall can also be applied to free recall, and in particular the free recall of items from within a single category, which will require the model to generate the well-known serial position function typical of free recall, with primacy and extensive recency (Murdoch, 1962), rather than the serial recall curves, with extensive primacy and limited recency, generated by Buchner and Erdfelder (2005) and Hulme et al. (1997).

### Lexicality and recall.

As with all multinomial models, the goodness-of-fit between the model and the data is assessed by finding the values for the free parameters ( $i$  and  $r$ , in this instance) which produce expected data closest to those observed in behavioral testing. A goodness-of-fit test then determines whether the expected values differ significantly from the observed data (Bachelder & Reifer, 1999). In Hulme et al.’s (1997) study,  $i$  was held constant across simulations of different experimental conditions but allowed to vary across serial position to produce the serial position curve indicative of serial recall. That is, for a 7-item to-be-recalled list, different parameter values would exist for  $i_1, i_2, \dots, i_7$ , but these would be identical regardless of experimental condition.  $r$  was held constant within an experimental condition but allowed to vary across conditions. Hulme et al. (1997) argued that variation of  $r$  across experimental condition reflected the effect of word frequency upon the redintegration process, with representations of higher-frequency words supporting the redintegration more effectively than representations of low-frequency words (so  $r_{\text{high-frequency}} > r_{\text{low-frequency}}$ ). It was assumed that verbal short-term memory is essentially a by-product of processes involved in speech perception and speech production (Hulme, Maughan & Brown, 1991), with redintegration an integral part of speech production, representing the “clean-up” of noisy representations (e.g., within an underlying connectionist network). Similarly, Buchner and Erdfelder (2005) concluded that the word-frequency of the *distracters* must impact upon the probability of retrieving an intact representation ( $i$ ) because a model varying  $r$ , but with equivalent values of  $i$  across experimental conditions differed significantly from the data, whereas the expected data from a model with equivalent  $r$  but varying  $i$  across the experimental conditions, such that  $i_{\text{high-frequency distractor}} > i_{\text{low-frequency distractor}}$  were statistically indistinguishable from the

observed data. Buchner and Erdfelder (2005) conclude in favor of an account in which, “low-frequency distracter words require more processing resources that could otherwise have been used for keeping the memory representations of the target words active and intact” (p. 89).

The study by Buchner and Erdfelder (2005) is curious in that there is no necessary *a priori* reason why low-frequency distracters should attract more attention, or require more processing resources, than high frequency distracters – as these authors are careful to note. Previous studies, however, all used immediate serial recall rather than – as studied here – categorical free recall which draws upon semantic memory and appears to be more sensitive to the lexical properties of the auditory distracters than serial recall (Marsh, Hughes & Jones, 2008). In particular, auditory distraction may also occur within a semantic-memory fluency task in which speech production processes presumably play a large part (Jones, Marsh & Hughes, 2012). On this basis, and using the logic employed by Hulme et al. (1997), if it is possible to apply the Schweickert (1993) model to categorical free recall then the lexical effects of the auditory distracters should be most evident on the  $r$  parameter, reflecting interference with speech production systems, rather than the  $i$  parameter which might be interpreted – as, for example, by Buchner and Erdfelder (2005) – as a more general effect, possibly the result of an attentional mechanism drawing off processing resources.

### Modeling Recall and Disruption Within and Across Languages

To test these possibilities and simultaneously test the generality of the Schweickert (1993) model, the model was applied to a set of data obtained from English monolinguals and Welsh-English bilinguals. Bilinguals were used to test the possibility that distraction effects associated with the meaning of speech cannot be inhibited, and by extension the idea that the meaning of speech cannot be ignored. The free recall task was presented in one language (English) with speech distracters in either English or Welsh. The distracting speech (in either English or Welsh) consisted of words related to the same subject, or to a different subject. The typical finding is that both unrelated and semantically related speech (distracter words from the same category as the to-be-recalled items) give a distraction effect, but that there is a greater distraction effect for related speech (Neely & LeCompte, 1999). The effect, even for unrelated speech, is lexical rather than acoustic, because non-words and sinewave speech tokens do not disrupt recall (Marsh et al., 2008).

Where does the disruption originate? If the effect of related speech is conceptual in nature, originating from the organization of the speech planning and production system, then one might expect bilinguals to show equivalent disruptive effects of the meaning of the words regardless of their language of origin (English or Welsh). Conceptual effects of the irrelevant speech arising from

the disruption of speech organization in this way should be reflected in reductions of the  $r$  parameter of the model. Alternatively, if the effect is a non-specific lexical/attentional effect akin to that reported by Buchner and Erdfelder (2005) then the bilinguals might be expected to perform more like monolinguals when the irrelevant speech accesses a lexicon (Welsh) other than the one they are employing for the focal task (English). Any residual difference between the two groups, or between the disruption caused by related and unrelated speech should be accountable in terms of the  $i$  parameter, with lexical/attentional effects reducing the values of this parameter for those conditions that show the most disruption.

For the experiment, twenty-eight English monolinguals and twenty-eight Welsh-English bilinguals each viewed 28 trials of 12 target words, in English, visually-presented for free recall. Stimuli were chosen from semantic categories of the Van Overschelde, Rawson, and Dunlosky (2004) category norms. Items from positions 13-24 in the category-norm lists were used to form target lists and items from positions 1-12 were used as distracters. On half the trials, the auditory distracters were taken from the same category as the targets (e.g., both sets of stimuli were types of animals, and no “shape” exemplars were presented). On the remaining trials, the distracter items were taken from one category of the pair (e.g., fruit) and targets from the other category (e.g., carpenter’s tools). Additionally, half of the distracters were presented in English, and half in Welsh, yielding four separate conditions each experienced by both English monolinguals and Welsh-English bilinguals: English unrelated distracters (EU), English related distracters (ER), Welsh unrelated distracters (WU) and Welsh related distracters (WR). Space precludes a full analysis of the behavioral results, but a bar chart of the overall impact of distracters on both groups is given in Figure 2.

Figure 2. Total frequency of correct recalls across all conditions, summed across serial positions.

### Unrelated distracters across languages.

As with Hulme et al. (1997) and Buchner and Erdfelder (2005)  $i$  was allowed to vary across serial position, thereby

implementing the serial position function, but there was a single value for  $r$  regardless of serial position. multiTree software (Moshagen, 2010) was used to implement the models. In what follows, only models which fit the data are presented graphically.

Examining first the unrelated speech condition for bilingual participants, that is distracters – presented in either English or Welsh – semantically unrelated to the English language targets, the results could be modeled by assuming that neither  $i$  nor  $r$  varied across conditions with no significant difference between observed and expected results,  $G^2 = 15.67$ ,  $df = 11$ ,  $p = .15$ . This confirms the viability of the Schweickert model for categorical free recall and shows that – for Welsh-English bilingual participants – semantically unrelated distracters have an equivalent effect upon free recall of English words regardless of the language of the distracter.

Figure 3. Frequency of correct recalls across serial position by Welsh-English bilinguals for unrelated distracters in English and Welsh. Expected values according to the MPT model are given by the solid line.

For the English monolinguals, a similarly constrained model differs significantly from the data,  $G^2 = 33.95$ ,  $df = 11$ ,  $p < .001$ . Thus, for English monolinguals, there is a difference between unrelated English and unrelated Welsh words as distracters. Relaxing the constraints upon the model by allowing  $r$  to vary across conditions does not improve the fit of the model,  $G^2 = 30.6$ ,  $df = 10$ ,  $p < .001$ . Thus, whatever effect the presence of unrelated verbal distracters in a known language (which have a lexical status) has over the effect of distracters in an unknown language (for which no lexical entry exists), cannot be accounted for within the Schweickert model by a reintegration process. Unfortunately, it is not possible to test the effects of similarly freeing the constraints upon the  $i$  parameter, as investigated by Buchner and Erdfelder (2005), because varying  $i$  across conditions as well as serial positions imposes too few constraints on the model (Bachelder & Reifer, 1999).

### Related distracters across languages.

Applying the model to bilingual English and Welsh speakers exposed to irrelevant distracter speech in either English or Welsh that was semantically related to the English language to-be-remembered stimuli, a model in which  $i$  varied across serial position but  $i$  and  $r$  were identical regardless of the language of the distracter provided a good fit to the data,  $G^2 = 8.67$ ,  $df = 11$ ,  $p = .65$ . Thus, the distraction effects for bilinguals can be modeled using the same parameter values regardless of the language in which the distracters were presented.

Figure 4. Plot of frequency of correct recalls by Welsh-English bilinguals for semantically related distracters in English and Welsh. Expected values according to the MPT model are given by the solid line.

Unsurprisingly, a similar attempt to model the impact of semantically-related auditory distracters in both English and Welsh on monolingual English speakers was unsuccessful, with the best-fitting model differing substantially from the data,  $G^2 = 60.27$ ,  $df = 11$ ,  $p < .001$ . Allowing  $r$  to vary between Welsh and English distracter conditions was also insufficient to substantially improve the fit of the model,  $G^2 = 26.62$ ,  $df = 10$ ,  $p = .003$ . Thus, in terms of the Schweickert (1993) model, the extra impact, upon a visual-verbal free recall task, of an auditory distracter being in a known language must be upon factors other than redintegration. This is true regardless of whether the auditory distracter is unrelated, or semantically related, to the to-be-remembered targets.

### Comparing unrelated and related distracters within languages.

In addition to looking at the effects of bilingualism upon auditory distraction when the distracters are presented in different languages, it is also of interest to compare the effects of distracters *within* a single language. Using the model to investigate the effects of shifting the language of distracters has revealed that the language of the distracter is irrelevant provided it is a known language (Figures 2-4) and that the difference between known and unknown language distracters cannot be captured by a single redintegrative

factor. This is consistent with reports by Buchner and Erdfelder (2005) that the frequency of occurrence of words presented as distracters impacted upon the  $i$  parameter and not the  $r$  parameter, which they interpret as an attentional effect. However, there are *a priori* reasons to suppose that the difference between semantically-related and unrelated distracters *could* be captured by just such a single, redintegrative factor.

Hulme et al. (1991, 1997) argued that – in immediate serial recall – the effects of word frequency, captured by the  $r$  parameter in the Schweickert model, reflect the operation of a speech production system yoked into supporting recall. In an investigation of the effects of distraction upon a verbal fluency task of the kind frequently used to explore the speech production system, Jones et al. (2012) found an effect of semantically-related speech. Thus, it seems reasonable to suggest,

- 1) In free recall as in serial recall, speech production systems may play a role – perhaps by supporting covert articulatory rehearsal. This may particularly apply to categorical free recall, free recall of items from specific, reasonably circumscribed semantic categories.
- 2) If so, the effects of specifically semantically-related distracters might be traceable to this system via their impact upon the  $r$  parameter in the model.

Applying the model to the data, this time for the effects of related and unrelated English speech upon free recall by monolinguals, a model that does not differ significantly from the data is obtained by varying only the parameter  $r$  between the unrelated and related speech conditions,  $G^2 = 15.51$ ,  $df = 10$ ,  $p = .11$ . The fit of the model is given in Figure 5. To ensure that this fit was not possible simply because there was no difference in the data between the effects of related and unrelated speech, parameter  $r$  was constrained to be equivalent in both conditions. The resulting model differed significantly from both the previous model,  $\Delta G^2 = 11.84$ ,  $df = 1$ ,  $p < .001$  and the data,  $G^2 = 27.35$ ,  $df = 11$ ,  $p = .004$ .

Figure 5. Correct recalls by English monolinguals for semantically related and unrelated distracters in English.

Expected values according to the MPT model are given by the dashed lines and observed values by the solid lines.

Finally, the model was applied to the performance of Welsh-English bilinguals in the presence of English and Welsh distracters that could be either semantically-related, or unrelated to the target lists. Constraining the values of  $i$  to be equivalent regardless of whether the distracters were semantically related or not, but allowing the values of  $r$  to vary, resulted – as in the case of the English monolinguals – in a model that did not differ significantly from the data observed,  $G^2 = 20.67$ ,  $df = 20$ ,  $p = .42$ . This was defined as the baseline model, and the output of this model is shown, for Welsh and English, in Figures 6a and 6b.

Figure 6a. Frequency of correct recalls across serial position by Welsh-English bilinguals for semantically related (R) and unrelated (U) distracters in Welsh (W). Expected values according to the MPT model are given by the dashed lines, and observed values by the solid lines.

Figure 6b. Correct recalls by Welsh-English bilinguals for semantically related (R) and unrelated (U) distracters in English (E). Expected values according to the MPT model are given by the dashed lines

Additionally constraining the  $r$  values for semantically-related speech distracters to be equivalent across languages, and likewise constraining  $r$  for unrelated distracters to be equivalent across languages, produced a model that did not differ significantly from the baseline model,  $\Delta G^2 = .007$ ,  $df = 2$ ,  $p = .996$ , nor from the data,  $G^2 = 20.67$ ,  $df = 22$ ,  $p = .54$ . However, it was not possible to fit a model in which the  $r$  values were equated within languages, regardless of the semantic relationship between distracters (i.e.,  $r_{EU} = r_{ER}$  and  $r_{WU} = r_{WR}$ ), and were allowed to vary across languages (i.e.,  $r_E \neq r_W$ ) – such a model differed significantly from both the baseline model,  $\Delta G^2 = 57.16$ ,  $df = 2$ ,  $p < .001$ , and from the data,  $G^2 = 77.83$ ,  $df = 22$ ,  $p < .001$ .

## Discussion

The modeling results reported here show that it is possible to extend the Schweickert (1993) model of immediate serial recall to also apply to free recall, consistent with research (such as that of Tan and Ward, 2000), emphasizing similarities between immediate serial and free recall. More importantly, the model also shows that – for bilinguals – the effects of distracters presented in either of their languages are equivalent, even if the primary task on which the impact is observed (free recall in this case) is conducted wholly within one of those languages. Important issues are still to be worked-out with regard to bilingualism, e.g., second-language (L2) proficiency and the age at which L2 was learned, but it is notable that no simple means was found to model, in a similar manner, the effects of English and Welsh distracters on the performance of English-speaking monolinguals. Clearly therefore, for monolinguals, the effects of English and Welsh speech upon categorical free recall performance differed, even when the English distracter speech was semantically-unrelated to the target words. In this, the categorical free-recall task differs from other, notably serial recall, tasks in which foreign speech (including Welsh) has been played to participants, with equivalent effects to speech in their native language (e.g., Jones, Miles & Page, 1990). Whatever the basis for this difference, it cannot be located within a redintegrative stage affected by distracters from known versus unknown languages as manipulation of this parameter did not improve the fit of the model. This is broadly consistent with Buchner and Erdfelder's (2005) finding that varying the word-frequency of distracters within a known language was also more accurately modeled by varying the  $i$  rather than the  $r$  parameter within the Schweickert (1993) model. Unfortunately, known limitations of the modeling methodology employed (principally, the requirement for the model to be identifiable; Bachelder & Reifer, 1999), prevent further exploration of this issue given the experimental design available (for more discussion of this issue, see Buchner & Erdfelder, 2005).

A more interesting, and more positive, finding arising from the current study is that the semantic effects of distraction within a known language *can* be accounted for in terms of a redintegration stage. Comparison of semantically-

related with unrelated English distracter words amongst English monolinguals and Welsh-English bilinguals, and a similar comparison of semantically-related with unrelated Welsh distracter words in the bilingual group, all produce this same result (see Figures 5, 6a and 6b).

This finding is consistent with the data from Jones et al. (2012) showing a semantic distraction effect upon verbal fluency tasks generally considered to tap recall from semantic memory prior to speech-formulation and production, and is consistent with the hypothesis that redintegration reflects a “clean-up” stage in recalling items within the speech production system (Hulme et al., 1991, 1997). “clean-up” may seem to imply simply the filling in of blanks, or correcting of misinformation, within a single already-recalled item by reference to longer-term memory or lexical storage (Levelt, 1999). However, it may fulfill a more important function, namely one of identifying – by means of “cleaning-up” an incomplete or noisy representation – which one of several possible items is the correct one to recall in a particular instance (Nairne, 2003, personal communication). This is likely to be particularly important when, as in the current situation, recall is always from a list in which all of the target items are drawn from the same semantic category and therefore share many semantic and conceptual features. Under such conditions, identifying the correct item from several possible candidates is likely to be particularly important.

In this instance, it seems reasonable to suggest that the presence of semantically-related distracters compromises the redintegrative process at the level of retrieval of the word-concept, resulting in greater distraction than is seen with semantically-unrelated distracters. This suggestion is further supported by the fact that bilinguals show a semantic distraction effect from a language other than the one in which they are nominally working (that is, the English-language memory task). This implies that although the effects of speech on categorical free recall may be lexical (Marsh et al., 2008) the specific effects of semantic distraction across languages are conceptual, not lexical, in nature.

### Acknowledgments

The multinomial modeling research reported here was supported by ESRC grant RES-062-23-1752 to Dylan M. Jones and C. Philip Beaman. Thanks to John Marsh for providing the experimental data and to Robert Hughes for the Welsh language stimuli.

## Abstract

As part of an inquiry into how diagrams figure in scientific practice, we examine diagrams that represent phenomena involving circadian rhythms. Different diagrammatic formats are developed and revised over time to best represent different phenomena for which explanations will be sought. Some diagrams are less transparent than others, so learning is often required in order to see the information conveyed.

**Keywords:** Diagrams; Graphs, Mechanistic explanation, Visual representation; Circadian rhythms.

## Introduction

The notion of representation covers a lot of territory in cognitive science, encompassing both internal and external encodings of information and a variety of formats. Cognitive scientists have long focused on language-like internal representations, with some dispute over possible ways they might be supplemented by analog formats. Recent years have brought increased attention to external representations and especially to those incorporating analog formats—that is, diagrams. For example, Hegarty (2004) has shown how individuals perform simulations with diagrams in solving problems, and Cheng (2011) has explored how alternative diagramming techniques can foster learning. However, except for the pioneering analysis by Nessessian (2008) of the role of diagrams in Maxwell’s discoveries, there has been little investigation of the use of diagrams in science. Almost all scientific papers include diagrams, and readers often focus on these as they navigate a paper. They are well suited not only for displaying instruments, techniques, multistep procedures, and results but also scientific reasoning. Most generally this involves the construction, evaluation and revision of hypotheses but our particular interest is in sciences pursuing mechanistic explanations, notably the life sciences.

The project of explaining a phenomenon by identifying and understanding the mechanism responsible for it has roots in the scientific revolution beginning in the 16th century. Descartes posited that phenomena such as magnetic attraction are generated by the coordinated activities of constituent parts (in his case, hypothesized corpusecles). He applied the idea of contact action between particles to explain not just physical phenomena, but nearly all phenomena exhibited by living organisms. The only exceptions were reasoning and language use, which he attributed to an immaterial mind because he could not conceive of a mechanism capable of constructing novel, semantically appropriate

thoughts or sentences. The idea of mechanistic explanation quickly took root in biology. Although resisted by vitalists, who contended that something beyond physical processes was required for the functions of life, other early investigators of physiological phenomena embraced mechanistic explanations. As their inquiries progressed, researchers expanded the range of operations involved in biological mechanisms beyond Cartesian physical contact. Newtonian forces, chemical bonding, and electrical conductance were among the operations used in explaining such phenomena as metabolism, nerve transmission, and heredity.

Mechanistic explanation was largely overlooked by 20<sup>th</sup> century philosophers of science, who drew from physics the idea that scientists explain phenomena by deriving them from laws (Hempel, 1965). More recently, philosophers focusing on the life sciences have moved the spotlight once again to mechanistic explanation (Bechtel & Richardson, 1993/2010; Bechtel & Abrahamsen, 2005; Machamer, Darden, & Craver, 2000). Typically, life scientists treat the system that generates a phenomenon as a mechanism. They decompose it into parts and operations and then recompose it (conceptually, physically, or mathematically) to arrive at an account of how the coordinated performance of these operations could indeed generate the phenomenon.

Although one may try to describe linguistically the parts and operations of a mechanism and how they interact, often telling a narrative about how each part in succession performs its operation, diagrams generally provide a more useful representational format for conceptualizing and reasoning about a mechanism. Parts may be represented by labels, symbols, or abstract shapes, and the operations by which they interact represented by arrows. Diagrams can illustrate the structural and functional relations between many components and allow viewers to direct their attention successively to different activities that may be occurring concurrently in the mechanism.

The initial step in mechanistic research, though, is delineation of the phenomenon to be explained, and that is where we begin our inquiry into diagrams. Linguistic descriptions of phenomena have been the focus in many philosophical accounts of mechanistic explanation (e.g., “proteins are synthesized by constructing strings of amino acids in the order specified in a sequence of DNA”). However, scientists typically work with much more specific accounts of phenomena, often incorporating numerical values determined in their research. Frequently the numerical data relied upon in char-

acterizing the phenomenon is presented in tables. As Bogen and Woodward (1988) made clear, however, explanations are directed not at the data but rather at the pattern extracted from the data—the phenomenon. Some data patterns can be captured in one or a few equations, such as  $\Delta I / I = k$  (Weber's law). Even when equations suffice, but especially when they do not, scientists turn to diagrams to present the phenomenon. Diagrams turn out to be extremely useful for phenomena that exhibit interesting dynamics—patterns of change over time. Well-known examples include tide tables and EEG recordings.

To gain an understanding of these uses of diagrams in the actual practice of science, we focus on a domain of biology in which dynamics are fundamental: circadian rhythm research. Circadian rhythms are oscillations in activity with an approximately 24-hour cycle. They are endogenously generated but entrained to the timing of the day-night cycle in specific locales at different times of the year. They have been identified wherever sought, not only in animals but also in plants, fungi, and even cyanobacteria. They regulate a vast array of physiological processes (e.g., basic metabolism and body temperature) and behaviors (e.g., locomotion and reaction times in cognitive tasks).

Diagrams, of course, are processed visually. Although visual processing is highly complex (involving nearly half of the cortex in primates; see van Essen & Gallant, 1994), seeing often seems transparent: as we look out into the world, we have the impression that we directly perceive the identity and arrangement of objects in the visual field. The apparent transparency of diagrammatic representations of phenomena is part of their appeal—but this is deceptive. Transparent seeing is often the result of a great deal of learning. There are numerous experiments showing this, using complex scenes or illusory stimuli, but diagrams offer potent demonstrations as well. Some techniques of diagramming are so familiar and straightforward that we readily *see* what the diagram is meant to convey. But other techniques are new to us, and we must go through a process of learning before we see what is presented in the diagram. This is clearly true of scientific diagrams, as we will illustrate in examining what are likely for most readers to be unfamiliar diagrammatic formats developed by circadian researchers.

A related characteristic of diagrams on which we will focus is that scientists develop techniques for diagrammatic representation over time. Sometimes in seeking to represent new phenomena, they can borrow a format that had been developed elsewhere and is already well understood. However, existing formats may not offer the best vehicle for revealing what is significant in the phenomenon or for engaging in further reasoning about it. This drives scientists to develop new representational formats. Like other innovators, scientists typically must apply multiple rounds of revision to their first attempts at novel diagrams, finally achieving a format that meets their cognitive needs. Accordingly, representational formats employed in a science are not static but are developed and changed, and such changes can in

turn alter the cognitive processes of the scientists who construct them.

In this paper we examine several diagrammatic formats that researchers have developed to represent circadian phenomena. We especially focus on how these formats were introduced and revised and show what users of the diagrams must learn in order to interpret them.

## Diagrammatic Representations of Circadian Rhythms

A very familiar way of representing rhythmic oscillation is to employ a Cartesian coordinate system in which time is presented on the abscissa and values of a variable of interest on the ordinate. Many such examples can be found in diagrams of circadian phenomena. Figure 1 shows Aschoff & Wever's (1981) plot of potassium levels in urine samples taken every four hours from six individuals. To make the circadian pattern immediately apparent, they shaded the hours of darkness and connected each individual's data points to yield six superimposed line graphs.

Figure 1. Circadian oscillations in potassium levels for six individuals across four days, measured every four hours (From Aschoff & Wever, 1981).

Such diagrammatic representations make manifest whether the oscillations are regular and sustained (versus damped), the duration of each cycle, and the average amplitude and extent to which it varies across cycles. These can also be compared across diagrams for different individuals (as in Figure 1), variables, or conditions. But there are limitations to the transparency of such diagrams; some types of information are much less perspicuously represented. Accordingly, circadian rhythm researchers have developed other diagrammatic formats, each making particular phenomena manifest.

## Actograms

Even when Cartesian plots incorporate some representation of a reference oscillation (e.g. the light-dark cycles in Figure 1), they are not the ideal display for tracking the variable of interest with respect to those cycles across multiple days. A far more suitable format for this purpose is an actogram, in which stacked horizontal lines represent successive days, and short vertical lines mark each time the variable exceeds some threshold. (Where the vertical lines are dense, some investigators simplify the plot by substituting a solid horizontal bar.) Visual inspection then quickly makes clear any systematic changes across days in the circadian cycles.

The technique of representing activity in actograms appears to have been developed by Johnson (1926), who was investigating the nocturnal versus diurnal behavior of various mammals. Johnson devised the use of a disk rotated by a clock on which movements of a mouse in a cage were recorded as deflections in an otherwise smooth tracing (Figure 2, left side). While one could compare multiple circular tracings to assess changes or stability over successive days, Johnson introduced the actogram as a better format for this purpose. In essence, he unrolled each circular tracing (one day's data) into a straight line and placed each line below the previous one such that the hours of all days were in alignment. In this first actogram (Figure 2, right side), three sets of lines were presented so as to compare mice from three different environments (greenhouse, from lab to woods, and woods). Within a set, the top line is Day 1, second line is Day 2, and so forth. Comparison was made more precise by running a vertical line at two-hour intervals, beginning and ending at 6 am. A shorter vertical line marked the onset of sunset, a convention not maintained by subsequent researchers. A major virtue of the actogram is that viewers can employ their visual ability to detect differences in the pattern of marks so as to compare circadian rhythms across days or conditions. It can be seen that these nocturnal animals are active primarily at night, with variations between conditions in onset time and in the extent of daytime activity but considerable stability across days within each environmental condition.

Figure 2. On the left, Johnson's (1926) tracing from a rotating disk illustrating periods of activity by a mouse. On the right, his first actogram in which activity for each day under different conditions is shown on successive lines and the time of sunset is indicated by a vertical line.

In a subsequent investigation (Figure 3) Johnson showed the effects of exposing a deer mouse to different light-dark conditions (as indicated by labels along the right edge rather than by spatially separating conditions): (1) normal light-dark cycle (light during daytime hours, dark at night); (2) constant darkness for several 24-hour periods; (3) reversed light-dark cycle (dark from 8 am to 8 pm, then light from 8 pm to 8 am); (4) again, constant darkness. One can immediately see that the periods of activity showed little change when the mouse was transferred from normal light-dark

cycles to constant darkness, but shifted dramatically when light was reintroduced in reverse: with the dark hours now in daytime, the mouse became active during day rather than night hours. This altered pattern was maintained when constant darkness was reintroduced. Thus, once entrained to a particular light-dark pattern (normal or reversed), mice kept to the same activity cycle when the entrainment stimulus (light) was removed.

Figure 3. Johnson's (1926) second actogram, which shows a mouse's activity as light-dark conditions were changed as indicated on the right.

Since introduced by Johnson, the actogram has become a standard way of representing circadian activity, especially in animals. While the basic format has been preserved (one line per 24 hours, hours aligned vertically, active times marked along the line), many variations have been introduced to make specific features of circadian behavior more explicit. As just illustrated, chronobiologists are particularly interested in activity under constant darkness (known as *freerunning* behavior). Since this condition eliminates any effects of daily entrainment to sunlight, it can reveal the animal's normal endogenously generated rhythm or (as in Figure 3) the enduring effects of resetting that rhythm via an abnormal light-dark condition. Various conventions have been adopted for conveying lighting conditions visually, rather than by labels along one side as in Figure 3. One is background shading of the actogram across those hours the organism is in darkness (similar to the shading superimposed on the Cartesian plot in Figure 1). Another common convention is horizontal bars at the top or bottom of the actogram, in which white indicates hours of light and black indicates hours of darkness. Thus, in Figure 4 the top bar indicates the normal light-dark condition used as a baseline on days 1-7 and the bar below it indicates that constant darkness was imposed thereafter. It can be seen that once in constant darkness, the mouse's activity begins about a half hour earlier each day. From this it can be concluded that the endogenous period is about 23.5 hours.

A variety of conventions have been developed to indicate temporary changes in conditions. In Figure 4, the gray arrow indicates a day on which a light pulse was presented four hours after activity onset. This not only caused activity to mostly cease for that evening, but also inserted a phase delay the next day into what was otherwise a continuing pattern of phase advance due to constant darkness.

Figure 4. Contemporary actogram in which the top bars indicate a normal light-dark condition for the first seven days and constant darkness for subsequent days. The grey arrow identifies the day a light pulse was administered. (From <http://www.photosensorybiology.org/id16.html>.)

A major innovation in actograms was the introduction of double-plotting—a procedure in which data from the next 24-hour period is plotted not only on the next line but also to the right of the current data. Thus, each line shows data from 48 hours, but the left half of the actogram stacks all 24-hour periods as usual (as does the right half, redundantly). One of the first uses of this technique, by Pittendrigh (1960), well illustrates its particular advantage when activity periods extend across the 24-hour boundary. Pittendrigh was seeking to represent what he called an “after effect”: altered circadian rhythms in the activity of a nocturnal animal after exposure to continuous light. He began with normal light-dark cycles (LD). As shown in the top third of Figure 5, the mouse is inactive when the light is “ON” and becomes active when the light switches to “OFF” (with some subtleties in the data we need not discuss). When he then imposed continuous light (LL), the resultant progressive delay in activity onset indicated the mouse’s day had been stretched longer than 24 hours. After a few weeks, however, it spontaneously shifted back to a nearly 24-hour period. Since double-plotting was new, Pittendrigh marked the divide between the two 24-hour periods with a double vertical line, a convention later dropped as researchers became accustomed to double-plotting. (The convention of indicating lighting conditions with white/black horizontal bars had not yet been adopted, hence Pittendrigh’s ON/OFF markers). The virtue of double-plotting is that one can easily see the full active phase even when it crosses the 24-hour boundary.

Figure 5. Double-plotted actogram from Pittendrigh (1960), in which data across the 24-hour boundary can be viewed in the middle of its redundant 48-hour display.

Because they provide an effective visual display by which researchers can immediately see variations in patterns of circadian activity, especially in relation to different lighting conditions, actograms have remained an important part of the toolkit for those circadian researchers who use animal behavior measures.

### Phase Response Curves

The circadian cycle can be thought of as a progression through phases, beginning at the time designated hour 0 (typically dawn) and ending at hour 24. The term *phase* may be used with respect to particular points on the curve (the peak and the trough being of particular interest) or for intervals (e.g., subjective day and subjective night under constant darkness). When two different cycles are closely aligned, they are said to be *in phase*. As already noted in the discussion of Figure 4 above, an actogram can show whether and by how much a rhythm is reset following a light pulse (its phase shift). As they explored this phenomenon in the 1950s, circadian researchers soon recognized that the direction and extent of the phase shift depended on the timing of light-dark cycles relative to the animal’s current circadian cycles. Individual instances of resetting could be shown in actograms, but to identify and represent the systematic pattern of resetting, researchers developed what are known as *phase response curves*.

Examining one of the first attempts to represent the effect of light on circadian phase makes evident the challenges in developing an easily interpreted diagrammatic format. Hastings and Sweeney (1958) grew *Gonyaulax polyedra*, a photosynthetic marine dinoflagellate that produces luminescence when disturbed, first under a normal light-dark cycle and then in constant darkness. Next they exposed these organisms to a three-hour pulse of light, varying the time of the pulse so as to determine how much that shifted the time of maximal luminescence. Their results are shown in Figure 6, where hour 0 is the onset of constant darkness. The time of maximal luminescence in control organisms (who were

not exposed to the pulse) is shown by the vertical lines at 7, 31, and 55 hours. The horizontal lines represent organisms exposed to the three-hour pulse at different hours of delay after the onset of darkness (3, 7, 11, . . .). Curves have been fit to data points marked by small triangles, which indicate the time of their subsequent maximum luminescence. The distance of each data point from the nearest vertical line represents the degree of advance or delay. It can be seen by following the horizontal line labeled “23” that organisms exposed to a 3-hour light pulse beginning 23 hours after onset of darkness show maximum luminescence at hour 32 rather than 30, a phase delay of 2 hours. In contrast, pulses beginning 7 hours after darkness produce a large phase advance. While this diagram does encode the crucial information, interpreting it takes considerable effort.

Figure 6. Hastings and Sweney's (1958) diagram showing the changes in peak luminescence of *Gonyaulax polyedra* after 3-hour light pulses. These changes are represented by the distance left or right from the vertical lines.

Shortly thereafter DeCoursey (1960) introduced a different format for representing the same information (Figure 7). In her study of flying squirrels kept in constant darkness she indicated on the abscissa the time of a ten-minute light pulse relative to the usual onset time of an animal's running-wheel activity. The data points indicate the consequent advance or delay in onset of running for two squirrels. With this representation, it is easy to see that light around the beginning of this nocturnal animal's usual activity period (corresponding to the beginning of its subjective night) delays its activity, whereas light 8 to 12 hours later (corresponding to the end of its subjective night) advances its activity. Light during its subjective day (from approximately 12 hours to 0 hours) has no effect. Having represented the phenomenon this way, one can also readily make sense of it—light exposure during subjective day does not indicate a need to reset the phase of one's activity, whereas light at the beginning of subjective night indicates either that the endogenous rhythm is out of synchrony with the external environment or that the period of daylight has expanded. The appropriate adjustment is to delay activity. Likewise, light experienced at the end of the subjective night indicates a need to stop its activity sooner.

DeCoursey's phase response curves quickly became the established means of representing the effect of a stimulus on the phase of an organism's circadian oscillation, although later researchers simplified the abscissa to circadian time (0-

24 hours) and, often, flipped the ordinate so that advances are shown as up and delays as down. Represented in this fashion, as in Figure 8, researchers were able to contrast two patterns of resetting—one producing gradual advances or delays (*Type 1*) versus an alternative (*Type 0*) in which, rather than small advances or delays, at a critical point the organism exhibits a large delay. If this delay is more than 12 hours, it can be seen as a large advance.

Figure 7. DeCoursey's (1960) phase response curve, which shows the advance or delay of a rat's activity onset for light pulses at different times relative to normal activity onset.

Figure 8. Type 1 and Type 0 phase response curves, with a simplified abscissa (0=dawn). From Johnson (1999).

To facilitate characterization of these two types of resetting, circadian researchers developed yet another diagram format, the phase transition curve, in which the new phase, not the amount of advance, is plotted on the ordinate. Diagonal lines indicate the situation in which the phase does not change. To see what happens in Type 0 resetting, one must plot 48 hours on the ordinate. As seen in figure 9, Type 1 resetting is characterized by a curve that stays very close to the diagonal and so approximates a slope of one (from which the name Type 1 is derived). In Type 0 resetting there is an abrupt jump from one diagonal to another, approximating a slope of 0. A virtue of the phase transition curve is that it makes clear the relation of the new phase to the old, which is not directly displayed in phase response curves.

Figure 9. Resetting represented in both phase response curves (left) and phase transition curves (right). From Johnson (1999).

## Discussion

Of the representational formats used by scientists in performing and communicating their research, diagrams are particularly important but not yet extensively studied. We began our exploration of this topic by examining the use of diagrams to delineate phenomena. More specifically, we examined how actograms, phase response curves, and phase transition curves each highlight, and enable scientists to see, different circadian phenomena. Once delineated, such phenomena are explained by working out the responsible mechanism, and in later work we will examine other kinds of diagrams and their roles in mechanistic explanation.

We have drawn attention to the fact that scientists are often developing new representational formats to make manifest the specific phenomena in which they are interested. It is important to note that the researchers who devised the formats in Figures 1-9 were not seeking the best way of representing all circadian phenomena in a single diagram; rather, each sought to elucidate a specific phenomenon, such as changes in phase or the susceptibility to entrainment by light. In highlighting one phenomenon, each format either obscures or leaves out others. Actograms make clear how the phase of rhythms changes when an animal is switched to a free-running condition or exposed to a specific perturbation, but they do not show whether the rhythm is dampening or how the phase would change across the full range of possible times of perturbation. Phase response curves do this

latter job, but do not display phase changes after a switch to free-running.

New representational formats make new cognitive demands on audiences. If these formats were new to you, you also experienced the learning that is required to see what each diagrammatic format is representing. Only after learning to see the phenomenon in the diagram can the scientist use that format to efficiently reason about the phenomenon and begin the work of explaining it.

## Abstract

In a novel experimental task, individuals are asked to navigate from a start word to a goal word through a semantic network. In this forced-choice task, individuals perform with a high success rate (73%) and frequently navigate to the target in the minimal number of required steps (22%). We utilize these experimental results to explore different search and decision strategies. Our descriptive modeling results suggest individuals are not guessing at random (or utilizing only local information) and that knowledge of the global structure is necessary for individuals to succeed. We further show that a latent semantic space model, such as word association space, can capture much of the global semantic knowledge necessary to explain participant decisions. We suggest that performance in this task might capture some of the underlying structure of semantic memory and, importantly, search within memory.

## Introduction

Much work within computer science and informatics has looked at humans as information foragers (Fu & Pirolli, 2007). In many analyses, foragers rely on the structure of the environment for information foraging cues. While we know humans are able to search and gather information from a variety of environments (Fu & Pirolli 2007; MacGregor et al, 1986), we ask what happens when individuals are themselves responsible for both the structure in the environment as well as for searching on and within the structured environment. We use semantic navigation as a task in order to examine this aspect of search.

Semantic navigation includes any and all orientation and search within semantic knowledge. This could be due to communication between individuals, comprehension of auditory and visual language or encoding and retrieval of vocabulary within memory. Semantic space is unique in that it has been shaped not only by individual experience but also through cultural and historical contexts. Unlike searching on the web (Fu & Pirolli, 2007) database menus (MacGregor et al, 1986) or Wikipedia (West et al, 2009), semantic search requires searching on a naturally evolved but explicitly learned representation.

This added level of implicit knowledge of the structure of the environment might allow for foragers within semantic space to utilize the environment more effectively and quickly. We know from past work, that humans are already very good at navigation even in foreign environments such as the web (Fu & Pirolli, 2007). We set out here to see if

individuals can explicitly navigate semantic space and how much individuals rely on local information, available in many types of foraging tasks, as well as global information, which is available through previous linguistic experience. We give individuals a start location in the semantic network and ask them to build chains of associates to get to a target location. This data provides us with the decisions of individuals which can in turn tell us about the underlying navigation process and semantic environment.

Results from computer science have also suggested what types of networks are most easily navigable and Kleinberg (2000) has done simulation work considering what properties networks must have for humans to successfully navigate through them. This work operates within a *message passing* paradigm, in which navigation occurs via a series of independent, uncoordinated routing decisions in which each node selects a neighbor to serve as the next decision maker in the passing chain. An important complement to this family of problems is a *route choice* paradigm, in which a single decision maker identifies the entire path to be followed.

More recently, work exploring human navigation of semantic network paths (from start to goal) has been conducted within the route choice paradigm. Specifically, in relation to this work, this has been studied in Wikipedia where individuals are given a start Wikipedia page and asked to navigate to a goal page (West et al, 2009). Whereas this work does rely on human cognition, the results of this work focus mostly on computer science implications. We hope to expand this work by exploring the cognitive implications of an individual's decisions.

To achieve this goal, we consider how humans navigate through realistic semantic network representations and, therefore, consider a novel task in which individuals are asked to navigate in a predefined semantic space. Because so little work has been done on semantic network navigation by a single individual, we set out in this paper to answer some fundamental questions. The most obvious being whether individuals *can* navigate a semantic network without being given explicit global information regarding network structure. To foreshadow our results, they can and will do so quite well in specific situations. This leads to other questions, such as what type of information might individuals be using in making routing decisions; how much local information is utilized in our specific network representation versus how much knowledge comes from global language knowledge. More generally, what can this tell us about human cognition, navigation and search?

We consider semantic space because individuals receive a great deal of linguistic input through a variety of different media. While we do not believe that every individual has the same semantic representations or knowledge, an important goal of language is communication, which facilitates the need for convergence to a similar, if not identical, representation. The fact, however, that imposing a pre-determined structure does not disallow success within this task suggests that even an impoverished representation of semantic knowledge still contains enough information for participant success.

We begin by describing the semantic network and the experimental task. Then we discuss the performance results and examine them in light of descriptive and cognitive interpretations. We consider descriptive statistics and qualitative models to help build the foundation for future modeling work. Our results importantly suggest that individuals have a specific route choice strategy, and that this strategy is greatly impacted by the similarity of an option to the end word. That is to say, individuals have some idea of distance from their current location to the goal and are often able to use this global information to navigate to the goal. With these main results, we then discuss the future for navigation models and their impact on our understanding of human cognition, navigation and search.

## Methods

### Semantic Network

Our task is rooted in the idea that individuals use both global and local information from the network. However, it is difficult to measure a semantic network for each individual, and moreover, sampling an individual's semantic network may bias the network and participant responses. To get away from these issues, we assume that individuals have similar semantic representations and that these representations can be approximated by a network based on the Florida Association Norms (Nelson et al., 2004). While it seems unlikely that each individual has precisely the same network, an important goal of language is communication with others, suggesting that convergence on the same underlying network would be highly beneficial. Such a network could be recovered through an aggregation process, such as the Florida Association Norms (2004).

The Florida Association Norms (2004) were generated by asking participants to indicate the first semantically related word that came to mind when given a cue word. Because this was asked of many participants, we have many different associations as well as a population level proportion of responses to each cue. For example the word DOG might often elicit CAT but a measurable proportion of participants may respond with BONE. We consider a directed link between words to exist from cue to response if the cue word reliably generated the response word. Each association also has a weight equal to the probability of its elicitation. For example we consider both CAT and BONE to have a link from DOG but the link to CAT receives a higher weight

since more individuals responded with CAT. This network is not symmetric. For example there exists a link from CAT to DOG but not from BONE to DOG.

Altogether 5008 words are included in the association norms with most responses being asked about as cues. However, in our experiment, we use a subset of the network. We trim the 5008-word network by including only words that had more than three words leading in as well as three leading out; we further removed the weakest connections when there were more than 12 associates. In cases where there were multiple associates with minimum strength, all were removed even when the resulting set was less than 12. We trimmed the network so that individuals would have fewer choices to sift through, were less likely to end up selecting an option that led to limited choices and to prevent trials with only a few successful paths. Limiting in-associations resulted in removing words like MOO since it is only generated in response to COW and thus all successful paths require going through COW. Further, LEFT elicits only the response RIGHT so we exclude LEFT and other similar words since it results in loops, or in the more general case, very limited options. This trimming resulted in a smaller network consisting of 2392 words. This network maintains the small world structure of the full network with a short average path length (4.19), a small overall diameter (8) and is a fully connected graph.

### Word Navigation Task

In this task, individuals were given a start word and asked to navigate to a goal word. They were presented with between 3 and 12 associations of the start word and asked to pick the option that they believed would get them closer to the goal word. The selection was then centered in the screen and the next available options were generated from this word. See Figure 1 for a screen shot from the actual experiment. Each subject repeated this process until he or she reached the goal word or made a total of 25 choices (steps). Individuals could also select an undo button, which took them back to their previous decision. This incremented the 25-step count and could be repeated until the start word was reached.

Because the options individuals received were based on the association norms, we had participants complete a quick version of the association norms task. We selected 50 words that were included in the original norming study but were excluded from our experiment based on our above network trimming. After participant completion of the association task, they received verbal instructions for the word navigation task—they were told that the choices they would be offered were generated in the same manner as the task that they just completed. This was done to aid in task understanding and minimize frustration during the task. Participants then began the computer task in which they again received written instructions, an example trial and 3 practice trials before a final set of written instructions. The example trial explained the layout of the experiment whereas the practice trials allowed them to try simplified variants of the word navigation task. On the practice trials,

participants received feedback as to how many steps it took them as well as what an optimal (fewest number of intermediate words) solution would have been. After the three practice trials, they were given a few lines reminding them of the goal of the task and the opportunity to ask the experimenter should they have any questions.

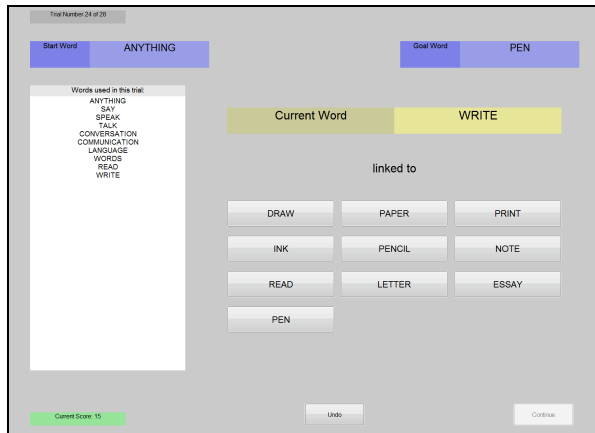

Figure 1: Screen shot of the experiment.

The test trials consisted of 28 trials divided into 4 blocks. Each block contained 7 trials, 3 requiring minimally 3 decisions, and 2 requiring each of 4 or 5 decisions. Trials were prescreened in a pilot study. Problems that were successfully completed in 15 steps or less by at least 1 out of 3 participants were selected. The block order was randomized and trials within each block were also randomized. When the 25-step limit was reached a screen popped up that said “Thank you for trying. You were # steps away,” where # was the number of words between the last word clicked and the goal. They could always see previously selected words as well as the start word, goal word and current word. At the end of the first block, participants received feedback on the overall number of steps taken in that block. In each subsequent block, they could see their current block score at the bottom left of the screen. After completion of each block, a screen reported their overall performance on the completed block as well as the minimum score on any block thus far.

Overall, 53 undergraduates at University of California, Irvine were run in an experiment that lasted maximally 1 hour. Two participants did not complete the task in the allotted time and their data were excluded before analysis. All participants received course credit for completion of the experiment. To prevent meaningless clicking, an experimenter was within earshot for the length of the experiment and participants were warned that they would not receive credit unless they completed at least one trial. Every participant satisfied this requirement.

## Results

### Experimental Results

The first important result of this work is that individuals can reliably navigate semantic networks, moving from start to goal words in a relatively small number of steps. Every trial was solved by at least 15.1% of individuals with the average trial being solved 73.3% of the time and maximal success rate at 92.9%. The information in the semantic network is sufficient for individuals to navigate effectively. Individual performance over all trials varied from 28.6% correct to 92.9%. Further 22.2% of trials were solved in the shortest number of intermediate steps.

Figure 2: Subject performance on trials of varying min. length. Dark gray bars: proportion of trials correctly solved, light gray: proportion of trials solved in minimal number of steps. The solid line indicates unweighted random walk performance and the dashed, weighted random walk.

We expected to see a difference in success rate based on the number of minimum decisions required and figure 2 shows a general population level trend that trials requiring minimally 3 decisions have the highest success rates; however, the variation across trials suggests that more is going on. Figure 2 shows the results for each problem organized by minimum number of required steps. The first frame contains trials with minimally 3 decisions, the second 4 decisions, etc. The dark gray bar indicates the proportion of individuals who correctly solved that trial in 25 steps or less. The light gray bar indicates the proportion who solved that specific trial in the minimum number of decisions. The trials are rank ordered from least to most solved within each set. We see a general trend here that problems requiring fewer minimum steps are solved more often. This is an interesting finding since participants are not told the minimum length of a trial. We are also not considering the strength of the connections, the number of options or how quickly these problems were solved—instead the fact that the minimum number of steps can be used to help explain performance suggests that the information individuals are using during this task is sensitive to distance in the network. Salient information about distance seems to be present locally given the correlation between distance and

performance. Further, we find a similar relationship between optimal performance and minimum distance with shorter trials finished more optimally.

The trend suggesting that problems with fewer minimum steps are easier does not capture the full complexity of the task or responses chosen. With a closer examination of the results in figure 2, we see that there are many trials that violate this trend. For example, there are a few trials of medium length that are more often solved than shorter trials (and some that are more often optimally solved). It is also interesting to note that the trial that is solved most often has one of the lowest rates of “optimal” performance. This may suggest that our definition of optimal is not the correct baseline for human performance.

We are also interested in capturing the descriptive trends within individual trials. To understand what these trends might look like, we explore one problem in depth. Figure 3 shows the breakdown of a single trial. Only correct responses are included and the weight of the arrow indicates the proportion of individuals who chose that path. This trial has a high success rate and a high percentage of minimum distance paths. The minimum distance path runs along the left. This figure helps illuminate the cognitive process that may be underlying the strategy.

Figure 3: Network based on successful trials; participant responses from start word ANYTHING to goal word PEN.

For instance we can see that each option of ANYTHING led to at least one correct response—that is to say, individuals do not remove their chance of success by picking the wrong option at the first decision. Another important feature is that there are multiple successful paths. Looking closely we can see that individuals are utilizing the undo button to further explore the semantic space. For example an individual at the word PAINT selected BRUSH, but then decided to go back to PAINT. While it is difficult to say exactly why s/he made that choice, it would seem plausible that s/he went back to PAINT because s/he felt

that it was closer to the goal word of PEN than BRUSH was. Another interesting result that we can see from a detailed examination is that the word definition might change based on the goal word. This is most clear in the path that goes from ANYTHING→EVERYTHING→WORLD→EVERYTHING(undo)→LIFE→MAGAZINE→PAPER→PEN. Here we see that the undo button was used to back up after making a decision to go to WORLD. Further, this individual selected the word LIFE from a list of words associated to EVERYTHING. This suggests that the definition coming to mind was one of living, however, with the goal of PEN, s/he utilized LIFE to get to MAGAZINE, suggesting an interpretation of life magazine. We can also see that s/he does a similar thing in going from MAGAZINE to PAPER (likely newspaper) but then from PAPER (something to write on) to PEN.

### Random Walk model

Though the data suggest that individuals are able to solve these semantic navigation problems (to varying degrees) it is possible that participants are guessing and that the structure of the network allows for high rates of success. To test this assumption we considered two types of random walk models. The first is a random walk model that simply checks if the goal word is present and if it isn't, randomly selects from the available options. The second random walk model picks the goal word if present and otherwise randomly selects from the available options with a probability distribution equal to the association norms data (e.g. if CAT was the response to DOG 80% of the time, this random walk would pick CAT 80% of the time as well). In figure 2, the two random walk models are indicated by a solid red (unweighted) and dashed blue (weighted) line. Both random walk models perform worse than our participants. The general trend does not follow that of the participants—problems frequently solved by random guessing are not those that participants most often solved. This confirms the hypothesis that individuals are utilizing global information present in semantic space in the task.

### Descriptive Geodesic model

Now that we know individuals are not guessing at random, we combine the results suggested by the data to build a descriptive model of the decisions individuals make. To do this we consider the geodesic distance (number of steps between two nodes) of the current word to goal word to see if individuals are more likely to select words with lower geodesic. We know that individuals do not always pick options that decrease the geodesic because that would result in optimal performance. However, we can plot the distribution of subject choices and the distribution of all options to see if some of the success can be explained by sensitivity to geodesic distance. Figure 4, top graph, shows the distribution of geodesic from current word (WRITE in figure 1) to goal word (PEN in figure 1) along the x-axis. Options (grey buttons in figure 1) to goal word fall along the y-axis. Here we can see that proportion of choices made

by individuals, as indicated by the size of the box, look different than the full set of options. This is particularly pronounced at low geodesics (heavy weight along the near-diagonal indicates more optimal decisions). The difference between subject choices and options becomes almost unrecognizable as the distance between current and end word increases to a geodesic near 4 or greater. This suggests that individuals have knowledge of the general location of the goal word and that this becomes more accurate as they get closer to in minimal number of steps to the goal. It also suggests that individuals may be picking up on a gradient but that they might be guessing until they get close enough to the goal word to find the gradient.

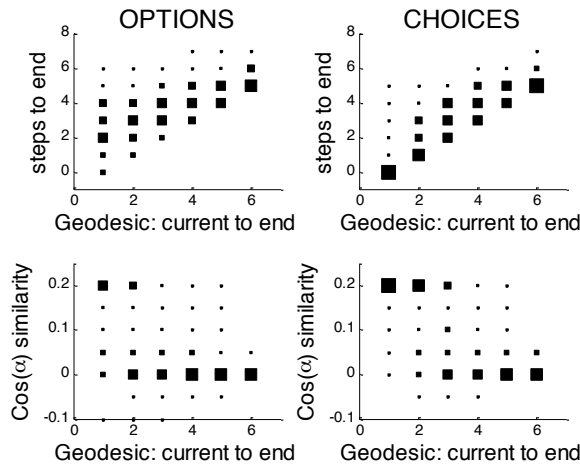

Figure 4: The top panels, based on geodesic distance, represent the distribution of options (left) and participant choices (right) with the size of the square indicating frequency of observation. The bottom panels capture local language-level information based on cosine similarity in latent space.

### Latent Space model

While we consistently have been talking about navigation within a network, it is not necessary to assume individuals represent a complete network in memory. Instead it is likely that the representation is a reduction of this network—a summary of global information that allows individuals to locate their current position in the network as well as access local knowledge of nearby words. One reduction that has been widely studied in semantic memory is that of a reduction of the dimensionality of the semantic space by vector decomposition (latent space analysis, e.g. Landauer & Dumais, 1997; Burgess & Lund, 2000). While we considered a variety of latent spaces, we present data only on the symmetric WAS space from Steyvers et al. (2004). Our goal is to capture the same population level trends as we did previously with the descriptive geodesic model but with a semantic latent space that would be more cognitively plausible and require less information than the full network. To do this, we again consider figure 4 (lower panels) and

the geodesic between current and goal (x axis) but compare that to the latent space cosine similarity of options (panel 1, lower row) and subject choices (panel 2). Whereas, in the geodesic case, weight along the diagonal indicates more optimal choices, high cosine similarity suggests nearness to the target. In this graph, we expect higher weight on similarity judgments to capture more optimal choices. We again see a noticeable difference between selected choices in comparison to all options, moreover, the general trends of the latent space model follow a similar pattern to that of the geodesic in that individuals’ choices are indistinguishable from guessing at higher geodesic. The latent space model offers an explanation—the cosine similarity is near zero for all options such that participants may not be able to use similarity and instead resort to guessing

### Discussion and Implications

Our results suggest that individuals are succeeding by utilizing information present in the network in order to get closer to the goal word. We know that their decisions can be explained at least in part by the local information in the options, especially relative to the goal word. Their success is not, however, based on random guessing or strong associates. This is an interesting finding since it suggests that the information individuals are using is not captured by the environment of the free association task alone. Further, the paths individuals do end up utilizing appear to suggest that the semantic space may be changed and altered by the goal word implying that individuals have a direct influence on their environment. That is to say, the entire structure of the network may be influenced and changed based on the goal. Though we only gave one example in the text, it is not unique. Individuals often interpret words in light of the goal word as opposed to the current word. This adds a dynamic component to network structure that we know exists in memory and knowledge more generally. This task, further gives us a way to study the dynamic nature of semantic knowledge and the role of context in speech.

We also see that there is a large variance in potentially successful paths and that the shortest path is not always the most salient to individuals. While we have not specifically analyzed the difference between shortest paths and participant paths, West et al. (2009, 2012) have looked more closely into this question in Wikipedia navigation and suggest that shortest paths often require out-of-the-box thinking whereas paths that are a bit longer allow for a more obvious chain of associates. We hope to test this directly utilizing our data in the future.

Another important finding is that individuals seem to be making more optimal decisions (ones that get them closer to the end word) when they are already close to the end word. This suggests that individuals can intuit how far away the goal word is without having exact knowledge of the space. This is a result that has been found in most navigation studies (e.g. West et al. 2009) but most studies suggest that the way individuals get closer to the goal is by navigating to hubs with many out-links and utilizing these hubs to get to

an area of the network. However, in our study, we thresholded much of the hub structure away by allowing maximally 12 options for any word. Participants could not simply navigate to a central hub and then jump towards the goal word. Instead, we believe that this ability to perform more optimally when closer comes from the fact that individuals have a semantic representation that allows them to compute distance between two words but that this semantic representation is limited to identification of a relative location. Further, the ability to identify a word as near requires a level of information about current location and goal location that is not always available, specifically when individuals are further away from the goal. Going back to Figure 4, we see that individual choices look very similar to options both in geodesic and WAS space when many words are needed to complete the trial. This suggests that, if individuals are far enough away, guessing might be their main strategy. However, guessing may be the best thing for individuals to do since there is little information available to them (as captured by WAS) and, based on network structure alone, often places them in a better or equal position (in terms of geodesic) than before.

WAS space captures most of these global trends. Particularly, WAS space is often near zero unless there is a strong similarity between words—implying that they are close enough in the network that individuals can sense it. This space also captures the noisiness of relative distance. Since individuals only have a very general idea of goal location, any estimates of which choice is closer to the goal is less exact as the distance between choice and goal increases—which is captured by cosine similarity.

In the future we hope to extend our understanding of network navigation through a relational event model (Butts, 2008). That is to say, we can assume every decision is independent once we condition on the goal word and current word. With independence, we can apply a multinomial logistic regression on linguistic and network-based covariates. We hope to use this model to show how the current and goal word influence decisions as well as more specifically exploring the specifics of language in this task.

We also hope to experimentally test subjects on other types of networks. Since all subjects in this study are natural "experts" in language, there is still the question of whether a more limited level of prior knowledge of the underlying network is still adequate to allow successful navigation and search. Work on folk knowledge of networks suggests that individuals are not very good at reconstructing social networks (Freeman et al., 1987) but our results suggest that success on this task may not require an accurate or even complete network representation, since most individuals succeeded on a variety of problems even though our underlying network of the task is impoverished.

Not only do the applications extend beyond cognitive understanding, but the fact that individuals can navigate suggests that network representations are useful. While we consider semantic space here, many other types of knowledge can be represented as a network, such as social

relationships or a schedule. We believe that the results in this paper speak much more broadly about navigation than they do about language navigation specifically. A model of network navigation may be useful in explaining search, decision-making and even memory. Network structure captures many naturalistic relationships. However, unless we understand ways in which individuals are able to navigate this type of structure, we cannot utilize this representation in cognitive architectures. With this paper, we've begun to address the first concerns of understanding how individuals navigate a network structure, providing us with a new direction for navigation within memory.

## Acknowledgments

This work was funded in part by an NSF GRFP to the first author and by ONR/MURI under grant number N0014-08-1-1015 to Carter Butts. Thanks to Michael Yi for help in concept development and Sarah Hunt for running subjects.

## Abstract

The abstract deontic selection task was developed with the aim of demonstrating abstract rule use in a specific domain (i.e., deontic rules). Yet, the solution rate, while being substantially higher than with abstract *non-deontic* tasks, did not reach the level obtained with *concrete* deontic tasks. What are the reasons for this—difficulties with abstract rule use? A task analysis based on deontic principles uncovers several problems with the formulation of the task. Three experiments replicate the difficulties with the original task and show that performance increases, when the problems are resolved. The results provide novel insights into the interpretation of deontic rules and into the role that such content-specific, but abstract tasks can play for the study of reasoning processes.

**Keywords:** Deontic reasoning; social rules; deontic selection task; dual process theory; pragmatic reasoning schemas.

## Introduction

Abstract reasoning is typically considered as more difficult and error prone than contextualized reasoning. A widely accepted and often cited case in point is *Wason's Selection Task*: The classical abstract task demands testing whether an arbitrary conditional statement is true or false (Wason, 1966) and is solved correctly only by few participants (10-20%). In contrast, structurally similar but contextualized versions that demand testing whether or not a concrete deontic conditional is being followed (e.g., Cox & Griggs, 1982) are solved correctly by the majority of participants (about 75%; Evans, 2003, p. 456; cf. Beller, 2010).

According to the *dual-process account* (Evans, 2008), abstract reasoning is characterized as domain-general, rule-based, sequential, controlled, and slow, and is limited by working memory capacity ("System 2 reasoning"); contextualized reasoning, on the other hand, is characterized as domain-specific, associative, parallel, automatic, and rapid, and is independent of working memory ("System 1 reasoning"). However, this distinction is often not clear cut: On the one hand, there are many examples for people making use of heuristic, associative System 1 processes when thinking about abstract, de-contextualized tasks; in the classical abstract selection task, for instance, they tend to apply the matching heuristic (Evans, 2003). On the other hand, people can also engage in analytic, rule-based System 2 processes when thinking about concrete, contextualized tasks as argued in Beller and Spada (2003).

The abstract deontic selection task is an interesting hybrid: It is domain-specific and contextualized, as it refers to a domain and a contextual framing we all are familiar with (to search for violators of a deontic regulation). But, instead of presenting a concrete, familiar rule like the *Drinking Age* rule "If a person is drinking beer, then that person must be over 16 years of age" (Cox & Griggs, 1982), which may activate an instance-based mode of reasoning, the task is formulated in an abstract way. Finding people's reasoning performance to be as accurate as with concrete, familiar material would thus provide evidence for abstract rule use in a specific domain (Smith, Langston & Nisbett, 1992).

The original version, introduced as "permission problem", reads as follows (Cheng & Holyoak, 1985, p. 403):

*Suppose you are an authority checking whether or not people are obeying certain regulations. The regulations all have the general form, "If one is to take action A, then one must first satisfy precondition P." In other words, in order to be permitted to do "A", one must first have fulfilled prerequisite "P". The cards below contain information on four people: One side of the card indicates whether or not a person has taken action "A", the other indicates whether or not the same individual has fulfilled precondition "P". In order to check that a certain regulation is being followed, which of the cards below would you turn over? Turn over only those that you need to check to be sure.*

Card (1) "Has taken action A"

Card (2) "Has not taken action A"

Card (3) "Has fulfilled precondition P"

Card (4) "Has not fulfilled precondition P"

Which cards does one need to check? This question is not too difficult to answer: The regulation is being followed if a person, who takes action "A", has fulfilled precondition "P". Therefore two cards need to be checked: Card (1) "Has taken action A" in order to find out whether this person has fulfilled precondition "P", and Card (4) "Has not fulfilled precondition P" in order to exclude that this person has taken action "A", as otherwise the regulation would be violated.

The task is about an abstract regulation. This should pose no problems as, according to *Pragmatic Reasoning Schema Theory* (Cheng & Holyoak, 1985), people possess abstract schemas for handling such rules. People should thus be able to solve the abstract deontic task as easily as they solve concrete ones. However, this is not the case as indicated by the meta-analysis reported in Beller (2010, p. 127): Instead, the

solution rate drops from 73.8% in concrete deontic selection tasks ( $N = 1,010$ ; 26 Experiments) to 58.4% in abstract deontic tasks ( $N = 320$ ; 10 Experiments), indicating—at first glance—some difficulties with abstract rule use in the sense of Smith, Langston and Nisbett (1992).

According to *Social Contract Theory* (Cosmides, 1989), this result comes not as a surprise because the abstract deontic task lacks a clear cost-benefit structure necessary to identify rule violators: persons who take the benefit (e.g., the beer) without “paying the costs” (i.e., fulfilling the age requirement). But if cost-benefit information were indeed necessary for the solution, should we then not expect a much stronger decrease in the solution rate than the observed 15%? And if, on the other hand, missing cost-benefit information is not the reason, what else then could be responsible for the reduced solution rate? In order to answer these questions, the “permission problem” needs to be analyzed in more detail.

## A Task Analysis

### How to Solve the Task

As suggested by Beller (2008), the first step in solving a deontic task is to identify which action constraint is imposed by a deontic rule (*constraint principle*). In the “permission problem”, the restriction concerns action “A”, and the condition is “P”. According to the description, condition “P” is necessary for the permission to do “A”. Consequently, if “P” is not fulfilled then action “A” is forbidden. Assuming that “P” is the only relevant condition (*exhaustivity*), the deontic constraint can then be represented according to the *equivalence principle* by the ban “If condition P is not fulfilled then action A is forbidden; otherwise it is allowed”:

Ban (B):  $\neg \text{condition\_P} \leftrightarrow \text{forbidden}(\text{action\_A})$

After the deontic action constraint has been identified, the second step consists of drawing the appropriate deontic inferences. From a deontic norm like ban (B), three types of inferences are possible (Beller, 2008): *Forward inferences* from the condition side of the norm to the deontic status of the regulated action (i.e., whether it is forbidden or allowed, obligatory or not), *backward deontic-to-factual inferences* from the deontic status of the regulated action to the condition (i.e., whether or not the condition is fulfilled), and *backward factual-to-deontic inferences* from information on whether or not the regulated action is taken to the deontic status of the condition (e.g., whether or not it is deontically necessary).

In order to come up with the correct solution to the selection task (“A & not-P”), one has to check *each* of the persons and to infer whether he or she might have *violated* the rule (i.e., has performed the banned action “A” without fulfilling condition “P”). The inference process might proceed as follows: For card (1) “Has taken action A”, one can conclude by a backward factual-to-deontic inference that this person must fulfil condition “P”; otherwise the rule is violated. For card (2) “Has not taken action A”, one can conclude by corresponding backward inferences that this person need not, but may fulfil condition “P”. Therefore, the rule cannot be

violated. For card (3) “Has fulfilled condition P”, one can conclude by forward inferences that this person may, but need not take action “A”; again, the rule cannot be violated. Finally, for card (4) “Has not fulfilled condition P”, one can infer by a corresponding forward inference that this person may not take action “A”; otherwise the rule is violated.

### Problems in the Original Task

Unfortunately, Cheng and Holyoak's (1985) original task is formulated in a way that renders it difficult to interpret the deontic regulation and to understand the task requirement correctly, with direct effects on how the task is solved.

With regard to the interpretation of the deontic regulation, several formulations are problematic: First, by stating that “The regulations *all* have the general form ...” (italics added), the “permission problem” suggests that not a single rule has to be checked, but a set of *possibly different* rules. Second, the formulation “If one is to take action A ...” can be understood as referring to an intention (“if someone *wants* to take action A ...”). However, it is not the *intention* that is deontically constrained, but *doing* the action. Third, the condition is described as a composition of “P” and an additional temporal constraint: “P” has to be fulfilled *prior* to action “A”. This might initiate some temporal reasoning, which cannot be resolved unequivocally, as the necessary temporal information is missing on the cards. Fourth, the precondition has to be fulfilled prior to the action, but the regulation mentions the two elements in the reverse order. And finally, the regulation qualifies condition “P” as *necessary* with the modal *must*, but does not specify whether “P” is *sufficient* for the permission to take action “A”.

With regard to the task requirement, two formulations are problematic: The first is the instruction “to check that a *certain* regulation is being *followed*” (italics added). It emphasizes that one particular regulation has to be checked. At the very beginning, the task speaks of regulations in the plural form, which may cause uncertainty about which specific regulation out of this set is meant. More severely, this instruction emphasizes rule *following*, whereas concrete selection tasks like the *Drinking Age Problem* focus on rule *violation*. This may appear to be a subtle distinction, but in fact it is one that makes an important difference: Whether a person does follow the regulation can be checked by turning over the “A”-card (1), but not by turning over the “not-P”-card (4), as rule following is relevant only for persons to which the rule *applies*: Person (1), who has taken the critical action “A”, is subject to the rule. If it turns out that this person has fulfilled prerequisite “P”, it is clear that he or she has *followed* the rule; otherwise he or she has *violated* it. For person (4), who has not fulfilled prerequisite “P”, the case is different: If this person has taken action “A”, it is clear that this person is subject to the rule and has *violated* it, but if this person has *not* taken action “A”, the rule is simply *not applicable*, and hence it is not possible to detect rule following. People, therefore, may neglect the “not-P”-card and select only the “A”-card. The second problematic formulation is the instruction “Turn over only those [cards] that you need to

check to be sure”. This might cause people to be *cautious* not to select too many cards. Some might think that finding one rule follower (or rule violator) would be sufficient.

In summary, the formulation of the task makes it difficult to extract the relevant deontic information, and the instruction induces a general preference for choosing only few cards (caution) as well as a specific preference for the “A”-card alone (to check rule following). In combination, this leads to a reduction of selection task performance and, accordingly, to an underestimation of people’s deontic competencies. By eliminating the problematic formulations, performance should increase. In the following, three experiments test this hypothesis. The results will be discussed with regard to the role this kind of content-specific, but abstract tasks can play in gaining new insights into content-specific reasoning.

### Three Experiments

In each of the experiments (taken from Beller, in press, and described here together for reasons of space), the original task from Cheng and Holyoak is compared to four new ones. By varying the formulation of the deontic rule (strong vs. weak; backward vs. forward), the question of *rule interpretation* is addressed; the problems of the *instruction* are addressed by focusing on rule violation instead of rule following.

The new tasks were constructed according to the schema shown below. Clues about intentions and temporal conditions are avoided; the instruction emphasizes that each person should be checked for rule violation; and explicit negatives are used to clarify when action “A” is *not* taken and when condition “P” is *not* fulfilled:

*Imagine you are a member of an authority that checks whether people conform to or violate a particular rule. The rule is: {one of the new rules from below}. The “cards” presented below represent four persons. On one side of each card is written whether or not the respective person takes action “A”, on the other side is written whether or not he or she fulfills condition “P”. Your task: Indicate all cards that you have to turn over—all of which you need to know the information on the back—in order to find out whether the respective person violates the rule.*

*Person (1) “Takes action A”*

*Person (2) “Does not take action A”*

*Person (3) “Fulfills condition P”*

*Person (4) “Does not fulfill condition P”*

Each task refers to a single deontic rule, which is given without further clarifications. In Experiment 1, the following four rules were used:

*Obligation O1: “If a person takes action A, then he or she must fulfill condition P.”*

*Release R1: “If a person does not take action A, then he or she need not fulfill condition P.”*

*Ban B1: “If a person does not fulfill condition P, then he or she must not take action A.”*

*Permission P1: “If a person fulfills condition P, then he or she may take action A.”*

All four rules can logically be derived from ban (B), with obligation O1 being analogous to the original rule. Two rules use a strong deontic modal and describe a deontic constraint explicitly (O1 and B1), the two other rules use a weak deontic modal (R1 and P1). Taken literally, these latter rules cannot be violated in the deontic sense, as they do not express a deontic constraint explicitly.

For Experiment 2, these rules were extended by one sentence that make their complementary side explicit in order to facilitate to derive ban (B) from the weak rules:

*Obligation O2: “If a person takes action A, then he or she must fulfill condition P; otherwise he or she need not fulfill it.”*

*Release R2: “If a person does not take action A, then he or she need not fulfill condition P; otherwise he or she must fulfill it.”*

*Ban B2: “If a person does not fulfill condition P, then he or she must not take action A; otherwise he or she may take it.”*

*Permission P2: “If a person fulfills condition P, then he or she may take action A; otherwise he or she must not take it.”*

In Experiment 3, it was manipulated, how the deontic modalities are expressed in the rules: not by deontic modals (e.g., *must not* or *may*) as in Experiment 1 and 2, but by semantically equivalent deontic verbs (e.g. *to forbid* or *permit*). With the verbs, explicit negations can be avoided, thereby eliminating another potential difficulty:

*Obligation O3: “If a person takes action A, then he or she is obliged to fulfill condition P; otherwise he or she is released from fulfilling condition P.”*

*Release R3: “If a person does not take action A, then he or she is released from fulfilling condition P; otherwise he or she is obliged to fulfill condition P.”*

*Ban B3: “If a person does not fulfill condition P, then action A is forbidden; otherwise action A is permitted.”*

*Permission P3: “If a person fulfills condition P, then action A is permitted; otherwise action A is forbidden.”*

For the original task, it is expected that people tend to avoid selecting too many cards (*caution hypothesis*) and tend to neglect the “not-P” card and to select the “A”-card alone (*rule-following hypothesis*) due to the various problems in the formulation of this task. For the new tasks, it is expected that people infer ban (B) more easily due to the clearer formulation. With ban (B) in mind, they should select the cards “A” and “not-P” when asked to check individuals for rule violation, independent of how the rule was formulated (*rule-violation hypothesis*). If asked for the literal meaning of the rules, however, people should differentiate between strong rules that can be violated by a person and weak rules that cannot be violated (*rule-evaluation hypothesis*).

## Method

**Materials.** In each experiment, five deontic selection tasks were used: the original task and four new tasks. The new tasks were constructed according to the general schema shown above and differed only in the way the rule was formulated. In addition to the selection tasks, each experiment was supplemented with a second task. In Experiment 1, a rule *evaluation task* was used in order to check which of the rules O1, R1, B1, and P1 participants consider as violable in a strict deontic sense. The instruction asked participants to *consider for each statement whether it expresses a rule that can in fact be violated by a person*. In Experiment 2, this instruction was used to compare the weak rules from Experiment 1 with the corresponding explicit rules from Experiment 2 (i.e. R1, P1, R2, and P2). In Experiment 3, participants were asked to rank the rules O3, R3, B3, and P3 with respect to comprehensibility (from 1 = best to 4 = worst).

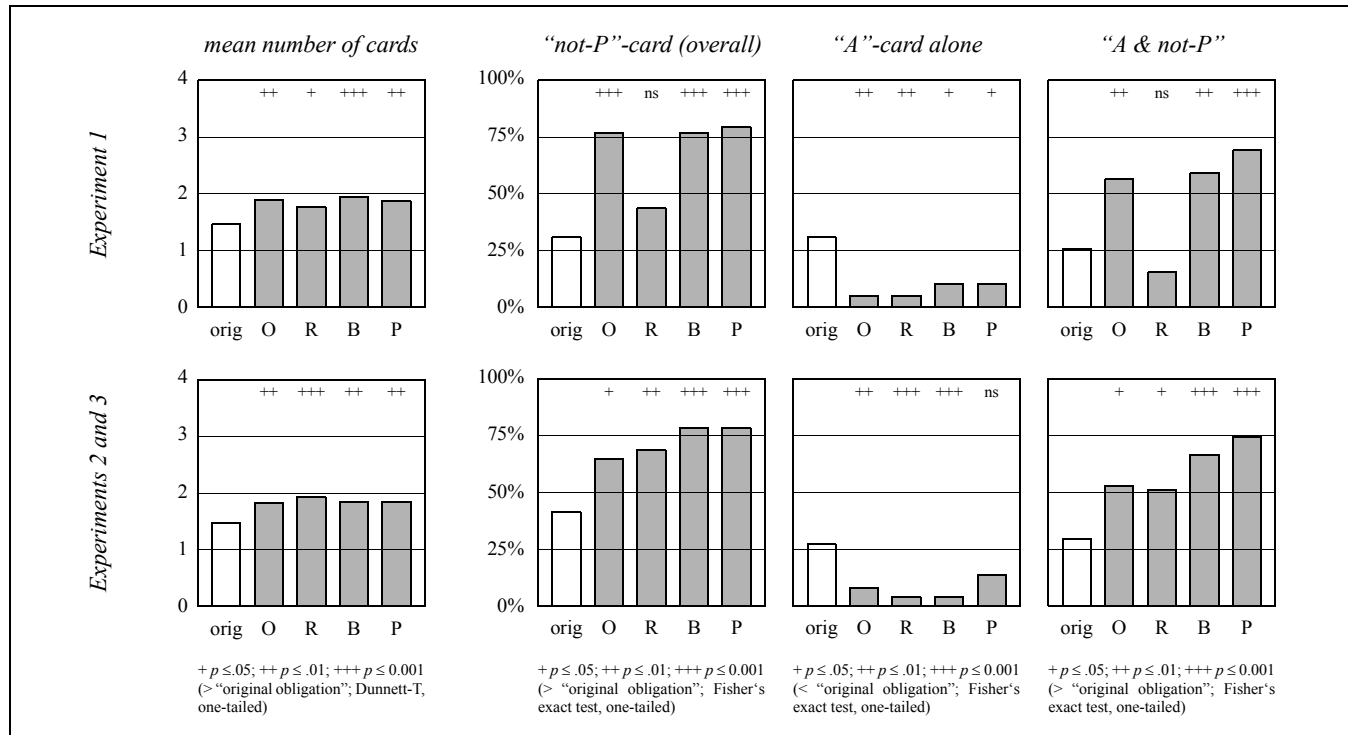

**Participants.** All participants were from the University of Freiburg and had no prior experience with the selection tasks. In Experiment 1, a total of 195 students (39 per condition) volunteered to participate for research credit (72 male, 123 female; mean age 23.2 years,  $SD = 3.57$ ). In Experiment 2, a total of 125 students (25 per condition) volunteered to participate for research credit (36 male, 89 female; mean age 23.1 years,  $SD = 5.27$ ). In Experiment 3, a total of 130 students (26 per condition) volunteered to participate as part of a study on a different subject for which they were paid (37 male, 91 female; mean age 23.5 years,  $SD = 3.94$ ).

**Design and Procedure.** These were the same for all three experiments: Each participant received a booklet with general instructions, one selection task, and the additional task (on separate pages). In both tasks, two orders of answer options were permuted equally frequently across conditions. The different versions of the booklet (with the different selection task versions varying between subjects) were randomly assigned to participants. They were investigated in small groups, were instructed to work on the tasks in the given order, and were granted as much time as they needed.

## Results

In the original selection task, people were expected to be cautious not to select too many cards, which should decrease the mean number of selected cards. With the focus on rule following, people should tend to neglect the “not-P” card and to select the “A”-card alone instead of the cards “A & not-P”. In the new tasks, performance should improve with respect to all these indicators; and exactly this was found.

**Overall analyses of the selection task data.** In Experiment 1, the five experimental groups differed significantly in the mean number of chosen cards ( $F(4, 190) = 3.99$ ;  $p = .004$ ) as indicated by an analysis of variance, and also in the overall frequency of the “not-P”-card ( $L^2 = 34.4$ ;  $N = 195$ ;  $df = 4$ ;  $p < .001$ ), in the frequency of the “A”-card alone ( $L^2 = 14.2$ ;  $N = 195$ ;  $df = 4$ ;  $p = .007$ ), and in the frequency of the combination “A & not-P” ( $L^2 = 36.2$ ;  $N = 195$ ;  $df = 4$ ;  $p < .001$ ) as indicated by the likelihood ratios. Almost all effects were in the predicted directions (cf. Figure 1).

**Figure 1:** Four deontic indices for the original selection task (white bars) and the four new tasks Obligation, Release, Ban, and Permission (grey bars) in Experiment 1 (top row;  $N = 195$ ) and aggregated across Experiments 2 and 3 (bottom row;  $N = 255$ ).

As explained above, the selection tasks used in Experiment 2 and 3 differed only in one aspect: in how the deontic modality was formulated. They were thus analyzed jointly by means of an analysis of variance and log-linear analyses (Kennedy, 1992). As none of these analyses indicated a main effect "Experiment" nor an interaction "Experiment"  $\times$  "Condition" (for all  $F$ s:  $p > .544$ ; for all  $L^2$ :  $p > .553$ ), aggregating the data over the two experiments seemed justified. This also means that it made no difference for the solution of the tasks whether the deontic modality in the rule was expressed by modals with explicit negation (Experiment 2) or by verbs without explicit negation (Experiment 3). As in Experiment 1, the five experimental groups differed in the mean number of chosen cards ( $F(4, 245) = 4.75$ ;  $p = .001$ ), in the overall frequency of the "not-P"-card ( $L^2 = 20.9$ ;  $N = 255$ ;  $df = 4$ ;  $p < .001$ ), in the frequency of the "A"-card alone ( $L^2 = 18.1$ ;  $N = 255$ ;  $df = 4$ ;  $p = .001$ ), and in the frequency of the combination "A & not-P" ( $L^2 = 25.2$ ;  $N = 255$ ;  $df = 4$ ;  $p < .001$ ). Again, almost all effects were in the predicted directions (cf. Figure 1).

**Original Selection Task.** As predicted by the *caution hypothesis*, participants selected too few cards, that is, less than 2.0, the value expected according to the correct "A & not-P" solution (Experiment 1: 1.462;  $t(38) = -6.06$ ;  $p < .001$ ; Experiments 2&3: 1.471;  $t(50) = -5.17$ ;  $p < .001$ ). As predicted by the *rule-following hypothesis*, the main problem was to recognize the relevance of the "not-P"-card (Experiment 1: 30.8% "not-P"; Experiments 2&3: 41.2%). The proportion of the "A"-card alone was rather high (Experiment 1: 30.8%; Experiments 2&3: 27.5%), and the frequency of the correct deontic solution "A & not-P" was low (Experiment 1: 25.6%; Experiments 2&3: 29.4%).

**New Selection Tasks.** The performance in the new tasks differed significantly from the original task in all aspects: The mean number of chosen cards was higher in all four conditions (Experiment 1: 1.872 on average; Experiments 2&3: 1.858). The relevance of the "not-P"-card was clearly recognized (Experiment 1: in three out of four conditions; Experiments 2&3: in all four conditions), the proportion of the "A"-card alone was reduced (Experiment 1: in all four conditions; Experiments 2&3: in three out of four conditions) and, complementarily, the correct combination "A & not-P" increased (Experiment 1: in three conditions; Experiments 2&3: in all four conditions). This pattern indicates that, in most conditions, the majority of participants inferred ban (B) and identified rule violators more often than in the original task, as predicted by the *rule-violation hypothesis*.

**Additional Tasks.** The additional task in Experiment 1 compared the weak rules permission P1 and release R1 with the two strong rules ban B1 and obligation O1. According to the *rule-evaluation hypothesis*, participants should indicate that weak rules cannot be violated in the deontic sense, only strong rules can. To test this hypothesis, a strength-index was calculated by adding 1 for each strong rule that a person marked as violable, subtracting 1 for each weak rule, and dividing the result by 2. This renders a maximum score of 1 if the two strong rules were marked only, a minimum score of -1 if the two weak rules were marked only, and a score of

0 if strong and weak rules were marked in a balanced way. An analysis of variance indicated that the strength-indices of the five selection task conditions did not differ from one another ( $F(4, 190) = .491$ ;  $p = .742$ ). The overall index was positive (.667) and different from zero ( $t(194) = 22.3$ ;  $p < .001$ ). The data clearly support the *rule-evaluation hypothesis*: The strong rules were regarded as violable by most participants (obligation: 80.0%; ban: 84.6%), the weak rules were not (release: 5.6%; permission: 25.6%;  $N = 195$ ).

The additional task in Experiment 2 compared the two weak rules from Experiment 1 (P1 and R1) that left the underlying deontic constraint implicit with the two explicit rules from Experiment 2 (P2 and R2) that expressed this constraint. A strength-index was calculated analogously to Experiment 1. If participants considered the explicit rules as the only violable ones then a high positive value should result. An analysis of variance indicated that the strength-indices of the five selection task conditions did not differ from one another ( $F(4, 120) = .612$ ;  $p = .655$ ). The overall index was positive (.652) and different from zero ( $t(124) = 14.9$ ;  $p < .001$ ). The data again support the *rule-evaluation hypothesis*: The explicit rules were regarded as violable by most participants (R2: 79.2%; P2: 81.6%), the implicit rules were not (R1: 11.2%; P1: 19.2%).

The additional task in Experiment 3 asked participants to rank the four rules from "easiest to understand" (= 1) to "most difficult to understand" (= 4). Two rules expressed an obligation and were formulated as backward rules: Obligation O3 focused on the obligation in the if-then clause, release R3 in the otherwise clause. The two other rules expressed a ban and were formulated as forward rules: Ban B3 focused on the ban in the if-then clause, permission P3 in the otherwise clause. All rules thus expressed a deontic constraint. But were they therefore equally easy to understand, too? In order to answer this question, an analysis of variance on the rank values was conducted with one within-subject factor "rule" (rank value assigned to each of the rules) and one between-subjects factor "condition" (the five selection task conditions). As comprehension of the rules should not depend on the type of selection task that individuals had solved before, an effect "condition" was not expected—and was not found either ( $F(4, 124) = .990$ ;  $p = .416$ ). But, a strong rule effect was found ( $F(3, 372) = 210.6$ ;  $p < .001$ ) with a clear rank order: Permission was regarded as most comprehensible ( $m = 1.26$ ), followed by the ban ( $m = 2.19$ ), the obligation ( $m = 2.92$ ), and the release from obligation ( $m = 3.60$ ). An interaction ( $F(12, 372) = 4.13$ ;  $p < .001$ ) indicated a slight difference between the experimental groups: The one exception from the general order *permission < ban < obligation < release* occurred in the group that had solved the selection tasks with obligation O3; here, the obligation switched to the second position: *permission < obligation < ban < release*.

## Conclusions

Any sound test of a psychological theory requires that we understand the applied behavioral paradigms in all relevant aspects. The task analysis presented in this paper (cf. Beller,

in press) indicated that a great deal of the difficulties with the original abstract deontic selection task arose from an inadequate formulation of the task. The experimental data confirm this analysis: They provide evidence for the specific difficulties with the original task and show that performance can be substantially improved, if the selection task is formulated more clearly with regard to its deontic nature.

The abstract deontic selection task was introduced in order to demonstrate that people possess abstract reasoning schemas for reasoning from deontic rules (Cheng & Holyoak, 1985). The reduced performance with the original version (as compared to concrete versions) was attributed by some scholars to lacking cost-benefit information, which is characteristic for social contract rules (e.g., Cosmides, 1989). This explanation can now be rejected: As all the tasks used in Experiments 1 to 3 have the same cost-benefit structure, the differences between the original task and the new tasks unequivocally show that the reduced performance in the original task must have other reasons.

What do the experimental data tell us about people's deontic competencies? Performance was best with tasks that combined a genuine violation instruction with a genuine permission rule: With 72.2% of participants choosing "A & not-P" on average across the three experiments, these tasks reliably approached the average result from the concrete deontic tasks (73.8%, according to Beller, 2010, p. 127). This finding may count as an indication for rule guided behavior in a specific content domain (Smith, Langston & Nisbett, 1992), that is, for System 2 reasoning in a domain-specific, contextualized task. Permission rules were also rated as most comprehensible even though rules like the one used in Experiment 1 do not express a deontic constraint explicitly. Consequently, before people can come up with the "A & not-P" solution in the selection task, they must infer from the rule which action is banned under which condition, and the data are consistent with the assumption that they do this according to the principles suggested in Beller (2008). As a consequence, the exact wording of the rule—whether it is formulated forwards or backwards, as permission or as obligation—is not relevant for the identification of rule violations, as long as people are able to infer the adequate deontic regulation. In this sense, the results constitute an instance of the rule-change phenomenon in showing that people infer cases of rule violation independently of their relation to the "logical form" of the conditional statement (Cosmides, 1989; cf. Beller, 2001; 2010; Beller & Spada, 2003).

Beyond that, tasks like the abstract deontic selection task are important tools for studying domain-specific reasoning processes as they combine two features: They are *content-specific* as they refer to a particular content domain (like deontic norms), and *abstract* as they do not refer to a specific instance, thereby avoiding content effects due to the experience that people have with particular instances (for a causal example see Beller & Kuhn münchen, 2007). As with content effects in general (cf. Beller & Spada, 2003), specific instances of deontic rules may facilitate performance, if experiences with a rule are available directly from memory (for an example see Beller, 2001). Likewise, experience with a

specific instance might also suppress performance, if inhibiting aspects like additional conditions or additional social norms are evoked by its content (for an example see Beller, Bender & Song, 2009). Our theories of reasoning—even the content-specific ones—are not formulated for single instances (like a specific drinking-age rule), but refer abstractly to classes of comparable situations (like deontic norms in general). Tasks that are both, content-specific and abstract, are thus a mean for testing domain-specific theories in a purer way, and can provide a baseline that help us to detect and to assess the extent of such instance-specific content effects.

## Abstract

We investigate the effects of alternative utterances on pragmatic interpretation of language. We focus on two specific cases: specificity implicatures (less specific utterances imply the negation of more specific utterances) and Horn implicatures (more complex utterances are assigned to less likely meanings). We present models of these phenomena in terms of recursive social reasoning. Our most sophisticated model is not only able to handle specificity implicature but is also the first formal account of Horn implicatures that correctly predicts human behavior in signaling games with no prior conventions, without appeal to specialized equilibrium selection criteria. Two experiments provide evidence that these implicatures are generated in the absence of prior linguistic conventions or language evolution. Taken together, our modeling and experimental results suggest that the pragmatic effects of alternative utterances can be driven by cooperative social reasoning.

**Keywords:** Pragmatics; Communication; Bayesian modeling

## Introduction

A central observation in the field of pragmatics is that alternative utterances affect our interpretation of language. If the teacher says, “Some of the students passed the test”, then this means that not all of them passed, because the teacher would have said so if they did. If someone is asked what they ate at the restaurant, and they say “salad”, then this means that they did not also get the lobster; otherwise they would have said so. If someone says, “I got the car to turn on,” then this means that turning on the car involved something more unusual than just turning the key. If it hadn’t, they could have just said, “I turned on the car.” Many other cases like this were described in Grice’s (1975) classic.

Horn (1984) proposed a unified account of these disparate cases in terms of his Q and R-Principles. These principles describe how conversational partners are expected to communicate with each other. The Q-Principle states: Say as much as you can. The R-Principle states: Say no more than you must. These principles explain how counterfactual utterances like the ones above have their effect on meaning. If the speaker behaves according to the Q-Principle, then when she says that some of the students passed the test, this must mean that she said all that she could. In particular, she must not have been in a position to say that all of the students passed. Similarly, if the speaker is following the R-Principle, then when she reports that she got the car to turn on, this means that a simpler utterance would not have sufficed to convey her meaning. In particular, simply saying that she turned on the car would not have conveyed her meaning.

A basic question about these principles (or Grice’s related maxims of conversation) is the extent to which they capture people’s online reasoning when they pragmatically interpret

language. The alternative is that such explanations merely provide a succinct way of summarizing pragmatic phenomena, and that pragmatic meanings are learned as part of the grammar, i.e. conventionalized as part of the language. Researchers have argued that some types of pragmatic meanings are computed from the grammar, and not from cooperative social reasoning (Chierchia, 2004). Intuitively, however, some pragmatic inferences generalize to settings in which they could not have been previously learned. Consider the salad/lobster inference described above. This inference is highly context-dependent, and must require a reasoning process that extends beyond what has been learned in the grammar. But then where is the boundary between conventionalized and socially-derived implicatures?

Here we investigate these questions using experiments and computational modeling. Despite the apparent simplicity of explanations in terms of the Q and R-principles, it has been notoriously difficult to develop a formal framework that captures these principles (or the maxims of conversation). In addition, there has been little empirical work investigating whether pragmatic inferences rely on conventionalized meanings. We will be looking at the minimal ways for contrasts between alternative utterances to drive pragmatic interpretation. Specifically, we will be looking at cases in which there are no linguistic conventions whatsoever. If people’s pragmatic interpretations show the same sensitivity to contrast in these settings, it will provide evidence that social reasoning explains more, rather than less, of their pragmatic abilities.

We focus on two traditional examples of counterfactual reasoning in pragmatics. The first, *scalar implicatures*, arise because of the contrast between words that fall on an increasing scale of informativeness. The less informative meaning is typically strengthened to the complement of the more informative meaning, as in the case of “some” vs. “all” above. Because the term “scalar implicature” is sometimes reserved to refer to cases where lexical items fall on a canonical scale of informativeness, we will use the term *specificity implicatures* to describe the strengthening of less informative meanings even in the absence of such a canonical scale. The second, which we will call *Horn implicatures*, guides the interpretation of utterances that differ in their complexity (Horn, 1984). Typically, more complex constructions receive marked (or less probable) interpretations. The car case above is an example of a Horn implicature, assuming (as is plausible) that the two expressions have the same literal content.

These two kinds of implicatures will allow us to explore pragmatic contrast effects along two distinct dimensions: informativeness and cost. While we will model both of these ef-

fects as recursive social reasoning, it will emerge that the simplest model of such reasoning that can account for specificity implicatures is insufficient to explain Horn implicatures. We begin with the simpler version of the model and later enhance the model to account for both kinds of effects.

### Specificity Implicatures

The Gricean tradition views pragmatics as a special domain of social cognition. Pragmatics, on this approach, is the study of social agents who want to cooperate with each other to exchange information. Pragmatic phenomena arise as a result of these goals and the agents' reasoning about each other.

Here we develop a model of ideal discourse between two rational agents, a speaker and listener, each with distinct social goals. The speaker wants to communicate a specific meaning to the listener, requiring her to reason about how the listener will interpret her possible utterances. The listener, in turn, wants to determine what meaning the speaker intended to convey, requiring him to reason about which meaning would have led the speaker to send her utterance. The speaker and listener are modeling each other; crucially, the listener takes into account the speaker modeling him, and the speaker takes *this* into account, and so on. In other words, the speaker and listener have *common knowledge* of each others' communicative goals (Lewis, 1969; Clark, 1996).

This recursive social reasoning bottoms out when the listener stops reasoning about the speaker's intentions. In this *base case*, the listener uses his knowledge of the language's semantics or contextual iconicity to interpret the utterance.

We now turn to the formal specification of the model. The literal content of the utterances is specified by a lexicon  $\mathcal{L}$ , which maps each utterance to a truth function on meanings. If an utterance has no conventional or iconic meaning, then it is given the all-*true* function (i.e. it is a tautology). The listener has a prior distribution  $P$  over meanings; in the base case, the listener uses Bayesian inference to update her belief about the intended meaning given the utterance's literal meaning. More precisely, the listener conditions the prior distribution on the utterance being true, essentially filtering  $P$  through the literal meaning, leading to a new distribution  $L_0$  with support only on meanings that are consistent with the utterance. That is:

$$L_0(m|u, \mathcal{L}) \propto \mathcal{L}_u(m)P(m), \quad (1)$$

where  $m$  is a meaning,  $u$  is the utterance sent by the speaker,  $\mathcal{L}_u$  is a function from meanings to  $\{0,1\}$ , with  $\mathcal{L}_u(m) = 1$  if  $m$  is in the denotation of  $u$ , and  $P$  is the listener's prior distribution over meanings.

Social reasoning enters the model through a pair of recursive formulas that describe how the speaker and listener reason about each other. The formulas describe Bayesian agents  $S_n$  and  $L_n$  of increasing sophistication. The least sophisticated speaker  $S_1$  reasons about the base, "literal" listener  $L_0$ ; a slightly more sophisticated listener  $L_2$  reasons about this speaker; and so on. The speaker  $S_n$  has a utility function  $U_n$  that simultaneously accounts for how informative an utterance is for listener  $L_{n-1}$  as well as for its complexity or cost.

This is intended to capture both the Q and R-Principles. The speaker's choice of utterance is determined by a softmax decision rule that describes an approximately optimal Bayesian decision-maker (Sutton & Barto, 1998). The listener  $L_n$  interprets an utterance by using Bayesian inference to integrate his prior expectations over meanings, given by  $P$ , with his model of  $S_{n-1}$ , which determines how likely the speaker would have been to use that utterance given each possible meaning.

This recursive model is defined as follows. The speaker's conditional distribution over utterances given interpretations is defined as

$$S_n(u|m) \propto e^{\lambda U_n(u|m)}, \quad (2)$$

where  $\lambda > 0$  is the gain on the speaker's softmax decision rule.  $U_n(u|m)$  is the speaker's expected utility from uttering  $u$  to convey  $m$ , defined as

$$U_n(u|m) = \log(L_{n-1}(m|u)) - c(u). \quad (3)$$

Here  $c(u)$  is the cost of uttering  $u$  (in, e.g., time and effort); the other term measures the communicative benefit of  $u$  as the number of bits of information remaining between the listener's posterior distribution  $L_{n-1}(m|u)$  and the true meaning  $m$  (Frank, Goodman, Lai, & Tenenbaum, 2009). Substituting equation 3 into equation 2, we see that

$$S_n(u|m) \propto (L_{n-1}(m|u)e^{c(u)})^\lambda. \quad (4)$$

Hence the speaker prefers low-cost utterances and also prefers to choose an utterance more as the listener is more likely to pick the correct meaning given the utterance. The listener's higher-order interpretations are simply defined as

$$L_n(m|u) \propto P(m)S_{n-1}(u|m). \quad (5)$$

The model defined here is very similar to the iterated best response model of (Jäger & Ebert, 2009).

In situations where the speaker has a choice between utterances one of whose literal meanings is a subset of the other, this model induces an inference that the utterance with the broader meaning should be interpreted as indicating that the narrower meaning does not hold—which we term a specificity implicature. To see why, suppose that there are two possible meanings, *pyramid* and *cube*, and two utterances, "pyramid" and "shape", both of which have equal cost. The literal listener interprets "pyramid" as meaning *pyramid* with probability 1, due to the truth-conditional component of literal interpretation, and interprets "shape" as meaning either *pyramid* or *cube* with probabilities based on the prior,  $P(\text{pyramid})$  and  $P(\text{cube})$  respectively. For the speaker  $S_1$  reasoning about the literal listener, conveying *pyramid* with "pyramid" has higher utility than conveying it with "shape", since the former term ensures the proper interpretation.  $S_1$  is thus more likely to say "pyramid" than "shape" when she means to convey *pyramid*; and she will obligatorily say "shape" when she means to convey *cube*. The more sophisticated listener  $L_2$  uses  $S_1$ 's distributions rather than literal meaning, and thus prefers to interpret "shape" as *cube* rather than *pyramid*, since

the likelihood of “shape” is greater when *cube* is to be conveyed than when *pyramid* is. As the speaker and listener reach higher levels of recursive reasoning, these tendencies to say “pyramid” for *pyramid* and to interpret “shape” as *cube* continue to strengthen, both ultimately asymptoting at probability 1 (Figure 2, pink bars; the asymptotes do not depend on  $\lambda$  or  $P$ , so long as  $\lambda > 1$  and  $P(m) > 0$  for all  $m$ ).

## Experiment 1

Experiment 1 investigated whether people will draw specificity implicatures in a novel communicative setting. We investigated this by looking at the simplest setting in which specificity implicatures are possible, a language with only two messages and two meanings. By varying the (non-conventional) semantic content of the messages, we can determine whether competing messages influence interpretations here as they do in richer, conventionalized settings.

We presented people with a simple communication game, which they played with a partner. In the game, one player was the “speaker”, who had a specific meaning to communicate, and one player was the “listener”, who had to infer this meaning based on the message sent by the speaker. The meaning for the speaker to communicate was randomly chosen to be either a pyramid or a cube. The speaker had the choice between two messages to send the listener: a shape with an iconic relationship with one of the meanings (a triangle for the pyramid), or an “alien” symbol with no obvious connection to either meaning (see Figure 1). If people’s reasoning about semantic competition extends to novel settings, then the alien symbol will get a strengthened interpretation: it should be interpreted as the cube, which is the meaning that the speaker could not directly pick out. Likewise, the speaker will recognize that choosing the alien symbol is more likely to communicate the meaning for which there is no iconic symbol available. We thus predict that the speaker will use the alien symbol to communicate this meaning.

Figure 1: Experiment 1 game interface for speaker.

## Methods:

We recruited 40 participants from Amazon Mechanical Turk. They were paid a small amount of money for participation, in addition to performance-based bonuses, as described below.

Participants were told that they had arrived on an alien planet that contained two objects, a pyramid and a cube. Their

goal was to successfully play a communication game with a partner, given these objects and two messages that they could send, a triangle and an alien symbol. Participants received 10 rounds of practice as the speaker in order to familiarize with the interface; however, they did not play these rounds with a partner or receive any feedback.

The communication game consisted of five rounds. In each round, participants were randomly assigned a partner and a role as either the speaker or listener. Between rounds, participants were told that they were being randomly matched with a partner. Participants were never identified to each other. The speaker was shown a randomly chosen object that needed to be communicated, and given the choice of the two messages to send. Once the speaker clicked on a message, it was sent to the listener, who was asked to determine what meaning was intended. The listener was given the choice of the two objects; once the listener clicked on one of these objects, the speaker and listener were informed whether their communication was successful. If they were successful, they each received a small bonus payment of \$0.06 for that round.

## Results and Discussion

There were two questions of interest in this experiment. The first was whether listeners would interpret the alien symbol as the unnamed object (i.e. the object without an iconic message), i.e. the cube. On every trial, the listener interpreted the alien symbol as the unnamed object and the iconic symbol as the corresponding object. The second question was whether the speaker would choose the alien symbol to convey the unnamed object. Participants selected the alien symbol on every trial on which they needed to communicate the unnamed object; and they selected the name on all but two trials on which they needed to communicate the named object. These results are shown in Figure 2. (The displayed model predictions were not sensitive to the value of the model parameters.)

These results provide evidence that participants were sensitive to the semantic contrast between available utterances. Listeners inferred that the speaker would have only used the alien symbol if she needed to communicate the unnamed object. Speakers similarly inferred that the listener would interpret the alien symbol as the unnamed object, and only chose the alien symbol in order to communicate this object.

## Horn’s Principle

HORN’S PRINCIPLE describes the effects of lexical competition when utterances differ in cost instead of semantic content. The principle states that phrases that are “costlier”—e.g., longer, or involving less-frequent subexpressions—are associated with less probable meanings. For example, *I turned on the car* and *I got the car to turn on* have approximately identical literal meaning; but most speakers would use the shorter sentence to refer to the typical turning of a car key and the longer sentence to some less typical manner of turning on the car. This is the efficient mapping between form and meaning; Horn (1984) and others have documented many instances of such efficient mappings in language.

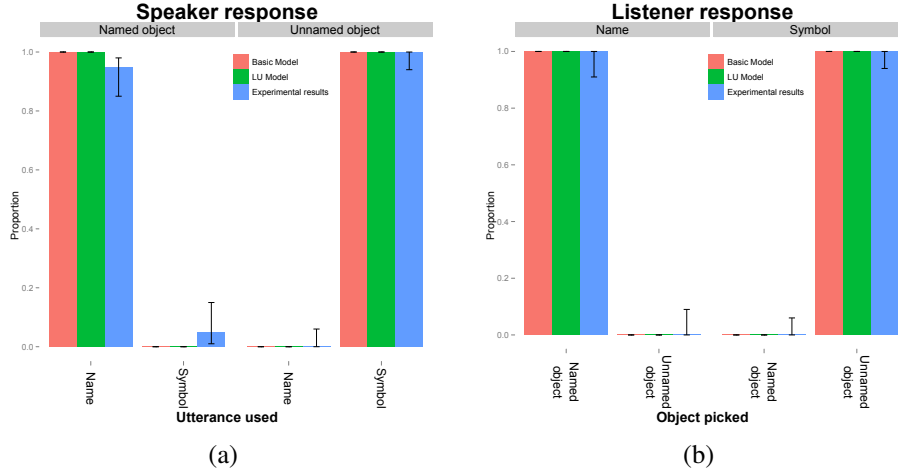

Figure 2: Experiment 1 results and model predictions. (a) Speaker responses given the goal of communicating the named object (left) or the unnamed object (right). The y-axis is the proportion of trials on which the speaker chose each utterance. Error bars are 95% confidence intervals. (b) Listener responses when the speaker chose either the name (left) or the alien symbol (right). The y-axis is the proportion of trials on which the listener chose each object.

Perhaps surprisingly, however, the model of intuitive cooperative communication we have introduced fails to predict Horn’s principle. Consider the problem of a one-shot speaker-listener signaling game with two utterances, “expensive” and “cheap” (the costs of these utterances reflect their names), and two meanings, *likely* and *unlikely*; nothing distinguishes the utterances other than their cost, and each has the all-true meaning. The literal listener  $L_0$  interprets both utterances identically, matching the prior probabilities of the meanings.  $L_0$ ’s interpretation thus provides no information with which the speaker  $S_1$  can distinguish among the utterances; the only thing distinguishing the utterances’ utility is their cost. This leads to an across-the-board dispreference on the part of  $S_1$  for “expensive”, but gives no starting point for more sophisticated listeners or speakers to break the symmetry.

In fact, Horn’s principle has been extraordinarily difficult to derive within other formal frameworks as well. The problem we posed is equivalent to the multiple equilibrium problem for signaling games in economics, which has been investigated for the last 30 years (Cho & Kreps, 1987; Chen, Kartik, & Sobel, 2008). The fundamental difficulty involves ruling out inefficient equilibria, e.g. those in which “expensive” is associated with *likely* and “cheap” with *unlikely*, in the absence of prior conventions or ad-hoc rules for choosing among equilibria. Some recent work by linguists (van Rooij, 2004, 2008; Franke, 2009) has attempted to derive Horn’s principle by using evolutionary game theory or hybrid game-theoretic models, but none has found a derivation for one-shot signaling games, without use of equilibrium refinement criteria specifically designed to pick out the desired equilibria.

Here we propose exactly such a derivation, by revisiting the assumption in our base model regarding the nature of literal meaning in the absence of prior conventions. Earlier in this section we assumed that the absence of prior convention should be represented as a single lexicon  $\mathcal{L}$  in which all utterances have the all-true (tautological) meaning. We revise that assumption in two respects. First, for any given utterance we allow  $\mathcal{L}_u$  to assume either truth value  $\{0, 1\}$  for each meaning,

allowing the lexicon to assign non-trivial semantic content to utterances. Second, we allow for *lexical uncertainty*, where the speaker and listener can reason about distributions over multiple lexica. In the signaling game described above, for example, lexicon  $\mathcal{L}^1$  might assign the meaning *likely* to “expensive” and the all-true meaning to “cheap”, whereas lexicon  $\mathcal{L}^2$  might assign the meaning *unlikely* to “expensive” and the same all-true meaning to “cheap”. The absence of prior conventions then means that the *marginal* interpretation, across lexica, is the same for all utterances.

Including lexical uncertainty generalizes the previous model; the base listener  $L_0$  remains unchanged from equation 1, but the more sophisticated speaker and listener are defined by:

$$S_n(u|m, \mathcal{L}) \propto e^{\lambda U_n(u|m, \mathcal{L})} \quad (6)$$

$$L_n(m|u) \propto \sum_{\mathcal{L}} P(m) P(\mathcal{L}) S_{n-1}(u|m, \mathcal{L}) \quad (7)$$

where

$$U_n(u|m, \mathcal{L}) = \begin{cases} \log(L_0(m|u, \mathcal{L})) - c(u) & \text{if } n = 1 \\ \log(L_{n-1}(m|u)) - c(u) & \text{if } n > 1. \end{cases} \quad (8)$$

We take  $P(\mathcal{L})$  to be the uniform distribution over all seven logically possible lexica in which every utterance assigns “true” to at least one meaning and every meaning is assigned “true” by at least one utterance.

Because this new *lexical-uncertainty* model reduces to the base model when conventions for literal meanings are already established and there is only a single lexicon  $\mathcal{L}$ , the new model continues to properly handle specificity implicature (Figure 2, green bars). Furthermore, the new model derives Horn’s principle. Consider the case we proposed above with two lexica,  $\mathcal{L}^1$  interpreting “expensive” as *likely* and  $\mathcal{L}^2$  interpreting “expensive” as *unlikely* (and both giving a trivial interpretation to “cheap”). Due to the role of the prior  $P(m)$ , the base listener  $L_0$  associates “cheap” with *likely* for both lexica. Now consider two speakers who can use the expensive utterance to precisely communicate their meaning: speaker  $S_1(\cdot|likely, \mathcal{L}^1)$  who wants to communicate *likely* and is using

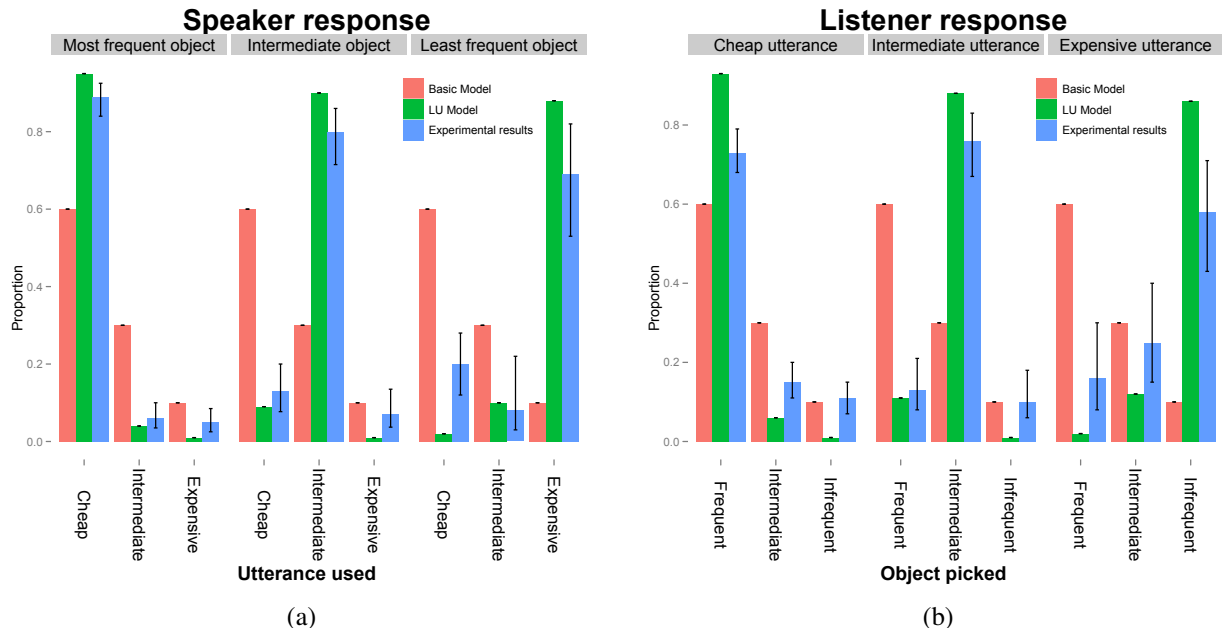

Figure 3: Experiment 2 results and model predictions. (a) Speaker’s message choice given that she needed to convey the most frequent (left), intermediate (center), or least frequent object (right). The y-axis is the proportion of trials on which each message was chosen. Error bars are 95% confidence intervals. (b) Listener’s object choice after receiving the cheapest (left), intermediate (center), or most expensive message (right). The y-axis is the proportion of trials on which each object was chosen.

lexicon  $\mathcal{L}^1$  and speaker  $S_1(\cdot|unlikely, \mathcal{L}^2)$  who wants to communicate *unlikely* and is using lexicon  $\mathcal{L}^2$ . For the speaker  $S_1(\cdot|likely, \mathcal{L}^1)$ , the extra precision of “expensive” is not valuable, because the base listener  $L_0$  will also interpret “cheap” as *likely*. However, for the speaker  $S_1(\cdot|unlikely, \mathcal{L}^2)$ , the extra precision of “expensive” is valuable, because it overrides the base listener’s prior bias against *unlikely*. This breaks the symmetry and leads  $L_2$  to start to prefer the efficient mapping, a preference that gets magnified by  $S_3$ ’s reasoning and continues to get magnified at higher levels of recursive inference.

The lexical uncertainty model can predict correct Horn equilibria beyond the case with two meanings and utterances; predictions (approximated by averaging over a finely gridded approximation to the parameter space) for the case with three meanings and utterances are shown in Figure 3.

## Experiment 2

In Experiment 2 we investigated whether people can coordinate on Horn’s principle in the absence of prior linguistic conventions. This experiment was designed to be a minimal test of this question: people were placed in the simplest setting in which Horn’s principle is possible. People played a communication game with a partner as in Experiment 1. There were three possible meanings for the speaker to communicate, which differed in how frequently they appeared in the game. The speaker was able to communicate the intended meaning by sending one of three messages, which differed only in their cost to the speaker—none was iconic. If the

same reasoning that gives rise to Horn’s principle extends to this novel setting, then we expect the speaker and listener to coordinate on the efficient mapping of meanings to messages.

## Methods:

We recruited 140 participants from Amazon Mechanical Turk, who were paid for participation in addition to bonus payments described below.

The interface and instructions for the experiment were very similar to Experiment 1. Participants were told that they landed on an alien planet containing three kinds of objects and three messages that could be used to communicate these objects. They were told that these objects occurred with different frequencies on the planet; one occurred 60% of the time, one occurred 30%, and the last occurred 10%. Of the three messages, one was free, one cost \$0.01, and the last cost \$0.02. The object frequencies and message costs were randomized between subjects. Participants received 10 practice rounds without a partner to familiarize them with the interface, object frequencies, and message costs, but received no feedback during these rounds.

Each participant played 5 rounds of the game with a partner randomly assigned each round. The game was the same as in Experiment 1, with two changes. The object that the speaker needed to communicate was randomly sampled according to the frequency of the objects on the alien planet (so, e.g., the most frequent object was sampled 60% of the time). Second, the speaker was charged the cost of the message sent.

Table 1: Experiment 2 analyses

Role	Response	Comparison	t-value	p-value
Listener	Frequent object	Cheap utterance > intermediate, expensive	6.07	0.001
	Intermediate object	Intermediate utterance > cheap, expensive	5.31	0.001
	Unlikely object	Expensive utterance > cheap, intermediate	5.55	0.001
Speaker	Cheap utterance	Frequent object > intermediate, unlikely	8.27	0.001
	Intermediate utterance	Intermediate object > frequent, unlikely	6.21	0.001
	Expensive utterance	Unlikely object > frequent, intermediate	5.55	0.001

## Results and Discussion

Human speaker and listener choices are shown in figure 3, alongside the predictions of our base model (pink bars), which does not predict the Horn equilibrium, and our lexical-uncertainty model (green bars), which does. We first analyzed whether listeners interpreted messages according to the efficient mapping, by carrying out three mixed logit regressions with random intercepts for participants. We analyzed whether, e.g., listeners responded with the frequent object more often when they received the cheap utterance than the other utterances. These comparisons are shown in Table 1. They show that the listener's responses were consistent with the efficient mapping. We next analyzed whether speakers chose messages efficiently. We addressed this question in a similar manner to the previous one, carrying out three mixed logit regressions with random intercepts for participants. The comparisons in table 1 show that the speaker was more likely to use the cheap utterance given the frequent object than given the other objects, and similarly for the other utterances.

By design, each participant only played five rounds of the game. This was done to ensure that observed efficiency effects were due to cooperative reasoning, and not due to language evolution. To validate this design, we analyzed whether participants played differently on the first round than on future rounds. To do this, we performed by-subject ANOVAs on the speaker and listener responses to determine whether there were main effects or interactions from the first round. For five of the six speaker and listener response types, there was no main effect of the first round or interaction with the object to communicate or message received ( $p > 0.05$ ). For the intermediate-cost message, there was a small but significant interaction between the first round and the object to communicate ( $p < 0.05$ ). These analyses provide evidence that learning or language evolution are not driving our results.

These results provide evidence that people can construct efficient strategies for communication on-line, in the absence of prior linguistic conventions. This suggests that Horn's principle, as it applies to ordinary language use, may arise from cooperative reasoning between people trying to communicate with each other, rather than from language evolution.

## Discussion

We have investigated two kinds of pragmatic contrast effects. First, we looked at the effect of varying the specificity, or informativeness, of the utterances available to the speaker. A simple model of social cognition was able to account for the strengthening of a non-specific utterance's interpretation. We found in Experiment 1 that listeners inferred this strengthened interpretation, and that speakers anticipated this, in the absence of any prior linguistic conventions.

We next turned to Horn's principle and the effect of varying the relative cost or complexity of utterances. We first found that the simple model of social cognition cannot explain Horn's principle, because it does not have the resources to exploit the asymmetry between more and less costly utterances. However, once the model included uncertainty about the underlying lexicon, it was able to predict Horn's principle, and explain this asymmetry: under the model, only someone who wanted to communicate an unlikely meaning would have an incentive to use an expensive utterance. Notably, this is the first proposed model of Horn's principle which does not rely on specialized equilibrium selection criteria. In Experiment 2, we found evidence that people expect costlier utterances to correspond to less frequent meanings, as predicted by Horn's principle.

Our results suggest that in two important cases, people's pragmatic knowledge extends beyond learned grammatical knowledge to novel, non-linguistic communicative scenarios. While we have not settled the question of how people arrive at ordinary pragmatic inferences, our experimental and modeling results do provide evidence that linguistic conventions are not necessary for them—social cognition will suffice.

## Abstract

This paper presents results from the first rational model of eye movement control in reading to make predictions for the full range of the eye movement record. The model identifies the text through Bayesian inference and makes eye movement decisions to maximize the efficiency of text identification, going beyond leading approaches which select model parameters to maximize the fit to human data. Two simulations with the model demonstrate that it can produce effects of word predictability and frequency on eye movements in reading similar to those produced by humans, providing evidence that many properties of human reading behavior may be understood as following from the nature of efficient text identification.

**Keywords:** eye movements; reading; rational analysis; computational modeling

## Introduction

During reading, comprehenders must decide when and where to move their eyes 3–4 times every second. Over the past decades, it has been demonstrated that comprehenders make these rapid, fine-grained decisions by combining information from a range of sources including visual input, the motor system, and linguistic knowledge (for reviews see Rayner, 1998, 2009), making reading one of the most complex learned tasks that humans face every day. Gaining a better understanding of this process promises to yield insights about how readers deploy linguistic knowledge for real-time comprehension as well as about how humans learn to perform complex tasks more generally. In this paper, we present the first rational model of eye movement control in reading that makes predictions for the full range of the eye movement record. We model readers as performing Bayesian inference on the identity of the text, combining their probabilistic language knowledge (the prior) with noisy perceptual input about the text (the likelihood) to form and repeatedly update a posterior distribution over the possible text identities. The model uses a parameterized behavior policy for determining when and where to move the eyes, which is sensitive to the posterior distribution over the text, and with parameters selected to optimize identification efficiency. We evaluate the model by examining the effects it produces for two linguistic variables: word frequency and predictability. We present the results of two simulations showing that the model produces effects of these variables similar to those of humans, across four different eye movement measures reflecting both the locations and durations of fixations. The success of the model in deriving these effects from principles of probabilistic inference and rational action suggests that many aspects of human reading behavior may be profitably understood as properties of the set of efficient solutions to the problem of reading.

This model goes beyond leading models of eye movement control in reading such as E-Z Reader (Reichle, Rayner, &

Pollatsek, 2003) and SWIFT (Engbert, Nuthmann, Richter, & Kliegl, 2005) in two ways. First, while those models select parameters to maximize the fit to human data, the current work selects parameters to optimize the efficiency of reading, here characterized as rapid and accurate identification of the contents of the text. To the extent that the model behavior reproduces effects seen in human data, then, it enables understanding those effects as resulting from the properties of efficient solutions to the task. Second, the current work includes a model of the process of identification from visual input, and in so doing derives effects of linguistic variables (such as word frequency and predictability) as resulting from efficient identification, while models such as E-Z Reader and SWIFT directly specify the effects of linguistic variables on eye movement behavior through functions whose form is stipulated exogenously to the model. Modeling identification from visual input should allow for the model to be used to understand a range of effects that are known to influence eye movements but which leading approaches cannot capture, such as information density within words (Hyönä, Niemi, & Underwood, 1989), word misidentification (Slattery, 2009; Levy, Bicknell, Slattery, & Rayner, 2009), and visual neighborhoods (Pollatsek, Perea, & Binder, 1999). The model also goes beyond the only previous rational model of eye movement control in reading, Mr. Chips (Legge, Hooven, Klitz, Mansfield, & Tjan, 2002), in making predictions about not only the location of fixations but also their duration, which is important to gaining a full understanding of a range of effects on eye movements in reading, especially the effects of linguistic variables.

In the following section, we describe our rational framework for reading and the details of our model of eye movement control in reading. We then focus the remainder of the paper on using the model to understand the effects on eye movements in reading of word frequency and predictability, two of the most reliable linguistic effects in the eye movement record. We first use the model qualitatively to provide explanations for why the effects of these variables seen empirically should result from efficient reading behavior, and then present the quantitative results of two simulations demonstrating that these effects are evident in the model's behavior.

## Reading as Bayesian inference

In the proposed framework, we model the goal of reading as efficient text identification. While it is clear that this is not all that readers do – inferring the underlying structural relationships among words in a sentence and discourse relationships between sentences that determine text meaning is a fundamental part of most reading – all reader goals necessarily in-

volve identification of at least part of the text, so we take text identification to be a reasonable first approximation. There are two sources of information relevant to this goal: visual input and language knowledge, which the model combines via Bayesian inference. Specifically, it begins with a prior distribution over possible identities of the text given by its language model, and combines this with noisy visual input about the text at the eyes' position (giving the likelihood term) to form a posterior distribution over the identity of the text taking into account both the language model and the visual input obtained thus far. On the basis of the posterior distribution, the model then decides whether or not to move its eyes (and if so where to move them to) and the cycle repeats.

An implemented model in this framework must formalize a number of pieces of the reading problem, including the possible actions available to the reader and their consequences, the nature of visual input, the nature of language knowledge, a means of combining visual input with prior expectations about the form and structure of the text, and a behavior policy determining how the model will choose actions on the basis of its posterior distribution over the identity of the text. In the remainder of this section, we present the details of our formalizations of these pieces.<sup>1</sup>

### Formal problem of reading: Actions

We assume that on each of a series of discrete timesteps, the model obtains visual input around the current location of the eyes, and then chooses between three actions: (a) continuing to fixate the currently fixated position, (b) initiating a saccade to a new position, or (c) stopping reading. If the model chooses option (a), time simply advances, and if it chooses option (c), then reading immediately ends. If a saccade is initiated (b), there is a lag of two timesteps, representing time required to plan a saccade, during which the model again obtains visual input around the current position, and then the eyes move toward the intended target. Because of motor error, the actual landing position of the eyes is normally distributed around the intended target with standard deviation given by a linear function of the intended distance, with parameters taken from Engbert et al. (2005).<sup>2</sup>

### Noisy visual input

The visual input obtained by a reader on a given timestep is generated from the following process, independently for each character position. Each letter is represented as a 26-dimensional vector, where a single element is 1 and the others are zeros, and visual input about a letter is a sample from a 26-dimensional Gaussian with a mean equal to the letter's true identity and a diagonal covariance matrix  $\Sigma = \lambda^{-1}I$ , where  $\lambda$  is the reader's visual acuity at that position. Higher visual

acuity, then, means a lower sample variance, yielding higher quality visual input. We use the visual acuity function from Engbert et al. (2005), in which  $\lambda$  decreases exponentially with retinal eccentricity and decreases asymmetrically, falling off more slowly to the right than the left.<sup>3</sup> In order to scale the quality of visual information, we multiply each acuity  $\lambda$  by the overall visual input quality  $\Lambda$  (values given in the simulations below.) Visual input about non-alphabetic characters is veridical knowledge of their identity. Visual input is limited to the 19 character positions with the highest acuity (eccentricities between -7 and 12), roughly corresponding to estimates that readers of English obtain useful information from about 19 characters, and more from the right of fixation than the left (Rayner, 1998). Note that in the model each letter is equally confusable with all others, following Norris (2006, 2009), but ignoring work on letter confusability (which could be added to future model revisions; Engel, Dougherty, & Brian Jones, 1973; Geyer, 1977).

### Language knowledge

In general, any generative model of linguistic knowledge that assigns probabilities to text can be used as the prior distribution on the identity of the text. For the simulations in this paper, we use very simple probabilistic models of language knowledge: word  $n$ -gram models (Jurafsky & Martin, 2009). These models encode the probability of each word conditional on the  $n - 1$  previous words. While this is obviously a crude representation of the rich knowledge of language that human readers have, it serves here to illustrate the qualitative effects of using linguistic context in reading.

### Inference about text identity

Given both visual input and language knowledge, the model makes inferences about the identity of the text  $w$  via standard Bayesian inference, where the prior is given by the probability of generating text identity  $w$  from the language model and the likelihood is the probability of generating the visual input  $\mathcal{I}$  from text with identity  $w$  under the visual input model:

$$p(w|\mathcal{I}) \propto p(w)p(\mathcal{I}|w).$$

### Behavior policy

The model uses a simple policy with two parameters,  $\alpha$  and  $\beta$ , to decide between actions based on the marginal probability  $m$  of the most likely character  $c$  in each position  $j$ ,

$$m(j) = \max_c p(w_j = c)$$

where  $w_j$  indicates the character in the  $j$ th position. A high value of  $m$  indicates relative confidence about the character's identity, and a low value relative uncertainty.

Given the values of this statistic  $m$ , the model decides between four possible actions, as illustrated in Figure 1. If the

<sup>1</sup>See Bicknell and Levy (2010b) for further computational details.

<sup>2</sup>In the terminology of the literature, the model has only random motor error (variance), not systematic error (bias). Following Engbert and Krügel (2010), systematic error may arise from Bayesian estimation of the best saccade distance.

<sup>3</sup>While we call refer to it here as visual acuity, it is clear from the asymmetric nature of this function that it also has an attentional component. For now, however, we make the simplifying assumption that it is unchanging over time.

- (a)  $m = [.6, .7, \mathbf{.6}, .4, .3, .6]$ : Keep fixating (3)
- (b)  $m = [.6, .4, \mathbf{.9}, .4, .3, .6]$ : Move back (to 2)
- (c)  $m = [.6, .7, \mathbf{.9}, .4, .3, .6]$ : Move forward (to 6)
- (d)  $m = [.6, .7, \mathbf{.9}, .8, .7, .7]$ : Stop reading

Figure 1: Values of  $m$  for a 6 character text under which a model fixating position 3 would take each of its four actions, if  $\alpha = .7$  and  $\beta = .5$ .

value of this statistic for the current position of the eyes is less than the parameter  $\alpha$ , the model chooses to continue fixating the current position (1a). Otherwise, if the value of  $m(j)$  is less than the parameter  $\beta$  for some leftward position, the model initiates a saccade to the closest such position (1b). If no such positions exist to the left, then the model initiates a saccade to  $n$  characters past the closest position to the right for which  $m(j) < \alpha$  (1c).<sup>4</sup> Finally, if no such positions exist to the right, the model stops reading (1d). Intuitively, then, the model reads by making a rightward sweep to bring its confidence in each character up to  $\alpha$ , but pauses to move left to reread any character whose confidence falls below  $\beta$ .

## Predictability and frequency in rational reading

The general findings about the effects of word predictability and frequency on eye movements in reading can be summarized relatively simply: words that are less predictable and lower frequency tend to receive more and longer fixations (Rayner, 1998, 2009). Here we describe intuitions for why our model should qualitatively reproduce these effects.

### Predictability

The basic intuition for why the model should produce effects of word predictability is very closely related to the reason for frequency effects in isolated word recognition reaction times given by Norris (2006, 2009). In short, the lower the prior probability of a word, the more visual input about it is needed to become confident in its identity. A bit more formally, this intuition is clearest if we make the simplifying assumption that prior to obtaining any visual information about a word, the model has near-veridical knowledge of the preceding context. In that case, the probability of the true identity of the word is given by the word’s predictability in context  $\pi$ . Visual input about the word will then (on average) increase the probability of the word’s true identity under the model’s beliefs. Recall that under our behavior policy, the eyes will remain in this position until the model’s confidence in the identity of the character at that position exceeds the threshold  $\alpha$ . Because information is being obtained about the entire word simultaneously, the probability of the identity of the fixated character is closely tied to the identity of the entire word. Specifically, the model’s confidence in the identity of the word gives a lower bound on the model’s confidence in the identity of a charac-

ter within that word. Thus, the initial probability of the true identity of the fixated character will start at or above the initial probability  $\pi$  of the true word, and – when the word is identified correctly – the model’s confidence about the identity of the fixated character is likely to reach the threshold  $\alpha$  near the same time that confidence about the identity of the fixated word reaches the threshold. As a consequence, the amount of visual input that is needed to reach the threshold which initiates a saccade is largely a function of the distance between  $\pi$  and  $\alpha$ . For more predictable words,  $\pi$  is closer to  $\alpha$ , so less visual input will be needed on average to reach  $\alpha$ , translating into shorter and fewer fixations on the word.

### Frequency

The most obvious intuition for the effect of frequency in the model is parasitic on the effect of predictability: words that are lower frequency are less predictable on average. Thus, as with words of higher predictability, there should be on average shorter and fewer fixations on words of high frequency.

## Simulation 1: full model

We now assess the effects of word predictability and frequency that the model does in fact produce. We use the model to simulate reading of a modified version of the Schilling corpus (Schilling, Rayner, & Chumblay, 1998) of typical sentences used in reading experiments. The arguments just described predict qualitatively that the model will make more and longer fixations on words of lower predictability and frequency. In addition, we quantitatively compare the model’s frequency effects to those of human readers of the Schilling corpus, which have been reported by Pollatsek et al. (2006).

### Methods

**Model implementation** We implemented our model with weighted finite-state automata (wFSAs) using the OpenFST library (Allauzen, Riley, Schalkwyk, Skut, & Mohri, 2007). While inference in the wFSA is exact, for efficiency we used Monte Carlo sampling from the wFSA to estimate the model’s confidence  $m$  in each character position.

**Model parameters and language model** We set the overall visual input quality  $\Lambda$  to 4. The model’s language knowledge was an unsmoothed bigram model created using a vocabulary set consisting of the 500 most frequent words in the British National Corpus (BNC) as well as all the words in our test corpus. From this vocabulary, we counted every bigram in the BNC for which both words were in vocabulary. Due to the intense computation required for exact inference, we then trimmed this set by removing rare bigrams that occur less than 200 times (except that we do not trim any bigrams that occur in our test corpus). This left a set of about 19,000 bigrams, from which we constructed the bigram model.

**Optimization of policy parameters** We define reading efficiency  $E$  to be an interpolation of speed and accuracy

$$E = (1 - \gamma)L - \gamma T$$

<sup>4</sup>The role of  $n$  is to ensure that the model does not center its visual field on the first uncertain character. For the present simulations, we did not attempt to optimize this parameter, but fixed  $n$  at 3.

where  $L$  is the log probability of the true identity of the text under the model's beliefs at the end of reading,  $T$  is the number of timesteps before the model stopped reading, and  $\gamma$  gives the relative value of speed. For the present simulations, we use  $\gamma = .05$ , which produces reasonably accurate reading. To find optimal values of the policy parameters  $\alpha$  and  $\beta$  for this definition of efficiency, we use the PEGASUS method (Ng & Jordan, 2000) to transform this stochastic optimization problem into a deterministic one on which we can use standard optimization algorithms. We then use coordinate ascent (in logit space) to find the optimal values of  $\alpha$  and  $\beta$ . This procedure resulted in optimal values  $\alpha = .88$  and  $\beta = .98$ .<sup>5</sup>

**Test corpus** To ensure that results did not depend on smoothing, we tested the model only on sentences from the Schilling corpus in which every bigram occurred in the BNC. Unfortunately, only 8 of the corpus sentences initially met this criterion, so we made single-word changes to 25 more (mostly proper names and rare nouns), producing a total of 33 sentences for which every bigram occurred in the BNC.

**Analysis** We used the model to perform 50 stochastic simulations of the reading of our modified version of the Schilling corpus. For each run, we calculated four standard eye movement measures for each word in the corpus: first fixation duration, gaze duration (defined to be the sum of all first pass fixations), skipping probability (whether or not word was directly fixated), and refixation probability (the probability of more than one first pass fixation). We then averaged each of these four measures for each word token in the corpus, yielding a single mean value for each measure for each word.

In order to compare the fixation duration measures to humans, we converted the model's timesteps into milliseconds. We performed this scaling by multiplying the duration of each fixation by a conversion factor set to be equal to the mean human gaze duration divided by the mean model gaze duration for the highest frequency bin. That is, we scaled the model predictions to exactly match the human mean for gaze durations in the highest frequency bin.

## Results

For each word in our modified version of the Schilling corpus, we defined its predictability to be its probability under the bigram language model, and we defined its frequency to be its overall probability in the data from which the bigram language model was constructed.

**Predictability** Figure 2 (red lines) shows the effect of predictability on the four aggregate measures. As predicted by both the intuition given above, and in agreement empirical human data, there are shorter fixations, more skipping, and

Figure 2: Effects of word predictability in both models on first fixation durations, gaze durations, the rate of skipping, and the rate of making a refixation, as estimated using Gaussian kernel regression with standard deviation equal to 1/8th of the range of log-predictability values. The 95% confidence intervals are bootstrapped from 1000 dataset replicates.

fewer refixations for more predictable words.

**Frequency** Figure 3 (red lines) shows the effects of frequency (binned by rounding down, to facilitate comparison to Pollatsek et al., 2006) on the four aggregate measures. The results across all four measures show a reasonable quantitative fit to the human data (blue lines). Further, comparing the overall size of the effect (i.e., the difference of the highest and lowest frequency bins) of the model to the human data shows a striking fit in effect direction and magnitude for all four measures. One unpredicted result here, however, is that the effect of frequency on the duration measures does not appear completely monotonic.

## Discussion

In summary, these results demonstrate that effects of predictability and frequency in the model's behavior resemble that of human readers in many respects. Predictability effects on all four aggregate measures are monotonic and in the same direction as predicted. Frequency effects on all four measures are in the same direction as predicted, and the total magnitude of the effect is quite similar to that displayed by human readers, despite the fact that we have not made any attempt to fit the human data, excepting only the scaling parameter that converts model timesteps to milliseconds. Overall quantitative fits on all four measures showed reasonable agreement to human data, but the fixation duration measures displayed

<sup>5</sup>It may at first seem puzzling that  $\alpha < \beta$ . However, this is a general property of optimal behavior for the model. While saccades to leave a character are initiated as soon as confidence  $m > \alpha$ , because of the saccade execution delay,  $m$  is usually substantially higher than  $\alpha$  when the eyes leave the character. Hence, it is a reasonable strategy for the threshold for regressions  $\beta$  to be accordingly higher. See also Bicknell and Levy (2010b) for further discussion.

Figure 3: Effects of word frequency in both models on first fixation durations, gaze durations, the rate of skipping, and the rate of making a refixation. The 95% confidence intervals are bootstrapped from 10000 dataset replicates. Mean values from human readers of the Schilling corpus reported by Pollatsek et al. (2006) are shown for comparison.

some non-monotonicity.

It is perhaps unsurprising that predictability seems to have the most consistent effect, given the large role that predictability plays in the model, and the relatively straightforward predictions made previously. More surprising are the apparent non-monotonicities in the predictions for how the fixation duration measures should vary with respect to word frequency. One possibility is that these arise from our artificial removal of many low-frequency words from the language model, which may have meant that some of the low-frequency words in the Schilling corpus had artificially few visual neighbors, yielding an anti-frequency effect. The next simulation investigates this hypothesis.

### Simulation 2: Model without context

The main goal of Simulation 2 is to explore the possibility that removing low frequency words from the model’s vocabulary (which was necessary for computational efficiency) contributed to the non-monotonicities we observed in the effects of word frequency on fixation durations. Our strategy is to simplify the language model, which makes the computations faster to carry out, allowing for the use of a larger vocabulary. Specifically, we replace the previous bigram language model, which made use of linguistic context, with a unigram language model that includes only word frequency information and cannot make use of linguistic context. This simplified language knowledge also allows us to test how the model’s

predictions change when it can no longer make use of linguistic context to help recognize words.

## Methods

Except the following, the methods were identical to those of Simulation 1. We replaced the bigram language model with a unigram language model. Training was performed in the same manner, except that instead of including only the most common 500 words in the BNC, we included all words that occur at least 200 times (corresponding to a frequency of 2 per million; about 19,000 words). Finally, we increased the overall visual input quality  $\Lambda$  from 4 to 10. Because the new language model gives poorer information about the text, more visual input is needed to reach similar levels of confidence in word identities. Increasing the overall input quality to 10 results in the new model taking a similar number of timesteps to read a sentence as the previous model.

## Results and discussion

**Predictability** Figure 2 (green lines) shows the effect of predictability on the four aggregate measures for the model without context. Because the model does not make use of linguistic context in identifying words, any apparent effects of predictability must reflect effects of other variables correlated with predictability (e.g., frequency and length). We can then use these results as a baseline to determine the amount of the full model’s apparent predictability effect that was in fact driven by predictability. The results across all four measures show that predictability effects are smaller for this model without context, indicating that the full model’s use of context was important in producing its predictability effects.

**Frequency** Figure 3 (green lines) shows the effect of frequency on the four aggregate measures. Across all four measures, the size of the frequency effect in this model also shows a reasonable quantitative fit to human data, although the refixation rates and first fixation durations are about twice as far from human data as the full model. As with the full model, however, the direction and magnitude of all frequency effects is a close match to human data. The higher refixation rate and lower word skipping rate of this model relative to the full model likely reflect the model’s poorer language knowledge (cf. Bicknell & Levy, 2010a). Finally, and most importantly, we see that the problem of non-monotonicity is substantially reduced for first fixation durations and completely eliminated for gaze durations, supporting our argument that trimming the vocabulary may have been responsible for some of the non-monotonicity in the previous simulation results.

## General discussion

In this paper, we presented the first rational model of eye movement control in reading to make predictions for the entirety of the reading record. We gave intuitions for why it should produce effects of word predictability and frequency qualitatively similar to those produced by human readers, and presented two simulations empirically testing the effects of

these variables on model behavior. Simulation 1, using a full version of the model with parameters selected to maximize the agent's reading efficiency, demonstrated that the model yields effects of frequency and predictability that are qualitatively – and in frequency's case, quantitatively – similar to those of human readers, though the predictions for fixation durations on words of intermediate frequency did not appear completely monotonic. We hypothesized that these non-monotonicities may have been a result of the full model's small vocabulary, which had to be artificially limited for technical reasons. Simulation 2 tested this hypothesis using a model with simpler language knowledge but a larger vocabulary, and provided some evidence that alleviating this limitation helps to make the frequency effects more monotonic. In addition, by demonstrating that a model that cannot make use of predictability information shows smaller apparent predictability effects, Simulation 2 demonstrated that the predictability effects obtained for the full model were not likely to have been merely an artifact of the correlation between word predictability and other variables such as word length.

Taken together, these results demonstrate that the rational reading framework can produce reasonable effects of word predictability and frequency on four aggregate measures of eye movement behavior: first fixation durations, gaze durations, skip rates, and refixation rates. While the quantitative fit to human data is not perfect, the fact that it is such a good match is striking given that we fit no free parameters to human data, except the conversion of timesteps to milliseconds – a parameter that all timestep-based models must include. (In future work, determining the model's best possible fit to human data will require tuning the only two other truly free parameters of our model – the agent's value of speed relative to accuracy  $\gamma$  and the overall visual input quality  $\Lambda$ .) Instead of being selected to maximize the model's fit to human data, the policy parameters  $\alpha$  and  $\beta$  of our model were set to values that optimized the efficiency with which the model identified the text, given the agent's particular goal function. Future work must be done to explore the predictions of our model for a wider range of eye movement phenomena observed in reading, extending our analyses of the model's behavior both with more dependent measures, such as character landing positions within words and regressive saccades, and with more independent variables, such as word length.

# The retriever-connector model: Matching Classroom Data and Agent-Based Computer Models to Simulate Students' Use of Multiple Epistemological Resources

Paulo Blikstein (paulob@stanford.edu)

TLT Lab, School of Education and (by courtesy) Computer Science Department, Stanford University  
520 Galvez Mall, CERAS 232, Stanford, CA 94305 USA

## Abstract

Utilizing data from a classroom intervention with 8<sup>th</sup> graders, I employ agent-based computer modeling to simulate the cognitive processes at play during the intervention, in which students transition between using multiple epistemological resources. The model substantiates the hypothesis of manifold epistemological resources, which can be activated with simple prompts and have a non-linear impact on learning.

**Keywords:** Cognitive modeling; agent-based modeling; classroom research; epistemological resources.

## Introduction

Agent-based modeling (ABM) has been increasingly used by scientists to study a wide range of phenomena such as the interactions of species in an ecosystem, the collisions of molecules in a chemical reaction, and the food-gathering behavior of ants (Bonabeau, Dorigo, & Theraulaz, 1999; Wilensky & Reisman, 2006). Such phenomena, in which the *agents* in a system (molecules, or ants) follow simple rules and interaction patterns, but exhibit complex emergent macroscopic behaviors, are studied in a young interdisciplinary field called complex systems or complexity studies (Holland, 1995). Although complex-systems perspectives initially arose from the natural sciences, complexity, emergence, and multi-level descriptions of phenomena are all highly relevant to social science research. In fact, recent decades have observed a surge in social-science studies employing ABM (Epstein & Axtell, 1996; Axelrod, 1997). Recently, ABM has also been used to illustrate aspects of cognitive development (Abrahamson & Wilensky, 2005; Blikstein, Abrahamson & Wilensky, 2006; Smith & Conrey, 2006), and collaboration and group work in classrooms (Abrahamson, Blikstein, & Wilensky, 2007).

ABM has the potential to advance theory in multiple ways, which I illustrate in this paper: (a) explicitizing—ABM demands a high level of specificity in expressing a theoretical model, and it provides the tools and standard practices to express those models; (b) dynamics—ABM enables researchers to mobilize an otherwise static list of conjectured behaviors and observe the macroscopic patterns that may unfold; (c) emergence—ABM can examine cognition and social behaviors as a collection of decentralized, simple rules; and (d) interdisciplinary collaboration—the *lingua franca* of ABM enables researchers from different fields to understand, critique and challenge each other's theories by modifying and extending the computational algorithms that underlie their theoretical models.

## Relevance to cognitive research

Agent-based modeling in cognitive research could address the limitations of current methodologies. First, because experiments with human subjects cannot be indefinitely conducted, replicating findings or exploring a wide parameter space is costly and oftentimes impossible. In the case of research in schools, once the classroom data are collected, the researchers can revisit the videotapes and transcriptions; however, they can never relive the situations. Second, as the field moves toward theories that conceptualize learning as a dynamic and adaptive phenomenon, the traditional medium of scientific discourse—static linear text—becomes limited in its capacity to express these theories. Both of these flaws could be addressed with a set of dynamic, adaptive computer models of learning. Third, tools such as brain imaging cannot yet offer the speed and resolution required to evaluate complex learning processes at a neuronal level, so such models are still far from being applicable to real classrooms. Lastly, ethnographic or micro-genetic methods still cannot offer a 'runnable,' systemic, task-independent account of human learning.

The ultimate goal of using agent-based simulation to explore human learning is to enable researchers to generalize and play "what-if" scenarios using in-depth interviews and ethnographic data and to help them investigate internal cognitive structures by observing external behaviors.

This work builds on previous seminal contributions to the field, in which theoretical models of cognition were implemented by using computer programs to attempt to predict human reasoning (Newell & Simon, 1972) in tasks such as shape classification (Hummel & Biederman, 1992), language acquisition (Goldman & Varna, 1995), memory (Anderson, Bothell, Lebiere, & Matessa, 1998); and other more general-purpose models (Anderson, 1983; Anderson & Bellezza, 1993; Anderson & Lebiere, 1998). My design, however, differs from extant approaches in two ways: (1) *Grain Size: Selecting a unit of analysis toward bridging the micro and macro perspective on learning.* Theories which slice human learning into diminutive pieces, when reintegrated into the larger context of classroom learning, could not account for any meaningful macro-cognitive phenomena, and (2) *Accessibility: Democratizing modeling-based research.* Most computational theories of the mind are so mathematically complex that only specialized researchers can examine and critique them; the intricacies

and jargon of these theoretical models render them incomprehensible for teachers, educators, and policymakers. Conversely, the computer language that I have used for modeling, NetLogo (Wilensky, 1999), has been developed for non-programmers so that users could not only run models but also modify their rules and compare scenarios.

My theoretical inspiration comes from the work of Minsky (1986), and Collins (1978). My computer-based models of human learning postulate non-intelligent cognitive entities with simple rules from which intelligent behavior emerges, or simple individual classroom behaviors that result in complex group-level patterns. To generate and validate such models, ABM tools enable researchers to initially feed a computer model with data from real-world experiments, such as classroom observations or clinical interviews and to subsequently simulate hypothesized scenarios in a safe virtual environment. Researchers from diverse disciplines (and with little, if any, programming background) can embody and articulate their theoretical models in a shared medium with shared nomenclature and shareable/replicable data, thus facilitating interdisciplinary discourse and critique.

However, the work described in this paper is not attempting to *reproduce reality*, which is oftentimes understood to be the goal of a computer model. My objective is to instantiate possible theories of learning in the agent-based form and use the data to qualitatively validate the models, with the goal of advancing theory. However, unlike classical cognitive models, this category of ABM models needs to be much more stylized and simple, as this paper will describe.

### Personal epistemologies & resources

Traditional research on personal epistemologies (Hofer & Pintrich, 2002) has considered them as stable beliefs. However, evidence of variability in student epistemologies suggests the need for more complex models (Hammer & Elby, 2002). The activation of the students' different epistemological resources might depend on context, as shown by Rosenberg, Hammer, & Phelan (2006). In other words, students might instantiate different epistemologies as they perceive contextual cues about the most efficient approach in a given situation. In the Rosenberg et al. case study, a brief epistemological intervention by an 8<sup>th</sup>-grade science teacher led to the students abruptly shifting from one epistemological mode to another. The narrative tells the story of a group of students who were given the task of explaining the rock cycle. For the first few minutes, before the teacher's intervention, they fail to engage in any productive work or to construct a coherent explanation of the rock cycle. Students employ a 'brute force' approach by quickly trying out several short explanations without evaluating if the elements of their explanations make sense together. They generate fragmented descriptions, which do not survive simple logical inference. Rosenberg et al. state that the reason is epistemological and that "They are treating knowledge as comprised of isolated, simple pieces of

information expressed with specific vocabulary and provided by authority." (Rosenberg, et al., 2006, pp. 270)

The authors provide three pieces of evidence for this hypothesis: (1) the students organize their efforts around retrieving information from worksheets, (2) they focus on terminology, and (3) they combine information and construct sentences to present a formal ordering rather than a causal sequence. The narrative goes on to describe how the teacher, realizing the ongoing failure, stops the activity and tells the students: "So, I want to start with what you know, not with what the paper says."

Abruptly, the students change their approach toward engaging in the activity. They immediately start to focus on the elements of the rock cycle that they understand, and they rebuild the story from there. Within minutes, one of the students comes up with a rather complete explanation:

"OK, the volcano erupts, and lava comes out. Lava cools and makes igneous rock. Rain and wind cause small pieces of rock to break off. Sediments form, and rain and wind carry it away, and rain and wind slow down and deposit sediments and this happens over and over again to form layers." (Rosenberg, et al., 2006, pp. 274)

It is impressive how the students, focusing on a single element of the story ("Lava comes out"), correctly connect all of the other pieces of the explanation. Although the "lava comes out" piece was the first to be mentioned, they realized that for lava to come out, the volcano has to erupt; similarly, if the lava comes out and is hot, it has to cool down. For the students to generate a coherent explanation, it was crucial for them to concatenate information while making sense of the connection rules, and they resorted to worksheets fewer times than in the previous activity.

In this paper, my goal is to employ ABM to help model what occurred during those 15 minutes and to answer two research questions concerning the abrupt epistemological shift observed: (1) what caused the two modes to generate very diverse student performance? and (2) how could a brief intervention cause such dramatic change? I built a model that simulates the construction of declarative knowledge in terms of two basic cognitive operations: retrieving information from external/internal sources and applying concatenation rules to join *content pieces*. I expect to answer the research questions by exploring the parameter space of the model for number, type, and efficiency of retrievers and connectors; this might result in emergent behaviors similar to those observed by Rosenberg et al. I warn the reader that the goal is to match an overall reference pattern based on simple theoretical assumptions about learning. The nature of ABM is such that this simplicity is required to generate a manageable parameter space.

### The Agent-Based Model

In the model, the world outside of the mind is composed of various disconnected *content pieces*, represented as green agents. A piece could be a simple statement, such as "Lava comes out of volcanoes," "Lava shoots up," or "Water erodes rocks." These pieces are retrieved by special agents,

called *retrievers* – represented as red agents – and accommodated into the simulated mind. Here, they interact with pre-existing structures until they connect to one of them, making use of a third type of agent, the *connectors*. These pre-existing structures could form an emergent, dynamic network with “hub ideas” (highly connected ideas) and peripheral ideas.

Therefore, the model consists of three independent elements: connectors, retrievers, and content pieces (line-shaped white agents, red agents, and green agents, respectively). Content pieces could be gathered by retrievers to simulate external information being exposed to the mind. Furthermore, the retrievers’ movement simulates the exposure and the searching for different content pieces over time. The recently retrieved information could be connected to preexisting mental structures to form a new knowledge “assembly.” This knowledge-construction process is represented by content pieces being connected to each other via connector agents. Accordingly, the students’ explanations are the ad hoc result of *pieces* of content collected by *retrievers* outside of the mind and assembled by *connectors* inside the mind. For the sake of the model’s simplicity, the internal and external processes occur in the same environment and have not been distinguished visually.

In the simulated world, the content pieces can have a different *stickiness* to the retrievers, thus the model can differently evaluate content from various sources. Content given from authority can have a different effect than previous knowledge in the virtual mind. In addition, retriever agents have been defined hypothesizing that content cannot simply enter the mind as raw information. Information needs to be retrieved and subsequently connected by internal knowledge structures (Piaget, 1952). Furthermore, retrieved content cannot be accessed until it is evaluated and internalized by connectors (Figure 1).

In the real classroom situation, students would assemble a textual explanation, such as: [*the volcano erupts + lava comes out + lava cools + lava makes igneous rock*]. In this model, textual explanation pieces are replaced with numbers, and a correct explanation is simply an ascending sequence of numbers (1, 2, 3, etc.), which reflects the nature of the task that students had at hand (sequencing information). I am aware of the limitations of the chosen approach, but this design principle was appropriate given the research questions and the target results.

Figure 1. The model’s initial state (left) and after some steps (right), with ‘clusters’ of content form around retrievers.

## Experiments and Data

Contrary to most cognitive modeling software, this model does not attempt to simulate human thinking in its immense range of complexities and detail. I selected, conversely, the particular features of learning processes that will possibly enable me to pair the model’s data and the observations of Rosenberg et al. Because I am only modeling the agent’s ability to construct correct connections between pieces, I am ultimately investigating the computational cost and accuracy in building probabilistic cognitive structures. “Success” in the model is defined by the correct assemblage of a *sentence* without errors (i.e., with all numbers correctly places in an ascending order). I measure the *time to completion* of the sentences as well as the *error rate* in building them. The final performance measure is the ratio between the *average time to completion* and the *average error rate*, which I call the *cost of accuracy*.

### First experiment: Effect of Retrieval Skills

The first round of model runs compares retrievers with different performances or *stickinesses*. When retrievers encounter content pieces, they stick to them and carry them to the connectors. Low-performing retrievers, however, might collide with a piece but fail at sticking to it. The net effect of a low-performing retriever is to bring fewer pieces to the connectors per unit of time. The performance property of retrievers is loosely analogous to the students’ short-term memory skills or the amount of sheer information they can gather within the environment. One conclusion from this simple experiment is that retrievers have a small impact on overall task performance. Dropping retriever success rates from 90% to 20% results in a modest 16% increase in time for the completion of the task; therefore, within the initial parameters and assumptions of the model, retrievers appear not to be the *controlling phase* of the process. This is a key *qualitative* result of the model: good information retrieval skill does not cause abrupt gains in learning. It is important here to restate that my goal is not to present a calibrated computer model that would emulate precise response times of the human brain. Rather, I am advancing the understanding of a cognitive task by using computer modeling to explicitize certain assumptions and refine our understanding of the problem. In this case, for example, the simple experiment drew my attention to the fact that retrieving information should be relatively faster than connecting information to existing knowledge structures, and therefore, an improvement in the quantity of available information or the speed of retrieval would have a relatively low impact on performance. The data from Rosenberg et al. qualitatively corroborate this hypothesis: during the first narrative, with books and worksheets readily accessible but with weak *connecting skills*, students were unable to weave a coherent explanation. From the narrative, it is clear that if students were given more time or more informational resources to complete the task, the impact in task performance would *not* have been significant. In other words, my model replicates one of the classroom

observations of Rosenberg et al.: the controlling phase of the students' cognitive work was not *information retrieval*, and the cause of students' failure in explaining the rock cycle was not due to a lack of information, a lack of time to retrieve the correct information, or weak memorizing skills.

## Second experiment: Effect of Connecting Skills

The goal of the second experiment was to investigate the influence of the connectors' performance on overall task completion time and accuracy. Connectors, in the model, represent more elaborate cognitive agents, which can evaluate different pieces of information and link them based on a simple rule (build ascending sequences of numbers.) Connectors can make "mistakes," for example, wrongly appending the number 41 to the otherwise correct ascending sequence [3, 45, 67]. The probability of such mistakes is controlled by an internal variable within each connector agent (*connector-strength*). The following plots show the impact on time to completion, and accuracy, for different values of *connector strength* (from 10% to 95% of probability of a wrong connection).

Figure 2. Connector strength, completion, and accuracy<sup>1</sup>.

<sup>1</sup> Note that each data point is an average of 50 model runs. Given the qualitative interpretation of the results and the limited space, I considered that error bars and more detailed statistics would not be informative to the research questions and would add unnecessary information.

At first sight, the *Connector strength vs. Time to Completion* plot (Figure 2, top) suggests that "Connector strength" has no impact on overall performance. However, even though the time to complete the task remains roughly the same, accuracy increases significantly (Figure 2, bottom). Combining the two plots (not shown) suggests a reasonable linear fit between computational cost of accuracy and connector strength, which suggests that increasing the *skill* of the connectors has a much greater impact on overall task performance than increasing the retrievers' skill (see previous experiment). This result confirms a second expected behavior, which is also qualitatively in agreement with the data from Rosenberg et al. When the students were told to "start from what they already knew" and evaluate the connections among the different phases of the rock cycle using previous knowledge (i.e., 'if lava is hot, it must cool down'), their performance increased significantly.

This second experiment hints that *connecting skills* are more significant for task performance than *retrieving skills*. However, the cost of training skilled connectors is still unknown; hence, comparing "unskilled but fast" and "skilled but slow" is crucial, which I attempt to illuminate in the next section.

## Third experiment: Explanation Complexity

The third experiment was aimed at discovering the impact of explanation complexity on performance. In this model, the complexity of the explanations is represented by the 'sentence-size,' which is the target number of *knowledge pieces* that the connectors need to put together (e.g., sentence size 3 would be "volcano erupts" + "lava comes out" + "lava cools"). The following plot shows a comparison between sentence sizes 2 and 3, for different values of connector strength.

Figure 3. Time to completion divided by the correctness (y axis) and the connector accuracy (x axis.)

One result of this experiment is that while the impact of increasing values of connector strength is linear for sentence size 2, it is roughly exponential for sentence size 3. This

finding suggests that for assembling ‘simple’ content the gain that students obtain from improved connecting skills is much lower than when they are struggling with complex knowledge.

Again, this finding seems to fit with Rosenberg et al.’s narrative. Even in the first moment of the narrative, when students are trying assemble explanations based on worksheets using a brute-force approach (quickly trying many different pairs), they were able to assemble a number of “sentence-size 2” explanations, such as [igneous rock forms] + [weathering occurs]. However, in that first part of the narrative, the students were never able to form “sentence size 3” explanations, which would require extra steps: connecting that initial pair of pieces to a third piece and evaluating all possible pieces for their fit. In the second part of the narrative, after only a few minutes, by trying to expand their explanation *making sense* of the connections between pieces (and not using the brute force approach), students formed a sentence size 4 explanation, and a few minutes later they formed a sentence size 10 explanation:

“Bethany: Listen up! OK, the volcano erupts [1] and lava comes out [2]. Lava cools [3] and makes igneous rock [4]. Rain and wind cause small pieces of rock to break off [5]. Sediments form [6], and rain and wind carry it away [7], and rain and wind slow down and deposit sediments [8] and this happens over and over again to form layers [9]. OK, so water is added to this [10]...” Rosenberg, Hammer, & Phelan (2006), pp. 274

To further investigate the role of the increase in sentence sizes to the overall cost of accuracy, I ran the model for sentence size 4 as well. The results, comparing sizes 2, 3 and 4, are in the following two plots:

Figure 4. Time to completion divided by the correctness (y axis) and the connector accuracy (x axis.)

To understand Figure 4, it is important to comprehend the intuition behind the results. Essentially, I am comparing a “brute force” versus a “smart” approach for assembling sequences of different sizes. For sentence size 4 (SS4), with low values of connector strength (CS), it is virtually

impossible to assemble a correct explanation (see the very high values of the top curve). For CS 10%, increasing SS from 2 to 4, the accuracy drops by a factor of 100. Increasing SS from 2 to 3, the accuracy drops 5 times. Figure 4, therefore, shows that increasing sentence sizes has a dramatic impact on performance. The important finding here is that this differently impacts “long” and “short” explanations. For SS 2, brute force assemblage is not so costly and works relatively well, so there would be no benefit for developing connecting skills. However, for SS 3 and 4, this ‘brute force’ (low CS) assemblage breaks down.

The events in Rosenberg et al. narrative tell a similar story. In the first half of the class, when students were using brute force methods instead of their own connecting skills, they could not go much further than assembling simple, “SS 2,” explanations. When they activated their ‘connectors,’ prompted by the teacher’s intervention, they switched from a brute force to a “sense-making” mode, in which most of their energy was spent connecting pieces instead of retrieving and randomly connecting them. That shift enabled them to assemble seamlessly explanations of SS = 10.

## Conclusion, limitations, and implications

Throughout this paper, I tried to pair computer model data with real classroom data. In the three experiments, I searched for instances that would resemble what Rosenberg et al. described in their classroom observations. The model seems to validate key elements of those observations:

1) The students’ failure in the first half of the narrative was epistemological (i.e., resulting from a particular approach toward learning) and not due to a lack of memorization or information retrieving skills (the first experiment).

2) The fundamental mathematical basis of the model, from which all other behaviors emerge, is that *brute-force methods are efficient for short sequences, but for long sequences, as the combinatorial space greatly increases, their performance drops accordingly*. In the high connector strength mode, the size of the sentence has a much lesser impact because of the evaluative rule of the connector: any connection will take the exact same computational time for any sentence size. This seems to be the case in the classroom, where the students could assemble long explanations quickly once they were in a ‘high connector strength’ mode.

3) In this simulated environment, I was able to verify that for learning intricate content (here, I equate that to assembling long explanations), there is a significant non-linear payoff from investing in sense-making skills, (connector strength) as opposed to memorizing skills (retrieving speed). For simple content (involving the connection of two content pieces), however, *sheer memorization can even outperform sense-making skills*. The data show that the payoff of improved connector strength only manifests itself after CS 80% (Figure 2, 3, 4).

4) Abrupt, non-linear shifts in student understanding are indeed possible, even within very short periods of time, by

activating different cognitive resources and different epistemological modes.

### Limitations and implication for design

The classroom data used in this paper was chosen because it described a relatively uniform macroscopic behavior that clearly derived from a change in simple, local rules. I acknowledge that many other typical classroom interventions might not exhibit such a uniform behavior. The goal of this model and paper, however, was not to match a computer model to a precise mechanism in the brain. Rather, my goal was to produce the “simplest possible” model that would exhibit the observed behaviors and generate further insight into the research questions. In that sense, this was a theoretical exercise made possible by formalizing the problem as agent rules. Therefore, given the assumptions of the model, I suggest that some possibly overlooked elements in classroom implementation might be more important than one would suspect: (1) the radically different payoffs for improving the *speed of retrieval* versus *sensemaking*, and the determination of which is the controlling phase in the learning process in different scenarios, (2) the non-linear impact of *sentence-sizes* on performance and accuracy, (3) the unexpected success of “brute force” methods for small sentences.

Given the limited space, it is impossible to go into detail about all possible implications, but one implication is very significant. *In earlier grades, exposed to simpler content, students might learn that brute-force methods ‘work.’ In later grades, they might insist on using this method, which would break down because the content is more complex.*

The computational task is of course an approximation of a real classroom task, and as with any model, it can only capture a portion of the real-world complexity. However, my goal here was to demonstrate the potential of agent-based models as a powerful and useful formalism for cognitive theory. This work could potentially have implications for the practice of curricular designers, teachers, and policy makers by offering researchers accessible, transparent tools to simulate, model and test hypotheses about human cognition in social contexts and to pair model data with real classroom data.

# Inducing Mathematical Concepts from Specific Examples: The Role of Schema-Level Variation

David W. Braithwaite (dwbraith@indiana.edu)

Robert L. Goldstone (rgoldsto@indiana.edu)

Indiana University, 1101 E. 10<sup>th</sup> Street  
Bloomington, IN 47405 USA

## Abstract

Previous research suggests that comparing multiple specific examples of a general concept can promote knowledge transfer. The present study investigated whether this approach could be made more effective by systematic variation in the semantic content of the specific examples. Participants received instruction in a mathematical concept in the context of several examples, which instantiated either a single semantic schema (non-varied condition) or two different schemas (varied condition). Schema-level variation during instruction led to better knowledge transfer, as predicted. However, this advantage was limited to participants with relatively high performance before instruction. Variation also improved participants' ability to describe the target concept in abstract terms. Surprisingly, however, this ability was not associated with successful knowledge transfer.

**Keywords:** mathematics; analogy; comparison; schemas; instruction; transfer

## Introduction

Part of the power of mathematics lies in its generality. The same mathematical formulae may be used to understand the growth of slime molds or the accumulation of interest from investments, the probabilities of hands in poker or outcomes of scientific experiments, and the oscillations of mechanical or electromagnetic systems. In order to fully realize this power, however, learners must be able to recognize and apply mathematical concepts in contexts different from those in which they were learned – that is, to transfer their mathematical knowledge from learned to novel contexts.

Learners' difficulties in achieving such transfer are well-documented (Novick & Holyoak, 1991; Ross, 1987). One reason may be that, when a general idea is learned in the context of specific examples, learners' concepts become tied to the details of the examples, inhibiting their ability to recall the concept or apply it correctly when faced with cases that do not share similar details (Ross, 1987). This difficulty may be especially strong when the examples are presented in a perceptually detailed format (Kaminski, Sloutsky, & Heckler, 2008), and is likely to be more serious for domain novices than experts (Novick & Holyoak, 1991).

One way to address this difficulty is to present mathematical ideas in abstract form, without specific examples. Such an approach has indeed been shown to promote transfer in some cases (Kaminski et al., 2008). However, in other cases, learners have experienced serious difficulties with abstractly-presented mathematics, despite being competent with the same mathematics encountered in

familiar contexts (Nuñez, Schliemann, & Carraher, 1993). In such contexts, learners can apply intuitions from everyday life to help in understanding the mathematical ideas involved. Abstract presentation of mathematical ideas therefore risks sacrificing learning for the sake of transfer.

It may, then, be desirable for learners to encounter mathematical ideas in a way that leverages their intuitive understanding of specific examples, while also drawing attention to the abstract structure present in those examples. Research on analogy suggests that this goal might be achieved through presentation of multiple specific examples followed by comparison (Gentner, Loewenstein, & Thompson, 2003; Gick & Holyoak, 1983). Comparing examples encourages learners to align their corresponding elements, and thereby to notice their common relational structure. Awareness of this structure, in turn, can facilitate understanding of new cases with the same structure. Thus, learning mathematical ideas by studying and then comparing multiple examples may enable learners to gain intuitive accessibility without losing generality.

The question then arises as to how the examples which will instantiate a mathematical concept during learning are to be chosen. Central to this question is the issue of how much, and in what ways, the examples should differ from each other. If, as the above research suggests, learners induce concepts that incorporate commonalities among the examples, it seems desirable that the examples should share the mathematical structure in question, but should not share other extraneous details. Extraneous commonalities might be misunderstood as part of the concept to be learned, limiting learners' ability to generalize (Medin & Ross, 1989), and so defeating the purpose of using multiple examples in the first place. These observations suggest that extraneous aspects should be systematically varied across examples, while holding mathematical structure constant.

The present study investigates the effects on mathematical concept learning of a particular type of variation among examples: variation at the level of "semantic schemas." This term here refers to structures more general than specific examples but less general than mathematical structure. Consider the three combinatorics problems shown in Figure 1. Problems (a) and (b) share a schema, termed "Objects Selected in Sequence" (OSS), in which a sequence of selections is made from a fixed set of options. Problem (c), by contrast, belongs to a different schema, termed "People Choosing Options" (PCO), in which several people each choose once from a fixed set of options.

(a) A piano student, when bored, plays random sequences of notes on the piano, using sequences of a fixed length, and choosing from a fixed set of notes. How many different sequences are possible, if there are 5 possible notes and the sequences are 6 notes long?	(b) A website generates user passwords by selecting a certain number of characters randomly from a fixed set of characters. How many different passwords are possible, if the passwords are 6 characters long and there are 5 permissible characters?	(c) A marketing research company conducts a taste test survey. Several consumers are each asked to choose their favorite from among several pizza flavors. How many different results of the survey are possible, if there are 6 consumers and 5 pizza flavors?
---	--	--

Figure 1. Three combinatorics problems.

Of course, all three problems share the same mathematical structure (discussed further in the Methods section), and the differences between them would likely not seem important to a mathematics expert. For mathematics novices, however, semantic schemas are known to exert a strong influence on the mathematical interpretation of contextualized problems. For example, Bassok, Wu, and Olseth (1995) found that learners were more likely to solve correctly problems in which schematic and mathematical roles were matched consistently with their default expectations than problems in which such matches were inconsistent. In light of the preceding discussion, learning about a mathematical structure via several examples based on the same schema might lead learners to induce concepts tied to that particular schema, and thus to perform poorly on problems involving other schemas. Conversely, systematic variation of the schemas encountered during learning should lead to induction of more general concepts and thus to more successful transfer to novel problems.

This hypothesis was investigated in the present study. Combinatorics problems were used as the domain for study and transfer for several reasons. First, the discovery of better methods for learning and teaching combinatorics would have considerable practical value due to the foundational role of combinatorics in applied mathematics – in particular, probability and statistics. Second, mathematics learners are known to have considerable difficulty correctly applying combinatorics methods to novel problems (Bassok et al., 1995; Ross, 1987). Finally, semantic schemas are known to play a role in the mathematical interpretation of combinatorics problems (Bassok et al., 1995).

## Methods

### Participants

Participants were 109 Indiana University undergraduate students, who participated in partial fulfillment of a course requirement.

## Materials

Sixteen story problems were constructed as stimuli. All of the problems had the same mathematical structure: Sampling with Replacement (SWR), in which multiple selections are made from a fixed set. The number of possible joint outcomes in such a case is given by the expression  $m^n$ , where  $m$  is the number of elements of the set and  $n$  is the number of selections, or sampling events.

The sixteen problems belonged to four different schema categories. The first two categories were those already illustrated above: PCO and OSS (OSS: Figure 1a-b, PCO: Figure 1c). Problems in these categories were used as learning examples. The other two categories were Options Assigned to Places (OAPlc) and Objects Assigned to People (OAPpl), illustrated below (Figures 2a and 2b respectively). OAPlc and OAPpl problems served as pretest and transfer problems. Note that in the learning examples (OSS and PCO) and OAPlc problems, people are either doing the choosing or are not mentioned at all. In OAPpl, by contrast, people are being chosen instead of choosing. Due to this role reversal relative to the learning examples, transfer to OAPpl problems was expected to be particularly difficult, as found in previous research (Ross, 1987).

(a) A homeowner is going to repaint several rooms in her house. She chooses one color of paint for each of the rooms. In how many different ways can she paint the rooms, if there are 3 colors and 5 rooms?	(b) A prize drawing is held at a small office party, and each of several prizes is awarded to one of the employees. In how many different ways can the prizes be awarded, if there are 6 prizes and 4 employees?
---	---

Figure 2. Combinatorics problems from the (a) OAPlc and (b) OAPpl categories.

Each problem category contained two pairs of problems, for a total of four problems. The problems within a pair involved the same back story but different numbers, while the two pairs within each category involved different back stories (and different numbers from each other). The order in which the two critical numbers, i.e. the size of the sampled set and the number of sampling events, were presented was varied among questions so that it could not serve as a cue to match the numbers to their respective roles.

Figure 3. Summary of experimental design.

The experiment employed a pretest-training-posttest design, summarized in Figure 3. The pretest consisted of one OAPlc problem pair and one OAPpl problem pair, for four problems altogether. The posttest consisted of the other OAPlc problem pair followed by the other OAPpl problem pair. Thus, all eight OAPlc and OAPpl problems appeared in either the pretest or the posttest.

The training consisted of worked solutions to four problems drawn from the PCO and OSS categories. Participants were assigned randomly to one of two training conditions. In the varied condition, participants were shown one pair of problems from each category, either PCO followed by OSS or vice versa (these two possible orders were balanced across participants). In the non-varied condition, participants were shown two pairs of problems from the same category, either both PCO or both OSS (again, the two possibilities were balanced across participants). If a certain problem category was shown in a given position (either first pair or second pair), it was always the same problem pair regardless of condition. For example, if PCO problems were shown first in the varied condition, they were the same problems that were shown first in the non-varied condition. An important consequence of this design is that each training problem was shown equally often across the two conditions.

## Procedure

Participants were randomly assigned to receive one set of OAPlc / OAPpl problems as pretest. The pretest problems were displayed to participants on a computer monitor together with a virtual calculator, which participants were encouraged to use as needed. Only one problem appeared on the screen at a time. Two spaces were provided below each problem: one in which to show work, and another in which to write the final answer. Participants were required to show their work and enter some number as their final answer before they could proceed to the next question.

After the pretest, answers were scored for correctness, and participants were classified as high pretest performers if they answered at least 50% of the pretest problems correctly and low pretest performers otherwise. They were then assigned randomly to one of the two training conditions with the constraint that, at each level of pretest performance, the number of participants in each condition was balanced. This manipulation was intended to reduce differences in pretest scores between training conditions.

The training problems corresponding to participant's training conditions were then presented in the same way as the pretest problems. However, after completing each problem, participants were shown the correct answer together with a brief explanation of how the answer was calculated and why this calculation was appropriate. These explanations utilized exponential notation but did not show the general expression  $m^n$ . Instead, they only showed specific versions of this expression instantiated with the numbers used in the problem. The explanation for a given problem did not differ between training conditions.

After completing each pair of training problems, participants were asked to choose from a list of options the correct method of solving problems like those just seen, independent of the specific numbers involved. For example, the correct answer to this question after the problems involving pizza flavors (Figure 1c above) was "Multiply the number of pizza flavors by itself as many times as there are consumers." Participants who chose incorrectly were not allowed to proceed until they chose the correct answer.

After answering the above question for the *second* pair of training problems (only), participants were asked to choose from a list of options the correct mapping between elements of the preceding two problem pairs. For example, the correct answer to this question if the preceding problem pairs involved a website generating passwords and consumers tasting pizza flavors (Figure 1b and 1c) was "The length of the note sequences corresponds to the number of consumers, and the number of possible notes corresponds to the number of pizza flavors." The purpose of this question was to encourage participants to think about the shared structure of the training problem pairs. After answering this question, participants were asked to describe, in free-response format, a general method for solving problems like those just seen. No feedback was given for either of these questions.

Finally, participants were administered the posttest. The posttest utilized whichever set of OAPlc / OAPpl problems had not been presented during the pretest, and the procedure was in all ways the same as for the pretest.

## Coding

For each problem, participants were assigned a score of 1 if their answer was correct and 0 otherwise.

Responses to the free-response question regarding a general solution method posed at the end of the training were coded on a 0-2 scale in each of two respects. For the first respect, Correctness, responses were assigned a score of 2 if they indicated that the number of elements in the sampled set should be raised to the power of the number of sampling events (or multiplied by itself as many times as the latter). Responses which implicated exponentiation but did not correctly identify the base and exponent were assigned a score of 1, and all other responses received a score of 0. The second respect, Abstractness, was intended to measure how well participants had generalized beyond the specific details of the learning examples. Responses were assigned a score of 2 if they referred to the two numbers using general words, such as "the options" (for the size of the sampled set) or "the number of times they are able to be chosen" (for the number of sampling events). Responses which used general words for one but not the other number were assigned a score of 1, and all other responses received a score of 0. All responses were coded by two independent coders, and all disagreements were resolved through discussion. In the analyses detailed below, scores of 0 and 1 were combined for both correctness and abstractness, so that responses were classified as either correct (2) or not correct (0 or 1) and abstract (2) or not abstract (0 or 1).

## Results

Average pretest and posttest scores are shown in Figure 4. Participants demonstrated considerable improvement on posttest, but the amount of improvement varied by problem category. The data were entered into a 2 (test section: pretest or posttest)  $\times$  2 (problem category: OAPlc or OAPpl) within-subjects ANOVA. The main effects of both factors and the interaction between them were all significant (test section:  $F(1,108)=69.8$ ,  $p<.001$ ; problem category:  $F(1,108)=14.6$ ,  $p<.001$ ; interaction:  $F(1,108)=16.4$ ,  $p<.001$ ). Participants improved from pretest (0.216) to posttest (0.489), but this improvement was greater for OAPlc (0.225 to 0.638) than for OAPpl (0.206 to 0.339).

Figure 4. Pre and posttest accuracy by problem category<sup>1</sup>.

Figure 5 shows average transfer scores, defined as the difference between posttest and pretest scores, for each training condition, among low and high pretest performers. Transfer scores were submitted to a 2 $\times$ 2 $\times$ 2 mixed ANOVA with training condition (varied vs. non-varied) and pretest performance (low or high) as between-subjects factors and problem category (OAPlc or OAPpl) as a within-subjects factor. The main effect of pretest performance was significant,  $F(1,105)=66.6$ ,  $p<.001$ , indicating more improvement from pretest to posttest among low pretest performers (0.404) than high pretest performers (-0.056). Also, the effect of problem category was significant,  $F(1,105)=12.3$ ,  $p=.001$ , indicating greater improvement on OAPlc (0.413) than on OAPpl (0.133). Problem category did not interact significantly with any of the other factors.

Figure 5. Transfer by condition and pretest performance.

More importantly, the main effect of training condition was significant,  $F(1,105)=4.0$ ,  $p=.049$ , indicating greater improvement in the varied (0.305) than in the non-varied (0.201) condition. However, this effect was qualified by a marginally significant condition by pretest performance interaction,  $F(1,105)=3.1$ ,  $p=.08$ . Consequently, the same model (excluding the pretest performance factor) was applied separately to the data from low and high pretest performers. This analysis found a significant effect of training condition among high performers,  $F(1,29)=.706$ ,  $p=.022$ , indicating higher transfer in the varied condition (0.047) than in the non-varied condition (-0.167), but no effect of training condition among low performers,  $F(1,76)=.042$ ,  $p=.838$  (varied: 0.410, non-varied: 0.397).

In addition to the effect of training condition on transfer, we were also interested in whether training condition affected participants' ability to induce a general method for solving SWR problems. The proportion of participants providing correct and abstract solution descriptions (i.e. receiving scores of 2 on the correctness and abstractness scales) within each training condition are shown in Figure 6. In the varied condition, 40% of participants' solutions were scored as correct, 62% as abstract, and 29% as both correct and abstract. In the non-varied condition, 56% of participants' solutions were scored as correct, 39% as abstract, and 20% as both correct and abstract.

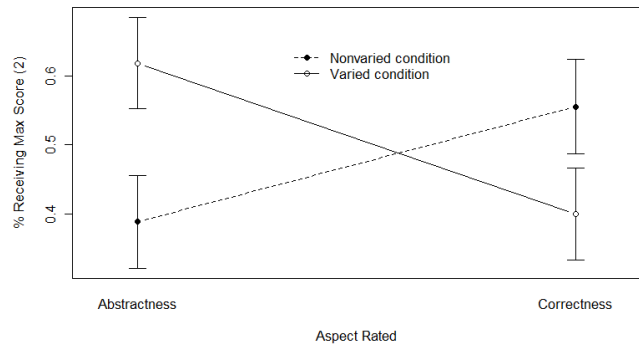

Figure 6. Percent generating correct or abstract general solutions by training condition.

The Breslow-Day test, a non-parametric test for stratified analysis of 2 $\times$ 2 tables, was applied to the frequencies of best (2) and other (0-1) scores within each training condition (varied or non-varied) for each aspect rated (correctness or abstractness). The relative frequencies of best vs. other scores between training conditions differed significantly according to aspect rated,  $p=.004$ . In other words, the effectiveness of varied relative to non-varied training was greater with respect to abstractness than with respect to correctness. To further clarify this effect, Pearson's Chi-square tests were applied to the contingency tables of best vs. other scores by training condition separately for each measurement respect. These analyses found that abstract solutions were more common in the varied than in the non-

<sup>1</sup> Here and elsewhere, error bars indicate standard errors.

varied condition,  $p=.028$ , but the proportion of correct solutions did not differ by training condition,  $p=.152$ .

Were participants who provided solutions that were abstract, correct, or both more likely to perform well on posttest? Average posttest scores among participants displaying each combination of solution abstractness and correctness are shown in Figure 7. (Participants were approximately equally distributed over these combinations.) Scores were virtually identical for each of these combinations: 0.50 for both correct and abstract, 0.49 for neither abstract nor correct, 0.48 for abstract but not correct, and 0.48 for correct but not abstract. A mixed ANOVA applied to posttest scores with solution correctness (correct or not), solution abstractness (abstract or not), pretest performance, and training condition as between-subjects factors and problem category as a within-subjects factor found no significant main effects of solution correctness or abstractness, no significant interaction between them, and no significant interaction of either or both with any other factor. (None of these effects were significant when transfer rather than posttest scores were entered into the model.)

Figure 7. Average transfer scores by correctness and abstractness of generated solution and test problem pair.

## Discussion

This experiment investigated whether exposure to multiple examples of an abstract mathematical concept followed by comparison among them would lead to better induction of the general concept when the semantic schemas of the examples were systematically varied during learning than when all examples were based on the same schema. As predicted, participants in the varied condition both induced more abstract solution methods for SWR problems, and showed greater improvement on a transfer test requiring them to apply such methods. These results suggest that schema-level variation of examples can be an effective way to promote transfer.

Caution is necessary in interpreting these results because the advantage of the varied over the non-varied condition in promoting transfer was almost entirely driven by high pretest performers. Low pretest performers did not benefit from the varied condition, although they were not hurt by it either. A possible reason is that the dissimilarity between examples in the varied condition made it difficult to notice their shared structure. This difficulty might be overcome by presenting several examples from the same schema, thus facilitating comparison and alignment of the examples,

before introducing schema-level variation. Consistent with this view, Kotovsky and Gentner (1996) found that children initially presented with several examples sharing both abstract structure and superficial details were later able to notice shared structure even in the absence of superficial similarity. Similarly, Elio and Anderson (1984) found that category learning was better after a learning schedule beginning with low variation among exemplars and later progressing to more variation, as opposed to one beginning with and maintaining a high level of variability.

Interestingly, Elio and Anderson (1984) also found that when learners were specifically instructed to take an analytical approach to category learning, the effectiveness of training with initially high variability improved. Similarly, high pretest performers in the present study, who may have been better equipped to take an analytical approach to learning the SWR concept, derived greater benefits from varied relative to non-varied training. One account for this result is that good learners are more attentive to the features and relations that are relevant to domain principles. Consequently, good learners would be less likely to be distracted by – and more likely to benefit from – variation in extraneous features and relations. Considering this conclusion together with the previous one regarding weaker learners, the best instructional approach might be an adaptive one, beginning with examples drawn from a single schema and transitioning to schema-level variation once learners demonstrate understanding of the target concept in the context of the initial schema. This interesting possibility deserves further investigation.

However, the observed advantage of the varied training for high pretest performers must also be interpreted with caution. Transfer scores among high pretest performers were rather low, averaging around zero in the varied condition and below zero in the non-varied condition. One interpretation of these data is that varied training merely helped to avoid negative transfer, and did not actually benefit learners. On the other hand, high pretest performers might be expected to show regression to the mean on posttest, resulting in negative scores on our measure of transfer. In this case, the actual (slightly above zero) transfer scores in the varied condition would represent a positive effect of training. It is difficult to disambiguate between these possibilities due to the lack of a control condition in the present study. Also, the inclusion of particularly difficult transfer problems, i.e. those in the OAPpl category, may have obscured the presence of positive transfer by bringing down the overall average. The beneficial effects of schema-level variation might be better explored in future studies by using a wider range of relatively easy transfer problems.

In addition to their differing effects on transfer, the varied and non-varied training conditions also led to differing levels of success in describing general solutions for SWR problems. In particular, while participants in both conditions were equally able to describe correct solutions, those in the varied condition were better able to characterize the elements of those solutions in abstract, general terms.

Previous research has demonstrated that comparison between multiple analogous examples can lead participants to induce their shared abstract structure (Gentner et al., 2003; Gick & Holyoak, 1983). The present findings build on that principle by suggesting that if the examples in question share semantic content not intrinsic to the desired structure, learners may induce a more limited, less general concept than if such extraneous semantic content is systematically varied across learning examples. Moreover, not only superficial elements but also more abstract semantic structures, such as the schemas of the present study, can count as extraneous content in this context. This conclusion implies that instructional design in mathematics could benefit from attention to variation of semantic schemas across examples of a given concept.

Although the varied condition led both to more abstract described solutions and to better transfer performance, the former effect did not mediate the latter as expected. In fact, participants who succeeded in describing general solutions were not more likely than other participants actually to demonstrate successful transfer. This result is surprising in light of previous research, in which the quality of participants' generalizations following exposure to multiple examples of a concept *did* predict their ability to apply the concept to novel cases (Gick & Holyoak, 1983; Novick & Holyoak, 1991). Several explanations are possible for this dissociation of described solution methods and problem-solving performance.

First, participants may not have attempted to apply their described solutions during the transfer test, possibly due to failure to recall the solutions or failure to recognize their relevance. However, these possibilities seem unlikely given that the transfer test was administered immediately after participants described their general solutions, and that the problems in the transfer test were presented in the same format and with very similar wording to those in the training. Second, participants may have attempted to apply their solutions, but failed to do so successfully on either or both pairs of transfer problems. Such failure might have been due either to inability to map the elements of the transfer problems to the roles mentioned in their solutions, or to inability to apply the solution procedure despite having correctly mapped the corresponding elements. Both of these issues have been implicated in failures of analogical transfer in mathematics learning (Novick & Holyoak, 1991). Future research might disambiguate between these possibilities by, on the one hand, directly testing whether participants could map elements in the transfer problems to those in training problems, and on the other hand, testing the effects of providing such a mapping to participants.

Regardless of why posttest performance was not predicted by participants' ability to describe correct and general solution methods, it is clear that such ability was not the cause of the superior transfer observed in the varied over the non-varied condition. The question then arises: what *was* the cause for that advantage in transfer? Because this advantage was dissociated from explicit, articulable

knowledge of how to solve the problems, it seems likely to relate to some form of implicit knowledge, e.g. improved perception / encoding of problems or improved procedural skill. Because the procedures required were essentially the same across problems and conditions, the perceptual explanation seems more likely. The varied condition may have encouraged learners to encode the elements of the problems in terms of their general roles in the mathematical structure of SWR, rather than in terms of their more specific roles in one or another semantic schema. Such improved encoding could, in turn, have facilitated application of the solution procedures learned during training to the transfer problems. This explanation is admittedly speculative, but offers a promising direction for future research.

## Abstract

Speech not only transmits semantic information through words and syntax, but also provides cues to a talker's identity. Differences in a listener's ability to recognize voices can be attributed to their language background, and in rare cases voice recognition can be selectively damaged in neurological patients. In this study we investigated a group of Korean-English bilinguals and non-Korean speakers' ability to learn to recognize unfamiliar Korean and English talkers by voice, and to generalize to utterances not heard during training. We observed an interaction between language background and stimulus language for speed of learning, however generalization performance indicated no such interaction when compared to baseline performance. Bilinguals' performance recognizing English (but not Korean) voices, was predicted by the age they learned English. We also observed that individuals who actively participated in music production exhibited significantly faster task learning than those who did not produce music. This study indicates that language background has a gradient effect on voice learning among bilinguals, and that non-linguistic auditory processing differences, such as music perception, impact voice identification.

**Keywords:** speech perception; music perception; voice; voice identification; individual differences; bilingualism

## Introduction

Speech is generally studied primarily for its ability to communicate semantic meaning from one individual to another. Many complex animal communication systems such as birdsong, however, evolved primarily to communicate more basic information, providing cues that other conspecific listeners use to evaluate fitness and individual identity. Any comprehensive understanding of the evolutionary origins of speech and language will draw both upon the role communication signals play in transmitting semantic meaning, as well as their role in providing cues to identity.

Human speech contains many acoustic cues that listeners use to recognize, for example, a talker's age, gender, emotional state, or even their identity. Collectively, these elements of the speech signal are known as "indexical cues". Voice recognition, or talker identification, is an important aspect of speech perception, and one that has been relatively little studied. Although often considered separate from the core speech perception system (some

neuroimaging results support this perspective, e.g. Belin, Fecteau, & Bédard, 2004), several studies suggest that talker-specific acoustic cues are intertwined with speech recognition. For example, listeners are better able to understand speech from familiar talkers than unfamiliar ones (Nygaard & Pisoni, 1998).

While several studies have characterized severe disability in voice identification, few have attempted to investigate differences among individuals' abilities to recognize voices, although the existence of dramatic individual differences has been noted for many years (Pollack, Pickett, & Sumby, 1954). In clinical cases, voice recognition can be lost completely in individuals with a neuropsychological disorder known as phonagnosia (Van Lancker, Kreiman, & Cummings, 1989). In a pioneering study, Goggin, Thompson, Strube, & Simental (1991) demonstrated that monolingual English speakers were better able to identify the voices of English-German bilinguals when listening to those individuals speak English than when they spoke German. This suggested that, despite many shared acoustic features (both English and German stimuli shared the acoustic features imparted by a particular talker's vocal tract), the listener's language background had a strong impact on their ability to recognize the voices. This study suggested that differences in phonological processing that arise from linguistic knowledge are important in voice recognition.

Goggin et al. (1991) observed no difference in performance on a voice recognition task for English-Spanish bilinguals when tested on English vs. Spanish speaking voices. They suggested that bilinguals might have equal ability recognizing voices from either language since they have extensive phonological knowledge of both. Bilinguals, however, are heterogeneous in their language background, and it may be the case that late learners, or those dominant in one of their languages do exhibit the voice identification deficits identified in monolinguals.

A recent study demonstrated that differences in phonological processing *within* a language can also affect voice identification. Individuals with dyslexia are significantly impaired in their ability to recognize voices relative to controls, but only in their native language (Perrachione, Del Tufo, & Gabrieli, 2011). This result implies that individual differences in phonological

processing, even among those who share a language background, can dramatically impact listeners' abilities to recognize voices.

Outside clinical populations, what other differences might affect voice recognition accuracy? One possibility is music experience. Extensive musical training may benefit the neural encoding of speech by driving brain networks involved in both speech and music perception to function with higher precision than normally necessary for speech perception alone (Patel, 2011). In fact, musicians have been demonstrated to outperform non-musicians on speech perception tasks, including enhanced perception of speech in noise (Parbery-Clark, Skoe, Lam, & Kraus, 2009) as well as enhanced second language phonological ability in bilinguals (Slevc & Miyake, 2006). Do differences in music background or music perception affect voice recognition ability?

In this study, we investigated these questions in a group of Korean-English bilinguals and a second group of non-Korean speakers. We examined whether differences in language and music background, as well as individual differences in music perception and phonological working memory, affected participants' abilities to learn to recognize a set of unfamiliar voices. We also tested recognition of novel sentences spoken by these voices.

## Methods

### Participants

We tested 48 participants, 22 of whom were bilingual, and spoke Korean and English fluently. The remaining 26 participants had no background or experience with Korean. All Korean-English bilingual participants learned Korean as their first language or in parallel with English, and learned English between 1-17 years of age (mean=7.1 years). All subjects studied at UC San Diego and received course credit for participation. All procedures were part of a protocol approved by the UC San Diego Human Research Protections Program.

### Stimuli

We recorded 15 Korean sentences spoken by each of four female native Korean speakers and 15 English sentences spoken by four female native American English speakers. English sentences were selected from the SPIN sentence set. All chosen sentences were high predictability, e.g. "He caught the fish in his net" (Kalikow, Stevens, & Elliott, 1977). Korean sentences were simple, high predictability, and of similar syllabic length to the English sentences, written by a native Korean speaker, e.g. "공책을 집에 놓고 왔다" ("Gongchek eul jibeh nohgo watda," "I left the notebook at home"). Recordings were made in a sound isolated recording booth, and each monaural recording was trimmed to begin at sentence onset and normalized to a mean of 70dB.

## Procedure

**Voice Learning Task** Participants learned to associate 20 training stimuli (5 sentences x 4 voices) with one of four cartoon objects, which differed in both shape and color. Each cartoon object represented a single talker. We chose cartoon objects rather than faces to control for differences in face discriminability across participants. To initiate a trial, participants clicked a cross in the center of the screen. On each trial, audio playback began simultaneously with the display of the two cartoon objects, one on the left and one on the right, equidistant from the center cross. During each training trial, participants clicked one of the two objects with the computer mouse and after clicking, the correct object remained on the screen to provide feedback until they made a second confirmation click.

Training blocks of 60 trials each were presented (with stimuli randomized within each block) until participants reached 85% correct—that is, they chose the target object on at least 51 of 60 trials in a single block (chance=50%). After reaching criterion, participants completed two test blocks, each with 120 trials. During test blocks, no feedback was provided and the screen was blank after making a response. Test blocks contained 60 trials encompassing the 20 training stimuli, as well as 60 trials containing 5 novel sentences produced by the 4 learned voices. The second test block contained 60 trials of the 20 stimuli learned during training and an additional 5 novel sentences. After completing the training and testing process for one language, participants completed the process in the other language (English or Korean). The language of the first block (Korean or English), the cartoon objects associated with each voice, and the positions of the two images on the screen on each trial were counterbalanced across subjects.

**Behavioral assessments** In addition to completing the voice learning task, participants completed assessments to identify individual differences in language and music background and perception. They completed a questionnaire describing their music training, including formal training and current performance activity. To assess their dominant language, bilingual subjects completed a bilingual dominance survey (BDS; Dunn & Fox Tree, 2009) and a picture naming task assessing lexical inventory in English and Korean (modified from Gollan, Weissberger, Runnqvist, Montoya, & Cera, 2011). All participants completed the pitch contour subtest from the Montreal Battery for the Evaluation of Amusia (MBEA) to measure differences in music perception ability (Peretz, Champod, & Hyde, 2003). During the MBEA test, participants heard 2 example melody pairs followed by 31 test melody pairs. For each pair, they provided a same/different judgment. All melody pairs had the same melodic contour and there were no out-of-key notes, making it a fairly subtle change. Each participant's score was recorded as the number of correct responses (observed range = 12-30, mean = 23.5).

For the Korean-English bilingual participants, language dominance measured using the BDS ranged from -15 (English dominant) to 20 (Korean dominant) and averaged -

0.22. Performance on the lexical naming task ranged from -27 to 18, with a mean of -9.48. These bilingual dominance measures were highly correlated ( $r=0.78$ ), and both BDS and MiNT scores were highly correlated with the age English was learned ( $r=0.92$  and  $r=0.75$ , respectively).

Phonological working memory was estimated by measuring each participant's digit span. Digit span has been used as an index of phonological working memory in many experiments (Baddeley & Hitch, 1977). Participants heard a series of 16 audio recordings with a female voice reading random sequences of English digits at a rate of 1 digit per second. Two sequences for each length were presented, in order, from 2-9 digits. After each recording, participants repeated the numbers they had heard. Scores were recorded as the number of sequences correctly repeated, with a maximum score of 16 (observed range = 7-15, mean = 10.7). Digit spans did not differ between language groups (Welch's  $t(45.95)=0.83$ ,  $p=0.41$ ).

## Results

### Language familiarity predicts learning speed

Previous research suggests that familiarity with a language is predictive of performance on voice identification tasks. However, its role predicting learning rate for unfamiliar voices has not been explicitly tested. We contrasted 22 Korean-English bilinguals with 26 listeners who did not speak Korean. We measured the number of blocks required to reach a criterion of 85% correct within a single block. A 3-way mixed model ANOVA (Figure 1) with Participant Language (English-only, Korean-English; between-participants), Talker Language (English, Korean; within-participants) and block order (English first vs. Korean first; between-participants) revealed no significant main effects of participant language background ( $F(1, 44)=3.19$ ,  $p=0.08$ ), stimulus language ( $F(1, 44)=0.44$ ,  $p=0.51$ ), or block order ( $F(1, 44)=1.09$ ,  $p=0.30$ ). However, there was a strong interaction between stimulus language and language background ( $F(1, 44)=24.02$ ,  $p<0.0001$ ).

Individually, Korean-English bilingual participants were faster to learn Korean talkers ( $M=1.9$  training blocks) than English talkers ( $M=3.5$  blocks; paired  $t$ -test  $t(21)=-3.03$ ,  $p=0.006$ ). Similarly, English-speaking participants learned English voices ( $M=2.5$  blocks) faster than Korean voices ( $M=4.5$  blocks; paired  $t$ -test  $t(25)=4.14$ ,  $p=0.0003$ ). No other interactions were statistically significant (all  $F$ s  $< 0.08$ ,  $p$ s  $> 0.78$ ). Together, these data show that differences in learning rates are present as a function of language background.

We then looked at participants' maximum accuracy on training trials. Although trained to reach a criterion of 85% correct in a block, some participants achieved higher accuracy than others. Again we observed an interaction

between language background and stimulus language (Figure 2a) in the maximum accuracy reached. A 2-way mixed ANOVA indicates no main effects of language background ( $F(1, 46)=2.08$ ,  $p=0.16$ ) or stimulus language ( $F(1, 46)=1.11$ ,  $p=0.30$ ), but a strong interaction ( $F(1, 46)=15.51$ ,  $p=0.0003$ ).

Figure 1: Korean-English bilinguals required fewer training blocks to reach 85% correct recognizing Korean speaking voices (red bars) than English speaking voices (blue bars). Non-Korean speakers show the opposite effect. Bars indicate mean number of training blocks  $\pm$  s.e.

However, we observed no difference in performance between training and generalization test trials in the 40 participants who reached 85% correct after a maximum of 9 training blocks. For each of these participants, we calculated a “generalization penalty” by subtracting the proportion of correct responses to novel tokens of learned talkers with the proportion of correct responses to trained talkers. All stimuli were interleaved and collected in the same test block. We computed a 2-way mixed model ANOVA predicting participant's generalization penalty using language background (between participants) and stimulus language (within participants) as factors (Figure 2b). We observed no main effect of language background (Korean-English vs. English-only; between participants,  $F(1, 39)=2.45$ ,  $p=0.13$ ), no main effect of stimulus language (within participants,  $F(1, 39)=1.72$ ,  $p=0.20$ ) and no interaction between language background and stimulus language ( $F(1, 39)=0.17$ ,  $p=0.68$ ). While language background appears to be important for *learning* to distinguish unfamiliar voices, it does not appear to constrain generalizing to new utterances after the voices have been learned, at least within the short retention period required in this experiment.

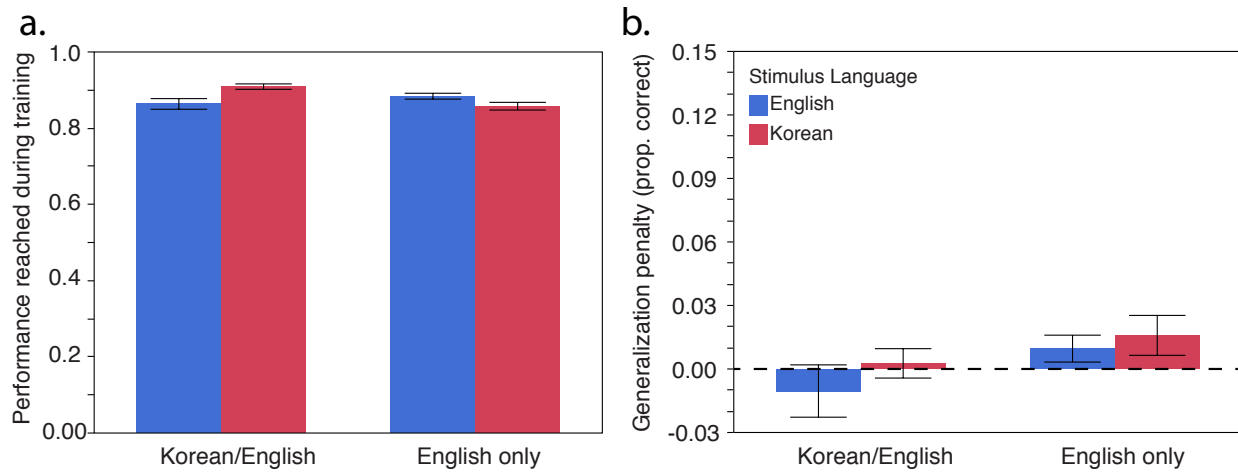

Figure 2: (a) Korean-English bilinguals were slightly more accurate at identifying the correct voice on novel sentences for Korean stimuli (red bars) than for English stimuli (blue bars). Non-Korean speakers show the opposite effect. (b) There were no generalization differences between groups

### Bilinguals' age of L2 acquisition predicts learning speed in L2, but not L1.

We further explored whether individual differences in age of learning English or relative dominance of English or Korean were predictive of task performance among the bilingual subjects. To do so, we computed the correlation between age of English onset (which was the second language for all bilingual participants) with their voice learning rate. Among Korean-English bilinguals, blocks to criterion on English talkers was positively correlated with the age they began learning English (Figure 3a,  $r(20)=0.62$ ,  $p=0.002$ ), while it is uncorrelated for Korean-language stimuli ( $r(20)=0.24$ ,  $p=0.28$ ).

We then separated Korean-English bilingual participants into two groups based on a median split of acquisition age:

those who learned English at or before 5 years old (early learners,  $n=12$ , mean age=3.3 years, mean BDS=-7.8, mean MiNT=-15.6) and those who learned after 5 years old (late learners,  $n=10$ , mean age=10.7 years, mean BDS=6.9, mean MiNT=-4.3). We then conducted a 2-way mixed model ANOVA with factors of Participant Language (between participants; English-only, early-English Bilingual, late-English Bilingual) and Talker Language (within participants). There was a main effect of language background ( $F(2, 45)=4.73$ ,  $p=0.014$ ), no main effect of stimulus language ( $F(1, 45)=1.31$ ,  $p=0.26$ ) and an interaction between language background and stimulus language ( $F(2, 45)=15.91$ ,  $p<0.0001$ ). This interaction resulted from three different patterns of talker learning. Early-learning bilinguals did not differ in their acquisition rate for Korean and English stimuli (paired  $t(11)=-1.74$ ,  $p=0.11$ ). However, late-English-learning bilinguals learned

Figure 3: (a) The number of blocks to learn English voices was correlated ( $r=0.62$ ,  $p=0.002$ ) with the age Korean-English bilinguals learned English. (b) Number of training blocks to reach criterion of 85% on each stimulus language for Korean-English bilinguals who learned English late ( $n=10$ ), early ( $n=12$ ) and English-only speakers ( $n=26$ ). Each bar represents the mean number of training blocks (60 trials/block)  $\pm$  s.e.

Korean stimuli faster than English stimuli (paired  $t(9)=-2.87$ ,  $p=0.018$ ), and, as reported above, non-Korean speakers learned English stimuli faster than Korean stimuli.

Taken together, these results are consistent with prior work suggesting that phonological processing is an important element of voice recognition. Our result extends previous work by demonstrating a *gradient* effect of bilingualism. Rather than showing similar patterns of behavior in both languages, age of acquisition is an important predictor of performance recognizing voices in L2, but not L1.

### Music experience predicts learning rate

We collected several behavioral measures of individual differences in auditory perception from our participants (see methods). Our hypothesis was that, since differences in individuals' language profiles (e.g. language familiarity, dyslexia) contribute to differences in voice learning, we might also observe differences among participants due to individual differences in auditory processing that are not strictly linguistic: pitch perception, music background, and music perception ability. We report the correlations between each of these measures and three performance measures: learning rate, generalization performance, and pitch shifted generalization performance (Table 1).

Several previous studies have identified perceptual advantages for individuals with extensive musical training. In particular, musicians have shown better brainstem encoding of pitch (Wong, Skoe, Russo, Dees, & Kraus, 2007), and high musical ability is associated with better second language phonology (Slevc & Miyake, 2006). Is musical experience important for learning to recognize voices?

**Table 1.** Correlations between music measures and voice recognition

	Years Training	MBEA Score	Tone Thres.	<i>Generalization</i>		
				<i>Learning rate (blocks)</i>	<i>Unshifted</i>	<i>Shifted</i>
Years Training	1.000	0.10	-0.02	<b>-0.42</b>	0.029	-0.095
MBEA Score		1.000	-0.26	-0.19	-0.048	-0.199
Tone Thres.			1.000	0.13	0.101	0.208
Learning rate				1.000	-0.202	0.246

We measured musical perceptual ability with the melody contour subtest of the MBEA (Peretz, Champod, & Hyde, 2003), and a pitch discrimination threshold task. Pitch difference threshold and MBEA did not correlate significantly with voice learning or generalization ability. However, measures of musical activity did show a relationship to voice learning rate. Participants who were currently active in producing music at least 1 hour per week

when the experiment was conducted ( $n=11$ ; musical training averaged 12.0 years, range 6-22 years) learned to recognize voices on average in fewer training blocks than those who were not active musicians ( $n=37$ ; who had less musical training, averaging 5.2 years, range 0-27; Welch's  $t(34.23)=-2.52$ ,  $p=0.017$ ). This difference seems to have been driven by musicians' more rapid learning for voices speaking the subject's non-dominant language. When tested on the non-dominant language (Korean for non-Korean speakers, English for Korean-English bilinguals), musicians learned faster than non-musicians (mean=2.71 blocks vs. 4.62 blocks, Welch's  $t(44.28)=-3.07$ ,  $p=0.004$ ). However, when learning to recognize voices in their dominant language, we observed no effect of music background (mean=2.00 blocks for musicians vs. 2.40 blocks for non-musicians, Welch's  $t(17.02)=-0.59$ ,  $p=0.56$ ).

As there are multiple ways of assessing music experience, we also considered the effect of years of musical training (this did not overlap completely with current musical practice). Years of training correlated negatively with average number of training blocks to reach criterion ( $r(46)=-0.42$ ,  $p=0.0036$ ). Again, the relationship to music training is driven by the non-dominant language ( $r(46)=-0.40$ ,  $p=0.006$ ); musical training was not significantly correlated with learning rate for voices in the dominant language ( $r(46)=-0.22$ ,  $p=0.13$ ).

### Discussion

Previous studies demonstrated that individual differences in phonological processing due to language background and dyslexia are important predictors of voice identification ability. The results of the current study extend these findings in a few important respects. In both adults and infants, knowledge of a language improves ability to recognize voices in that language (Goggin et al., 1991; Johnson, Westrek, Nazzi & Cutler, 2011; Perrachione et al., 2011). We extended this work by investigating both monolinguals and bilinguals, and looking at the bilingual participant's language dominance. Not only did we find a crossover interaction between listeners' native-language backgrounds and talkers' language, but we also found that early second-language acquisition facilitated talker learning without loss in performance on the first language. This acquisition effect—if viewed as such—is particularly interesting because it mimics acquisition of phonology: as age of acquisition increases, receptive and productive phonology are less native-like (Flege et al., 2006; Oh et al., 2011).

We also observed significantly faster voice learning for participants with more extensive musical training, particularly those actively involved in music production. This could be associated with changes in auditory encoding that have been observed among musicians that give rise to differences in pitch, music and speech perception. Our result extends this area of research, suggesting that not only is speech comprehension enhanced, but perception of indexical features in the speech signal may be enhanced as well. The effect of music experience appeared only to apply

to participants' learning to recognize voices in a less familiar language. We point out, however, that this study does not actually manipulate music training, so we cannot assert that it *causes* improvement in learning to recognize voices. Perhaps some third variable—inherent or learned individual differences in auditory perception—confers benefits to both voice recognition and music production.

Further work is also needed to identify whether the kinds of individual differences that give rise to enhanced voice recognition also extend to other indexical cues. Are individuals who performed better on individual recognition tasks also more sensitive to acoustic cues such as a talker's emotional state, age, or gender?

We explored how language experience and non-linguistic factors contributed to talker identification in two different languages. Native-language talkers were learned faster than second-language or unfamiliar-language talkers, and among bilinguals, earlier L2 acquisition predicted faster learning. Further, some measures of music experience predicted faster learning in the less-familiar language. Our work suggests a role for early language learning, or at least extent of exposure, in talker identification. This is consistent with a tight linkage between language processing and talker identification, which presents an interesting puzzle given the evidence of specialized neural mechanisms for speech recognition and talker identification.

### Acknowledgements

MRB was supported by the Kavli Institute for Brain and Mind at UC San Diego, and SCC was supported by an NSF CAREER Award (BCS-1057080). We would like to acknowledge the help of undergraduate research assistants Shawn Cho and Hye Young Lee who were instrumental in developing Korean language stimuli and collecting data on participant's language background.

## Abstract

Although the study of how learners approach emergent phenomena is relatively new, a consistent set of misconceptions associated with emergence have been documented. However, little consideration has been given as to whether some misconceptions manifest more frequently in one domain than another, or take on a different character depending on the agents or phenomenon involved. We examined participants' explanations of emergent phenomena from three domains. We found significant differences between domains, showing greater or lesser evidence of misconceptions. We propose that novices bring prior knowledge, folk psychology, and folk biology to bear in determining the capabilities of the agents involved in a phenomenon, and that these beliefs guide their explanations. We believe that the study of how people perceive emergence would benefit from drawing upon research on folk theories, anthropomorphism, developmental constraints, and other areas that will help us understand how learners characterize agents, environments, and their interactions.

**Keywords:** emergence; complexity theory; misconceptions; science education; folk biology; folk psychology

## Introduction

We live in a complex world. Not just in the everyday sense, but in a mathematical, or scientific, sense. Many of the phenomena we encounter in everyday life are of the emergent, or complex, sort. Emergent phenomena play a

central role in every scientific discipline. Color and convection are emergent phenomena, as are weather patterns, earthquakes, and the evolution of galaxies. The activities carried out by ant colonies, bee hives, and American voters exhibit emergence, as does the co-evolution of flowers and bees. There is, therefore, potential for great benefit in developing an understanding of how emergent systems arise and behave, but this is a difficult task for learners.

In non-complex, or "direct," systems, the overall behavior of the system and its outcomes tends to be deterministic, linear, and predictable, often organized by a centralized process or individual leader. The circulatory system (Chi, 2005, in press) follows a clear path, each step having a clear purpose in a system that is regulated by nerves keeping the heart beating at a regular pace. A problem in Newtonian mechanics, say, the building of a bridge, involves identifying forces that sum to indicate the stresses on a particular element of the bridge, stressors which can be offset directly by adding new elements in a cumulative way, or inventing new structures that alter how the forces sum.

In contrast, complex systems are unpredictable, nonlinear, and give rise to novel, or emergent, behavior (Holland, 1999). Even when the exact rules governing each agent are fully specified, the resulting phenomenon will be unpredictable and irreducible, and adding new elements multiplies the possible interactions between agents, leading to unexpected, non-replicable outcomes. There are no set

leaders or controllers; an agent may appear to have such powers, such as the lead goose in a flock, but they are in the lead simply because the other geese fell in line with them.

It is not surprising that the naïve learner struggles when faced with explaining and understanding emergent phenomena. Previous studies have well-documented the challenges that emergent systems present for learners (Jacobson, 2001; Hmelo-Silver & Azevedo, 2006). Learners new to emergent systems are likely to expect clear patterns of cause-and-effect, purposeful encounters between agents, and a central control system that oversees their movements and actions (Chi, 2005; Resnick, 1996). Complex systems introduce the notion that order can emerge out of random interactions; stochastic movements and actions are central to how emergent phenomena arise and evolve. This challenges the commonsense belief that ascribes purposefulness to events in the universe (Jacobson, 2001). In a deterministic, linear system, small changes to the starting conditions generally lead to small changes in outcomes. In a complex system, the smallest change can have a drastic effect on the outcome, as interactions amplify and reshape the actions of individual agents and their encounters with their environment. The learner tries to make sense of these patterns by invoking centralized control, in the form of a “queen” bee or other sort of leader, who has knowledge of the entire goings-on and can shift the pattern according to their needs or the needs of the group. But there is no leader to be found.

The study of how people perceive, explain, and understand emergent systems is a relatively new area, and both logistical considerations and underlying assumptions have led us, as researchers, to pursue our investigations through a close examination of single phenomenon (Chi, in press), a single self-contained ecosystem (Hmelo-Silver & Pfeffer, 2004), or a small set of phenomena within a single domain, such as chemistry (e.g., Talanquer, 2008; Rappoport & Ashkenazi, 2008) or evolution (e.g., Evans, 2001; Poling & Evans, 2004).

Logistically, this approach has been fostered by the fact there are only a few tools for modeling emergent systems (e.g., Colella, Klopfer & Resnick, 2001; Tisue & Wilensky, 2004), and creating such models is highly time-consuming. Data collection is similarly time-consuming, and research has focused heavily on case studies and close observation of small groups in complex settings (e.g., Charles & d'Apollonia, 2004; Wilensky & Resnick, 1999), or larger groups interacting with a single aspect of a phenomena. We have spent little time looking at whether and how learners' actions and ideas change from one domain to the next.

Theoretically, too, there is a basic reason why we might believe that, with time, these individual studies would come together to create a fuller account of how learners perceive, represent, and think about emergent systems. To be considered an emergent system, a phenomenon must meet specific mathematically-defined criteria. At the mathematical level, diffusion, chemical bonds, and traffic jams have a great deal in common; emergent phenomenon

belong to a class that is unaffected by features specific to a particular domain.

It remains to be seen, then, to what degree the abstract features and behaviors of an emergent system actually do cross domain boundaries for learners. If I become proficient in understanding diffusion, for example, will this make learning about traffic jams or chemical bonds any easier for me? We not only do not have such comparisons, we lack assessments that allow us to directly compare a learner's understanding of the principles of emergence in one domain to their understanding in another.

Our goal for the project we describe here was to create an assessment of key aspects of emergent systems that could be applied across topics. Learners' understanding of each phenomenon was assessed using an instrument that had identical stems representing each component of emergence, into which the particular phenomenon could be inserted. If learners respond to the basic patterns that underlie the phenomenon, they should show similar levels of understanding (or misunderstanding) across domains. If a person showed a low understanding of diffusion, they should show a similarly low understanding of geese flocking, as the same basic principles are needed to make sense of these two phenomena. Thus, we can determine whether their knowledge is tied to a particular system, or is available at a more abstract level.

If domain knowledge plays a role, however, then responses may be influenced by folk theories that ascribe greater capacity for volition, control, and decision making to certain sorts of entities, and less to others. A bacterium may be seen as relatively incapable of engaging in goal-oriented behavior, of communicating with other bacteria, or of choosing a course of action. A goose, given that it has a brain and nervous system, may be seen as more capable. The social behavior of ants, likewise, may cause us to assume they are more intentional and communicative, and less driven by instinct and environment. Given people's bias to find centralized, intentional causes for emergent patterns, it may be harder to believe that animals with greater neurological development are subject to random processes, do not engage in communication and group planning, and do not make choices when they act.

We therefore decided to test our domain-general stems in the context of three different domains: unicellular slime molds aggregating before sporing, ants, a social animal, foraging for food, and geese, the most “advanced” neurologically, flocking. These three entities not only come from different locations on the phylogenetic tree, they differ in the ways that we describe above.

We designed a study in which participants watched simulations of three phenomena. Participants responded to an open-ended written protocol that used the same questions for each domain, altered only to refer to the domain at hand. We then coded participants' responses and compared their conceptualizations of each phenomena.

If misconceptions arise due to the features that all emergent phenomenon have in common, we would expect

responses to our probes to be roughly the same across the simulations. If, however, domain-specific considerations come into play, we expect to see misconceptions arising more often in some domains than in others. In particular, we predicted that misconceptions would be invoked less often with regard to slime molds than ants or geese. In addition, we predicted ants would give rise to the greatest number of misconceptions due to the familiarity of their social nature.

## Methods

### Participants

Forty participants, undergraduates from a large Southwestern University, completed the written protocol, receiving \$20 in compensation. None had formal training in emergence or complexity theory. The protocol took approximately 60 minutes to complete.

### Materials and Procedure

The participants completed a written protocol posing questions about three emergent phenomena: geese flocking, ants foraging for food, and slime molds aggregating to spore. The order in which the phenomena were presented was counterbalanced across participants.

Each phenomenon was illustrated with a NetLogo simulation that had been video-captured, so that the same run could be shown to all participants. Agents were represented by icons that captured the basic appearance of the real entity (i.e., ant, slime mold, goose), and participants were told before the simulation began what symbols would be used, and what they would mean.

Each simulation lasted approximately 90 seconds, and were roughly divided into three phases. First, there was a brief section that allowed participants to orient themselves to the simulation, the symbols used for the agents and environmental objects, and the agents' behavior. Next, the behavior began to develop emergent properties, i.e., patterns began to form at the group level. Finally, the simulation reached equilibrium (in the case of the flocking and slime mold simulations) or the agents achieved their goal (of finding food, in the ant simulation). Pilot runs of the simulations and the responses of the participants suggested that few had any difficulties mapping the real phenomenon onto the simulation.

There were a total of 7 questions. We began each of the three protocol sections with broad questions (e.g., #1 and #2 below), moving to more specific questions that capture key aspects of emergent phenomena (e.g., #3 and #4 below). The questions were designed to be as similar as possible across entities, substituting in the appropriate phrases:

1. Describe the patterns that the *ants/geese/slime mold organisms* make in as much detail as possible.
2. What do you think causes the *ants/geese/slime molds* to make the patterns you see?

3. Do you think that there are special leader *ants/geese/slime molds* that signal the others to *follow them/ follow them/ come to them and form clusters*?
4. If we make a new video with the same *ants and food/geese/slime molds* in the same starting positions, how similar do you think the patterns they form will be?

We instructed participants to write as much as they could, giving as much detail as they could provide. They were told to answer the questions in the order they were given, and not to go back and change any of their answers.

## Results

To create the coding system used to categorize participants' answers, two of the authors (SKB and GSS), conducted an open coding of the data, allowing codes to emerge, rather than searching for codes based on existing expectations and hypotheses. We iteratively coded sections of the data and discussed our codes, coming to agreement on 13 themes that were present across all domains. No theme arose that was not present at least once in each domain. Two of the other authors (RR and BH) who did not have contact with GSS and SKB during the development of the codes, applied the codes to the data. Both were blind to the hypotheses regarding the relationship between a given domain and possible patterns for that domain. They applied the codes with 94.5% agreement, resolving disagreements through discussion. Less than 5% of the answers were deemed uncodable. Multiple codes could be applied to a single answer, if all of the criteria for each code was met.

Although we arrived at 13 themes, not all of these codes spoke to the issue of misconceptions about emergence. Some were not directly relevant (e.g. "descriptive," used when for a play-by-play description of the simulation, without interpretation, or "external factors," when characteristics of the simulation itself were the focus, instead of the content.) Other codes proved complex and potentially misleading because they captured different concepts for different individuals (this is further discussed below).

We chose to focus on the codes that, based on prior research, are most central to identifying whether participants hold a misconception or correct representation. We chose four that directly invoke misconceptions well-documented in the literature, and two providing evidence that the participant held a correct representation of the phenomenon (see Table 1 for a description of the codes, and a sample response). Regarding the misconceptions, people tend to assume that there is a controlling force directing the agents, that the agents are communicating and cooperating, that certain agents have special powers that allow them to direct the pattern, and that all of the agents are acting out of a sense of purpose. In contrast, the last two suggest understanding of two basic principles of emergence: the

lack of centralized control, and the role of stochastic processes.

Table 1: Codes Used in The Analysis

Code	Description	Example
Centralized Control	Reference to a group member determining, directing, or guiding the actions of the rest of the members.	<i>The slime mold that produces more pheromones will signal the others to come and cluster around them.</i>
Cooperation	Agents cooperatively determine their behavior, or work together as a group.	<i>Each geese are telling each other where to move</i>
Differentiation	Members have different abilities, roles, or attributes from one another.	<i>Maybe the ones clustered have a similar pheromone (sic). Also the levels of what they give off could be different.</i>
Goal-oriented	Specifies a behavior being performed to fulfill a specific, stated purpose.	<i>He takes the path he does because he's searching for food.</i>
Lack of Central Control	Refers to lack of a group member determining, directing, or guiding the actions of other members.	<i>I think the ants are generally just concerned with getting some food, so following a leader was not the goal. They all followed very similar paths because they shared a common goal.</i>
Random Processes	Describes movement or other activity explicitly as "random." Does not include descriptors such as "haphazard" or "scattered," but only those which or seem to be referring to a reasonably accurate version of statistical randomness.	<i>I think this is a random pattern while they search for food. The first makes random search while the followers more directly follow.</i>

Our first step in analyzing the data was to calculate the means and standard errors for each domain on each of these 6 codes (see Table 2 for descriptive and inferential statistics). We took a "token-counting" approach, adding up the number of times a particular code was used a participant in a domain. This gives a sense of how strongly the participants relied on a particular conception in providing their explanations for the phenomena. Since a participant could have invoked a particular concept or principle in answering each question, the maximum token score for each code is seven.

Table 2. Descriptives For Each Domain, By Code (alpha corrected to account for experiment-wide error)

Code	Slime	Ants	Geese	F(2, 78)
Centralized Control	0.23 (.07)	3.35 (.27)	1.18 (.21)	64.22***
Cooperating Agents	1.08 (.17)	0.55 (.13)	1.50 (.27)	8.10**
Differentiated	1.05 (.22)	3.95 (.26)	1.85 (.28)	35.86**
Goal-Oriented	2.70 (.29)	3.77 (.25)	3.03 (.29)	5.34*
Lack Central Control	0.78 (.09)	0.32 (.17)	0.38 (.13)	3.40 <sup>m</sup>
Random Processes	0.70 (.22)	0.48 (.14)	0.38 (.13)	1.51 <sup>ns</sup>

We also calculated participants' use of these codes using a binary process; a score of "1" meant that the participant used the code at least once within that domain; "0" indicated they did not use the code at all in that domain. The results were quite similar; the same pattern of significant findings was found for all but two of the codes. In the case of "goal-oriented," the differences decreased, and the F-value fell to 2.69 (non-significant). In the case of "lack of centralized control," differences increased, and the F-value rose to 16.98 ( $p < 0.01$ ). We believe these differences are due to the following: in the case of goal-orientation, almost every participant invoked it at least once in every domain, restricting the range when using binary scoring. The opposite is true in the case of a lack of centralized control; so few participants invoked this, a binary analysis was able to detect differences that were swamped by non-responses in the token analysis.

### Other Points of Interest

As noted above, there were themes in the data that were not as central, but might shed some light on how participants conceptualized emergence. For example, in reviewing the protocols, we found that participants were expressing quite different ideas, even when using similar language. In one

case, we inquired as to whether the participants believed that the agents followed rules in carrying out their actions. The consensus seemed to favor that they did not follow rules (approximately 2/3 of the replies).

However, we also discovered that participants had different ideas about what constituted a “rule.” For some, following a rule meant making a conscious decision based on a learned rule—we learn to stop at red lights, for example, and we (usually) follow that rule. For others, rules could also be innate or instinctual. Some even went so far as to explicitly state “if you mean conscious rules, no, but if you mean instincts, then yes, they follow instincts.”

Because we could not go back and further probe to see what meaning of “rule” each participant used, we excluded it from further analysis, but we think this disagreement about what constitutes a rule is interesting, for reasons we will address in the discussion.

## Discussion

As predicted, slime molds elicited fewer misconceptions overall than the other two entities, and produced the lowest level of misconception use in three of the four categories associated with misconceptions. Ants also elicited the predicted performance, with the highest use of misconceptions in three of the four categories. Trends in the two categories related to correct conceptions were unclear; reference to an explicit lack of centralized control was only significant in the binary coding of the data; this trend did favor our prediction, in that slime molds had the highest invocation of this correct concept. However, random processes produced no significant differences in either analysis.

The mathematical and scientific power of complexity theory and emergence comes from the ability of these theories to draw bridges between seemingly disparate disciplines. These isomorphisms, along with the tremendous overhead involved in modeling any phenomenon, have led educational researchers and cognitive scientists to focus on a small sub-set of emergent phenomena, reasonably inferring that the errors that crept up in one domain would appear in another, given the underlying similarities. Even if novices did not know the phenomena were isomorphs, the phenomena were governed by the same principles, manifest in similar ways, and created similar puzzles.

There was indeed some similarity in how the participants responded to phenomena; of the 13 themes we identified, every one was present at least once in each domain. That suggests a relatively high degree of consistency across domains in terms of how participants describe and explain phenomena.

However, we also believe that researchers have not been paying enough attention to the fact that each phenomenon is carried out by a different cast of characters—be it molecules, ants, geese, or air streams—and novices might rely on prior knowledge and beliefs in perceiving a phenomenon and devising an explanation for it. As a result, the likelihood of invoking a particular concept or

misconception is not just due to the phenomenon’s abstract characteristics, but also what the novice brings to the phenomenon, perhaps in the form of specific knowledge of the entities, or perhaps in the form of folk theories.

The problem of interpreting participants’ use of the word “rules” illustrates our account well. Differences in one’s beliefs about what constitutes a rule, and whether an entity is capable of acting on rules created differences in the way participants responded. Most participants seem to think of rules as learned guides to appropriate behavior to which one consciously refers. They were reluctant to ascribe that ability to the entities we used in this study. Those who believed that instincts could be thought of as rules were much more willing to think of agents as following rules.

Similarly, we believe that the differences between the three domains on the codes we examined are driven less by specific knowledge of emergence, and more by one’s beliefs about the entities’ capacity for thinking, consciousness, and deliberate decision making. They invoked misconceptions less for slime molds, unicellular microorganisms, than for geese and ants, and there is some evidence that they were more likely to invoke a correct explanation for the slime molds, based on a lack of centralized control and random processes.

Their accounts of ants consistently showed the greatest number of misconceptions; only for cooperation did geese outperform ants. Anecdotally, a fair number of participants spontaneously stated that they knew how ants worked because (a) they have had extensive experience with ants, usually trying to get them out of their houses, and (b) because they had seen the movie ‘Antz.’ They were also inclined to mention that ants were social creatures, and that ability suggested organization, and the mental capacities needed to create organization.

At very least, this should serve as a warning to those of us engaging in research about complexity and emergence. By relying on one or a few phenomena to characterize how people perceive, explain, and understand emergence more generally, we may be greatly over or underestimating the abilities depending on the domains and agents we choose. Testing a model on a variety of phenomena, with agents at different levels of familiarity and perceived cognitive capacity would be a good step to take before deciding that a particular pattern of results arises because of the character of emergent systems generally, and because of the specific properties of the agents and the activities they undertake.

We believe, however, that there is something more interesting going on here, and that a better understanding of how people experience emergence will require us to draw upon research into folk theories (Arico, Fiala, Goldberg & Nichols, 2011) developmental constraints (e.g., intentionality, teleology; Sinatra, Brem & Evans, 2008), anthropomorphism (Tamir & Zohar, 2006), and sociocultural accounts of the differences in ways that different groups of people characterize animals, people, and objects. We need a better sense of how people characterize agents and their abilities to exhibit volition, teleological

thinking, to communicate, and to control themselves, others, and their environment.

We hypothesize that the greater the perceived capabilities of an agent or group of agents, the more likely it is that people will reject explanations that invoke emergence in favor of accounts that give agents greater control over the events that occur. Alternatively, the differences between simulations were due to differences in the phenomena we chose. It may be, for example, that flocking seems to require greater mental skill than following a pheromone trail.

As a first step in addressing these hypotheses, we are currently running a study in which we present isomorphic phenomena across different levels of agents (physical, "lower animal," "higher animal," and human), and are also gathering data about the perceived capacities of each of these agent types. We believe that simulations depicting agents deemed more mentally capable will correlate with greater misconceptions, even when the underlying mechanisms are actually identical. However, if it is the type of phenomenon that drives the differences in our first study, this should surface in this study; responses should be more similar by phenomenon than by level of agent.

In either case, having a better understanding of how perceptions of phenomena and agents vary, this should improve our ability to understand how people look at emergent phenomena, and suggest ways to dispel misconceptions.

### Acknowledgments

This work was made possible by a grant from the National Science Foundation to the first and third authors (0910115). We also thank Katherine G. Nelson and Susan Shapcott for their assistance in preparing this manuscript.

## Abstract

We rely on both our own observations and on others' testimony when making causal inferences. To integrate these sources of information we must consider an informant's statements about the world, her expressed level of certainty, her previous accuracy, and perhaps her apparent self-knowledge – how accurately she conveys her own certainty. It can be difficult to tease apart the contributions of all these variables simply by observing people's causal judgments. We present a computational account of how these different cues contribute to a rational causal inference, and two experiments looking at adults' inferences from causal demonstrations and informant testimony, focusing on cases where these sources conflict. We find that adults are able to combine social information with their own observations, and are sensitive to the reliability of each. Adults are also sensitive to the accuracy, certainty, and self-knowledge of the informant, a result confirmed by comparing predictions from models with and without these variables.

## Introduction

People face challenging causal learning problems on a daily basis. They have a variety of information they can use to help solve these problems, including directly observed patterns of cause and effect, and social data such as others' statements about existing causal relationships. Having multiple sources available should enhance our causal reasoning, but integration can be difficult, especially when sources disagree. If an informant's causal statements contradict our causal observations, which source should we trust? Informants can be ignorant, mistaken, even deceptive, so one might think we should always trust what we see over what we hear. Yet the world is unpredictable: Observing a phenomenon once does not mean we will reliably observe it again. How do we evaluate these sources and determine which to rely on? We attempt to better understand how people combine different sources of information when making causal inferences, how they integrate their own observations with conflicting testimony, and how this affects their future evaluation of the social informant.

Informant testimony is a key type of social information that guides learning across domains, but the role of testimony in causal learning has not been extensively explored. Research on how we incorporate information from the social context into our causal judgments has shown that both children and adults are skilled causal learners, and can use information from social demonstration to inform their causal inferences (e.g., Kushnir, Wellman, & Gelman, 2008; Sobel & Sommerville, 2009; McGuigan, Makinson, & Whiten, 2011). This work has investigated how we learn by observing other people (e.g., Goodman, Baker, & Tenenbaum, 2009; Buchsbaum, Gopnik, Griffiths, & Shafto, 2011), and by observing different types of people (e.g., Kushnir et al., 2008),

but has not examined in detail how we make inferences about their credibility based on their causal statements. Here, we explore how people combine information from causal observations and testimony, both to make causal judgments and to evaluate the informants themselves.

Recently, there has been a growing literature on how people, especially children, evaluate informants (e.g., Borckardt, Sprohge, & Nash, 2003; Corriveau, Meints, & Harris, 2009; Koenig & Harris, 2005), including how children integrate their prior knowledge with informant testimony (e.g., Jaswal, 2010; Jaswal & Markman, 2007). Integrating testimony with our observations is particularly challenging because multiple aspects of informants and their testimony contribute to the value of the information they provide, and to how much they should be trusted in the future. These aspects include the level of certainty informants express, their past accuracy, and their self-knowledge – how well their certainty reflects their true knowledge (for an exploration of a similar idea in the context of eye-witness testimony see Tenney, Small, Kondrad, Jaswal, & Spellman, 2011). The difficulty of combining information from what someone says and what we see is especially apparent when an informant's statements appear to be incorrect. It could be that the informant is actually right, and our own observations were inaccurate. Alternatively, the informant may be a knowledgeable person who has simply misspoken, or she could truly be clueless. Finally, an informant could express certainty or uncertainty about her knowledge, shedding a different light on her inaccuracy. Deciding whether an informant has erred, and if so, why, and whether to trust her in the future is therefore a complex problem.

Bayesian modeling provides a mechanism for explicitly representing the contributions of different sources of information to judgments about causal structure and informant credibility. Previous work has used such models to explore the role of social observations in causal learning (e.g., Goodman et al., 2009), and to evaluate the role of informant knowledgeability and helpfulness (Shafto, Eaves, Navarro, & Perfors, in press). Here, we present a model that helps us evaluate the roles of observed cause and effect patterns, as well as an informant's expressed certainty, current and past accuracy, and awareness of her own knowledge level, when making a causal inference.

In this paper, we first review a study exploring how preschoolers combine information from informant testimony with conflicting information from observed causal data. Next, we introduce a computational model of causal inference from testimony that explicitly represents the roles of informant certainty, accuracy, and self-knowledge, as well as direct causal observations, allowing us to assess the

<sup>1</sup>These authors contributed equally to this work.

contributions of each to a rational causal inference. We then present a series of adult experiments motivated by both the model and the child experiments. Finally, we conclude by discussing how predictions by models including some or all of these variables provide us with further insight into our ability to learn from multiple sources, and the information we use to determine when to trust what other people say.

### Children’s Causal Inferences from Testimony

Bridgers, Buchsbaum, Seiver, Gopnik, and Griffiths (2011) presented preschoolers with either an informant who claimed to know which of two blocks was better at activating a machine or an informant who claimed to be guessing, and with observed statistical data that contradicted the informant’s claim. The study investigated which source of information (the person or the data) children would rely on, as well as how likely children would be to trust the informant in a new situation. Though both informants made incorrect predictions, the naïve informant demonstrated more self-knowledge because she knew she did not know, while the knowledgeable informant was unaware she was mistaken.

Results from this study imply that preschoolers are sensitive to the certainty and accuracy of an informant – they were more likely to trust the informant’s endorsement over the data when the informant was knowledgeable than when she was naïve, and were more likely to trust the knowledgeable informant before her inaccurate statements than afterwards. However, these results also suggest that children may not be as sensitive to an informant’s level of self-knowledge since children were as likely to trust the knowledgeable informant (who was mistaken in her certainty) as they were to trust the naïve informant (who was correctly uncertain) in a new situation.

Intuitively, an informant’s certainty, past accuracy, and self-knowledge should all be useful indicators of her credibility. However, it is challenging to infer the influence of each of these variables and of the causal data simply by examining people’s resulting inferences. For example, does children’s failure to differentiate between the informants in Bridgers et al. (2011) mean they lack a concept of self-knowledge altogether or that they weigh other cues to reliability more heavily? Given children’s performance, would adults trust a previously inaccurate but uncertain informant over one who was certain and inaccurate, or would they also use a simpler strategy, for instance mistrusting anyone who was previously incorrect? A computational model of how people combine information from both observed data and an informant to determine the likelihood of a causal relationship could help clarify the factors impacting people’s resolution of the conflict, and their decision of whether or not to trust the informant in the future.

### Modeling Causal Inference From Testimony

People may take into account a variety of social information when making causal inferences from testimony. As noted earlier, there is evidence that both children and adults are sensitive to an informant’s expressed certainty and previous

accuracy. People may also have pre-existing assumptions about how knowledgeable others tend to be, and how often others make mistakes in their assertions. Finally, there is some evidence that at least adults are sensitive to others’ self-knowledge (Tenney et al., 2011).

This social information also interacts with the individual’s own causal observations. It can therefore be difficult to determine which of these variables contribute to people’s resulting causal inferences. We present an explicit model of how these variables could interact. We then evaluate the roles of these different variables by comparing people’s causal judgments to those that would be normative under our model, as well as under simpler models that do not explicitly represent the informant’s knowledge and self-knowledge.

Our model is defined in terms of observed variables representing causal outcomes, statements by an informant about the causal strengths of potential causes, and about her level of certainty about her causal knowledge. The model also has hidden variables representing the actual causal strengths of the potential causes, the informant’s general level of knowledgeability, her specific knowledge of the individual causes, and her level of self-knowledge – how well she knows what she knows. We capture the complex relationships among these variables in a graphical model (see Figure 1).

In this model, we assume that all the variables are binary valued, as they were presented to children in the Bridgers et al. (2011) experiments. Each cause  $c$  has a causal strength  $w_c$ , such that  $p(e_c = 1 \mid c, w_c) = w_c$  for effects  $e_{c,i}$  where  $p(w_c = \rho) = \gamma$  and  $p(w_c = 1 - \rho) = 1 - \gamma$ . Here,  $\rho$  is some relatively high probability of effect, corresponding to the causal strength “almost always makes it go” in Bridgers et al. (2011), with  $1 - \rho$  corresponding to “almost never makes it go.”

The informant’s prediction  $r_c$  about the causal strengths of each cause depends on the true causal strength  $w_c$ , and on her knowledge of the cause  $k_c$ . Here, we assume that  $k_c \in \{0, 1\}$ , corresponding to two possible states of knowledge of a cause: guessing and knowing. If  $k_c = 1$  (the informant knows about the causal strength of  $c$ ) then  $p(r_c = w_c \mid k_c = 1, w_c) = 1 - \epsilon$ , meaning an informant with knowledge of cause  $c$  will predict the true value of  $w_c$  with probability  $1 - \epsilon$ , but with small error probability  $\epsilon$  will report the incorrect value. On the other hand, if  $k_c = 0$  and the informant is guessing about cause  $c$ , then  $p(r_c = w_c \mid k_c = 0, w_c) = p(r_c = w_c \mid k_c = 0) = 0.5$ , that is, the informant will choose uniformly at random between the two possible causal strengths.

We assume that the probability of the informant knowing about a particular cause depends on the informant’s global knowledgeability  $g \in \{0, 1\}$ , with the informant having probability  $\kappa$  of being globally knowledgeable. If  $g = 1$  then the informant is globally knowledgeable and  $p(k_c = 0 \mid g = 1) = 1 - \tau$  and  $p(k_c = 1 \mid g = 1) = \tau$ , that is, the informant is knowledgeable about cause  $c$  with some relatively high probability  $\tau$ . Conversely, if  $g = 0$  and the informant is globally ignorant then  $p(k_c = 0 \mid g = 0) = \tau$  and  $p(k_c = 1 \mid g = 0) = 1 - \tau$ .

Finally, we need to represent the informant’s statement

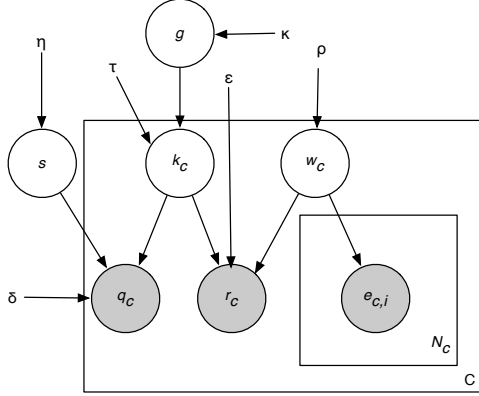

Figure 1: Causal testimony graphical model

about her knowledge of cause  $c$ . The informant’s statement  $q_c$  depends on her knowledge  $k_c$ , and her level of self-knowledge  $s$ . We assume that  $s \in \{0, 1\}$ , corresponding to two possible states of self-knowledge: accurate and inaccurate. If  $s = 1$  (the informant has accurate self-knowledge) then  $p(q_c = k_c | s = 1, k_c) = 1 - \delta$ , meaning the informant will accurately report her level of knowledge  $k_c$  with probability  $1 - \delta$ , but with small error probability  $\delta$  will report her level of knowledge inaccurately.

If  $s = 0$  and the informant has inaccurate self-knowledge then  $p(q_c = k_c | s = 0, k_c) = p(q_c = k_c | s = 0) = 0.5$ , that is, the informant will choose uniformly at random when stating her knowledge of the causal system. We assume that any given informant has probability  $\eta$  of having accurate self-knowledge, and  $1 - \eta$  of having inaccurate self-knowledge.

We assume  $p(\text{choose } c) \propto p(\text{effect} | c, \text{obs})$ , meaning people choose causes in proportion to how likely they think they are to produce the effect, given their observations (including the informant’s statements). This is computable from the model and the dependencies defined in our graphical model (see Figure 1). To evaluate our model, we conducted a series of experiments with adults, exploring whether they can successfully use an informant’s certainty, accuracy, and self-knowledge when making causal inferences.

## Experiment 1: Adult Inferences from Testimony

We investigate how adults resolve a conflict between an informant’s explanation of how a causal system works and actual demonstrations of that system, closely following the procedure of Bridgers et al. (2011). We hypothesized that like preschoolers, adults would be sensitive to the certainty and accuracy of the informant, and be more likely to trust an informant who claimed to be knowledgeable over one who claimed to be naïve, and less likely to trust a previously inaccurate informant. However, unlike children, we predicted that adults would be sensitive to an informant’s level of self-knowledge, and would be more likely to extend their trust to a previously incorrect informant who had claimed ignorance than a previously incorrect informant who had claimed knowledgeability.

## Methods

**Participants** A total of 204 participants were recruited: 100 were UC Berkeley undergraduates who received course credit and 104 were Mechanical Turk workers who were compensated \$0.50. Participants were randomly assigned to one of two experimental groups: the Knowledgeable condition ( $n = 103$ ) or the Naïve condition ( $n = 101$ ).

**Stimuli** The experiment was a web-administered survey involving text and pictures. An image of a brown-haired woman was the informant, and an image of a blonde woman was her assistant. The machine was an image of a green box with a black top. The activated machine had a yellow top and musical notes were placed around it. The blocks were a green rectangle, a pink disk, an orange cube, and a blue cylinder.

**Procedure** First, a woman named Ann (the *informant*) introduced a machine that could light up and play music when certain blocks were placed on top. She then introduced two different blocks and explained that one block almost always activated the machine (the *endorsed* block), while the other block almost never did (the *unendorsed* block). In the Knowledgeable condition, the informant claimed that she really knew which block was better at activating the machine, while in the Naïve condition, the informant claimed that she was just guessing. Besides this difference, the procedure was identical across conditions. Ann then said she needed to leave, and her assistant Jane continued the experiment.

Jane first asked participants to rate how likely each block would be to activate the machine on a scale from 0 (definitely will not) to 10 (definitely will) (the *prior* rating). Jane demonstrated each block on the machine, providing probabilistic evidence that contradicted Ann’s claim: the endorsed block only activated the machine 2/6 times, while the unendorsed block activated it 2/3 times.<sup>1</sup> Participants were then again asked to rate how likely each block would be to activate the machine (the *causal* rating).

Finally, Ann returned with two new blocks, and in both conditions, claimed she *knew* that one block almost always activated the machine and that the other almost never did. Ann then left once more, and Jane asked the participants to rate how likely they thought these new blocks were to activate the machine (the *generalization* rating).

## Results and Discussion

For a summary of the results see Table 1. We analyzed causal efficacy ratings with a  $2 \times 3 \times 2$  repeated measures ANOVA, with endorsement (endorsed or unendorsed), and rating phase (prior, causal, generalization) as the within subject variables, and knowledge condition (Knowledgeable or Naïve) as the between subjects variable. There was a main effect of endorsement – adults rated the endorsed block more highly across phases and conditions ( $F(1, 1206) = 77.69$ ,  $\text{MSE} = 372.1$ ,  $p < 0.001$ ). There was also an effect of endorsement

<sup>1</sup>This pattern of probabilistic data is the same as was used in Experiment 3 of Kushnir and Gopnik (2007).

$\times$  condition ( $F(1, 1206) = 73.19$ ,  $MSE = 350.5$ ,  $p < 0.001$ ), with the endorsed block rated higher in the Knowledgeable condition across phases, and of endorsement  $\times$  phase ( $F(2, 1206) = 62.18$ ,  $MSE = 297.8$ ,  $p < 0.001$ ), with the rating of the endorsed block decreasing and of the unendorsed block increasing in the causal phase. Finally, there was a significant three-way interaction of endorsement  $\times$  phase  $\times$  condition ( $F(2, 1206) = 13.89$ ,  $MSE = 66.5$ ,  $p < 0.001$ ), indicating that the degree to which the ratings change between phases varied by the claimed knowledge level of the informant and whether the block was endorsed.

We explored the particulars of these findings via planned  $t$ -tests. In the prior phase of both conditions, adults were more likely to give the endorsed block a higher rating (paired  $t$ -tests, Knowledgeable:  $t(102) = 17.76$ ,  $p < 0.001$ . Naïve:  $t(100) = 5.02$ ,  $p < 0.001$ ) though participants in the Knowledgeable condition gave the endorsed block a higher rating than those in the Naïve condition (two sample  $t$ -test,  $t(202) = 5.72$ ,  $p < 0.001$ ). These results suggest that before seeing any data, adults in both conditions were likely to trust the informant’s testimony, but were also sensitive to the certainty expressed by the informant.

In the causal phase, there was no difference in adults’ ratings of the endorsed and unendorsed blocks in the Knowledgeable condition (paired  $t$ -test,  $t(102) = 1.39$ ,  $p = 0.17$ ), while adults in the Naïve condition gave the unendorsed block a higher rating (paired  $t$ -test,  $t(102) = 7.18$ ,  $p < 0.001$ ). Adults in the Knowledgeable condition gave the endorsed block a higher rating than adults in the Naïve condition (two sample  $t$ -test,  $t(202) = 2.00$ ,  $p < 0.05$ ) and vice versa for the unendorsed block (two sample  $t$ -test,  $t(202) = 3.62$ ,  $p < 0.001$ ). The fact that in the causal phase adults thought the two blocks had approximately equal causal efficacy in the Knowledgeable condition but rated the unendorsed block more highly in the Naïve condition suggests that participants were responding to both the observed statistical data and the claimed knowledge level of the informant.

Finally, in the generalization phase, adults in both conditions gave the endorsed block higher ratings (paired  $t$ -tests, Knowledgeable:  $t(102) = 13.21$ ,  $p < 0.001$ . Naïve:  $t(102) = 8.23$ ,  $p < 0.001$ ). Unlike the previous phases, there was no difference between conditions in ratings of the endorsed block (two sample  $t$ -test,  $t(202) = 0.82$ ,  $p = 0.41$ ).

We can also compare ratings in the two no-data phases – prior and generalization – to capture how participants’ evaluation of the informant might have changed after receiving evidence about her accuracy in the intervening causal phase. Adults’ ratings decrease between prior and generalization in the Knowledgeable condition (paired  $t$ -test  $t(102) = 3.30$ ,  $p < 0.01$ ), while they increase in the Naïve condition (paired  $t$ -test,  $t(100) = 2.12$ ,  $p < 0.05$ ). This difference suggests that adults may actually be sensitive to an informant’s self-knowledge, increasing their trust in an informant who was incorrect but uncertain in the past over an informant who was incorrect but certain. Our results in the generalization phase

Table 1: Mean ratings and standard errors for Experiment 1

Mean Rating (std err)	Endorsed	Unendorsed
Prior Naïve	6.46 (.24)	4.16 (.25)
Prior Knowledgeable	8.22 (.19)	1.94 (.19)
Causal Naïve	4.09 (.18)	6.29 (.20)
Causal Knowledgeable	4.66 (.22)	5.18 (.23)
Gen Naïve	7.20 (.25)	3.27 (.25)
Gen Knowledgeable	7.45 (.18)	2.71 (.20)

Table 2: Mean ratings and standard errors for Experiment 2

Mean Rating (std err)	Endorsed	Unendorsed
Prior Naïve	6.58 (.31)	3.68 (.32)
Prior Knowledgeable	8.61 (.18)	1.47 (.18)
Causal Naïve	1.15 (.35)	9.45 (.11)
Causal Knowledgeable	2.82 (.54)	8.0 (.45)
Gen Naïve	7.0 (.44)	3.47 (.47)
Gen Knowledgeable	5.88 (.52)	4.15 (.51)

imply that adults are willing to trust both informants more or less equally regardless of their level of self-knowledge. However, due to the stochastic nature of the data, participants may have made excuses for the discrepancy between the data and the knowledgeable informant’s endorsement, possibly appealing to hidden causes such as a faulty machine part that would explain away the conflict. In Experiment 2, we contrasted an informant’s testimony with deterministic data to see if increasing the apparent inaccuracy of the informant would reveal a use of informant self-knowledge.

## Experiment 2: Deterministic Data

We replicated Experiment 1 but with deterministic data, to explore how changing the strength of the data might impact adults’ inferences. We predicted that adults would weight conflicting deterministic data more heavily than conflicting probabilistic data, and would therefore prefer the unendorsed block more often in the causal phase. We also predicted that the stronger data would exaggerate the knowledgeable informant’s lack of self-knowledge, leading adults to consider the naïve informant’s testimony as more reliable than the knowledgeable informant’s in the generalization phase.

## Method

**Participants** A total of 74 participants recruited from Mechanical Turk were compensated \$0.50 and randomly assigned to the Knowledgeable condition ( $n = 34$ ) or the Naïve condition ( $n = 40$ ).

**Stimuli** Stimuli were identical to those in Experiment 1.

**Procedure** The procedure was the same as in Experiment 1 except that the endorsed block activated the machine 0/6 times, while the unendorsed block activated it 6/6 times.

## Results and Discussion

We performed the same analyses for Experiment 2 as we did for Experiment 1. Due to limited space, we discuss only the most relevant results here. Results are summarized in Table 2.

Adults in both conditions of Experiment 2 gave lower ratings to the endorsed block in the causal phase as compared to Experiment 1 (two sample t-tests. Knowledgeable:  $t(135) = 3.77$ ,  $p < 0.001$ . Naïve:  $t(139) = 7.90$ ,  $p < 0.001$ ). Adults thus were sensitive to the increased strength of the data in the second experiment, and were less likely to trust the knowledgeable informant’s claim over the data than participants who observed probabilistic data.

In the generalization phase of Experiment 2, adults rated the endorsed block in the Naïve condition as more causally efficacious than in the Knowledgeable condition, though this effect was only marginal ( $t(72) = 1.69$ ,  $p < 0.10$ ). Thus, adults in the Knowledgeable condition were less inclined to trust the informant’s endorsement than adults in the Naïve condition. This finding suggests that differences in self-knowledge *do* impact adults’ evaluations of informants since adults appeared to place more confidence in the statement of the person whose prior certainty reflected their accuracy.

Comparing across experiments, we found that adults in the Knowledgeable condition of Experiment 1 gave the endorsed block a higher generalization rating than those in Experiment 2 (two sample t-test.  $t(135) = 3.77$ ,  $p < 0.001$ ). On the other hand, there was no difference in adults’ generalization ratings of the endorsed block in the Naïve condition (two sample t-test.  $t(135) = 0.41$ ,  $p = 0.68$ ) across experiments. As predicted, increasing the strength of the conflicting data magnified the knowledgeable informant’s inaccuracy. However, since the naïve informant claimed ignorance, this change did not affect how adults evaluated future information from this informant. In general, trust in the knowledgeable informant decreased with increasingly conflicting data (i.e. from situations of no conflict (prior phases) to situations of prior conflicting data (generalization phases) to situations of directly conflicting data (causal phases)).

Finally, comparing between phases of Experiment 2, in the Knowledgeable condition, adults’ ratings of the endorsed block decrease between prior and generalization phases (paired t-test,  $t(33) = 4.99$ ,  $p < 0.001$ ). Thus, adults are likely to initially trust the endorsement of an informant, whereas they are less likely to extend that trust to a new situation (the generalization phase) after observing evidence that contradicts the informant’s prior claim. Conversely, in the Naïve condition there was no difference between adults’ prior and generalization phase ratings (paired t-test,  $t(39) = 0.79$ ,  $p < 0.43$ ). Thus, adults’ evaluation of the credibility of the naïve informant does not appear to have changed after observing the conflicting data. This further suggests adults are sensitive to self-knowledge when determining the usefulness of an informant’s statement: They found a previously uncertain, inaccurate informant more trustworthy than a previously certain, inaccurate one.

One alternative account is that adults consider the knowledgeable informant to be deceptive rather than having poor self-knowledge. However, if adults suspect the knowledgeable informant is deceiving them by saying the opposite

Figure 2: Adult performance vs model predictions

of what she knows, then we would expect them to go against her endorsement in the generalization phase, rating the unendorsed block as more causally efficacious than the endorsed block. However, while adults’ ratings of the endorsed block decrease in the generalization phase, they are still greater than their ratings of the unendorsed block, implying that adults view this informant as less reliable rather than intentionally dishonest.

## Modeling People’s Inferences

We can use our model to further test whether an informant’s expressed certainty, accuracy, and apparent self-knowledge inform adults’ causal judgments. We first evaluate the model by fitting it to data from Experiment 1. In order to be consistent with Bridgers et al. (2011), where children were asked to choose the better block, we assumed that for each set of ratings adults would choose the block they had rated as most likely to be effective. We then optimized the log likelihood of these choices under the model. The best fitting model corresponded to model parameters of  $\rho = 0.91$ ,  $\gamma = 0.40$ ,  $\epsilon = 0.01$ ,  $\delta = 0.1$ ,  $\tau = 0.91$ ,  $\kappa = 0.74$  and  $\eta = 0.93$ , (Pearson’s  $r=0.999$ ,  $p < 0.001$ ). However, a reasonable range of values around these settings also fit the data well. Of particular note are the values of  $\kappa$  and  $\eta$ , corresponding to a belief that most people have good general knowledge, but a substantial minority are relatively clueless, and that almost everyone is aware of their own knowledge level, but a small number of people tend to inaccurately assess what they know.

We tested the generalization of these model parameters by looking at how well they predict adult performance in Experiment 2. The parameters fit to the Experiment 1 data also provide a good fit to the results of Experiment 2 (Pearson’s  $r=0.9664$ ,  $p < 0.001$ ). This suggests that our model is accurately capturing human performance, so we can use it to tease apart the contributing variables to adult causal inferences.

We then conducted a nested model comparison, examining whether including the informant’s global knowledgeability and their self-knowledge adds explanatory value to the model, by creating a series of “lesioned” models, lacking global knowledge  $g$  and self knowledge  $s$ . This approach controls for the additional free parameters in the more complex model. Removing global knowledge corresponds to a model that assumes that all informants have the same probability of knowing about all causes, and that an in-

formant knowing about one cause does not make her any more likely to know about others. Removing self-knowledge corresponds to a model where informants' statements of certainty always reflect their true knowledge – if they say they know something, then they must really know it.

Compared to a model lacking both global knowledge and self-knowledge variables, adding global knowledge to the model resulted in a marginally significant ( $\chi^2(1) = 3.29, p = .07$ ) improvement in model fit. Adding self-knowledge on its own did not improve model performance ( $\chi^2(1) = 0.392, p = 0.53$ ), however adding both self-knowledge and global knowledge variables significantly improved model fit over having only global knowledge ( $\chi^2(1) = 22.04, p < 0.001$ ), or having neither ( $\chi^2(1) = 25.30, p < 0.001$ ) (see Figure 2).

Qualitatively, the addition of global knowledge and self-knowledge only modestly improves the model fit to Experiment 1, their biggest effect is on the fit to Experiment 2. Of particular interest in Experiment 1, the full model and the “lesioned” model (without both variables) appear to make similar predictions about adults' performance in the generalization phase, suggesting that contrary to our initial intuitions, even with a concept of self-knowledge it may still be rational to extend trust equally to both informants. However, these two models make different predictions for generalization performance in Experiment 2, with the full model more accurately capturing adults' inferences. This supports the interpretation that in the first experiment, participants continued to extend trust to the knowledgeable informant not because they lacked a concept of self-knowledge but by explaining away the informant's apparent incorrectness, inferring that the ambiguous data could have been “unlucky.” However, in Experiment 2, where the data more strongly supports the inference that the informant was incorrect, these model results suggest that it requires both a concept of general knowledge (“if this person was wrong before, they're more likely to be wrong again”), and self-knowledge (“they said they ‘knew’ before and they didn't, why should I think they know now?” vs. “they said they didn't know, so it's okay that they were wrong”), in order to infer that the naïve informant is more deserving of trust in the generalization phase.

Overall, our nested model comparison demonstrates that adults take into account the informant's past performance when deciding how much to weight their current testimony, and in particular that adults are sensitive to both the apparent knowledgeability of the informant and their level of self-knowledge.

## Conclusion

We examined how people combine an informant's statements about a causal system with direct observations of that system, and how this influences their evaluation of the informant's knowledgeability and credibility. Together, Experiments 1 and 2 suggest that adults are weighting and integrating evidence from both observed data and the informant in their causal inferences, and that their trust in the informant is moderated by the degree to which the informant's testimony

conflicts with the data. Adults were sensitive to both the informant's certainty and accuracy, and to how well the informant's certainty reflected her accuracy. These findings support our intuition that self-knowledge is a valuable cue adults can use to determine the trustworthiness of an informant's testimony. The close fit of the model to adult performance, and its ability to generalize from Experiment 1 to Experiment 2, confirms that adults are rationally integrating their direct observations with testimony from a social informant when making causal inferences. Our model also strongly suggests that representing self-knowledge is necessary to making these inferences, and that adults could not be using a simpler strategy such as only tracking previous inaccuracy. Overall, these results provide us with further insight into how we learn from and evaluate the sources of information available to us and in particular, revealing that knowing that you do not know can be just as important as knowing that you know.

# Revisiting the Relationship between Allocentric-Heading Recall and Self-Reported Sense of Direction

Heather Burte (Burte@psych.ucsb.edu)

## Abstract

Sense-of-direction (SOD) has been described as a system that tracks the body's facing direction relative to an environmental reference frame (allocentric heading). To study this system, Sholl, Kenny, and DellaPorta (2006) developed a heading-recall task and found that task accuracy correlated highly with self-reported SOD measures. This study attempts to replicate and extend their findings, by increasing task accuracy, and testing alternative hypotheses about factors that could affect task performance. In a heading-recall task, participants estimated allocentric heading from pictures of familiar locations on a college campus. Previous results were replicated, but a weaker relationship between SOD and performance, and a novel relationship between location familiarity and performance were found. These results provide support for a human allocentric heading system but suggest that self-reported SOD potentially measures a range of abilities and not solely the operation of this system.

**Keywords:** allocentric heading; sense of direction; spatial orientation; spatial memory; head-direction cells; heading-recall.

## Introduction

In everyday situations, people describe their ability to accurately navigate through cities or neighborhoods using phrases like 'I have a great sense-of-direction' or 'I lack a sense-of-direction'. Kozlowski and Bryant (1977) transformed these colloquial assessments into a 7-point scale which assessed sense-of-direction (SOD). They found that these assessments were related pointing ability to familiar landmarks and updating one's location while traveling in an underground maze. Kozlowski and Bryant used a single item scale: "How good is your sense-of-direction?" Other researchers have measured SOD in a multi-faceted way. For example, the Santa Barbara Sense of Direction scale (SBSOD) is a 15-item scale that asks people about a variety of environmental tasks, such as giving directions and estimating distances, as well as their "sense-of-direction" (Hegarty, Richardson, Montello, Lovelace, & Subbiah, 2002). Hegarty et al. found that this measure of self-assessed SOD is related to several different environmental-scale tasks, including learning the layout of a new place, blindfolded updating, and pointing to familiar landmarks. These environmental-scale tasks require locomotion and integration from multiple viewpoints to acquire and access spatial knowledge. As such, the SBSOD

scale was created around the idea that one's SOD is multi-faceted.

Recently, Sholl, Kenny, and DellaPorta (2006) proposed that SOD is single-faceted, and relates to the performance of a head-direction system in humans, similar to that found in animals. The head-direction system in rats was first discovered by Ranck (1984), who identified brain cells that fire when an animal's head is facing a specific direction. The directions that these cells respond to are not directions based on the axis of the body (also called egocentric headings). They respond to the angles between the forward axis of the body and a reference direction that is grounded in the environment (i.e. the animal's allocentric heading). An example of one allocentric reference system is the cardinal directions, but head-direction cells use the environment's intrinsic structure, not cardinal directions.

Sholl, et al.'s (2006) goal was to discover if humans have an allocentric-heading system that is functionally similar to the head-direction system of animals and to elucidate the functional architecture of this system, including its inputs, outputs, organization, representations, and computations. To accomplish that goal, they developed an allocentric-heading recall task in which students were shown a picture of a familiar landmark on their campus, and had to indicate the direction (with respect to the global environment) from which the photo was taken. They found that a person's current facing direction influences their accuracy and decision latency in recalling allocentric headings: when a person's facing direction matches the allocentric direction to be recalled, there is a facilitation effect; and, when the facing direction is 180° from the allocentric direction to be recalled, there is a detrimental effect. According to the author's, one's current body-direction signals interfere with retrieval of allocentric-headings being remembered from other locations, at which one's body-direction signals were different. These results would be predicted if the human allocentric-heading system works similarly to the animal head-direction system. Sholl et al. also found strong correlations between performance on the heading recall task and both Kozlowski & Bryant's (1977) single-item question (K&B) and the SBSOD. They proposed that SOD measures a single-faceted ability, which reflects the operation of a human head-direction system.

To expand upon Sholl et al.'s (2006) findings, the goal of

this paper is to replicate Sholl et al.'s findings in a different location, test new hypotheses, and to provide further evidence on the single- or multi-faceted nature of what is measured by self-reported SOD measures.

### **Allocentric-Heading Recall and SOD**

The heading-recall task used by Sholl et al. (2006) was a four-alternative, forced-choice task, using campus pictures as stimuli. The pictures were taken from magnetic north, east, south or west. Magnetic compass directions were used because the intrinsic structure of the Boston College campus is aligned as such (and will also be used in the following experiment as the UCSB campus is similarly aligned). However, while cardinal directions will be used for simplicity in writing this article, it should be noted that cardinal directions were never used in written or verbal instructions, as the task can be completed without using cardinal directions.

First, we will define key terminology used: picture heading is the photographer's orientation when taking the picture; default heading is the orientation of participant before each trial; response heading is the participant's response orientation that s/he moved to, decision latency is the participant's time to decide on a response heading and rotation time is the time taken to rotate from the default to the response heading.

In the heading-recall task, participants were asked to indicate picture heading by rotating in a chair. According to Sholl et al. (2006), when viewing a building, the allocentric-heading of that view is stored in memory and is linked to signals of body-direction. Upon seeing a picture of that building, a person recognizes the building, and then recalls the allocentric-heading from spatial memory. Therefore, participants can rotate in a chair to replicate the picture heading because they can compare their current body-direction to the body-direction signals from their memory and move to face the picture heading. The two main measures of this task were accuracy and decision latency. Participants responded more accurately and faster when the picture heading was consistent with their default heading; therefore, accuracy increased and decision latency decreased with increasing angular deviation between the default and picture heading.

Sholl et al. (2006) found that self-reported SOD was related to accuracy in the heading-recall task, especially at the extremes of the SOD scale, and concluded that SOD measures reflect people's awareness of their own allocentric-heading abilities. In their first experiment, accuracy in heading-recall was correlated .74 with the SBSOD and .68 with the K&B scale. However, the SOD scales were administered at the end of the study and so participants' self-assessed SOD ratings could have reflected an assessment of their performance on this task, rather than a more general assessment of their abilities (cf. Heth, Cornell, & Flood, 2002). Thus, the correlations might be inflated. In our study, participants completed the SOD scales before the heading-recall task.

Another concern is that some of Sholl et al.'s, (2006) participants performed very poorly on the heading-recall task, with only 18/40 participants in Experiment 1 and 10/19 participants in Experiment 2 surpassing a 50% accuracy rate. Low accuracy could reflect failure to understand the task, because the heading-recall task is abstract, unlike everyday directional tasks. In fact, Sholl et al. reported instructional difficulties. Thus, the high correlations with SOD measures may reflect the fact that those with poor SOD were unable to understand the task.

The goals of this study are (1) to replicate the results of the heading task in a new context, (2) to maximize accuracy, (3) to reassess the relationship between self-assessed SOD and allocentric-heading recall, and (4) to test two alternative hypotheses. First, this study serves to replicate the methods used by Sholl et al. (2006) and confirm that their experimental effects are robust with differing campus locations, target pictures and participants. Second, we attempt to maximize accuracy in the heading-recall task by offering more practice trials and feedback to participants in the instruction phase, to ensure that participants understood the task. Third, this study reassesses the relationship between SOD and heading-recall when measures of SOD are taken before the heading-recall task rather than after.

Fourth, two alternative hypotheses were tested. The first alternative hypothesis was that performance on the heading task would be correlated with familiarity. Sholl et al. (2006) found no correlations of performance on the heading recall task with familiarity of the landmarks or distance to target. They used landmarks that had been rated as highly familiar by other students, but did not assess familiarity in the context of their experiment. With regards to familiarity, if one must recognize the target before the allocentric-heading can be retrieved from memory, then familiarity might be related to performance on the heading-recall task. Other studies have found that familiarity predicted directional accuracy on a mental wayfinding task (Prestopnik & Roskos-Ewoldsen, 2000). Therefore, our experimental participants completed a familiarity rating task, to test the hypothesis that familiarity is related to accuracy and decision latency.

The second alternative hypothesis concerns unfamiliar targets or targets for which participants cannot retrieve an allocentric-heading straight from memory. In these cases, people might perform the heading task by imagining walking a route from the experiment location to the target location. In this case, target distance should be correlated with decision latency. This prediction is based on the assumption that mental route taking is an analog process similar to mental rotation (Shepard & Metzler, 1971). Just as participants take longer to mentally rotate with larger angles, so might participants take longer to calculate allocentric-heading with larger distances, if they use a mental walk strategy. Just and Carpenter (1985) found that participants with poor spatial abilities rotated at a slower rate than those with good spatial ability, so the relationship between distance and decision latency might be particularly

strong for poor SOD participants. Sholl et al. (2006) failed to find correlations between objective distance and decision latency, but increasing the task understanding of poor SOD participants might reveal these participants' use of the "mental walk" strategy. Therefore, we tested the hypothesis that participants' estimated distances for each landmark would be related to decision latency on the heading-recall task.

## Method

**Pretesting of Stimuli** Twenty students (8 males and 12 females) rated 124 photographs of the University of California, Santa Barbara (UCSB) campus for familiarity and confidence in knowing the location from which the photograph was taken. The photographs were taken from four different headings (facing north, south, east and west). On the basis of this pretesting, 40 photographs (10 from each heading) were selected for the main study. The selected photographs did not differ in familiarity or rated confidence of location across headings. The ratings of familiarity were similar to those reported by Sholl et al., (2006) with the grand mean for the forty photographs being 1.6 on a scale from 1 to 7 with 1 being "Very familiar" and 7 being "Very unfamiliar".

**Participants** Sixty-one students (29 males and 32 females) participated in the main experiment to fulfill a research participation requirement. Participants were required to have spent at least two full quarters on campus. Each participant was assigned to one of the default headings (N, S, E, or W).

**Materials** The experiment took place in a room on campus that was aligned with the main axes of the campus (and the cardinal directions). The experimental room had one west-facing window that was open during the experiment. The view directly out that window was of a courtyard and another large (three storey) adjacent building. However, if one stood next to the window, one could see the mountains and ocean (major orientation markers for the campus), and a few major buildings. Therefore, the window afforded excellent views for initial orientation to the campus (when standing by the window), but only basic information while participants were seated at a desk when completing the experimental tasks.

Markers on the floor denoted four cardinal directions (which were also the default and response headings). Experimenters arranged a swivel chair and desk towards the assigned default heading before the participant arrived. Assigned default headings are used to determine if a participant's actual heading differentially affected the retrieval of picture headings.

A trial started with viewing a photograph of campus on a computer. Participants determined the direction (with respect to the campus environment) in which the photographer stood when taking the photograph (i.e., picture heading) and turned in the chair to reproduce that orientation. For example, if the photograph was taken facing

south, and the participant's default heading was facing north, the participant should turn 180° to face south. In addition to accuracy in completing this task, latency (time to complete the task) was recorded. Latency was recorded by computer and by the experimenter using a stop-watch, so that decision latency and rotation latency could be separately calculated. Both the computer and experimenter started timing when the picture was shown to the participant. The computer stopped timing when the participant indicated via a button press that s/he was about to turn (decision latency). Then the participant turned and indicated to the experimenter when s/he had finished rotating (total latency). The rotation latency was acquired by subtracting decision latency from the total latency. Participants were asked to rotate using the shortest angle.

**Design.** The methodology of the study was both experimental and correlational. The experimental factors were picture heading (within subjects) and default heading (between subjects). Participants were randomly assigned to one of the four default headings and completed forty trials, ten for each picture heading. Accuracy and latency were correlated with self-assessed SOD, average familiarity and accuracy of distance estimates.

**Procedure** Participants were introduced to the experiment, completed a demographics questionnaire, and completed the K&B and SBSOD rating scales. Next, participants were asked to orient to the layout of campus while looking out the window. The experimenter pointed to major points-of-reference (ocean and mountains) and then asked the participant to point towards four major campus buildings, to ensure that s/he was oriented to the global layout of the campus. The experimenter provided feedback, if needed, but most participants oriented and pointed correctly.

Participants were then introduced to the heading-recall task and presented with twelve practice trials in a fixed order. Participants were given feedback, and told the correct answer for any incorrectly answered trials. Next, the forty experimental trials were completed without feedback.

Afterwards, participants completed a distance estimation task, in which they estimated straight-line distances from their current location to the forty photograph locations, using a visually-presented standard unit (20 meters in length). Participants were given two practice distance estimation trials with correct answers provided as feedback. Then the task was completed for all forty photographs without feedback. Finally, participants rated their familiarity with each photograph location on a 7-point Likert scale.

The major procedural differences from Sholl et al. (2006) were that (1) more detailed instructions were provided, (2) more practice heading-recall trials were given, (3) the SOD scales were answered before the heading-recall task rather than after, and (4) distance estimation and familiarity tasks were used to test alternative hypotheses.

## Results

**Pretest and experimental photograph familiarity** The familiarity ratings for pictures from the pretest and from the main experiment correlated significantly,  $r(38) = .63$ ,  $p < .001$ . The mean familiarity in the main experiment was 2.3, which ranged from 1.1 to 3.9 across participants and from 1.1 to 5.3 across pictures. Even though there was a strong correlation between the two familiarity measures, participants in the main experiment rated some pictures as unfamiliar. Four pictures (three east facing and one north facing) had familiarity ratings that exceeded 2.5  $SD$  above the mean familiarity and were removed from analyses.

**Accuracy** To aggregate across default-heading conditions, a new variable called heading disparity was created to denote the angle disparity between the default heading and the picture heading for the four different default headings. For example, if the picture heading is aligned with the default heading, then these responses would be labeled as  $0^\circ$  heading disparity. A 2 (Gender) X 4 repeated measures (Heading disparity:  $0^\circ$ ,  $90^\circ$ ,  $180^\circ$ ,  $270^\circ$ ) ANOVA comparing mean accuracy indicated a main effect of heading disparity,  $F(3,177) = 7.73$ ,  $MSE = .22$ ,  $p < .001$ . The mean correct proportions by heading disparity are shown in Figure 1. Post hoc tests revealed that the  $180^\circ$  condition was the least accurate, the  $90^\circ$  condition was less accurate than the  $0^\circ$  condition and the  $270^\circ$  condition was midway between  $0^\circ$  and  $90^\circ$ . This can be interpreted as an inhibitory effect of having one's body positioned  $180^\circ$  away from the response of one's head-direction system, and is predicted if the human head-direction system operates similarly to that of animals. There were no other main effects or interactions.

Figure 1: Mean accuracy rate as a function of heading disparity. Error bars are the standard errors of the mean.

To further examine the conditions that lead to the previous analysis, a 2 (Gender: male, female) X 4 (Default heading: N, E, S, W) X 4 repeated measures (Picture heading: N, E, S, W) ANOVA compared mean accuracy. A main effect of picture heading was found,  $F(3,159) = 20.62$ ,  $MSE = .45$ ,  $p < .001$ , with north-facing pictures ( $N = 78\%$ ) and west-facing pictures ( $N = 74\%$ ) having the highest accuracy, south ( $N = 66\%$ ) with moderate accuracy and east

( $N = 58\%$ ) with the lowest accuracy. The mean proportion correct by picture and default heading is shown in Figure 2. This main effect was qualified by an interaction of picture heading with default heading,  $F(9,159) = 3.44$ ,  $MSE = .08$ ,  $p = .001$ . Accuracy was highest when picture and default headings were aligned and lowest when the default and picture headings were misaligned by  $180^\circ$ . Supporting the previous analysis, these findings confirm our main finding that your current heading affects the accuracy with which you can recall allocentric-heading. Aligned headings are easier to recall and  $180^\circ$  unaligned heading are harder to recall. There were no other main effects or interactions.

Figure 2: Mean accuracy rate as a function of picture heading (PH) and default heading (DH). Error bars are the standard errors of the mean.

However, there were some qualifications to this result, (1) with north picture headings there was no difference between default headings, and (2) west picture headings were highly accurate for north and south default headings. These findings might have been particular to the campus used as there are large global orientation cues, such as the local mountains when facing North and Isla Vista (an undergraduate housing area) when facing West. In debriefing, some participants reported using heuristics such as determining if the picture heading faced the mountains or Isla Vista.

**Rotation time** A one-way, repeated measures ANOVA investigated the effects of turn magnitude on rotation times. There was a significant linear trend,  $F(1,59) = 145.23$ ,  $MSE = 19.42$ ,  $p < .001$ , with rotation times of 1.56, 2.10, and 2.36 seconds for rotations  $0^\circ$ ,  $90^\circ$  and  $180^\circ$ , respectively. The magnitude of the turn accounted for 71.1% of the variability in turn time, indicating that decision latency was successfully separated from the time to physically turn.

**Decision latency** Outliers greater than 2.5  $SD$  above each participant's mean correct decision latency (3.3% of trials) were recoded to the mean and participants with less than 50% accuracy on the direction task were removed from all decision latency analyses. This was done, as there would be too few decision times to provide a meaningful measure for these participants. Fifty of the 61 participants (82%, 26

male, 24 female) had more than 50% accuracy in the present experiment, in contrast with only 18 of 32 (56%) participants in Sholl et al.'s first experiment. Thus, performance was generally more accurate in the current study.

A 2 (Gender) X 4 repeated measures (Heading disparity: 0°, 90°, 180°, 270°) ANOVA indicated a marginal main effect of heading disparity,  $F(3,144) = 2.45$ ,  $MSE = 7.71$ ,  $p = .07$ . Post hoc tests revealed the 180° and 90° heading-disparity conditions had longer decision latencies than the 0° condition. While suggestive, this pattern is not exactly what is predicted by the animal model and it is only marginally significant, but interestingly, a similar pattern was observed by Sholl et al. It might be due to the specific environments used in both experiments. The mean decision latency as a function of heading disparity is shown in Figure 3.

Figure 3: Mean decision latency as a function of heading disparity. Error bars are the standard errors of the mean.

**Correlations with Self-Reported Sense of Direction** The correlation between the two self-reported sense of direction measures was  $r(59) = .60$ ,  $p < .001$ . Mean accuracy and mean correct decision latency were correlated with participants' SOD measures, as shown in Table 1. Both of the SOD measures were positively correlated with mean accuracy and negatively correlated with mean correct decision latency, as expected. However, the correlations were substantially lower than those found by Sholl et al. (2006), and were significant only for accuracy.

**Photograph familiarity** Significant correlations between participants' mean familiarity rating (averaged across the 36 pictures) and their mean accuracy on heading-recall were found,  $r(59) = -.40$ ,  $p < .001$ , supporting our familiarity hypothesis. Therefore, as familiarity approaches 1 for 'very familiar', accuracy increases, however, there was no significant correlation between participants' familiarity and decision latency. Correlating mean familiarity per picture (averaged across individuals) with mean accuracy and decision latency per picture resulted in significant correlations (Table 2).

As seen in Table 1, SOD measures were negatively correlated with participants' mean ratings of familiarity of the landmarks,  $r_{K\&B}(59) = -.34$ ,  $p < .01$ ,  $r_{SBSOD}(59) = -.27$ ,

$p < .05$ , indicating that participants with good SOD rate their familiarity closer to 1 for 'Very familiar'. Furthermore, if one controls for mean landmark familiarity, correlations between accuracy and the SOD measures drop, to  $r_{K\&B}(59) = .19$ ,  $p = .14$  and  $r_{SBSOD}(59) = .29$ ,  $p < .05$ . In sum, the only significant correlation after controlling for familiarity is between accuracy and SBSOD. Therefore, the strong correlation between accuracy and SOD is partially due to high SOD participants being more familiar with the buildings shown in the pictures. In contrast with Sholl et al.'s conclusion that SOD reflects only ability to recall the allocentric heading of the picture, we have found that SOD is related to familiarity. Thus failure to recognize the locations from the pictures may be a source of error in this task.

Table 1: Mean Accuracy and Correct Decision Latency Correlations with Sense of Direction Ratings.

	Accuracy <sup>a</sup>	Decision Latency <sup>b</sup>	Familiarity <sup>a</sup>
K&B	.30*	-.13	-.34**
SBSOD	.37**	-.22	-.27*
Accuracy	--	-.03	-.40**
Familiarity	--	.02	--

\* p-value < 0.05; \*\* p-value < 0.01;

<sup>a</sup>  $N = 61$ ; <sup>b</sup>  $N = 50$

Table 2: Correlations of Familiarity with Accuracy and Correct Decision Latency, with Participants and Pictures as the Unit of Analysis

	Accuracy <sup>a</sup>	Decision Latency <sup>b</sup>
Across participants	-.40**	.01
Across pictures	-.54**	.33*

\* p-value < 0.05; \*\* p-value < 0.01; <sup>a</sup>  $N = 61$ ; <sup>b</sup>  $N = 50$  across participants;  $N = 34$  across pictures

**Distance Estimation** To test our mental walk hypothesis, we correlated mean correct decision latency per picture (averaged across individuals) with participants' estimates of the distance to each picture location. The correlation was not significant,  $r(34) = .23$ ,  $p = .17$ , providing no evidence for the mental walk hypothesis.

## Discussion

Using a heading-recall task, we replicated Sholl et al.'s (2006) finding that individuals can recall allocentric-directional information from pictures and that their performance is related to SOD. We replicated their finding that the least accurate directional estimates come from heading disparities of 180° and that the longest decisions latencies come from heading disparities of 180° and 90°. These results provide support for the theory that humans have an allocentric-heading system similar to those found in animals. We also replicated a significant correlation

between SOD measures and heading-recall measures. However, while our correlations reached significance, they were noticeably lower than those observed by Sholl et al. In addition, we found significant correlations between performance measures and familiarity that Sholl et al. did not find. But we failed to find support for our hypothesis that decision latency would be correlated with estimated distance.

We successfully replicated Sholl et al.'s experimental findings and were also successful in increasing the general accuracy level on the heading-recall task. Thus, people can be quite accurate in providing allocentric-heading for pictures, when adequate training and feedback are provided. Our results demonstrate that the effects replicate across campuses. However, our results also indicate that specific aspects of the local environment, such as the nearby mountain range, may also have affected the accessibility of the views. This study and Sholl et al.'s study were conducted on campuses with structures intrinsically aligned with magnetic compass directions. Using campuses with a less regular structure, or different allocentric reference systems for the pictures, would allow for further testing of the generality of these results.

Our study also attempted to replicate Sholl et al.'s high correlations between SOD measures and heading-recall performance. In contrast we found moderate significant correlations. There are two potential causes for the reduced correlations: administration of SOD measures before the heading-recall task and the increase in accuracy resulting from better instructions and additional practice trials.

With regards to our alternative hypotheses, the hypothesis that heading-recall performance measures would be correlated with familiarity found support. Since recognition is the likely first step in recalling an allocentric-heading, recognizing the view of the location is likely a first step in completing the task. It is possible that poor SOD individuals require more experience with locations than good SOD individuals to attain similar levels of recognition performance. Although Sholl et al. (2006) did not find effects of familiarity, they did not measure familiarity of their experimental participants and we found that the familiarity ratings from our pretest were not perfectly correlated with the familiarity ratings from our experimental participants. In summary, we found that significant correlations between accuracy and SOD are partially due to familiarity. In contrast to Sholl et al.'s conclusion that SOD reflects solely the ability to recall the allocentric heading of the picture, we found that SOD, familiarity and allocentric-heading accuracy are all related.

Our hypothesis that decision latency would be related to distance estimates was not supported. This suggests that people do not accomplish this task by imagining a mental walk to the locations in the pictures, or at least that this mental walk process is not an analog process. On the other hand, in debriefing interviews, many participants mentioned imagining how they would travel past the target location or extrapolating allocentric-heading from the direction of the

target location. This, and the fact that global orienting cues (like the mountains) seem to have affected performance, suggests that there may be several strategies employed in this task.

In conclusion, this study has replicated the result that ability to judge the heading from which a picture was taken is related to one's current heading, and provides motivation for further studying the possibility of a human allocentric orientation (or head-direction) system. On the other hand, our results do not support the view that self-reported SOD measures simply reflect the operation of a human head-direction system. Previous studies have found that SOD measures are related to multiple spatial skills, including learning spatial layout and updating, and the correlations we observed between SOD and the heading recall task are similar in size (in the moderate range) to the correlations typically found with these other tasks. Thus it is likely that self-report SOD measures reflect a range of navigation abilities, not just the operation of a head-direction system, and future studies of this system should rely on objective measures of performance, such as the heading-recall task, rather than relying on self-reports as a measure of a human allocentric heading (or head-direction) system.

# Space-Time Interdependence and Sensory Modalities: Time Affects Space in the Hand But Not in the Eye

Zhenguang G. Cai (zhenguangcai@gmail.com)

## Abstract

Time and space are intimately related, but what is the real nature of this relationship? Is time mapped metaphorically onto space, or do the two domains share a common representational format? In the present paper, participants touched (but could not see) physical sticks while listening to an auditory note. Judgements of stick length were affected by concurrent note duration, but not vice versa. When participants were allowed to see as well as touch the sticks, however, the effects reversed. These findings run counter to the spatial metaphor account of time, which claims that effects of space on time should always be stronger than those of time on space. Rather, our findings support the spatial representation account, in which time and space share a common neural substrate that may be affected by concurrent temporal or spatial information, depending on the perceptual acuity of the modality used to perceive space.

**Keywords:** Time; space; representation; haptic perception; visual perception; sensory dominance; metaphor

Though our immediate perception of the world is limited to our senses such as vision and hearing, we use these senses to perceive and represent other dimensions of the world besides colours and sounds. For instance, we can perceive the spatial information of an object (e.g., its length, height and size) by looking at it or touching it. How we perceive and represent more abstract domains such as time, however, has been a perennial philosophical question. Many researchers have suggested that abstract domains are grounded to some extent in more familiar concrete domains that we develop through sensorimotor experience (e.g., Barsalou & Wiemer-Hastings, 2005; Gibbs, 2006; Lakoff & Johnson, 1980, 1999). Time, for example, can be understood through the domain of space, as reflected in our use of language. Speakers of English often talk about time in spatial terms (e.g., *a long/short time*) and sometimes space in temporal terms (e.g., *I am 5 minutes from the airport*). A range of studies has provided evidence that these linguistic expressions reflect a deeper conceptual bridge between time and space. For example, people perceive the passage of time either as if they are moving in space towards the future, or as if the future is moving towards them (e.g., Boroditsky & Ramscar, 2002; McGlone & Harding, 1998). Other studies have shown that space affects the perception of temporal durations such that people experience longer subjective time when they imagine themselves inside a larger scale model of a room than inside a smaller one (DeLong, 1981), with a larger square than a smaller one (Xuan, Zhang, He, & Chen,

2007), and with a longer line than a shorter one (Casasanto & Boroditsky, 2008).

There are two alternative accounts of the relationship between time and space representations. According to the *spatial metaphor* account, people employ spatial metaphors in thinking or talking about time such that they use their concrete spatial experience to support their understanding of abstract time processing (Boroditsky, 2000; Gibbs, 2006; Lakoff & Johnson, 1980, 1999). The temporal relation of two events can be expressed metaphorically as a relation between two locations in space (e.g., tomorrow is ahead of yesterday). Similarly, a temporal duration can be metaphorically envisioned as the distance from a spatial location representing the onset of the duration and a spatial location representing the offset of the duration. Critically, the spatial metaphor account assumes that time and space remain two separate representational systems with an asymmetric mapping between them: concurrent spatial information should always affect its dependent domain of time to a greater extent than concurrent temporal information can affect space (Casasanto & Boroditsky, 2008; Casasanto, Fotakopoulou, & Boroditsky, 2010; Merritt, Casasanto, & Brannon, 2010).

Alternatively, according to the *spatial representation* account of time, temporal and spatial information are processed in a common neural substrate and share representational and attentional resources. Time is closely related to space in action and perception (e.g., Walsh, 2003): space and time are often coordinated in action and correspond to each other in movement (e.g., things travel a certain distance in a certain time). Thus, temporal duration and spatial distance may share a representational format (e.g., Locke, 1689/1995), such that two events are separated by a particular duration in the same way that two locations are separated by a particular distance. Some stronger versions of spatial representation theories have argued that time, space and number all share a common magnitude representation (Burr, Ross, Binda & Morrone, 2010; Walsh, 2003), but a weaker version of the spatial representation theory of time does not necessarily require the magnitude assumption. Critically, rather than comprising separate representational domains, time and space occupy an overlapping temporo-spatial representation that may be affected by concurrent temporal or spatial information. Since the same representation can subserve both temporal and spatial processing, the spatial representation account thus differs from the spatial metaphor account in allowing

the effects of time on space to be as strong as or stronger than the effects of space on time, depending on factors we describe below.

Empirical evidence has thus far favoured the spatial metaphor account, with the strongest evidence coming from studies showing apparently robust asymmetric effects of space on time in nonlinguistic paradigms. For example, Casasanto and Boroditsky (2008; see also Casasanto et al., 2010) showed participants a horizontal line onscreen and then asked them to reproduce either the length of the line or its duration of presentation. They found that people's estimates of the line's duration increased as a function of its length, but that estimates of length remained unaffected by the duration of the line onscreen. Furthermore, the same pattern emerged whether the line was static or grew to its full length, when the line was replaced with a moving dot, or when a concurrent auditory note provided an additional source of temporal information. A later variant of this nonlinguistic task, where participants categorised the length or duration of a line as long or short according to learned standards, did find an effect of time on space (Merritt et al., 2010), but since this effect was smaller than that of space on time, the asymmetric hypothesis of the spatial metaphor account was supported.

The above studies all use the visual modality to present spatial information. However, spatial representations are not themselves visual, and are rather handled by a multimodal or supramodal system that draws perceptual input from visual, haptic, or auditory modalities (or even from linguistic descriptions) in order to create a common spatial representation (Bryant, 1992; Giudice, Betty, & Loomis, 2011; Lacey, Campbell & Sathian, 2007). Visual perception has the best spatial acuity (i.e., the sharpest or most detailed resolution) of all human perceptual modalities, and so spatial representations resulting from vision have a level of specificity that is not found in spatial representations resulting from other perception. Therefore, the asymmetric effects of space on time found by Casasanto and colleagues may be due to the high spatial acuity from vision being relatively impervious to distortion rather than to an asymmetric mapping between domains.

In the present paper, we examined the interaction of time and space using touch rather than vision. Participants perceived spatial information regarding the length of a stick via haptic (i.e., tactile and proprioceptive) perception while concurrently perceiving a note for a particular duration. As in Casasanto and Boroditsky (2008), participants attended to both the spatial length and temporal duration in each trial and then reproduced either length or duration. If the spatial metaphor account is correct, any effects of time on spatial judgements should be substantially weaker than the usual effects of space on temporal judgements. In contrast, if the spatial representation account is correct, then whether time affects space depends on the relative acuity of spatial representations. Though space can be perceived either visually or haptically, research has suggested that haptic-spatial representations are more prone to distortion than

those of vision (e.g., Lederman, Klatsky & Barber, 1985); hence, we predicted that haptic space would be susceptible to interference from concurrent temporal information. Furthermore, since haptic-spatial representations are less acute than visuo-spatial representations (e.g., Schultz & Petersik, 1994), they may not be able to distort time as visuo-spatial representations do. Thus, when spatial information relies on touch, we expected the effect of time on space to be substantially stronger than the effects of space on time.

## Experiment 1

In this study, people were presented with a stick that they could touch but not see, so information regarding spatial length was haptically (but not visually) perceived while hearing a concurrent note for a particular duration. We then asked participants to reproduce either the spatial length of the stick by holding their hands apart (still with no visual feedback) or the temporal duration of the note by holding down a button. Following the spatial representation account, we expected concurrent temporal duration to affect the reproduction of spatial length, but for spatial concurrent information to have limited or no effects at all on the reproduction of duration.

## Method

**Participants** Thirty-two right-handed native speakers of English were recruited from the University of Manchester community (30 women, mean age = 19.2; two were later excluded from data analysis; see below). They all had normal or corrected-to-normal vision and had no hearing impairments. Participants received £5 or course credits for their participation.

**Materials** Eight rigid, hollow plastic sticks (ca. 16 mm in diameter) were divided into varying lengths (100 – 450 mm in steps of 50 mm). Eight sine waveform notes of 440 Hz were created in varying durations (1000 – 4500 ms in steps of 500 ms) with Audacity (Version 1.2.6). Crossing stick lengths with note durations, we created 64 stick-note stimulus sets. Each stimulus set was then combined with a length or duration reproduction task and divided into two stimulus lists, such that if a stimulus set occurred in List 1 with a length task, it occurred in List 2 with a duration task (i.e., task was counterbalanced across stick length and note duration). Each list thus had 32 stick-note pairs, half with a length task and the other half with a duration task.

**Procedure** Each participant was individually tested in a cubicle. The participant sat at a table with a response button box on his or her lap, and placed the hands and forearms through the gap at the bottom of a barrier, with a cape fastened around the neck to block all visual access to the hands and arms (see Figure 1). During the testing procedure, the experimenter (first author) sat at right angles to the participant and had a box to one side containing the eight sticks. The experiment was run with Superlab 4.0,

with the order of trials individually randomized per participant. In each trial, the experimenter placed the relevant stick (as designated by the experimental programme) on the table and the participant pressed against the ends of the stick with index fingers; at point of contact, the experimenter pressed a key to begin playing the note. When the note stopped, the participant let go of the stick and withdrew the hands to the base of the barrier (i.e., to disrupt hand positioning so stick length was not passively preserved between the index fingers). The experimenter then returned the stick to the box and verbally instructed which judgement the participant was to make (as designated by the experimental programme). When the experimenter said “Time”, the participant held down a button on the response box (located on the lap) for the same duration as the note. When the experimenter said “Length”, the participant reached forward (until they touched a board held up by the experimenter) and indicated the length of the stick between the index fingers; the experimenter then removed the board and took a photograph of the hands' position using a fixed camera. Use of the board (at location 'X' in Figure 1) ensured that the participants' hands were at a fixed distance from the camera. The photographs were taken at a resolution that allowed distance discrimination finer than 1 mm. Each participant performed a practice session of 4 trials before the real experiment, and the whole procedure lasted about 30 minutes.

Figure 1: Schematic of the experimental setup: 'X' marks the location of both haptic perception and reproduction of length. The cape and barrier (both opaque) were used in Experiment 1 to block visual access to spatial information, and were absent in Experiment 2 to allow access.

**Measures** Duration reproductions in milliseconds were measured from onset to release of the response button). Length reproductions were measured by the first author from digital photographs by presenting each picture (condition-blind) and clicking on the centre of the left and

right index fingertips; distance was calculated as the difference between x-coordinates. For reliability analysis, the second author blind-coded a random 12% sample of pictures: agreement between coders was very high ( $r = .999$ ) and accurate to within 1 mm distance. All references to length are in mm.

**Design & Analysis** We excluded failed trials in which the participant did not proceed as instructed (e.g., wrong key presses; missed trials), and then removed outliers more than 2.5 SDs away from the mean for each length or duration condition. The data trimming resulted in the exclusion of less than 2% of either the length or duration trials. Following the criterion in Casasanto and Boroditsky (2008, p. 581), two participants who did poorly in either the length or duration judgements (i.e., when the regression coefficient fell below 0.5 in either the regression of reproduced durations with note duration or reproduced lengths with stick length) were excluded from the analysis.<sup>1</sup> We then used linear mixed effects (LME) modelling to analyse condition means for each participant (e.g., average reproduced duration per participant was regressed on each different stick length). The final model always included the fixed effect; the random effects always included the participant intercept.<sup>2</sup> Regression coefficients are reported as unstandardised  $\beta$  values with standard errors.

## Results and discussion

Reproduced length was significantly affected by experienced duration,  $\beta = 0.0033$ ,  $SE = 0.0015$ ,  $t(209) = 2.27$ ,  $p = .024$ , but reproduced duration was unaffected by stick length,  $\beta = 0.113$ ,  $SE = 0.114$ ,  $t(209) = 0.99$ ,  $p = .324$ . Sticks that were accompanied by a longer duration note were judged to be longer in length, and sticks accompanied by a shorter duration note were judged to be shorter in length (see Figure 2). People's judgements of spatial distance perceived through touch were influenced by their temporal experience, but not vice versa. Both spatial and temporal estimates were highly accurate: reproduced durations were well predicted by actual note duration,  $\beta = 0.771$ ,  $SE = 0.014$ ,  $t(209) = 53.56$ ,  $p < .0001$ , and reproduced lengths were well predicted by actual stick length,  $\beta = 0.818$ ,  $SE = 0.011$ ,  $t(209) = 76.20$ ,  $p < .0001$ .

The results of the experiment support the spatial representation rather than spatial metaphor account of time. When space is haptically perceived, it does not affect time perception; instead, time interferes with the perception of haptic space. Our findings stand in direct contrast to those of previous studies that found visual space influenced time but not the other around (Casasanto & Boroditsky, 2008; Casasanto et al., 2010; Merritt et al., 2010). These

<sup>1</sup> The inclusion of these two participants did not change the statistical pattern of the results in this experiment.

<sup>2</sup> The random subject slope did not significantly contribute to the model fit in any of the LME analyses; thus, we did not include it as a random effect.

discrepancies can be attributed to the different acuities of spatial representations in different modalities, as haptic-spatial representations (as in our Experiment 1) are of lower acuity than visuo-spatial representations (as in previous studies), and hence are prone to distortion by temporo-spatial information to a greater extent. Such an account then predicts that if space is visually perceived, the effects in Experiment 1 will be reversed. That is, highly acute visual perception of the stick will affect participants' time judgement, but spatiotemporal information will not be powerful enough to affect the vivid visuo-spatial memory in the length task. We test this hypothesis in Experiment 2.

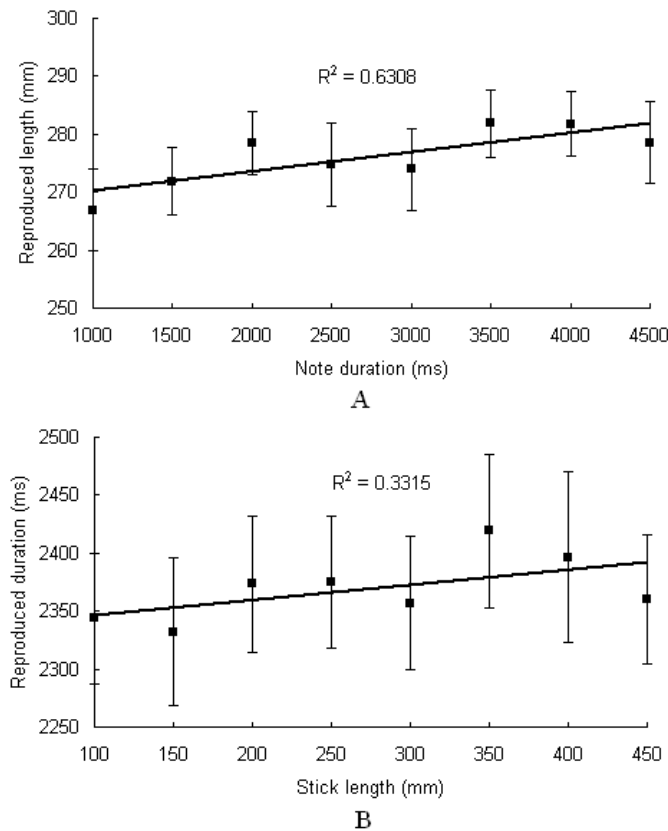

Figure 2: Effects of time on space for haptic perception in Experiment 1 (A), with no corresponding effects of space on time (B). Error bars show one SE.  $R^2$  fit is for graphed means.

## Experiment 2

This study used the same paradigm as Experiment 1 with one exception: people were allowed to see as well as touch the stick, so information regarding spatial length was both haptically and visually perceived. Since the visual modality tends to be dominant in perception (e.g., participants tend to report only visual perception when a visual stimulus is simultaneously presented with an auditory or haptic stimulus: Colavita, 1974; Hartcher-O'Brien et al., 2008), we expected the high spatial acuity of vision in Experiment 2 to affect

temporal judgements but not vice versa (i.e., a restoration of the usual asymmetric effect of space on time).

## Method

**Participants** Twenty-six participants were recruited as in Experiment 1 (22 women, mean age = 19.3; six were later excluded from data analysis; see below).

**Materials** As per Experiment 1.

**Procedure** The procedure was the same as in Experiment 1, except 1) the cape and barrier were removed (see Figure 1) so that participants could see the stick as well as touch it, and see their hands when reproducing length; and 2) the stick was presented at jittered transverse positions in order to discourage participants from using the visual cues of the desk (e.g., distance from side edge) when reproducing the length of the stick.

**Measures** As per Experiment 1. Double-coding of 15% of the lengths shows very high agreement between the two coders ( $r > .999$ ) and accurate to within 1 mm distance.

**Design & Analysis** The same data trimming method as in Experiment 1 resulted in the removal of less than 2% of either the length or duration trials. Six participants were excluded according to the exclusion criterion adopted in Experiment 1.<sup>3</sup>

## Results and discussion

Reproduced length was unaffected by experienced duration,  $\beta = 0.0016$ ,  $SE = 0.0016$ ,  $t(139) = 0.98$ ,  $p = .329$ , but reproduced duration was significantly affected by stick length,  $\beta = 0.325$ ,  $SE = 0.133$ ,  $t(139) = 2.44$ ,  $p = .016$ . Actual durations that were accompanied by shorter sticks were judged to take less time than durations that were accompanied by longer sticks (see Figure 3). People's judgements of time were influenced by their visual-haptic perception of spatial distance, but not vice versa. Both spatial and temporal estimates were again highly accurate: reproduced durations were well predicted by actual duration,  $\beta = 0.773$ ,  $SE = 0.017$ ,  $t(139) = 43.72$ ,  $p < .0001$ , and reproduced lengths were well predicted by actual length,  $\beta = 0.739$ ,  $SE = 0.010$ ,  $t(139) = 70.71$ ,  $p < .0001$ .

Results in Experiment 2 thus demonstrated that when space was perceived in vision, the effects in Experiment 1 were reversed; that is, visual space influenced time but not the other way round, just as found in previous studies by Casasanto and colleagues. As predicted by the spatial representation account of time, the ability of time to affect space depends on the relative acuity of spatial representations.

<sup>3</sup> Again, the inclusion of these 6 participants did not change the statistical pattern in the experiment.

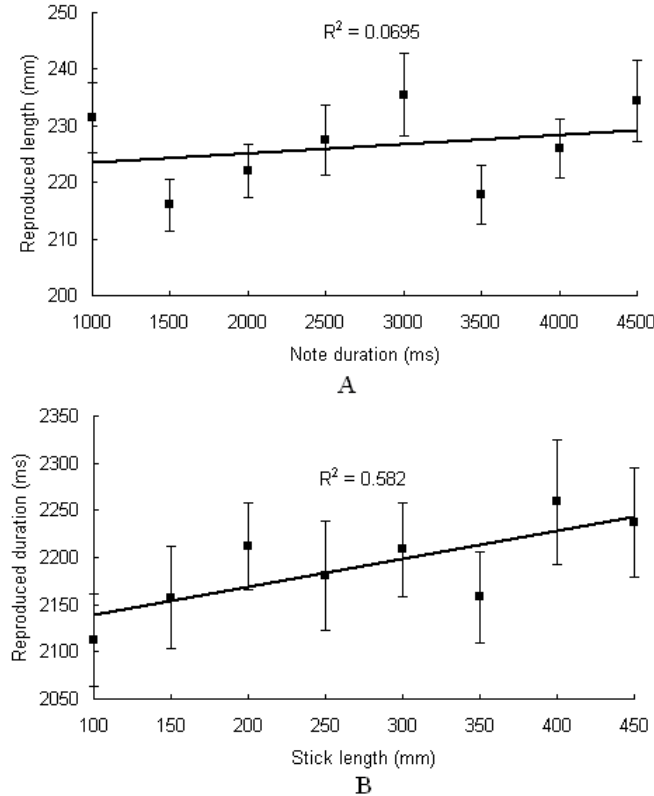

Figure 3: No effects of time on space for visuo-haptic perception in Experiment 2 (A), with instead effects of space on time (B). Error bars show one SE.  $R^2$  fit is for graphed means.

## General discussion

Two experiments revealed a double-disassociation of time and space effects according to sensory modality: time influenced haptic space but not the other way around, and visual space influenced time but not the other way round. The latter findings are in line with previous observations that time perception is subject to spatial interference (Casasanto & Boroditsky, 2008; DeLong, 1981; Xuan et al., 2007). However, when space is perceived haptically, concurrent spatial information fails to affect time perception; on the contrary, the perception of haptic space is influenced by concurrent temporal information. Such findings are, to our best knowledge, the first clear demonstration of a “reverse” asymmetry between space and time, i.e., time affects space to a greater extent than space affects time. This reverse asymmetry is therefore inconsistent with the spatial metaphoric mapping account of time representation (Casasanto & Boroditsky, 2008; Casasanto et al., 2010; Merritt et al., 2010), according to which space should always have a greater effect on time than time on space, as temporal perception metaphorically employs spatial representations. Instead, our findings are more consistent with the spatial representation account, according to which space and time share a common representation that is subject to interference from either

direction.

The spatial representation account thus allows for a two-way interdependence between time and space, which is mediated by the acuity of the sensory modality in which space is perceived. Highly sharp and stable visuo-spatial representations exert a strong influence on time judgements and are relatively impervious to temporal interference, while more distortable haptic-spatial representations are not acute enough to influence time and instead are prone to interference from temporal information. This spatial representation account is also consistent with the findings of Merritt et al. (2010), who found symmetric effects between space and time in rhesus monkeys but not in humans. Merritt et al. argued that one explanation for the discrepancy between humans and monkeys is that human language facilitates the use of metaphoric mappings in spatial representations of time thinking; monkeys, lacking space-time metaphors, also lack asymmetric mappings between the domains. However, it is possible for human language to facilitate greater precision in visuo-spatial tasks without recourse to time-space metaphoric mappings. In their paradigm, Merritt and colleagues required participants to memorise two standard reference lines: one short (6 cm) and one long (24 cm). When later presented with another line, monkeys had only their visuo-spatial memory of the reference lines to help them decide if this new line was long or short, whereas humans also had a verbal numeric label available for what constituted long or short. Previous work has shown that availability of verbal numerical labels enhance accuracy in dot estimation tasks (Izard & Dehaene, 2008; Pica, Lemer, Izard, & Dehaene, 2004), and that verbal shadowing disrupts spatial memory in adults so that they show behaviour patterns similar to young children and rats (Hermer-Vasquez, Spelke, & Katnelson, 1999). It is therefore possible that availability of number words helped to preserve spatial acuity of the reference lines in humans (thus rendering spatial memory less susceptible to temporal interference), whereas lack of number words in monkeys allowed their spatial memory of the reference lines to be distorted by temporo-spatial information.

It should be noted that space-time interdependence may arise from other shared dimensions such as quantity or magnitude, on which space and time are closely interconnected (e.g., *more* space travelled in *more* time). In other words, the underlying representation of both space and time (and number) may be magnitude-based (Burr et al., 2010; Walsh, 2003), which therefore gives rise to the interdependence between space and time. Though such an account is compatible with our data, it would require that magnitude information from haptic space be less acute than magnitude information from visual space, an assumption that has yet to be tested. The spatial representation account of time that we put forward here can explain the current effects in terms of differential perceptual acuity without positing a magnitude system.

Finally, our study has implications beyond space-time interdependence. It suggests that previous findings of

space-time asymmetry have more to do with differential acuity in perceiving space than the use of linguistic metaphor extending into nonlinguistic thought, thus casting considerable doubt on space-time asymmetric as evidence for the effects of language on thought (e.g., Boroditsky, 2000; Whorf, 1956). Furthermore, previous research has shown that visuo-spatial and haptic-spatial information are functionally equivalent (e.g., Giudice, et al, 2011), therefore suggesting a common storage (e.g., Lacey et al., 2007). Our findings lend further support to such a conclusion. That is, in order for time to interact with both haptic space and visual space, spatial information in these different modalities should be encoded in the same format.

In conclusion, the present experiments show that time is not asymmetrically dependent on space, and hence offer evidence against the spatial metaphor account of time representation. Rather, time and space share a common spatial representation: time *affects* spatial information that emerges from relatively low-acuity perceptual modalities like touch, and time *is affected by* spatial information from relatively high-acuity perceptual modalities like vision.

## Abstract

An important difference between traditional AI systems and human intelligence is our ability to harness common sense knowledge gleaned from a lifetime of learning and experiences to inform our decision-making and behavior. This allows humans to adapt easily to novel situations where AI fails catastrophically for lack of situation-specific rules and generalization capabilities. In order for machines to exploit common sense knowledge in reasoning as humans do, moreover, we need to endow them with human-like reasoning strategies. In problem-solving situations, in particular, several analogous representations of the same problem should be maintained in parallel while trying to solve it so that, when problem-solving begins to fail while using one representation, the system can switch to one of the others. Sentic panalogy is a technique that aims to emulate such process by exploiting graph-mining and dimensionality-reduction techniques to dynamically interchange both different reasoning strategies and the foci around which such strategies are developed.

**Keywords:** AI; NLP; Cognitive systems; Sentic computing.

## Introduction

Emotions are different Ways to Think (Minsky, 2006) that our mind triggers to deal with different situations we face in our lives. Our decision-making and problem-solving skills, in fact, are strictly dependent on both our common sense knowledge about the world and the appraisal associated with this (Scherer, Shorr, & Johnstone, 2001). The capability to accordingly compress and exploit such information, which we term affective common sense reasoning (Cambria, Olsher, & Kwok, 2012), is a fundamental component in human experience, cognition, perception, learning, and communication.

For this reason, we cannot prescind from emotions in the development of intelligent user interfaces: if we want computers to be really intelligent, not just have the veneer of intelligence, we need to give them the ability to recognize, understand, and express emotions. Furthermore, in order not to get stuck and to be able to tackle different problems from different perspectives, an intelligent machine should not have a unique way to deal with a task, but rather be endowed with different reasoning strategies and with the capability to accordingly switch among these.

This work further develops a recently proposed approach (Cambria, Mazzocco, Hussain, & Durrani, 2011) for the emulation of the human capability to switch between different perspectives and find novel ways to look at things. Such approach is inspired by Minsky's notion of 'panalogy' (parallel analogy), which states that several analogous representations of the same problem should be maintained in parallel while trying to solve it (Minsky, 2006).

To show the effectiveness of the proposed approach, termed sentic panalogy, we employ it for the natural language processing (NLP) task of sentiment analysis, for which a faceted and nuanced analysis is mostly needed.

The structure of the paper is as follows: the first section provides some background information on sentiment analysis; the second section introduces the concept of affective common sense reasoning and explains why and how this can aid sentiment analysis; the third and fourth sections describe the implementation of the switch among different strategies and among the foci around which such strategies are developed, respectively; the fifth section provides an evaluation of the proposed approach; the last section, finally, comprises concluding remarks and future directions.

## Sentiment Analysis

Sentiment analysis is a branch of the broad field of text data mining and refers generally to the process of extracting interesting and non-trivial patterns or knowledge from unstructured text documents. It can be viewed as an extension of data mining or knowledge discovery from (structured) databases (Fayyad, Piatetsky, & Smyth, 1996; Simoudis, 1996). As the most natural form of storing information is text, sentiment analysis is believed to have a commercial potential higher than that of data mining. Sentiment analysis, however, is also a much more complex task as it involves dealing with text data that are inherently unstructured and fuzzy. It is a multi-disciplinary research area that involves the adoption of techniques in fields such as text analysis, information retrieval and extraction, auto-categorization, machine learning, clustering, and visualization.

Most of the existing approaches to opinion mining and sentiment analysis rely on the extraction of a vector representing the most salient and important text features, which is later used for classification purposes. Some of the most commonly used features are term frequency (Wu, Luk, Wong, & Kwok, 2008) and presence (Pang, Lee, & Vaithyanathan, 2002). The latter, in particular, is a binary-valued feature vectors in which the entries merely indicate whether a term occurs or not, and formed a more effective basis for polarity classification. This is indicative of an interesting difference between typical topic-based text categorization. While a topic is more likely to be emphasized by frequent occurrences of certain keywords, overall sentiment may not usually be highlighted through repeated use of the same terms.

Differently from topics, in fact, sentiments can often be expressed in a more subtle manner, making it difficult to be identified by specific keywords, especially when considering multiple domains. Humans readers do not face such difficulty as they can infer the cognitive and affective information associated with natural language text through their affective common sense knowledge, that is, obvious or widely accepted things that people normally know about the world, but which are usually left unstated in discourse, e.g., that people smile when they are happy and things fall downwards (and not upwards). An important feature of affective common sense reasoning, in fact, is the sensitivity to nuanced readings of natural language.

A sentence can be read differently depending on nuances in opinionated text and such nuanced reading can lead to markedly different reasoning trajectories. The first step in human cognitive and affective information processing, in fact, is in an appraisal of the current situation (Scherer et al., 2001). In order to accordingly infer semantics and sentics (Cambria, Benson, Eckl, & Hussain, 2012), i.e., the cognitive and affective information associated with natural language text, next-generation sentiment analysis methods need to go beyond a mere word-level analysis and use affective common sense reasoning to better grasp the conceptual rules that govern sentiment and the clues that can convey these concepts from realization to verbalization in the human mind.

### Affective Common Sense Reasoning

Current thinking in cognitive psychology suggests that humans process information at a minimum of two distinct levels. There is extensive evidence for the existence of (at least) two processing systems within the human brain, one that involves fast, parallel, unconscious processing, and one that involves slow, serial, more conscious processing (Kirkpatrick & Epstein, 1992; Chaiken & Trope, 1999; Smith & DeCoster, 2000; Epstein, 2003; Kahneman, 2011). Dual-process models of automatic and controlled social cognition have been proposed in nearly every domain of social psychology.

Evidence from neurosciences supports this separation, with identifiably different brain regions involved in each of the two systems (Lieberman, 2007). Such systems, which we term U-level (unconscious) and C-level (conscious), can operate simultaneously or sequentially, and are most effective in different contexts. The former, in particular, works intuitively, effortlessly, globally, and emotionally. The latter, in turn, works logically, systematically, effortfully, and rationally. According to different contexts and purposes, moreover, the systems should be capable to dynamically swap both different reasoning strategies and the foci around which such strategies are developed.

In this work, we emulate such dual-process model through an ensemble application of dimensionality-reduction and graph-mining techniques on AffectNet (Cambria & Hussain, 2012), an affective common sense knowledge base built upon WordNet-Affect (WNA) (Strapparava & Valitutti, 2004), a

linguistic resource for the lexical representation of affect, and ConceptNet (Havasi, Speer, & Alonso, 2007), a semantic network of common sense knowledge. In particular, multi-dimensionality reduction techniques are employed on AffectNet to dynamically configure it and, hence, to model the switch between different reasoning strategies, while graph mining and clustering methods are applied to model the switch between the foci around which those strategies are developed, in order to accordingly exploit the different facets of the affective common sense knowledge base.

### Swapping Reasoning Strategies

To some extent, our reasoning capability can be re-conducted to the identification of useful patterns in our acquired knowledge about the world. Our experience and common sense knowledge is likely to be organized in our mind as interconnected concepts and events and most of these links are weighted by affective information, as we tend to forget or hardly recall memories that are not associated with any kind of positive or negative emotion. Therefore, the human capacity to envision possible outcomes of a decision might lie both in the capability of crawling the semantic network of concepts we have acquired through experience (C-level), and in the capability of summarizing the huge amount of inputs and outputs of previous situations to find useful patterns that might work at the present time (U-level).

The latter capability, in cognitive science, is termed ‘compression’ and refers to transforming diffuse and distended conceptual structures that are less congenial to human understanding so that they become better suited to our human-scale ways of thinking. Compression is hereby implemented by representing affective common sense knowledge in a way that it is neither too concrete nor too abstract with respect to the detail granularity needed for performing a particular task.

To this end, we first generate a matrix representation of AffectNet by applying blending (Havasi, Speer, Pustejovsky, & Lieberman, 2009), a technique that performs inference over multiple sources of data simultaneously, taking advantage of the overlap between them. In particular, the alignment of ConceptNet and WNA yields  $A$ , a matrix in which common sense and affective knowledge coexist, i.e., a matrix  $14,301 \times 117,365$  whose rows are concepts (e.g., ‘dog’ or ‘bake cake’), whose columns are either common sense and affective features (e.g., ‘isA-pet’ or ‘hasEmotion-joy’), and whose values indicate truth values of assertions. Therefore, in  $A$ , each concept is represented by a vector in the space of possible features whose values are positive for features that produce an assertion of positive valence (e.g., ‘a penguin is a bird’), negative for features that produce an assertion of negative valence (e.g., ‘a penguin cannot fly’), and zero when nothing is known about the assertion. The degree of similarity between two concepts, then, is the dot product between their rows in  $A$ . The value of such a dot product increases whenever two concepts are described with the same feature and decreases when they are described by features that are negations of each other.

In particular, we use truncated singular value decomposition (TSVD) (Wall, Rechtsteiner, & Rocha, 2003) in order to obtain a new matrix containing both hierarchical affective knowledge and common sense. The resulting matrix has the form  $\tilde{A} = U_k \Sigma_k V_k^T$  and is a low-rank approximation of  $A$ , the original data. This approximation is based on minimizing the Frobenius norm of the difference between  $A$  and  $\tilde{A}$  under the constraint  $\text{rank}(\tilde{A}) = k$ . For the Eckart-Young theorem (Eckart & Young, 1936), it represents the best approximation of  $A$  in the least-square sense, in fact:

$$\begin{aligned} \min_{\tilde{A} | \text{rank}(\tilde{A})=k} \|A - \tilde{A}\| &= \min_{\tilde{A} | \text{rank}(\tilde{A})=k} \|\Sigma - U^* \tilde{A} V\| \\ &= \min_{\tilde{A} | \text{rank}(\tilde{A})=k} \|\Sigma - S\| \end{aligned}$$

assuming that  $\tilde{A}$  has the form  $\tilde{A} = USV^*$ , where  $S$  is diagonal. From the rank constraint, i.e.,  $S$  has  $k$  non-zero diagonal entries, the minimum of the above statement is obtained as follows:

$$\begin{aligned} \min_{\tilde{A} | \text{rank}(\tilde{A})=k} \|\Sigma - S\| &= \min_{s_i} \sqrt{\sum_{i=1}^n (\sigma_i - s_i)^2} = \\ &= \min_{s_i} \sqrt{\sum_{i=1}^k (\sigma_i - s_i)^2 + \sum_{i=k+1}^n \sigma_i^2} = \sqrt{\sum_{i=k+1}^n \sigma_i^2} \end{aligned}$$

Therefore,  $\tilde{A}$  of rank  $k$  is the best approximation of  $A$  in the Frobenius norm sense when  $\sigma_i = s_i$  ( $i = 1, \dots, k$ ) and the corresponding singular vectors are the same as those of  $A$ . If we choose to discard all but the first  $k$  principal components, common sense concepts and emotions are represented by vectors of  $k$  coordinates: these coordinates can be seen as describing concepts in terms of ‘eigenmoods’ that form the axes of AffectiveSpace, i.e., the basis  $e_0, \dots, e_{k-1}$  of the vector space. For example, the most significant eigenmood,  $e_0$ , represents concepts with positive affective valence. That is, the larger a concept’s component in the  $e_0$  direction is, the more affectively positive it is likely to be. Concepts with negative  $e_0$  components, then, are likely to have negative affective valence.

Thus, by exploiting the information sharing property of TSVD, concepts with the same affective valence are likely to have similar features - that is, concepts conveying the same emotion tend to fall near each other in AffectiveSpace. Concept similarity does not depend on their absolute positions in the vector space, but rather on the angle they make with the origin. For example we can find concepts such as ‘beautiful day’, ‘birthday party’, ‘laugh’, and ‘make person happy’ very close in direction in the vector space, while concepts like ‘sick’, ‘feel guilty’, ‘be laid off’, and ‘shed tear’ are found in a completely different direction (nearly opposite with respect to the centre of the space). By reducing the dimensionality of the matrix representation of  $A$ , AffectiveSpace compresses the feature space of affective common sense knowledge into one that allows to better gain global insight and human-scale understanding.

The number  $k$  of singular values selected for building AffectiveSpace, in fact, is a measure of the trade-off between precision and efficiency in the representation of the affective common sense knowledge base. Switching between different vector space dimensionalities can be seen as looking at the data from many different points of view. Balancing the number of singular values discarded when synthesizing AffectiveSpace, hence, corresponds to calibrate the affective common sense knowledge representation in a way that it is neither too concrete nor too abstract with respect to the detail granularity needed for performing a particular task. Different  $k$  values, for example, work differently according to the affective dimension we consider, e.g., for Pleasantness the best  $k$  appears to be closer to 100, while for Sensitivity a space of about 70 dimensions appears to be enough for precisely and efficiently represent affective common sense knowledge.

The capability to look at things from a different perspective, moreover, can be emulated by applying different space transformations to AffectiveSpace. The distribution of the values of each AffectiveSpace dimension is bell-shaped, with different centers and different degree of dispersion around them. In order to more uniformly distribute affective common sense knowledge in the vector space, an alternative strategy to represent AffectiveSpace consists in centering the values of the distribution of each dimension on the origin and in mapping dimensions according to a transformation  $x \in \mathbb{R} \mapsto x^* \in [-1, 1]$ . This transformation is often pivotal for better clustering AffectiveSpace as the vector space tends to have different grades of dispersion of data points across different dimensions, with some space regions more densely populated than others.

The switch to a different space configuration helps to distribute data more uniformly, possibly leading to an improved (or, at least, different) reasoning process. Switching between different space configurations, in fact, changes how each dimension is influent in the vector space representation of AffectNet and, hence, changes how we are looking at the affective common sense knowledge because similarity in AffectiveSpace does not depend on concepts’ absolute position, but rather on the angle they make with the origin of the vector space. In particular, the transformation  $x_{ij} \mapsto x_{ij} - \mu_i$  is first applied, being  $\mu_i$  the average of all values of the  $i$ -th dimension. Then a normalization is applied, combining the previous transformation with a new one  $x_{ij} \mapsto \frac{x_{ij}}{a \cdot \sigma_i}$ , where  $\sigma_i$  is the standard deviation calculated on the  $i$ -th dimension and  $a$  is a coefficient that can modify the same proportion of data that is represented within a specified interval.

Finally, in order to ensure that all components of the vectors in the defined space are within  $[-1, 1]$  (i.e., that the Chebyshev distance between the origin and each vector is smaller or equal to 1), a final transformation  $x_{ij} \mapsto s(x_{ij})$  is needed, where  $s(x)$  is a sigmoid function. Different choices for the sigmoid function may be made, influencing how ‘fast’ the function approaches 1 while the independent variable approaches infinity.

Combining the proposed transformations, two possible mapping functions are expressed in the following formulae:

$$x_{ij}^* = \tanh\left(\frac{x_{ij} - \mu_i}{a \cdot \sigma_i}\right)$$

$$x_{ij}^* = \frac{x_{ij} - \mu_i}{a \cdot \sigma_i + |x_{ij} - \mu_i|}$$

This space transformation leads to two main advantages, which could be of notable importance depending on the problem being tackled. First, this different space configuration ensures that each dimension is equally important by avoiding that the information provided by dimensions with higher (i.e., more distant from the origin) averages predominates. Second, normalizing according to the standard deviations of each dimension allows a more uniform distribution of data around the origin, leading to a full use of information potential.

### Swapping Reasoning Foci

The capability of switching among different Ways to Think can be thought as changing the foci around which we develop our different reasoning strategies. Such approach can be implemented in AffectiveSpace by changing the centroids around which the vector space is clustered. Such a clustering process is implemented by adopting a  $k$ -medoids approach (Kaufman & Rousseeuw, 1990) to partition the given observations into  $k$  clusters around as many centroids, trying to minimize a given cost function. Differently from the  $k$ -means algorithm, which does not pose constraints on centroids,  $k$ -medoids do assume that centroids must coincide with  $k$  observed points.

The most commonly used algorithm for finding the  $k$  medoids is the partitioning around medoids (PAM) algorithm, which determines a medoid for each cluster selecting the most centrally located centroid within the cluster. After selection of medoids, clusters are rearranged so that each point is grouped with the closest medoid. Since  $k$ -medoids clustering is a NP-hard problem, different approaches based on alternative optimization algorithms have been developed, though taking risk of being trapped around local minima. We use a modified version of the algorithm recently proposed by Park and Jun (Park & Jun, 2009), which runs similarly to the  $k$ -means clustering algorithm.

This has shown to have similar performance when compared to PAM algorithm while taking a significantly reduced computational time. In particular, we have  $N$  concepts ( $N = 14,301$ ) encoded as points  $x \in \mathbb{R}^p$  ( $p = 100$ ). We want to group them into  $k$  clusters and, in our case, we can fix  $k = 24$  as we are looking for one cluster for each sentic level of the Hourglass of Emotions (Cambria, Livingstone, & Hussain, 2012), a novel biologically-inspired and psychologically-motivated emotion categorization model, based on Plutchik's studies on human emotions (Plutchik, 2001), that can potentially describe any human emotion in terms of four independent but concomitant dimensions, whose different levels of activation make up the total emotional state of the mind.

Specifically, we need to cluster AffectiveSpace four times, once for each dimension. According to the Hourglass categorization model, in fact, each concept can convey, at the same time, more than one emotion (which is why we get compound emotions) and this information can be expressed via a sentic vector specifying the concept's affective valence in terms of Pleasantness, Attention, Sensitivity, and Aptitude. Therefore, given that the distance between two points in AffectiveSpace is defined as  $D(a, b) = \sqrt{\sum_{i=1}^p (a_i - b_i)^2}$ , the used algorithm, applied for each of the four affective dimensions, can be summarized as follows:

1. Each centroid  $C_n \in \mathbb{R}^{100}$  ( $n = 1, 2, \dots, k$ ) is set as one of the six concepts corresponding to each  $s$  in the current affective dimension
2. Assign each record  $x$  to a cluster  $\Xi$  so that  $x_i \in \Xi_n$  if  $D(x_i, C_n) \leq D(x_i, C_m)$   $m = 1, 2, \dots, k$
3. Find a new centroid  $C$  for each cluster  $\Xi$  so that  $C_j = x_i$  if  $\sum_{x_m \in \Xi_j} D(x_i, x_m) \leq \sum_{x_m \in \Xi_j} D(x_h, x_m) \quad \forall x_h \in \Xi_j$
4. Repeat step 2 and 3 until no changes on centroids are observed

After such a clustering process (performed at U-level), concepts that are semantically and affectively related to the input data can be intuitively retrieved by analogy and unconsciously crop out to the C-level. According to the initial centroid we choose, the final clusterization of AffectiveSpace can be very different. Hence, the way such initial medoids are chosen can be re-conducted to the human capability to switch between different perspectives to grasp the different facets of a problem.

At C-level, moreover, reasoning is performed by exploiting AffectNet's connectivity to find semantically and affectively related concepts by means of spectral association (Havasi, Speer, & Holmgren, 2010). Spectral association is a technique that involves assigning activation to seed concepts and applying an operation that spreads their values across the graph. This operation, an approximation of many steps of spreading activation, transfers the most activation to concepts that are connected to the seed concepts by short paths or many different paths in affective common sense knowledge.

Seed concepts can also be associated with negative activation values in order to reduce the spreading operation in the parts of the graph we are specifically not interested in. If we want to find concepts semantically related to 'bank' as a financial institution without getting concepts related to 'river bank', for example, we can set as positive seeds concepts like 'money', 'savings', or 'investment', and, as negative seeds, concepts like 'river', 'water', or 'shore'. The outcomes of spectral association can be very different according to which seeds we select as starting points for the spreading activation steps. Since spectral association involves TSVD, results also depend on the number  $k$  of singular values selected.

While choosing different  $k$  values can be seen as developing different reasoning strategies, choosing different seeds can be associated to changing the foci around which those strategies are developed. Through spectral association, positive and negative values of these concepts are spread across the graph representation of AffectNet, resulting in a set of contextually semantic related instances. Letting a machine switch between such seeds according to its own intuition (e.g., concepts obtained through AffectiveSpace at U-level) can be re-conducted to the human capability to change the foci around which different reasoning strategies are developed and, hence, to iterate on the ways to look at a problem until one that works is found.

## Evaluation

In order to efficiently and timely swap different reasoning strategies and foci, we perform all the computations (relative to the most significant configurations) a priori and save the results in a semantic-aware format, using an approach previously adopted for building SenticNet (Cambria, Havasi, & Hussain, 2012). The result is a system for affect recognition that has multiple ways to deal with natural language semantics and sentics. We tested sentic panalogy on a benchmark for affective common sense knowledge (BACK) built by applying CF-IOF (concept frequency - inverse opinion frequency), a technique similar to TF-IDF, on a 5,000 blogpost database extracted from LiveJournal<sup>1</sup>, a virtual community of users who keep a blog, journal, or diary. An interesting feature of this website is that bloggers are allowed to label their posts with both a category and a mood tag, by choosing from predefined categories and mood themes.

CF-IOF identifies common domain-dependent semantics in order to evaluate how important a concept is to a set of opinions concerning the same topic. Firstly, the frequency of a concept  $c$  for a given domain  $d$  is calculated by counting the occurrences of the concept  $c$  in the set of available  $d$ -tagged opinions and dividing the result by the sum of number of occurrences of all concepts in the set of opinions concerning  $d$ . This frequency is then multiplied by the logarithm of the inverse frequency of the concept in the whole collection of opinions, that is:

$$CF-IOF_{c,d} = \frac{n_{c,d}}{\sum_k n_{k,d}} \log \sum_k \frac{n_k}{n_c}$$

where  $n_{c,d}$  is the number of occurrences of concept  $c$  in the set of opinions tagged as  $d$ ,  $n_k$  is the total number of concept occurrences, and  $n_c$  is the number of occurrences of  $c$  in the whole set of opinions. A high weight in CF-IOF is reached by a high concept frequency in a given domain and a low frequency of the concept in the whole collection of opinions. Specifically, we exploited CF-IOF weighting to filter out common concepts in the LiveJournal corpus and detect relevant mood-dependent semantics for each of the Hourglass sentic levels. The result was a benchmark of 2000 af-

fective concepts that were screened by 21 English-speaking students who were asked to map each concept to the 24 different emotional categories that form the Hourglass of Emotions. BACK's concepts were compared with the classification results obtained by applying the AffectiveSpace process, spectral association, and sentic panalogy. Results showed that sentic panalogy achieves +9.7% and +6.2% accuracy than the standard (i.e., 100-dimensional) AffectiveSpace process and the default (i.e., fixed on the Hourglass sentic levels) spectral association, respectively.

## Brain-Inspired Sentiment Analysis

In order to test sentic panalogy also within a real-world scenario, we developed a brain-inspired software engine for sentiment analysis. This software engine consists of four main components: a pre-processing module, a semantic parser, a target spotting module, and an affect interpreter.

The pre-processing module firstly interprets all the affective valence indicators usually contained in opinionated text such as cross-linguistic onomatopoeias, exclamation words, degree adverbs, and emoticons. Secondly, it lemmatizes text and splits the opinion into single clauses according to grammatical conjunctions and punctuation. Then, the semantic parser deconstructs text into concepts using a lexicon based on sequences of lexemes that represent multiple-word concepts extracted from AffectNet.

The target spotting module aims to individuate one or more sentiment targets, e.g., people, places, events, and ideas, from the input concepts. This is done by projecting the retrieved concepts into both the graph and the vector space representation of AffectNet, in order to assign these to a specific conceptual class. The categorization does not consist in simply labeling each concept, but also in assigning a confidence score to each category label, which is directly proportional to the value of belonging to a specific conceptual cluster (number of steps in the graph and dot product in the vector space). The affect interpreter, similarly, projects the retrieved concepts into the vector space representation of AffectNet, in order to assign these to a specific affective class and, hence, calculates polarity in terms of the Hourglass dimensions.

## Approach Comparison

In order to evaluate the different facets of the engine from different perspectives, we used a PatientOpinion<sup>2</sup> dataset and compared results obtained using standard AffectiveSpace, default spectral association, and sentic panalogy. The resource is a dataset obtained from PatientOpinion, a social enterprise pioneering an on-line feedback service for users of the UK national health service to enable people to share their recent experience of local health services on-line. It is a manually tagged dataset of 2,000 patient opinions that associates to each post a category (namely, clinical service, communication, food, parking, staff, and timeliness) and a positive or negative polarity.

<sup>1</sup><http://livejournal.com>

<sup>2</sup><http://patientopinion.org.uk>

Category Label	Affective-Space	Spectral Association	Sentic Panalogy
clinical service	62.4%	71.5%	80.0%
communication	62.3%	59.8%	71.2%
food	70.7%	69.6%	78.5%
parking	56.3%	53.7%	69.4%
staff	58.5%	49.2%	63.9%
timeliness	69.2%	61.9%	75.1%

Table 1: F-measures relative to PatientOpinion evaluation.

We used it to test the detection of opinion targets and the polarity associated with these (F-measure values are reported in Table 1).

## Conclusion

Sentic panalogy is novel approach to affective common sense reasoning inspired by Minsky's notion of parallel analogy. It employs different KR strategies and reasoning techniques to maintain several analogous representations of the same problem so that, when a particular strategy begins to fail, the system can switch to one of the others. In the future, we plan to develop heuristics to swap reasoning strategies and foci in real-time, rather than performing all the computations a priori, in order to pave the way for more brain-inspired approaches to affective common sense reasoning.

## Abstract

Unobserved objects are typically discovered by making backward inferences from effects to causes. The inverse reasoning account proposes that inferences of this kind are carried out by postulating unobserved causes that best support the forward inference from causes to effects. We evaluated the inverse reasoning account by asking people to reason about hidden attractors and repellers that caused an observed particle to move about an arena. We found that people often evaluated specific hypotheses in a manner consistent with the inverse reasoning account but that hypothesis discovery involved processes that were inconsistent with inverse reasoning.

**Keywords:** object discovery; inverse reasoning; inverse problem; Bayesian inference; physical reasoning

## Introduction

Inferences about unobserved objects are common in both scientific and everyday reasoning. Scientists originally postulated the existence of the planet Neptune to explain perturbations in the orbit of Uranus. Similarly, a jilted lover may postulate the existence of a romantic competitor in order to explain the behavior of his or her partner. This paper describes an experimental study of object discovery that is loosely inspired by the discovery of Neptune. Participants observed particles that moved along paths such as the one in Figure 1 and attempted to infer the unobserved attractors and repellers responsible for the particle's motion.

Object discovery typically involves reasoning from effects (e.g., an observed motion) to causes (e.g., an unobserved attractor). Here we refer to inferences from causes to effects as *forward inferences* and inferences from effects to causes as *backward inferences*. We explore the hypothesis that forward and backward reasoning are tightly coupled, and that backward inferences are made by postulating unobserved causes that best support the forward

inference from causes to effects. We refer to this approach as *inverse reasoning* because it achieves backward reasoning by inverting the process of forward reasoning.

One natural way to formalize the inverse reasoning approach makes use of Bayesian inference, which specifies the normative relationship between backward and forward reasoning. Specifically, given some observations  $D$  and a hypothesis  $H$  about the existence and properties of the unobserved causes, Bayes' theorem requires that

$$P(H|D) \propto P(D|H)P(H). \quad (1)$$

Backward and forward reasoning are captured by the posterior  $P(H|D)$  and likelihood  $P(D|H)$ , respectively. Bayes' theorem therefore suggests that backward reasoning should be carried out by combining the forward inferences specified by the likelihood with judgments of plausibility specified by the prior  $P(H)$ . In our setting, this approach suggests that a configuration of unobserved attractors and repellers is a good explanation for a particle's motion to the extent that (1) the configuration predicts the particle's motion and (2) the configuration is relatively parsimonious. Inverse reasoning implies that backward inferences will be consistent with forward inferences, but does not imply that backward inferences will always be accurate. Studies of physical reasoning have documented situations where people's forward inferences deviate from the predictions of classical mechanics (e.g., Clement, 1982; McCloskey, 1983), and faulty forward inferences could produce faulty backward inferences through inverse reasoning.

The inverse reasoning approach has a mixed record as an account of human reasoning. On one hand, the approach has been successfully used to develop models of causal reasoning (e.g., Griffiths & Tenenbaum, 2005), perception (e.g., Yuille & Kersten, 2006), sensorimotor control (e.g., Kording & Wolpert, 2006) and social reasoning (e.g., Baker,

Figure 1: This sequence of bird's-eye-view snapshots shows a particle's motion over time. The particle in this "wall-motion" scene moved along a diagonal path until it reached the top wall. It then continued along the wall.

Saxe, & Tenenbaum, 2009). On the other hand, psychologists have documented several respects in which backward inferences seem inconsistent with inverse reasoning (e.g., Kahneman, Slovic, & Tversky, 1982; Fernbach, Darlow, & Sloman, 2011). People often, for example, erroneously ignore or underutilize the prior when estimating the posterior (Bar-Hillel, 1980).

Based on these findings it is not clear whether the object discovery task considered in this paper should produce results that are consistent with inverse reasoning. Because physical reasoning is a core aspect of cognition that is present early in development (Spelke, Breinlinger, Macomber, & Jacobson, 1992), one might expect that backward physical reasoning will tend to be consistent with normative inverse reasoning. Previous studies of physical reasoning provide some evidence for this claim. For example, Sanborn, Mansinghka, and Griffiths (2009) found that backward inferences about the relative masses of colliding objects were consistent with a Bayesian account of inverse reasoning. Object discovery, however, appears to be more challenging than the tasks considered by previous studies of backward physical reasoning. Inferring hidden properties of observed objects (e.g., the mass of a colliding object) is a relatively well-constrained problem, but object discovery is a more open-ended problem that involves inferring the existence and number of the hidden objects, the locations of those objects, and the properties of those objects. To preview our results, we found that when participants evaluated specific hypotheses about the locations and properties of the hidden objects, their inferences were broadly consistent with inverse reasoning. When asked to generate their own explanations, however, many participants gave responses that were incompatible with the inverse reasoning account.

## Experimental overview

To explore the problem of object discovery we conducted an experiment where participants reasoned about “attractors” and “repellers” that controlled the movements of some observed “particles.” The attractors and repellers were unobserved, and participants attempted to infer their locations given the observed particle motions.

There were three experimental phases: the discovery, prediction, and evaluation phases. In the discovery phase, participants observed the motion of a particle and were asked to infer the locations of hidden attractors and repellers. In the prediction phase, participants were given the locations of one or more attractors or repellers and were asked to predict the trajectory that a particle would follow. In the evaluation phase, participants were given two possible explanations of a particle motion and were asked to decide which explanation was better. Note that the discovery and evaluation phase both assessed backward reasoning and that the prediction phase assessed forward reasoning.

The simplest possible observed trajectory is a straight line, and the obvious explanation for this trajectory is that the particle is either moving towards an attractor or moving away from a repeller. The particle motions presented in the discovery phase (Figure 2.i) include some of the next simplest cases. Each motion can be explained in at least two ways. First, there is a parsimonious explanation that invokes a relatively small number of stationary attractors and repellers. For example, the “wall-motion” scene (Figure 1 and Figure 2.a.i) can be explained by assuming a single repeller (see the first row of Figure 2.ii). Second, each explanation had a less parsimonious explanation where the particle always moved directly towards an attractor or directly away from a repeller, but where the attractors and repellers spontaneously appeared, disappeared, or moved. The second row of Figure 2.ii shows a less parsimonious explanation of the wall-motion scene.

Our primary goal is to explore whether participants generate the parsimonious explanations during the discovery and evaluation phases. If participants agree that the parsimonious explanations are in fact parsimonious and valid, then the inverse reasoning account predicts that these explanations should be generated during the discovery phase and rated favorably during the evaluation phase. If participants fail to generate these explanations in the discovery phase but tend to prefer them in the evaluation phase, this result would be inconsistent with the inverse reasoning view.

The prediction phase asked participants to generate particle trajectories for several kinds of configurations. Each configuration can be viewed as an explanation (plausible or implausible) of a motion observed during the discovery phase. Some of the prediction trials presented participants with their own explanations from the discovery phase. For our purposes, however, the most important prediction trials are those that presented participants with the parsimonious explanations for the three motions in Figure 2.i. Including these trials allowed us to assess whether participants agreed that the parsimonious explanations could in fact explain the observed motions – if not, it would be unsurprising if these explanations were rarely chosen during the discovery phase.

## Method

### Participants

Thirty undergraduates at Carnegie Mellon University participated for course credit.

### Materials and Procedure

Participants were asked to imagine themselves working for a scientist who studies “attractors” and “repellers.” The instructions explained that the participants would view scenes where “particles” moved within a rectangular arena. Participants learned that the particle motions were caused by attractors and repellers located outside the arena.

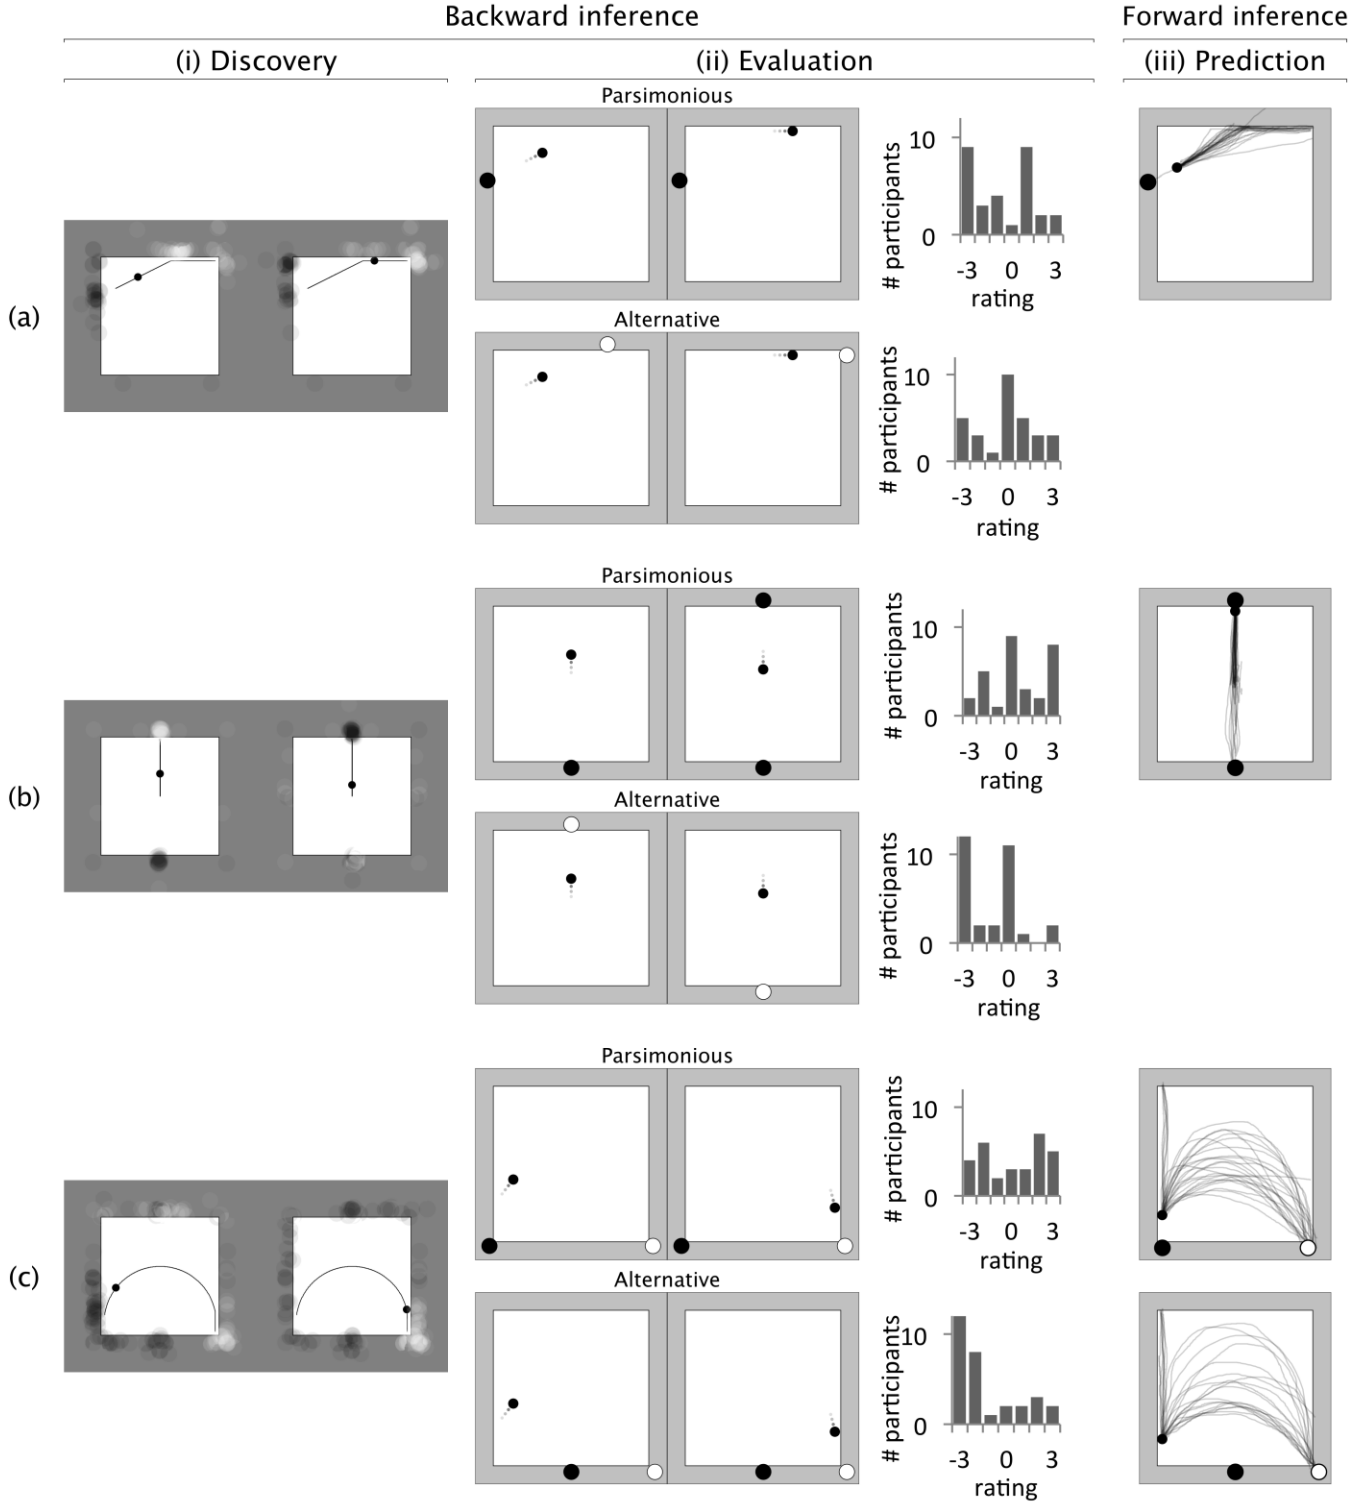

Figure 2: Experimental method and results for the (a) wall-motion, (b) center-return, and (c) curved-motion scenes. (i) The discovery phase. The paths illustrate the motion of the particle, and the circles illustrate the location of the particle in the first and second response pictures. (The particle in the center-return scene moved from its initial position to the top wall, paused, and then returned to the center.) The surrounding area is a heatmap. Areas where attractors were often placed are shown as brighter areas and areas where repellers were often placed are shown as darker areas. (ii) The evaluation phase. The pictures at left show the experimenter-provided explanations. Repellers and attractors are shown as large black and large white circles, respectively. The histograms show the preference ratings (-3 = strongly preferred own explanation; 3 = strongly preferred experimenter-provided explanation). (iii) The prediction phase. The paths in the figure represent the paths drawn by the participants. Trivial prediction trials (i.e., those involving a single attractor or repeller) are not shown.

Participants then viewed three scenes that demonstrated the properties of the attractors and repellers. Each scene was displayed as a sequence of bird's-eye-view snapshots showing the motion of the particle over time. The first two scenes showed that particles move towards attractors and away from repellers, depicted as green and red circular objects, respectively. The third scene showed that a particle placed between two attractors moved towards the closer one, and the instructions explained that distant attractors and repellers exert less force than close ones.

### Discovery phase

Participants were asked to explain a number of scenes where the attractors and repellers were not visible. After completing a practice trial, participants generated explanations for the three scenes in Figure 2.i. Participants also generated explanations for 12 variants of the three primary scenes, but we do not discuss these results here because the variant scenes did not have analogues in the prediction and evaluation phases. In the wall-motion scene (Figure 2.a.i), the particle traveled along a diagonal until it reached the top wall of the arena. It then continued along the top wall of the arena. In the center-return scene (Figure 2.b.i), the particle moved from the center of the arena to the top wall, paused, and then returned to the center. In the curved-motion scene (Figure 2.c.i), the particle moved along a curved path from the lower-left corner of the arena to the lower-right corner of the arena.

Participants explained each particle motion by specifying where the attractors and repellers would have been at two different points in the particle's motion (see Figure 2.i). The instructions explained that the participants were being asked to report the locations of the attractors and repellers in two distinct response pictures because "there may be some situations where you think that something has changed." Responses were made using a computer interface that showed the two response pictures and a summary of the to-be-explained particle motion. Participants could place attractors and repellers by clicking on any location outside the arena. Participants could move or erase placed attractors and repellers. A "reuse" button located between the two response pictures copied the attractors and repellers in the first picture to the second picture.

Participants were allowed to provide up to three explanations for each scene. Each explanation was entered on a separate screen. Participants were allowed to provide written explanations to supplement the picture-based explanations, but few participants did so.

After providing the explanations, the participants rated each provided explanation on a scale ranging from 1 (very unlikely to be the true explanation) to 7 (very likely to be the true explanation). Participants were also asked to rate the likelihood that the true explanation was "fundamentally different" from the provided explanation(s).

### Prediction phase

Participants were asked to predict the particle paths given the locations of the attractors and repellers. Figure 2.iii

presents some of the prediction trials. The prediction pictures in Figure 2.a.iii, b.iii, and c.iii top correspond to the parsimonious explanations. There were other prediction trials that corresponded to less parsimonious explanations. Three other prediction trials presented each participant with the configurations that corresponded to his or her own explanations in the discovery phase.

### Evaluation phase

In the evaluation phase, participants once again viewed the wall-motion, center-return, and curved-motion scenes. In explaining each scene, participants chose between their own explanations and the parsimonious explanation. The parsimonious explanations are shown as the first, third, and fifth rows in Figure 2.ii.

For each forced choice, the participant rated his or her preferred explanation as "much more," "more", or "slightly more" likely to be the true explanation than the competing explanation. Because participants occasionally generated the parsimonious explanations themselves, participants were sometimes presented with a choice between two identical explanations. For these situations, participants were provided with a "these explanations are identical" button. We coded responses on a scale ranging from -3 (own explanation "much more likely" to be the true explanation) to 3 (parsimonious or alternative explanation "much more likely" to be the true explanation). When a participant claimed that the explanations were identical, his or her preference was coded as 0.

Three other trials required the participants to choose between their own explanations and some less parsimonious explanations. These alternative explanations, shown in the second, fourth, and sixth rows of Figure 2.ii, required additional assumptions to explain the particle motion. These trials served to control for the task demand of asking the participants to choose between their own explanation and an experimenter-provided explanation. To further limit any task demands, all competing explanations were described as responses provided by other participants.

## Results

The inverse reasoning account predicts that participants ought to generate the parsimonious explanations during the discovery phase and endorse them during the evaluation phase. In contrast, we found that participants rarely generated the parsimonious explanations during the discovery phase but often preferred them during the evaluation phase. We begin by documenting this general result and then provide more detailed descriptions of the results for the discovery and prediction phases.

### Parsimonious explanations

A wall-motion explanation was coded as parsimonious when it invoked a single stationary attractor or repeller. A center-return explanation was coded as parsimonious when it invoked two balancing repellers above and below the arena or two balancing attractors to the left and right of the

Figure 3: Proportions of the participants generating a parsimonious explanation in the discovery phase and endorsing the parsimonious explanation in the evaluation phase.

arena. A curved-motion explanation was coded as parsimonious when it invoked exactly two stationary attractors or repellers and did not invoke any moving, appearing, or disappearing attractors and repellers. Our coding criteria were intended to be conservative: note, for example, that any curved-motion explanation with two stationary objects was coded as parsimonious regardless of the locations of these objects.

Figure 3 shows that participants rarely generated parsimonious explanations in the discovery phase but often preferred them in the evaluation phase. The differences between the rates of generation and endorsement were significant for each scene (Fisher's exact test yields  $p < .01$  in all cases). This finding cannot be attributed to task demands alone: as shown by the distribution of the preference ratings in Figure 2.ii, participants did not prefer non-parsimonious explanations (rows two, four, and six) to the same extent that they preferred the parsimonious explanations (rows one, three, and five).

## Discovery

The difference between the results for the discovery and evaluation phases suggests that object discovery in our paradigm is not accurately characterized as inverse physical reasoning. Figure 2.i gives some sense of how participants were approaching the discovery task. Each plot in this column is a "heatmap:" locations where participants often placed attractors are shown as brighter areas and locations where repellers were often placed are shown as darker areas.

For the wall-motion trials, 14 participants posited one hidden object along the particle's diagonal trajectory and one hidden object along its horizontal trajectory, 5 participants posited a single attractor or repeller that moved, and 8 participants generated combinations or variations of those explanations. For the center-return trials, 12 participants posited appearing and disappearing attractors and repellers along each path of motion, 9 generated an explanation that involved balancing attractors or repellers but also invoked other attractors and repellers (e.g., had balancing repellers in the second response picture but

Figure 4: Particle motions predicted by participants given their own explanations for the wall-motion, center-return, and curved-motion scenes.

posited an attractor in the first response picture), and 5 participants generated other explanations. Responses to the curved-motion scene were more variable, and there was less agreement on the locations of the attractors and repellers (see Figure 2.i.c). Most of the participants posited multiple attractors and repellers that were simultaneously present. For example, 7 participants posited three or more stationary and constantly present attractors and repellers, and 12 participants posited two or more attractors or repellers that were simultaneously present at some point during the motion but were either non-stationary or not constantly present. The remaining non-parsimonious explanations most commonly posited a single attractor or repeller along the particle's path of motion in each response picture. Overall, then, responses to the discovery phase reveal a variety of strategies, but one consistent element is that many participants placed objects in line with a particle's instantaneous direction of motion.

## Prediction

Figure 2.iii summarizes the responses on selected prediction trials. The critical question for present purposes is whether participants agreed that the parsimonious explanations would indeed account for the observed motions during the discovery trials. When provided with the parsimonious explanations, 15 of the 30, 24 of the 30, and 23 of the 30 participants predicted that the particle would approximately reproduce the particle motions from the discovery trials for the wall-motion, center-return, and curved-motion scenes respectively. Note that these counts are substantially higher than the number of participants who generated the parsimonious explanations during the discovery phase. The prediction data therefore provide further evidence that some participants failed to generate the parsimonious explanations during the discovery phase even though they considered these explanations to be valid.

Although participants did not always predict that the parsimonious explanations would produce the observed motion, their predictions were usually sensible given some additional assumptions. For example, various participants seemed to assume that friction would stop the particle when it hit the wall in the parsimonious wall-motion prediction trial, that momentum would carry the particle past the center in the parsimonious center-return prediction trial, and that the motion of the particle would be influenced *only* by

nearby repeller in the parsimonious curved-motion prediction trial.

Figure 4 shows the participants' predictions given their own explanations for the wall-motion, center-return, and curved-motion scenes. Some predicted motions diverged dramatically from the particle motion in the to-be-explained scene, and the discrepancies for the curved-motion scene were especially dramatic. These discrepancies should be interpreted cautiously, however, because the participants may have made different assumptions during the discovery and prediction phases. For example, it was natural to assume that the particle had an initial velocity in the first response picture of a trial in the discovery phase (the particle had already moved), but there was no reason to assume a particle velocity in the prediction phase. As a result, future studies are needed before concluding that participants sometimes generate explanations that are truly incompatible with the trajectories that they have observed.

## Discussion

Our data support the conclusion that hypothesis evaluation is consistent with the inverse reasoning account but that hypothesis discovery is not. In some respects, the failure of the participants to discover the parsimonious explanations is quite surprising. The parsimonious explanations were straightforward, requiring the participant to posit at most two stationary attractors or repellers. It should have been possible for participants to discover the parsimonious explanations, and some of them indeed did so. In other respects, the failure of the participants to discover the parsimonious explanation makes sense. Even in the simple object discovery task presented in this paper, there are infinitely many explanations that might be considered. The inverse reasoning account is often unhelpful in these situations. Bayes' theorem admonishes the reasoner to consider all the possible explanations for the observations, but does not provide guidance when doing so is impossible.

Although generating the best explanation from an infinite class may be computationally challenging, evaluating the merits of a handful of selected hypotheses seems substantially easier. It is therefore not surprising that hypothesis evaluation was broadly – although perhaps not absolutely – consistent with the normative inverse reasoning account. The dissociation between discovery and evaluation is consistent with the view that people rely on non-Bayesian strategies to generate candidate explanations for evaluation, but are able to approximate Bayesian reasoning when deciding which of these candidates is best (Bonawitz and Griffiths, 2010).

Participants may have used several different kinds of strategies to generate candidate explanations during the discovery phase of our experiment. For example, an initial explanation might have been generated using the idea that objects often move directly towards attractors. If needed, this initial explanation might have been improved using search heuristics such as hill-climbing. The process of discovery might also rely on analogical reasoning—for

example, many participants explained the curved-motion scene by placing a repeller at the focal point of the curve, and it is tempting to view this inference as a loose analogy to orbital motion. Like any other kind of creative behavior, object discovery is likely to be difficult to characterize in full detail. Future studies, however, can aim to characterize some of the psychological processes involved.

## Abstract

Research in inductive category learning has demonstrated that interleaving exemplars of categories results in better performance than presenting each category in a separate block. Two experiments indicate that the advantage of interleaved over blocked presentation is modulated by the structure of the categories being presented. More specifically, interleaved presentation results in better performance for categories with high within- and between-category similarity while blocked presentation results in better performance for categories with low within- and between-category similarity. This interaction is predicted by accounts in which blocking promotes discovery of features shared by the members of a category whereas interleaving promotes discovery of features that discriminate between categories.

**Keywords:** category learning; order effects; interleaving;

## Introduction

How to present information so that learning and memory are optimized is an important issue in teaching and training contexts (Rohrer & Pashler, 2010). It has long been demonstrated that spacing repeated presentations of the same information results in better memory than repeating the same information at a single occasion, even when time and number of presentations are equated (Ebbinghaus, 1885). This memory phenomenon, known as the “Spacing Effect,” is a highly robust finding (Delaney, Verkoeijen, & Spiguel, 2010; Proctor, 1980) that has been shown both in experimental situations with words and pictures and more applied situations such as flashcard studying (Kornell, 2009). Although demonstrating the critical importance of carefully considering how to present information, the importance of maximizing memory for specific concepts or problems might not be as relevant as learning general concepts. Indeed, in educational contexts, often times inferring what characterizes or defines a concept or problem is more relevant than memorizing a single instance of that concept or fact. In this sense, a more interesting question might be to know whether the way instances are presented influences inductive learning and subsequent generalization of the acquired knowledge.

The question of how to present information in order to optimize category learning and generalization has been raised before and several proposals have been put forward. Some of these proposals are related to the categories being

taught. For example, Elio and Anderson (1984; see also, Sandhofer & Dumas, 2008) have proposed that learning should start with low variability items and later introduce items with greater variability. Another proposal is that items that present the same generalization should be presented close together in temporal sequence (e.g., Elio & Anderson, 1981; Mathy & Feldman, 2009).

More recently, researchers have proposed interleaving items from the categories being taught (i.e., presented in alternating fashion), rather than grouping items together from the same category. The advantage of alternating categories has been observed in different kinds of concepts such as artists’ styles (Kornell & Bjork, 2008), bird species (Kornell, Castel, Eich, & Bjork, 2010; Wahlheim, Dunlosky, & Jacoby, 2011), novel category learning in children (Vlach, Sandhofer, & Kornell, 2008) and also mathematical operations in primary school students (Taylor & Rohrer, 2010).

Initial accounts of this advantage for interleaving related the interleaved presentation with spacing of exemplars. However, Kang and Pashler, (2012) used a procedure similar to the one used by Kornell and Bjork (2008), but with added presentation conditions. In one experiment, the authors compared categorization performance in a generalization test preceded by one of four conditions: (1) blocked, (2) interleaved, (3) blocking in which every presentation of a painting was followed by an unrelated filler task (Temporal Spaced Condition), and (4) when all exemplars from the same painter were presented simultaneously (Blocked Simultaneous Condition). The results showed that only the interleaved condition resulted in better performance than the blocked condition, thus providing evidence that greater temporal spacing of presentations is not the critical factor in the interleaved advantage. The authors argue that the real advantage of interleaving might be a result of the greater opportunity to contrast and compare examples, making the differences between the artists’ styles more salient (see also, Goldstone, 2003; Goldstone & Steyvers, 2001).

Further evidence for this proposal was provided in a second experiment in which the interleaved and blocked conditions were compared to a simultaneous presentation of two paintings by different artists. This latter condition

resulted in similar performance to interleaved presentation and better performance than the blocked condition.

Interleaving examples from different categories, thus, may improve inductive learning because it promotes discrimination between the categories. Rapid alternation between examples of different categories, as well as simultaneous presentation of multiple categories, might lead to enhanced attention to the features that discriminate between the categories and differentiation of the dimensions on which the categories vary (Goldstone & Steyvers, 2001; Kang & Pashler, 2012; Nosofsky, 1986). However, there are also situations in which these conditions are not ideal and previous studies have also demonstrated an advantage of blocked presentation (Goldstone, 1996; Kurtz & Hovland, 1956).

Goldstone (1996) proposed that category learning might be difficult for two different reasons: high between-category similarity or low within-category similarity. High between-category similarity refers to category structures in which both categories share most of their features, making discriminating the categories a matter of finding subtle differences between exemplars (as is the case of distinguishing between alligators versus crocodiles, for example). Low within-category similarity, on the other hand, refers to category structures in which the exemplars of the same category share very few features (as is the case for the category “animal,” for example).

Each one of these two kinds of categories requires different mechanisms for efficient category learning. In the case of high between-category similarity, one has to identify subtle differences between categories, which might be facilitated by frequent alternation. However, rapid alternation between two categories with low within-category similarity will not allow for the identification of the relevant properties characteristic of a category. In this case it might be more beneficial to block exemplars of each category separately so that the learner can identify the shared features among members of a category hidden within their diversity.

By this analysis, the best presentation schedule would depend upon the learning situation at hand. In this paper we approach this question directly by manipulating only the characteristics of the stimuli presented during learning. We aim to demonstrate that interleaving or blocking can both be beneficial for inductive category learning. In Experiment 1 participants were taught three categories with high within- and between-category similarity, in both an interleaved and blocked schedule. In Experiment 2 we employ the same learning procedure but using three categories that possess low within- and between- category similarity. Performance during category learning and in a subsequent generalization task are measured.

### Experiment 1: High Similarity

In this experiment we aim to replicate previous results showing an advantage for interleaved presentation of categories for category learning. Participants were presented with 3 categories (either blocked or interleaved). These 3

categories had high within- and between- category similarity. In this sense, every stimulus from the same category shared several features, some category relevant and others not, while they also shared almost every feature with every stimulus from the other categories. We believe this is a situation close to previous work on sequencing effects in category learning (e.g., Kornell & Bjork, 2008) and literature on perceptual discrimination learning showing an interleaving advantage (Mitchell, Kadib, Nash, Lavis, & Hall, 2008; Mundy, Honey, & Dwyer, 2007). Under this situation, rapid alternation between categories will lead to the direction of attention to the diagnostic features because identifying what is changing from category to category is relatively easy given the high overall similarity.

### Method

**Participants** Forty-four Indiana University undergraduate students participated in this experiment in return for partial course credit. All participants completed every condition. Fifteen participants did not reach the criterion of 34% correct responses during categorization learning and were excluded from further analyses.

Fig. 1: Examples of stimuli used in Experiments 1 and 2.

**Apparatus and stimuli** In this and the subsequent experiment, blob figures were used as stimuli (see Fig. 1). All blobs were created by randomly generating curvilinear segments. The blobs used were very similar, sharing almost every feature. Variation within each category was exactly the same for all categories, so that a difference that could exist between two exemplars in Category 1 would also exist between 2 exemplars of Categories 2 and 3. As a cover story, participants were told that a recent expedition to Mars recovered several cells of alien organisms. Each cell could be categorized into one of 3 species based solely on its perceptual features. Stimuli were presented on a computer screen and participants responded using keys on the keyboard with a consistent mapping to the category assignment.

**Design and procedure** This experiment had two conditions (blocked category learning and interleaved category learning), manipulated within-subject. Each condition was composed by 2 phases. The first phase was a category learning task. During this task participants were presented with a stimulus in the center of the screen for 500 ms. After the blob was removed, the participant was asked to classify the blob into one of 3 species (Q, Y or P) by pressing the corresponding key on the keyboard. After a participant's response, the blob was presented again for 2000 ms together with the presentation of feedback on the accuracy of their response and the correct species of the blob (e.g., "CORRECT! This cell belongs to species Q" or "Sorry, that is INCORRECT! This cell belongs to species Y").

A 1000 ms inter-trial interval followed and then a new trial began. In the blocked condition, the categories presented alternated 25% of the time while in the interleaved condition they alternated 75% of the time. Thus, in the interleaved condition, the probability of a blob being followed by a blob of the same category was low, whereas for the blocked condition this probability was high. We used this probabilistic approach rather than creating purely interleaved or blocked conditions in order to diminish the possibility that participants noticed the pattern of alternation in responses, which would affect categorization accuracy. Furthermore, if a purely blocked condition had been used there would be no way to guarantee participants' attention to the task, as there would be no uncertainty as to the correct categorization. This approach has been used before in similar tasks with successful results (Carvalho & Goldstone, 2011; Goldstone, 1996).

The learning phase was composed of 4 blocks. Each block had 48 trials (8 exemplars of each category repeated 2 times each). After the 4<sup>th</sup> block of categorization learning a new set of instructions was presented on the screen and the second phase began. This second phase was a generalization task during which 48 stimuli were shown in random order – the 24 blobs participants studied during the learning task and 24 new stimuli. The new stimuli were generated in the same manner as training stimuli, with new instantiations of the unique features. Each stimulus was presented in the center of the screen for 500 ms, after which participants were asked to classify it into one of the species just learned. After a 1000 ms inter-trial interval, a new trial would begin. No feedback was provided during this phase.

The two learning conditions (blocked vs. interleaved) differed only in the frequency of category change and the species labels. In one of the conditions Q, Y and P labels/keys were used, while in the other, A, G and L were used, by random assignment. Which condition was presented first was counterbalanced across participants and the allocation of the stimuli to each category and condition was randomized across participants.

## Results and Discussion

The top panel of Fig. 2 depicts the main results of the categorization task. A 2 x 4 repeated measures ANOVA

with learning condition (blocked vs. interleaved) and learning block (1 vs. 2 vs. 3 vs. 4) as factors revealed main effects of learning block,  $F(3,81) = 59.42$ ,  $p < .00001$  and condition,  $F(1,27) = 18.58$ ,  $p = .0002$ , but no interaction between the two variables,  $F(3,81) = 1.43$ ,  $p = .24$ . Thus, there is an improvement in categorization accuracy during the task, regardless of presentation schedule, and blocked presentation results in the overall best accuracy rates.

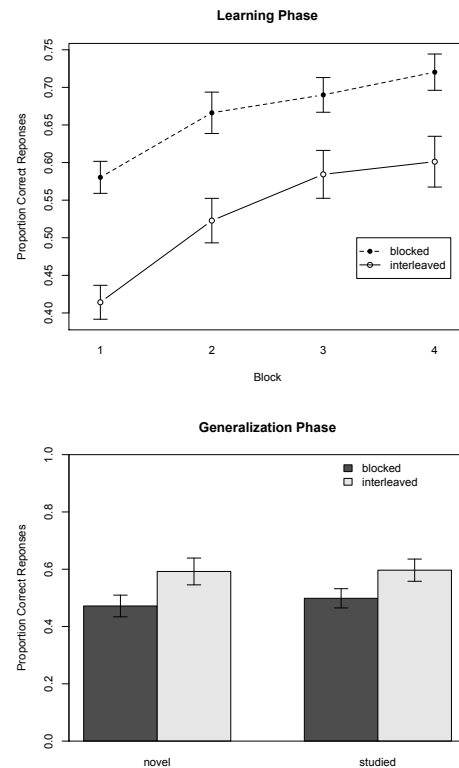

Fig. 2: Results from Experiment 1. The top graph represents accuracy during the learning phase for both conditions across the four blocks of trials. The bottom graph represents accuracy during the generalization phase for novel and studied stimuli for each condition. Error bars represent standard errors.

The results from the generalization task are depicted in the bottom panel of Fig. 2. A 2 x 2 repeated measures ANOVA with learning condition (blocked vs. interleaved) and stimulus presented (novel vs. studied) as factors, revealed a main effect of condition,  $F(1,27) = 4.50$ ,  $p = .04$ , with higher accuracy for the interleaved condition, but no main effect of stimulus presented,  $F(1,27) < 1$ , or interaction between the two variables,  $F(1,27) < 1$ .

Overall these results replicate previous demonstrations that interleaving very similar categories during learning results in better memory for the presented items (as seen by the higher accuracy rates for the studied stimuli) but also better generalization to novel items. The finding that blocked presentation results in higher accuracy rates during learning has also been demonstrated before and has been explained by a relative ease in performing the training task (Taylor & Rohrer, 2010), which would make the interleaved

condition a desirable difficulty in this kind of task (Kornell & Bjork, 2008).

The results are consistent with the hypothesis that interleaved presentation promotes the discovery of features that discriminate between alternative categories, which is important when categories are highly similar.

## Experiment 2: Low Similarity

In this Experiment we analyze the effect of the schedule of presentation in a categorization situation different from that of Experiment 1. We tried to create a category learning task in which blocked presentation of the category exemplars would allow for the discovery of hard-to-find common features among dissimilar category members.

We employ the same procedure as in Experiment 1 but the 3 categories now have low within- and between-category similarity. In this sense, exemplars from the same category share only one feature (the category relevant feature) while differing in all other features. Moreover, exemplars from different categories are also highly dissimilar, sharing none of their features. Thus, in this condition, it is not expected that interleaving will have a beneficial effect on learning. Rapid alternation of categories would not allow for the identification of important features because all the features change from trial to trial. On the contrary, we expect blocked presentation to result in superior category learning and performance on a later generalization task, by promoting comparison of objects from the same category and thereby promoting discovery of their subtle commonality.

## Method

**Participants** Thirty-two Indiana University undergraduate students participated in this experiment in return for partial course credit. All participants completed every condition and all reached the criterion of 34% correct responses or more during categorization learning.

**Apparatus and stimuli** The same kind of blob figures as in Experiment 1 were used. However, the blobs used in this experiment differed from every other blob in all the segments except the one that defined each one of the six categories (each one of the discriminating features). In this experiment, Blobs also differed in their overall shape, some being more circular and others more elongated. All other details were kept the same as in Experiment 1.

**Design and procedure** This experiment followed the same procedure as Experiment 1 with the exception of the stimuli used.

## Results and Discussion

The graph in the top panel of Figure 3 depicts response accuracy during category learning as a function of both learning block and schedule of presentation.

A 2 x 4 repeated measures ANOVA with both learning condition (blocked vs. interleaved) and learning block (1 vs. 2 vs. 3 vs. 4) as repeated measures factors, revealed a main effect of learning block,  $F(3, 93) = 169.74$ ,  $p < .0001$ ,

showing an overall improvement for both presentation conditions. Moreover, categorization is overall better for the blocked condition when compared to the interleaved condition,  $F(1, 31) = 29.03$ ,  $p < .0001$ . Finally, a significant interaction between presentation condition and learning block was also found,  $F(3, 93) = 7.06$ ,  $p = .0002$ , indicating that the difference in accuracy between the two conditions decreases as the categorization progresses.

Fig. 3: Results from Experiment 2. The top graph shows accuracy during the learning phase for both conditions across the four blocks of trials. The bottom graph shows accuracy during the generalization phase for novel and studied stimuli for each condition.

The bottom panel of Fig. 3 shows accuracy performance in the generalization task as a function of stimulus presented (novel vs. studied) and presentation condition during learning (blocked vs. interleaved). A 2 x 2 repeated measures ANOVA with both presentation condition (blocked vs. interleaved) and stimulus presented (novel vs. studied) as factors revealed a main effect of stimulus,  $F(1, 31) = 74.20$ ,  $p < .00001$ , with higher accuracy for the studied than novel stimuli. There was no significant main effect of presentation condition during learning,  $F(1, 31) = 1.14$ ,  $p = .30$ . However, the interaction between the two variables was significant,  $F(1, 31) = 14.61$ ,  $p = .0006$ . To further investigate this interaction, pairwise *t*-test comparisons were performed correcting for the error associated with multiple comparisons using Bonferroni correction (critical  $\alpha = .025$ ). This analysis revealed that blocked presentation results in higher accuracy in categorizing novel stimuli,  $t(31) = 2.47$ ,  $p = .02$ , but there is

no difference between the two conditions for studied stimuli,  $t(31) = 1.21, p = .24$ .

Thus, the results of this experiment demonstrate an advantage of blocked presentation of category exemplars in accuracy during learning, although participants in the interleaved condition approach that performance by the last trial. Perhaps more interestingly, blocked presentation resulted in better performance when categorizing new stimuli when compared to interleaved presentation. However, for studied stimuli no difference was found.

These results directly challenge the proposal that interleaving categories during learning improves performance due to the increased spacing of exemplars. They are, however, consistent with our proposal that the interleaving advantage was due to greater opportunity for contrasting categories and discovery features that distinguish between categories. When finding feature differences between categories is easy, as in Experiment 2, then the more important task is to find features shared by members of the same category, a task promoted by blocking. This clearly demonstrates that the category structure has a modulating effect on the advantage of one sequencing over another.

## General Discussion

Learning the characteristics of concepts and categories inductively takes place frequently. In learning contexts, it is also important to be able to generalize that knowledge to new exemplars. In this work we studied the interaction between object presentation during learning and the structure of the category being taught for inductive learning and generalization optimization.

Experiment 1 replicated previous results demonstrating that interleaving categories being taught results in better memory and generalization for those categories. Additionally, in Experiment 2 we presented results pointing to an advantage of blocking by category. In Experiment 2 generalization was better for categories that had their exemplars presented in adjacent temporal sequence during learning.

Critically, the only difference between these two experiments was the properties of the categories being taught. While in Experiment 1, the three categories were highly similar among each other and were constituted by exemplars that were also very similar, in Experiment 2 the similarity within and between the categories was low, resulting in categories that did not share any features and were composed of stimuli that shared only one feature with other objects in their same category.

A possible explanation to at least some of the results presented here could be that interleaving constitutes a “desirable difficulty” (Bjork, 1994). In both experiments, blocked presentation during the learning phase resulted in a higher proportion of correct responses. This could indicate that interleaved presentation involved a greater effort on the participants’ part, maintaining their attention to the stimuli and leading to better performance in the subsequent task.

Although this can, in fact, account for the results found in Experiment 1, that is not the case for Experiment 2. In that experiment, the condition resulting in greater accuracy during learning also resulted in better generalization.

In line with Goldstone (1996) we propose that interleaving categories allows for the identification of the features that are different between each category while blocked presentation promotes the identification of the features that are common among stimuli from the same category. This dichotomy is the result of the same principle: the opportunity to compare and contrast the properties of the categories, what will emphasize different features in different situations,

We further build on this proposal by suggesting a mechanistic account of how it takes place in a trial by trial basis. It has previously been demonstrated that during category learning participants take into account information from the previous few trials to decide whether a stimulus belongs to one category or another (Stewart & Brown, 2004; Stewart, Brown, & Chater, 2002). We further propose, that when two successive stimuli are similar and in different categories, participants’ attention will be directed to the differences between exemplars by a comparison process. On the other hand, if stimuli are very dissimilar but in the same category, participants’ attention will be directed towards the similarities between successive stimuli. This proposal can account for both the advantage of interleaving over blocking with high-similarity categories and the reversal with low-similarity categories.

Rapid alternation of categories allows participants to identify differences between categories, which will be particularly beneficial if those differences are hard to detect, as in the case of the stimuli used in Experiment 1 and the artists’ styles or bird species used in previous studies. Infrequent alternation of categories, on the other hand, will allow participants to identify the commonalities within each category, which is particularly beneficial if categories are composed by members with high variability, like the ones used in Experiment 2.

In appreciating the benefits of blocking it is important to keep in mind that not all concept learning takes place by identifying discriminating features among categories. For example, sometimes it is possible to create an absolute characterization of a category in terms of its prevalent features, regardless of their discriminative values (Markman & Ross, 2003). Furthermore, in other situations, memorizing instances might be a highly useful strategy.

In sum, the results presented here show that there may not be a single answer to the question of how should an instructor sequence information so that the learner acquires the knowledge and is able to generalize it more efficiently. Best sequencing practices will depend on the nature of the categories being sequenced.

## Abstract

This paper reports two experiments on the implicit learning of second language word stress rules and presents a methodological innovation. In both experiments L1 Cantonese L2 English participants practised pronouncing two-syllable Spanish words. Learning of a hidden stress regularity was measured by a judgment task. We assessed participants' awareness of the stress rule by verbal reports, confidence rating and a novel methodology: inclusion-exclusion production tasks adapted from Destrebecqz and Cleeremans (2001). Experiment 1 demonstrated the implicit learning of association between the ending phoneme and word stress and experiment 2 the implicit learning of a more abstract rule of stress placement. We conclude that L2 word stress rules may be learnt implicitly.

**Keywords:** implicit learning, word stress, Spanish, binary confidence ratings, process dissociation procedure

## Introduction

Previous studies of implicit learning have demonstrated that small-scale artificial grammar (Reber, 1967) and sequence of visual stimuli presentation in Serial Reaction Time (SRT) task may be learnt without awareness. In the domain of language, while early first language acquisition is essentially implicit, it remains cloudy whether implicit learning is relevant to second language acquisition (SLA) at all. The theoretical and pedagogical significance of implicit learning in SLA has stimulated recent research interests (e.g. Leung & Williams, 2011; Robinson, 1996, 2005; Saffran, 2001; Saffran et al., 2008; Rebuschat & Williams, 2011).

In the realm of L2 phonology, it has been shown that phonotactics (Dell, Reed, Adams, & Meyer, 2000; Onishi, Chambers, & Fisher, 2002; Warker & Dell, 2006), segmental features (Goldrick, 2004) and metrical stress rules (Gerken, 2004; Gerken & Boltt, 2008) may be learnt implicitly. Yet, to our knowledge, it is not known whether word stress regularities can be learnt without awareness, despite their importance in the parsing of speech stream. In the context of SLA, previous studies on the learning of lexical stress revealed that learners from a non-stress language background may have a different stress system than native speakers do, leading to a non-native "accent" of stress. For example, Mandarin speakers associated high flat tone with stress and Cantonese learners pronounce English stress and unstressed syllables as though they were high and low tones in their mother tongue (Chao, 1980). In light of the difficulty of learning stress, L2 stress pedagogy begs for further research. A crucial theoretical issue in implicit learning research is whether the knowledge acquired is abstract rules or

memorised chunks. Knowlton and Squire (1994, 1996) have proposed that both abstract information about grammar patterns and concrete information about the learning materials may be involved in implicit learning and they both contribute to performance in grammaticality judgment tasks. Whether abstract rules or chunks are learnt is of great relevance to the learning of prosody in that it would shed lights on how knowledge of prosodic signals is represented.

Relevant studies have been met with methodological challenges. Critics have challenged the validity of assessing awareness by verbal reports. The inability to verbalise knowledge might reflect low confidence on the part of the participants, lack of appropriate vocabulary to describe their knowledge or the intrinsic complexities of the regularity, and the knowledge assessed by verbal reports might not be responsible for performance on the measure of learning (Dienes & Berry, 1997; Shanks & St. John, 1994). Dienes et al. (1995) have sought to improve awareness measurement by asking participants to rate their confidence in judgment; a lack of correlation between judgment performance and confidence rating suggests that knowledge is unconscious (zero-correlation criterion). Tunney and Shanks (2003) found that binary confidence ratings are more sensitive to low levels of awareness than continuous ratings and were therefore adopted in our experiment.

More recently, Destrebecqz & Cleeremans (2001) have developed an objective awareness measure called the "method of opposition", modelled on the process dissociation procedure, a methodology framework first proposed by Jacoby (1991) to differentiate between the influences of implicit and explicit knowledge on performance. The method of opposition was applied to the SRT task (e.g. Curran, 2001; Haider, Eichler, & Lange, 2010). After completing the SRT task, participants were told there was a hidden sequence governing the presentation of visual stimuli and they were asked to complete free-generation tasks under both inclusion and exclusion instructions. Participants were asked to press response keys in an order that followed the sequence (inclusion condition) and that did not resemble the sequence (exclusion condition). According to the Global Workspace theory (Baars, 2003), when knowledge becomes conscious, the possibility for voluntary control of performance is opened up. A difference between inclusion and the exclusion performance indicates top-down processing and thus explicit knowledge. On the contrary, people with no explicit knowledge would tend to perform equally well in both inclusion and exclusion tasks (inclusion = exclusion) as they do not have control over how the implicitly learnt knowledge

influences behaviour (Curran, 2001). The experiment below demonstrates how the method of opposition could be employed as an awareness measure in other implicit learning tasks.

## Experiment 1

### Method

**Materials** The learning target was a simplified Spanish stress rule: words that end in “o” have their stress on the penultimate syllable (e.g. *busco* and *burro*) and words that end in “ar” on the last syllable (e.g. *gustar* and *tumbar*). Two-syllable real Spanish words were employed as stimuli and they were generated, using a Spanish male diphone database<sup>1</sup>, by the MBROLI speech synthesizer (Dutoit, Pagel, Pierret, Bataille, & Vrecken, 1996). The specific values were based on those used by Enríquez, Casado and Santos (1989): 100Hz and 60 ms for unstressed vowels and 116 Hz and 120ms for stressed vowels. Albeit the artificiality of the synthesizer, it was still preferred to voice recordings because a Spanish native speaker is likely to be biased against incorrectly stressed words, which raises a possibility that participants rely on the speaker’s fluency rather than knowledge of stress placement in the judgement task.

**Procedure** 37 university students (14 males and 16 females, *Age* = 21.8 years old) were recruited as the experimental group and 15 university students aged 20 to 26 (7 males and 8 females, *Age* 21.4) as the control group. All of them were native Cantonese speakers with English as an L2. None of them reported any knowledge of Spanish or Portuguese. They were told that the experiment aimed to study how people learn words. The experiment took around 25 minutes to complete.

**Training phase:** The training phase consists of 64 randomised trials, each containing a Spanish word and its English translation (See Fig 1, left). A set of 16 Spanish words, half of which end with *-ar* and the other half *-o*, was repeated four times. Participants repeated aloud after the recording. This provided participants with exposure to the target stress rules without explicitly directing their attention to them.

**Testing Phase (pronunciation judgement):** The testing phase consists of 40 trials, each of which includes an English verb and two sound icons (See Fig 1, right). Participants pressed the corresponding keys to listen to two audio presentations and choose the one that “sounds better” to them. As Scott and Dienes (2008) have shown that familiarity is the essential source of knowledge in artificial grammar learning, preference judgment is used rather than accuracy judgment (e.g., “choose the correct one”) because the former may encourage the use of intuition and discourage rule search during the testing phase (Rebuschat & Williams, 2011).

speak

hablar

like

Word 1

Word 2

**Figure 1: A sample trial used in learning (left) and testing phase (right) in experiment 1**

All the 16 critical items (8 *-ar* ending and 8 *-o* ending) were novel to the participants. Those sound pairs differed only in stress placement. Other previously seen items were randomly shuffled with the critical items so as to reduce the likelihood of participants consciously deducing the difference between the sound pairs.

To test whether, for *-ar* ending words, participants’ judgements were based on the *-ar* ending, *-r* ending or the vowel “a” at the end, 8 *-a* ending words were added in the testing phase. Like the *-o* ending words, words that end in “a” have their stress on the penultimate syllable and those sound pairs differed only in stress placement.

**Inclusion-exclusion Tasks.** Adapted from Destrebecqz and Cleeremans (2001), the tasks required participants to read aloud 8 two-syllable words in each of the two conditions: 1) “as similarly to Spanish pronunciation as possible” (inclusion) and 2) “as differently from Spanish pronunciation as possible” (exclusion). A small dot was given in each word (see Fig 2) to indicate syllabification which serves to remind the participants that all words consist of two syllables. Their voices were recorded.

Tum.bar

**Figure 2: A sample trial in the inclusion-exclusion tasks**

**Verbal reports.** Participants were probed for whether they had any knowledge about the pronunciation patterns and stress rules of Spanish words. They were also told there were underlying stress patterns and if they could not report knowledge of the regularities, they would be asked to provide as many guesses as possible.

All the items used are presented in table 1 below.

<sup>1</sup> <http://tcts.fpms.ac.be/synthesis/mbrola.html>

A: Items used in training (16 items)			
Words ended in "ar"		Words ended in "o"	
Hablar	Barrar	Soplo	Borro
Rascar	Roncar	Marco	Busco
Tumbar	Lanzar	Zumbo	Forzo
Contar	Gustar	Tosto	Gasto
B: Critical items used in the testing phase (16 items)			
Words ended in vowels		Words ended in consonants	
Probar	Tratar	Broto	Grabo
Juzgar	Firmar	Colgo	Formo
Saltar	Cantar	Bastar	Pinto
Montar	Costar	Falto	Junto

**Table 1: Items used in training, testing, and inclusion-exclusion tasks in experiment 1**

## Results and Discussion

**Overall performance** Participants' performance on the pronunciation judgment task served as the measure of learning. The experimental group attained an average of 59.6 % accuracy ( $SD = 1.41$ ;  $SEM = .23$ ) on the 16 critical items. Further analysis using *t*-test showed that their performance was significantly above chance,  $t(36) = 6.57$ ,  $p < .001$ ,  $d = 1.55$ . They achieved above-chance-level performances on both -ar ending and -o ending words,  $M = 64.2\%$ ,  $SD = 1.42$ ,  $SEM = .24$ ,  $t(36) = 4.81$ ,  $p < .001$ ,  $d = 1.13$  and  $M = 55.1\%$ ,  $SD = 1.13$ ,  $SEM = .19$ ,  $t(36) = 2.16$ ,  $p = .019$ ,  $d = .51$  respectively. Their performance on -ar ending words was significantly better than that of -o ending words,  $t(69) = 2.41$ ,  $p < 0.01$ ,  $d = .57$ , suggesting more learning of -ar ending words than -o ending words in relation to stress placement.

**Awareness measures** Verbal reports and inclusion-exclusion tasks were used to determine whether the acquired knowledge was conscious or not.

**Verbal reports:** 32 out of 37 participants remained unaware of the underlying stress rules based on verbal reports. One participant was able to verbalize the whole target stress rules.

Four participants reported some knowledge that overlaps with our target rules (i.e. "r" is stressed; intonation falls when a words ends in -o; stress is related to the "ar" ending; stress is related to word length). They were classified as aware. In fact many participants did not notice any stress patterns and were surprised when they were asked to guess.

**Inclusion-exclusion tasks:** Participants' audio recordings for the tasks were analysed using *Praat* to locate their stress placement based on the fundamental frequencies (F0) of the two syllables, as it was found that Chinese speakers rely on F0 as the most important cue in stress judgement (Wang, 2008). The difference between inclusion and exclusion scores was calculated. The five aware participants scored higher under the inclusion instruction than the exclusion instruction (from +2 to +3), showing congruence with their awareness level revealed in verbal reports. 15 out of the 32 remaining participants scored equally for both tasks and they were classified as our truly unaware participants. The other 17 participants who showed some difference in their scores for both tasks (from -3 to +3) were re-classified as aware and were not included in our analysis of unaware data.

**Pronunciation Judgment Task:** The 15 unaware participants achieved an average of 58.8% accuracy ( $M = 9.4$ ;  $SD = 1.20$ ;  $SEM = .32$ ) on the 16 critical items and their performance was significantly above chance,  $t(14) = 4.37$ ,  $p < .01$ ,  $d = 1.65$ . Their performances on both -ar ending and -o ending words are both significantly above chance,  $M = 59.1\%$ ,  $SD = 1.12$ ,  $SEM = .30$ ,  $t(14) = 2.44$ ,  $p = .014$ ,  $d = .92$  and  $M = 58.3\%$ ,  $SD = 1.07$ ,  $SEM = .29$ ,  $t(14) = 2.32$ ,  $p = .018$ ,  $d = .88$  respectively. There is evidence of implicit learning of L2 ending-phoneme-to-stress rules by young Cantonese-speaking adults with only short and limited exposure. However, their accuracy on -ar ending words was not significantly higher than that of -o ending words,  $t(28) = 0.16$ ,  $p = 0.44$ .

**Control:** The control group completed only the pronunciation judgement task. Their accuracy on critical items was not significantly different from chance,  $M = 47.1\%$ ,  $SD = 1.09$ ,  $SEM = .29$ ,  $t(14) = 1.61$ ,  $p = .065$ .

While previous studies suggest that novel L2 stress perception may pose challenges to learners from a non-stress language background, participants' proficiency in English and their prior general knowledge of word stress might have been helpful in this experiment. Moreover, it was found that participants in general performed significantly better for -ar ending words than -o ending words. This may be explained by their prior linguistic knowledge. A previous study (Bailey, Plunkett, & Scarpe, 1999) showed that native English speakers, when learning a novel stress pattern, had a significant bias for non-word-final stress. In our study, when participants were asked if they had any feelings about pronunciation patterns of Spanish words, 12 participants mentioned "the intonation of the words tended to go up", "the last syllable seemed to be louder and higher in pitch" and "stress tends to lie on the final syllable", despite the fact that words with a word-final stress and a non-word-final stress appeared equally frequently in the experiment. These

statements are an indication that stress patterns that are distinct from English (word-final stress in this case) might have appeared more salient to our participants given their prior linguistic experience. In addition, heavy syllables tend to be stressed in English. This may explain why there appeared to be more learning of *-ar* ending words (which has a heavy syllable at the end) than that of *-o* ending words.

It is worth mentioning that there is a medium negative correlation between participants' accuracy on *-ar* ending words and that of *-a* ending words,  $r(35) = -0.51$ ,  $p = .001$  for all participants and  $r(13) = -0.72$ ,  $p = .002$  for unaware participants. On the other hand, a medium positive correlation was found between their accuracy on *-o* ending words and that of *-a* ending words for both the whole experimental group,  $r(35) = 0.49$ ,  $p = .002$ , and the unaware participants,  $r(13) = 0.64$ ,  $p = .001$ . These suggest that participants might have made their judgements based on the last phoneme (i.e. the *-r* ending instead of the vowel *a*) in the last syllable. While it is still unclear whether participants learnt an abstract rule or a set of probabilities, their higher sensitivity to the difference between open and closed syllables provided initial evidence of rule learning. This issue was addressed in a follow-up experiment, whose design was similar to experiment 1.

## Experiment 2

### Method

**Materials** The learning target was more complicated stress regularities: words that end in a consonant (closed syllable) have their stress on the final syllable (e.g. *felol* and *cerroz*) and words that end in a vowel on the last syllable (e.g. *pato* and *bona*). Two-syllable nonwords with four or five phonemes (vowel-ending words and consonant-ending words respectively) were generated by the same speech synthesizer based on Spanish pronunciation. The words were combination of phonemes illustrated below:

1. First phoneme: /b/, /b/, /d/, /d/, /f/, /g/, /h/, /k/, /k/, / / (l), /m/, /n/, /p/, /s/, /s/, /t/, /t/ or /v/.
2. Second phoneme: /a/, /e/ or /o/.
3. Third phoneme: /b/, /b/, /d/, /d/, /g/, /k/, /k/, /l/, /m/, /n/, /n/, /p/, / /, /r/ (trilled), /s/, /t/, /t/ or /v/.
4. Fourth phoneme: /a/, /e/ or /o/
5. Fifth phoneme (consonant-ending words only): / /, /l/, /θ/ (z).

**Procedure** 44 participants were recruited. The experimental group consisted of 22 young adults (9 male and 13 female, *Age* = 21.0 years old). The other 22 young adults (12 male and 10 female, *Age* = 22.3 years old) were the control group. They were all native Cantonese speakers with English as an L2 with no knowledge of Spanish or Portuguese. The experiment took around 30 minutes to complete.

**Training phase:** Participants were presented with a Spanish word (See Fig 2, left). They repeated aloud after the recording. 36 Spanish-based words, half of which end in a

vowel and the other half consonant, were repeated three times to form 108 trials.

**Testing Phase (pronunciation judgement):** Participants clicked to listen to two possible Spanish pronunciations (See Figure 2, right) and chose the one that “sounds better” to them.

domal | Word 1 Word 2

**Figure 2: A sample trial used in learning (left) and testing phase (right) in experiment 2**

**Confidence rating:** A binary confidence rating was included to further improve awareness assessment. After making a judgement, participants were asked to indicate whether they made a guess or were certain about their choice.

Critical data came from 18 novel words, half of which ends in /a/, /e/ or /o/ and the other half /ɔ/, /l/ and /z/. To determine whether participants had learnt an abstract rule or memorised chunks, 12 “extension items”, half of which ends in /i/ or /u/ (vowel ending) and the other half /d/, /x/ (consonant ending) were included. Those sound pairs differed only in placement of stress.

**Inclusion-exclusion tasks:** Same as experiment 1, except that there were 18 items for each condition.

**Verbal reports:** Same as experiment 1.

A: Items used in training (36 items)					
-a ending	-o ending	-e ending	-r ending	-l ending	-z ending
Beba	Gobo	Coge	Botor	Bogel	Cerroz
Bona	Navo	Dade	Coder	Domal	Gapez
Cepa	Pato	Fane	Llaner	Debal	Hocaz
Doca	Seco	Mete	Penar	Felol	Natoz
Hara	Sorro	Tome	Socor	Madel	Tobaz
Llada	Telo	Vese	Tevar	Sasol	Verez
B: Critical items used in the testing phase (18 items)					
-a ending	-o ending	-e ending	-r ending	-l ending	-z ending
Dada	Goto	Cebe	Decar	Mebel	Cepez
Moda	Llemo	Sage	Llager	Savol	Gadoz
Teca	Savo	Tope	Tomor	Sotal	Today
C: Extension items used in the testing phase (12 items)					
-i ending		-u ending	-d ending		-j ending
Llepi		Dotu	Saded		Gotej
Gomi		Sacu	Cemod		Llecaj
Cabi		Tedu	Tobad		Dapoj
D: Items used in inclusion-exclusion tasks (18 items)

Tela	Co.po	Se.ge	Ce.ror	Fo.tal	Te.maz
Do.sa	Be.to	So.ne	Lle.car	Par.rel	Ho.dez

**Table 2: Items used in training, testing, and inclusion-exclusion tasks in experiment 2**

## Results and Discussion

**Verbal reports:** Among the 22 participants, one participant was able to report our target rules. Two other participants mentioned “rising intonation for -z ending words” and “stress is affected by length of the word”, which overlap with our target rules. These three participants were classified as aware. Still, many participants reported they paid no attention to any stress patterns and were surprised when they were asked to guess.

**Confidence rating:** The Chan difference score (Chan, 1992; Dienes et al, 1995) was computed for each participant to determine whether learning was implicit by the zero correlation criterion. It is the difference between the proportion of ‘certain’ responses which were correct (hit) and those which were incorrect (false alarm). Participants with a positive score were classified as aware and those score 0 or below were classified as unaware.

**Inclusion-exclusion tasks:** Participants who scored the same in inclusion and exclusion tasks were classified as unaware; otherwise they were classified as aware.

**Pronunciation Judgment Task:** Only 8 out of 22 participants were classified as unaware based on the above criteria. Their average accuracy in the judgement task was 68.1% ( $M = 12.25$ ;  $SD = 1.67$ ;  $SEM = .59$ ) on the 18 critical items, which was significantly above chance,  $t(7) = 5.51$ ,  $p < .001$ ,  $d = 1.95$ . They achieved better-than-chance accuracy for both vowel and consonant ending words,  $t(7) = 2.12$ ,  $p = .03$ ,  $d = 0.75$  and  $t(7) = 3.86$ ,  $p = .003$ ,  $d = 1.37$  respectively, but accuracies on vowel and consonant ending words are not significantly different,  $t(14) = .30$ ,  $p = .39$ . These serve as evidence of learning the target regularities.

An analysis of their accuracy on extension items showed that their accuracy was significantly higher than chance,  $t(7) = 4.73$ ,  $p = 0.001$ ,  $d = 1.67$ . They achieved better-than-chance accuracy for both vowel and consonant ending words,  $t(7) = 5.00$ ,  $p < .0001$ ,  $d = 1.77$  and  $t(7) = 2.39$ ,  $p = .023$ ,  $d = 0.85$  respectively, with no significant difference on accuracies for vowel and consonant ending words,  $t(14) = 1.25$ ,  $p = .15$ . Such findings revealed that the resultant knowledge was abstract rules rather than memorized chunks. Participants were sensitive to the difference between the ending phoneme (vowel or consonant) and syllable type (open and closed syllables) in relation to stress placement and were able to apply their abstract knowledge to novel items.

**Control:** The control group completed only the testing phase. Their accuracy on critical items was not significantly higher than chance,  $M = 52.0\%$ ,  $SD = 1.24$ ,  $SEM = .27$   $t(21) = .74$ ,  $p = 2.33$ .

## Conclusion

The two experiments above suggest that, under incidental learning conditions, young adults were able to learn L2 word stress rules, which are supra-segmental phonological patterns, with only short and limited exposure. The knowledge obtained was implicit, abstract, and may be applied to novel items. Their lack of awareness was verified by verbal reports, binary confidence ratings and process dissociation procedure

in the experiments. We conclude that young adults are able to acquire L2 word stress implicitly.

The present study bears theoretical, methodological and pedagogical significance. On the theoretical level, it extends previous findings on the implicit learning of language: not only may syllable regularity (at the segmental level) and metrical stress rules be learnt implicitly (as shown in previous studies), but sensitivity to lexical stress rules (at the supra-segmental level) may also develop without awareness. This raises the possibility of implicit learning of other kinds of prosodic rules such as tonal rules. Importantly, the rules and stimuli in the experiment were all based on a natural language and so there is little question of transferability of findings to the context of language acquisition.

Our study is also methodologically interesting as it is the first implicit learning study which integrates verbal reports, subjective measures of confidence and process dissociation procedure to establish strict criteria for awareness measurement. It is also, to our knowledge, one of the first successful attempts to apply the process dissociation procedure outside of SRT tasks. Based on our data, the verbal reports were useful in identifying three aware participants who were able to verbalize partial knowledge of the target rules. However, other participants whose awareness was not reflected in the verbal reports nevertheless performed differently in the inclusion-exclusion tasks, which appeared to be more sensitive in identifying participants with low confidence or low awareness about the rules. The findings demonstrated the usefulness of inclusion-exclusion tasks as an objective measure of participants’ awareness, and their potentially higher sensitivity than verbal reports.

From the perspective of L2 pedagogy, the present study provides an insight into how L2 stress patterns may be taught and learnt. The possibility of learning L2 stress patterns implicitly offers an alternative to the widely-adopted explicit approach to teaching word stress. It would be theoretically and practically interesting to determine the relative effectiveness of explicit and implicit teaching and learning of word stress and explore their potential synergetic effects in different settings.

Other further research directions include exploring 1) the implicit learning of other supra-segmental phonological rules such as tonal rules; 2) whether the ability to implicitly learn L2 phonological rules is sensitive to individual differences; and 3) whether age has a significant impact on the implicit learning of L2 phonological patterns.

## Abstract

Many psychologically interesting tasks (e.g., reading, lexical decision, semantic categorisation and synonym judgement) require the manipulation of semantic representations. To produce a good computational model of these tasks, it is important to represent semantic information in a realistic manner. This paper aimed to find a method for generating artificial semantic codes, which would be suitable for modelling semantic knowledge. The desired computational criteria for semantic representations included: (1) binary coding; (2) sparse coding; (3) fixed number of active units in a semantic vector; (4) scalable semantic vectors and (5) preservation of realistic internal semantic structure. Several existing methods for generating semantic representations were evaluated against the criteria. The correlated occurrence analogue to the lexical semantics (COALS) system (Rohde, Gonnerman & Plaut, 2006) was selected as the most suitable candidate because it satisfied most of the desired criteria. Semantic vectors generated from the COALS system were converted into binary representations and assessed on their ability to reproduce human semantic category judgements using stimuli from a previous study (Garrard, Lambon Ralph, Hodges & Patterson, 2001). Intriguingly the best performing sets of semantic vectors included 5 positive features and 15 negative features. Positive features are elements that encode the likely presence of a particular attribute whereas negative features encode its absence. These results suggest that including both positive and negative attributes generates a better category structure than the more traditional method of selecting only positive attributes.

**Keywords:** semantics; semantic representations; neural networks; computational modelling; connectionist models.

## Introduction

Computational models are frequently used to simulate human behavioural data and help understand the underlying cognitive processes. Any type of computational model requires decisions to be made about what representation scheme to use. Semantic representations are particularly important for models of many linguistic processes including spoken and written language. This paper aims to find a method of generating semantic representations, which can fulfil a set of requirements derived from the constraints imposed by incorporating semantic knowledge within a large-scale connectionist model. A list of criteria that we

considered essential for sophisticated and efficient simulation using a connectionist model includes: (1) Binary coding: a binary coding scheme is essential for use in connectionist models because the models consist of many neuron-like units whose activation values vary between 0 and 1. The models are trained to match their activation values to predefined targets, which need to be at the extreme ends of the possible activations; (2) Sparse coding: a sparse coding scheme is one in which an item is represented by using a small number of active units in each vector. A sparse representation is attractive from a computational viewpoint because it allows efficient computation. By controlling sparseness, the redundancy of a code can be minimized and learning is generally fast and relatively easy. Importantly, it is likely to reflect the natural structure of the representation system in the brain; (3) Fixed number of active units in each vector: the idea of using a fixed number of active units in each semantic vector is not common in most existing coding schemes. However, it has an advantage that this coding is uniform and it makes sense to think about how similar items are by measuring the Euclidian distance between them – if items have different numbers of features then measuring Euclidian distance does not give a good indication of similarity (Furber, Bainbridge, Cumpstey & Temple, 2004). For connectionist models, there is a particular reason to want to adopt a fixed number of active units, which is that only the active units can contribute to activation in later layers. Units with a zero level of activation do not propagate information in the network and therefore do not generate any weight updates in response to the error signal; (4) Scalable semantic vectors: to keep the simulations computationally tractable, it is important to keep the size of semantic vectors manageable. Vector size is an important design consideration because it determines how many units in the model are needed for modelling semantic knowledge. Given a code length  $n$ , it has a maximum theoretical number of items that it can code for, which is  $2^n$ . The capacity increases dramatically as the code length grows. Thus, the selection of the vector length also needs to consider the number of items to be represented; (5) Preservation of inherent semantic structure: the most important criterion is that the semantic vectors can support human-like semantic classifications. They need to preserve

the inherent semantic structure of the lexicon. Words which are semantically similar should be represented by vectors that are relatively close in the semantic space; by contrast, semantically unrelated words should tend to be far from each other. Preserving these semantic relationships will allow for the possibility of modelling tasks like categorization and synonym judgment, which are commonly used to probe semantic effects.

### Review of existing semantic representation schemes

Several semantic representation schemes have been proposed either for behavioural studies or for use in computational modelling (Dilkina, McClelland & Plaut, 2008; Harm & Seidenberg, 2004; Plaut, 1997; Rogers, Lambon Ralph, Garrard, Bozeat, McClelland, Hodges & Patterson, 2004). These schemes are based on different techniques and there does not seem to be a consensus view as to how to produce a set of representations. It is therefore important to review these competing coding schemes from a modelling perspective using the criteria described above.

**Feature Norms** One traditional method is to obtain the feature norms through experiments (e.g., McRae, Cree, Seidenberg & McNorgan, 2005). In these experiments, subjects are given a list of words and asked to write down attributes about each word. To categorise the attributes and make proper constraints on subjects' responses, some lexical relations such as "is" and "has" are used to prompt subjects to list the features of the stimulus word. The most commonly listed features for a particular word are then considered as the core semantic attributes for that word. The collected attributes for an item can be easily converted into binary codes with the presence of an attribute coded as "1" and the absence as "0". Controlling for sparseness is not so easy, but it may be possible to rank the features by the number of subjects that identified them, and use this as a method for deciding which features to drop. Moreover, this method is not very flexible and practically can only be used for a small set of words.

**Arbitrary Features** Another way to generate semantic representations is to use random features. Features for a word are assigned randomly but the assignments may still respect broader aspects of semantic knowledge such as category knowledge. For example, the words within the same category can be designed to share more features than words belonging to different categories. This method has been applied to various computational studies designed to capture abstract semantic properties including simulations of lexical decision (e.g., Plaut, 1997) and semantic impairment (e.g., Rogers et al., 2004). The features for an item are assigned manually and are binary codes. The control of sparseness can be achieved by adjusting the fraction of the number of active units in a vector over the code length. The fixed number of active units in a vector is also controllable. In addition, the size of vector length is scalable and determined by the modellers. Although this

coding scheme is good for producing coarsely structured semantic representations, it is not easily scalable and it would be very difficult to generate an artificial semantic structure that can capture the complexity found in human semantics.

**Co-occurrence Statistics** Semantic representations can also be derived from very large text corpora by evaluating which words appear in similar types of documents or co-occur within a fixed window. Several semantic representation schemes have been developed on the basis of this statistical co-occurrence including Latent Semantic Analysis (LSA) (e.g., Landauer, Foltz & Laham, 1998), Hyperspace Analogue to Language (HAL) (e.g., Lund & Burgess, 1996) and Correlated Occurrence Analogue to Lexical Semantics (COALS) (Rohde et al., 2006). These methods are all based on similar ideas but they are slightly different in the ways they collect data and deal with the high-dimensional co-occurrence matrices. LSA derives vectors based on a collection of segmented documents in which the number of occurrences of a word in various types of documents is computed as an element in the high-dimensional co-occurrence matrix. The dimensionality of the matrix is then reduced by using Singular Value Decomposition (SVD) while preserving the semantic relations between words as much as possible. Unlike LSA, the derivations in both HAL and COALS are based on words co-occurring within a fixed window in an un-segmented document. The key differences between these three systems are in their ways of expressing the tendency of two words to co-occur: LSA computes the cosines between the vectors of two words, HAL uses distance measure and COALS uses the correlation measure. In addition, HAL reduces the dimensionality of the matrices by eliminating all but the few thousand columns with the largest variant values, which is different from the SVD technique adopted by both LSA and COALS (see Rohde et al., 2006 for more detailed comparisons).

The semantic vectors generated by reducing a high-dimensional matrix are typically real-value vectors but COALS also provides binary-valued vectors. For the other two systems, however, it is relatively easy to convert the real values to binary values by thresholding. The vectors with values greater than a certain level are replaced with the value "1" and all others are replaced with the value "0". Sparse coding can be enforced by adjusting the threshold level used when converting real-value vectors into binary. Similarly, the fixed number of active units in a vector can be designed by modellers during the binarization process by restricting the number of 1's to the top *n* elements of the vector. By using the co-occurrence statistics, the sizes of semantic vectors for lexical items are scalable, which is particularly suitable for the computational modellers seeking a set of representations with low computational cost. The key advantage of this scheme is that it should be able to generate realistic semantic codes for any word lists of any length provided that the latent semantic information contained in the structure of large corpora is sufficiently

detailed and can be extracted efficiently.

**WordNet** WordNet is an online semantic database, which was developed by Miller in 1990. Information in WordNet is organised by many synonymous sets. These sets are linked by their lexical relations such as “is a” or “is part of” relations. A unique feature of WordNet is that it provides multiple word senses, which can be obtained from the database separately while other semantic systems do not distinguish between word senses. Similar to the feature norms, the attributes generated from WordNet have direct semantic interpretations. The semantic vectors generated by WordNet are binary to represent the presence and the absence of attributes, and generally rather sparse. But the number of semantic features for each word is not fixed and the range could be very wide. The size of the semantic vectors is less flexible because the size depends on how words relate to each other within the word list of interest. As a general rule the longer the list of lexical items to be coded the longer resultant semantic vector. Since the vectors are, directly derived from many synonymous sets in Word Net based on the researchers’ semantic knowledge, the semantic structure is likely to be well preserved.

Table 1 summarises the results of these evaluations. Among these, COALS appears to be the best choice because it satisfied most of the criteria than other systems.

Table 1: Summary of the evaluations of different semantic representation schemes

	Feature Norms	Arbitrary Features	Co-occurrence Statistics			Word Net
			LSA	HAL	COALS	
Criterion 1 (Binary coding)	✓	✓	Δ	Δ	✓	✓
Criterion 2 (Sparse Coding)	Δ	Δ	Δ	Δ	Δ	✓
Criterion 3 (Fixed Number of Active Units)	X	Δ	Δ	Δ	Δ	X
Criterion 4 (Scalability)	X	✓	✓	✓	✓	X
Criterion 5 (Semantic Structure)	✓	X	✓	✓	✓	✓

Note: ✓: good fit; Δ: can be adapted to fit; X: poor fit or difficult to support

## Method

The correlated occurrence analogue to the lexical semantics (COALS) system (Rohde et al., 2006) is designed to be very flexible. Although two of the criteria (i.e., sparse coding and fixed number of active units) are outside the scope of the original COALS system, they could be easily achieved by manipulating the semantic vectors generated from the system. However, it is crucial to examine whether the semantic codes generated from COALS preserve enough semantic structure that they can be used to predict the human semantic data. In addition it is important to investigate the best method of transforming the COALS vectors into binary codes. To generate binary vectors Rohde and colleagues simply set negative components to 0 and positive components to 1 based on the original real-valued

vector from the SVD. This means that information contained in negative parts of the vector is lost. Thus the questions asked here are whether negative components also contribute to a good semantic similarity structure and, if so, what is the optimum number of positive and negative features required to produce a best fit to human data. The following sections describe how to generate semantic vectors based on COALS in a way that satisfies all the criteria discussed previously. We then go on to compare the performance of the vectors on a semantic categorisation task using human data taken from Garrard et al.’s (2001) categorisation study.

## Generating Semantic Vectors based on COALS

To explore whether negative components were as important as positive components, a binarization process of coding both positive and negative components were used. A 100-dimensional semantic vector was generated for all items in the Garrard et al.’s (2001) word list except one item “watering can”, which was discarded because the system did not support the compound words. The 100-dimensional vector was duplicated to create two 100-dimensional vectors with the first 100 dimensions coding the positive elements and the second 100 dimensions coding the negative elements. The two 100-dimensional vectors were combined into a 200-dimensional semantic vector. The first half of the 200-dimensional vector contained only the positive components and the second half of the 200-dimensional vector contained only the absolute values of negative components. Assuming the best number of positive and negative components is  $n$  and  $m$  respectively then the top  $n$  values of the first half of the combined vector and the top  $m$  values of the second half of the vector were selected as the key features. All the selected features were set to 1 and others are 0. This resulted in a 200-dimensional binary vector with the property that matching elements from the two halves of this vector (e.g., the 1<sup>st</sup> and 101<sup>st</sup> elements) code for the same feature and have a special relationship whereby if one is on then the other must be off. (Note: both paired vectors can be off indicating that neither the presence nor the absence of this feature is particularly important to the meaning of the item.)

## Testing Procedure

To determine the usefulness of the binary semantic codes we examined the relationship between the category structures derived from the artificially generated sets of semantic vectors and human data taken from Garrard et al.’s (2001) study. In their study, Garrard and colleagues asked subjects to categorise items into a living thing group and nonliving thing group. On a finer scale, the living thing group can be divided into animals, birds and fruit and the nonliving thing group also can be subdivided into household objects, tools and vehicles. There were in total 6 subgroups. Semantic vectors for 61 items in the Garrard et al.’s (2001) list were generated using the method described above. Each vector had a length of 200. The  $n$  features of the first half of

the semantic vector represent the important positive features and the  $m$  features of the second half of the semantic vector indicate the important negative features. The numbers of positive features ( $n$ ) and negative features ( $m$ ) were varied to determine the optimum values of  $n$  and  $m$ .

### Evaluation of semantic vectors

Two parameters based on semantic distances between words can be used to evaluate the match with the semantic structure in the human data: distance validity index ( $DVI$ ) and distance ratio ( $DR$ ).  $DVI$  counts the number of groups where the within group distance (i.e., the averaged Euclidean distance between items in the same group) is smaller than all the between group distances (i.e., the averaged Euclidean distance between items in the different groups). The larger the value of  $DVI$  the better the semantic categories have been partitioned. This is rather coarse measure of semantic structure and for this data the value of  $DVI$  ranges from 1 to 6 (i.e., the number of subgroups). The expected best value is  $DVI=6$  indicating that all the within group distances are smaller than between group distances.  $DR$  computes the average of all the distance ratios. The distance ratio is the sum of between group distances to the sum of within group distances. Ideally there will be a larger between group distance and a smaller within group distance so that  $DR$  should be as large as possible. It should be noted that the value of  $DR$  is also positively correlated with the total number of features within a vector because it is computed on the basis of the Euclidean distance. The distance for the vectors having more features is generally larger than that for the vectors having less features. This indicates that  $DR$  is only a useful comparator for code sets with the same number of features.

Thus far we have tacitly assumed that the subgroups will be exactly the same as those from human data. However, even if a set of semantic codes can be shown to have a  $DVI$  of 6 and a high  $DR$ , it cannot be guaranteed that all its items would actually be categorized into the correct groups based solely on their intrinsic correlations. To evaluate this we needed to test whether the clustering results based on the intrinsic correlations among semantic vectors were similar to semantic categories from human data. We tested this by using the adjusted rand index ( $ARI$ ) (Hubert & Arabie, 1985).  $ARI$  is commonly used to measure the similarity between two different ways of partitioning a set of items. To compare the partitions of human data and the artificial semantic codes,  $ARI$  counts the number of agreements and disagreements between them. It ranges from 0 to 1, with 0 indicating the two partitions are completely different and with 1 indicating the two partitions are exactly the same.

All three indices ( $DVI$ ,  $DR$  and  $ARI$ ) were used to evaluate the semantic vectors. The maximum number of active features including positive and negative in a semantic vector was set to 40 and the minimum was 10. Thus, the population sparseness ranged from 0.05 to 0.2. The numbers of positive ( $n$ ) and negative ( $m$ ) features varied in a complementary manner which was dependent on the total

active features ( $t$ ). To find out what were the optimum numbers of  $n$  and  $m$ , 24 different combinations of positive and negative features were assessed by using the three indices:  $DVI$ ,  $DR$  and  $ARI$ . The evaluations were performed in two steps. The first step was to compare different sets of semantic vectors based on the predefined categories by choosing the combinations with a  $DVI$  of 6 and using the  $DR$  score to select the top candidates within groups with the same number of features. The second step was to use the  $ARI$  score as an independent additional test to confirm that the candidate with the highest  $ARI$  was also one of the possible candidates from the first step.

## Results

### Searching the best semantic vectors

Table 2 shows the results of the six candidates from 24 sets of semantic codes with different combinations of positive and negative features, in which they had the maximum possible number of  $DVI$  (6). The set with 5 positive and 15 negative features (ID 2) had the largest value of  $ARI$ . This set was one of those with the maximum value of  $DVI$  and the value of  $DR$  for this set was also larger than that for other candidate sets with the same total number of features. These results suggest that for this application a set of semantic vectors with 5 positive features and 15 negative features best captures the semantic categories generated from human data. It is also interesting to note that among the top candidates ID 1 was the only one with only positive features and its  $ARI$  was much lower than that for all the other possible candidates. The differences between  $ARI$  for the top candidate and for the two other candidates (ID 3 and ID 5) which included both positive and negative features were relatively small, suggesting that the exact number of positive and negative features may not be critical. However the majority of candidate codes (4/6) did have more negative than positive features.

Table 2: Results of searching the best semantic vectors

ID	Total	Positive	Negative	$DVI$	$DR$	$ARI$
1	10	10	0	6	5.62	0.38
2	20	5	15	6	5.74	<b>0.57</b>
3	20	10	10	6	5.70	0.54
4	30	5	25	6	5.83	0.45
5	30	10	20	6	5.77	0.52
6	40	5	35	6	5.84	0.49

Note: ID: identification;  $DVI$ : distance validity index;  $DR$ : distance ratio;  $ARI$ : adjusted rand index

To further test the significance of including negative codes, 20 sets of semantic codes for each of three groups (positive, neutral and negative-biased) were generated. Each set had the same number of features, ranging from 10 to 48. In the positive group, the vector included only positive

features whereas the vector in the neutral group had an equal number of positive and negative features. In the negative-biased group, the vector had more negative than positive features with a ratio of 3:1. One-tailed paired t-tests were conducted to compare both the neutral and negative-biased groups to the positive group, where the three indices were used as dependent variables. As predicted, the *DVIs* and *ARIs* of the neutral and negative-biased groups were significantly higher than that for the positive group (Table 3). For the *DRs*, the difference between the negative-biased and the positive groups was not significant while there was a significantly lower mean *DR* for the neutral group than for the positive group. The comparison between the negative-bias and neutral groups showed that both *DVI* and *DR* were higher for the negative-biased group than for the neutral group and there was no difference in their *ARIs*. Overall the results demonstrated the negative-biased group was superior to both the positive and neutral groups, confirming that the inclusion of negative codes is important to capturing the way semantic knowledge is represented in humans.

Table 3: Results of Significance Tests

Group	Index	MD	MSE	t Value	df	P Value
Neutral -Positive	<i>DVI</i>	0.05	0.01	3.63	19	.001*
	<i>DR</i>	-0.10	0.03	-3.08	19	.003*
	<i>ARI</i>	0.45	0.14	3.33	19	.002*
Negative-Biased -Positive	<i>DVI</i>	0.04	0.02	1.78	19	.046*
	<i>DR</i>	-0.04	0.03	-1.25	19	.114
	<i>ARI</i>	0.75	0.12	6.10	19	<.001*
Negative-Biased -Neutral	<i>DVI</i>	0.30	0.11	2.85	19	.005*
	<i>DR</i>	0.06	0.01	7.58	19	<.001*
	<i>ARI</i>	-0.02	0.02	-0.87	19	.197

Note: *DVI*: distance validity index; *DR*: distance ratio; *ARI*: adjusted rand index  
MD: mean difference; MSE: mean standard error; \*: *P* value is significant at the .05 level.

## Hierarchical Clustering Analysis

Figure 1 shows the hierarchical clustering based on the optimum vectors indicated in Table 2.

Figure 1: Hierarchical cluster analysis of 61 words based on the 200-dimensional semantic vectors with 5 positive and 15 negative features. (Items coloured base on human categories: Animal (Red), Birds (Orange), Fruit (Purple), Tool (Green), H'hold (Dark Blue), Vehicles (Purple)).

The y axis shows the Jaccard's distance, a measure of similarity between words. The lower the value the more similar the clusters are. The semantic vectors can accurately represent the semantic categories at a coarse scale, which means that the living things and nonliving things are well separated. To compare the clustering results with human data collected by Garrard et al. (2001), the items in Figure 1 were coloured according to its category in the human semantic data. This clearly shows whether the clustering results were consistent with human categories. Ideally, items with the same colour would be clustered together, indicating the items are clustered into the same group as in the human category. Most of the items are correctly clustered. However there are a few interesting exceptions, for example, the word "chicken" was clustered into the fruit category (items coloured in purple) based on the artificial semantic codes, while it should have been clustered into the bird category (Orange). Presumably this is because in many texts the word "chicken" might more frequently co-occur with other food (including fruit) in the kitchen context so this category might be more accurately described as food. Within the nonliving things, it appears that the broader category of tool is well distinguished from the vehicle group but the boundaries between tools and household items is less clear. It is likely that most of the tools and household objects tend to occur in a similar context in the text so it would be difficult to differentiate them in a fine scale by using the co-occurrence statistic approach.

## General Discussion

Several schemes for generating semantic codes have been reviewed in this paper with a focus on the requirements of computational modelling. The primary aim was to determine an appropriate system for representing semantic knowledge, which could be used for a large-scale computational modelling of semantic related tasks.

The desired computational criteria were as follows: (1) binary coding; (2) sparse coding; (3) fixed number of active units in a vector; (4) scalable vectors; (5) preservation of inherent semantic structure. The COALS system (Rohde et al., 2006) provided the best fit to the criteria. The original COALS system discretizes the real-valued vectors based only on the positive components. However, we evaluated codes with varying numbers of positive and negative features by comparing the semantic categories generated from the artificial semantic codes with human category data from Garrard et al.'s (2001) study. The results showed that a set of semantic vectors having 5 positive and 15 negative features could best account for the human semantic categories. It was perhaps surprising that the best binary vectors found here had more negative features than positive features (i.e., 15 negative features v.s. 5 positive features). This is at variance with the prevalent assumption that only positive components should be used to construct semantic codes. Positive features reveal what attributes are likely to be present; in contrast, the negative features provide information about what attributes are likely to be absent. So this result implies that knowledge of the absence of features (e.g., knowing that washing machines cannot walk) is as important as knowledge of positive features. Given both of these types of information, it is possible to separate categories on the basis of their distance in the semantic space, as the optimisation results shown in Table 2. Further significance tests reveal that there was a clear trend for semantic vectors containing both positive and negative features to show a more human-like semantic structure, suggesting that this may be a generally applicable principle. Overall the best performing set of semantic vectors matched the human categorisation data quite well. Further work may be conducted to investigate the performance of the present semantic codes on other types of semantic tasks (e.g., synonym judgement) for a more complete evaluation.

In addition, there are some inherent limitations of using these semantic vectors. The first is that the semantic features are not interpretable because they only encode the semantic regularities among word meanings. What exactly the feature represents is difficult to interpret. But this is only a problem in applications where a direct interpretation of features is required. Another limitation is that it can generate good semantic vectors for most of the uninflected words but it could be difficult to properly account for the deeper meaning of words like morphological regularities (e.g., bake/baker) (Harm, 2002), which would require some additional coding.

To summarise, a novel semantic representation scheme was produced based on modifications to the COALS system. This was evaluated against human categorisation data, and the resultant coding scheme was able to reproduce the human data quite closely. The key finding was that the negative features, which indicate what attributes definitely do not belong to a lexical item, were at least as important as the positive features. The semantic system developed here can be applied to generate semantic codes for a larger word

list used to train more sophisticated computational models.

## Abstract

Employing the implicit priming task, we examined whether Chinese words that shared the initial onset consonant could be typed, using the phonetic-based method (called zhuyin), with faster response times than words that did not share the initial onset consonant. We also examined the effect of sharing the initial tonal syllable. A significant onset preparation effect and a significant syllable preparation effect were both observed. The latter was found to vary linearly with the number of segments in the syllable. The slope of 63 ms was similar to the 70-ms onset effect, suggesting that the syllable effect was segment-based. The results contrasted with the lack of an onset effect previously reported for speaking, and were interpreted as supporting the Output Constraint Hypothesis which states that the kind of outputs a production system is designed to produce (speaking vs. typing) can flexibly and adaptively alter the way the system is organized and operates.

**Keywords:** Chinese; Typing; Speaking; Phonological Encoding; Word-Form Encoding

## Introduction

With the popularization of computers and internet, typing has become a new form of communication that may someday dominate our social life. It is, therefore, of interest to study the cognitive processes involved in typing, in particular, how typing as a language production activity may differ from speaking. Past research has studied typing more as a skilled motor activity during transcription (Shaffer, 1975; Sternberg et al., 1978; Rumelhart & Norman, 1982; Norman & Rumelhart, 1983; Salthouse, 1986; Crump & Logan, 2010a, 2010b) than as a language production activity.

In a spoken language production model (e.g., Dell, 1986; MacKay, 1987; Levelt et al., 1999), word form encoding refers to the hierarchically organized processes that translate the semantic/syntactic representation of a word into its phonological and phonetic forms. The processes involve retrieving the structural frame and the phonemic segments of a word, followed by assigning, in a sequential order, the segments to their categorized slots in the frame. An issue under much debate concerns the units that make up the stored phonological representation of a word and drive the phonological encoding process. In some models, they contain the syllables (e.g., Dell, 1986; MacKay, 1987), while in others they do not (e.g., Levelt et al., 1999). Prevailing evidence from Indo-European languages suggests that the units are the segments (e.g., Meyer, 1990, 1991; Roelofs & Meyer, 1998; Roelofs, 1999; Schiller, 1998, 2004; Schiller & Costa, 2006). But in Mandarin Chinese, they appear to be the syllables (J.-Y. Chen et al., 2002; J.-Y. Chen et al., 2003; T.-M. Chen et al., 2007; O'Seaghdha et al., 2010). The

varying units of a word's stored phonological representation in different languages may have something to do with the rhythmic structures of the languages (Cutler et al., 1986; Otake et al., 1996).

The units may also vary with different kinds of outputs targeted by different production tasks within the same language, e.g., typing as opposed to speaking. Mandarin Chinese provides an excellent testing bed for evaluating this hypothesis. A popular method of typing in Chinese uses the phonetic alphabet called zhuyin in Taiwan and pinyin in China. For example, to type the character 潔 ('clean', jie2) in zhuyin, the onset consonant j, the medial glide i, the rhyme e, and the tone 2 are typed on a keyboard sequentially, followed by the selection among a list of homophones. To this extent, zhuyin typing requires accessing the phonological codes of the character, much like speaking. Employing a traditional (unmasked) priming task and comparing naming with zhuyin typing, our previous study (Chen & Li, 2011) investigated whether syllable onset priming was absent in naming, which would be consistent with our findings for speaking (J.-Y. Chen et al., 2002; J.-Y. Chen et al., 2009; O'Seaghdha et al., 2010), but might be present in zhuyin typing.

A possible reason for predicting onset priming in zhuyin typing is that the output of zhuyin typing consists of discrete manual keystrokes that correspond to the onset, medial, rhyme and tone of a syllable. This is different from the output of naming (and speaking), which consists of syllable-sized articulatory gestures. That is, the different output characteristics constrain the way a word is planned during speaking and typing. Indeed, Berg (2002) observed that slips of the key resembled slips of the pen, but not slips of the tongue. He suggested that 'speaking is characterized by a hierarchical strategy of activation while typewriting is subject to the so-called staircase strategy of serialization in which activation is a function of linear distance' (p.185). Although such a prediction seems obvious and only expected, there are reasons to predict otherwise too. Studying handwriting, Kandel and colleagues (Kandel et al., 2006; Lambert et al., 2007; Alvarez et al., 2009) found that interletter intervals were longer between syllables than within syllables and that the number of syllables of a word modulated the time course of handwriting production, indicating that word syllable structure constrains motor production both in French and Spanish. Given that very similar processes are believed to underlie typing and writing (Berg, 2002), it is reasonable to assume that syllables are also essential units of processing in typing. Direct evidence for this assumption has also been reported (Nottbusch et al., 2005). The results from primed naming and primed zhuyin

typing showed significant onset priming for zhuyin typing but not for naming, supporting the hypothesis that the units of the stored phonological representation of a word vary with different kinds of outputs targeted by different production tasks within the same language. We will refer to this hypothesis as the Output Constraint Hypothesis (OCH).

In the present study, the OCH was tested further with the implicit priming task. The implicit priming task (also known as the form preparation task) has been used extensively in investigating the word form encoding processes in spoken production (Meyer, 1990). The task requires the participants to learn a set of prompt-target word pairs during the learning phase. During the testing phase, the prompt words are shown one at a time and the participants have to say the corresponding target words as responses. The target words are arranged in a homogeneous context such that they share the initial portion of their phonological forms (e.g., the onset consonant). In a heterogeneous context, the same target words are re-arranged such that they no longer share the initial portion of the phonological forms. Response latencies tend to be shorter when the target words are produced, upon the presentation of the prompt words, in the homogeneous context than in the heterogeneous context. The response benefit is attributed to the suspension-resumption mechanism in the production system, according to which the system prepares a word from left to right in an incremental fashion, and it can prepare the word as far to the right as the left portion is known. The system suspends the operation when everything that is known has been prepared, and resumes operation as soon as information about the rest of the word is received. It is assumed that the portion that can be prepared by the system represents the unit of word form encoding during spoken production (Roelofs, 1997a, 1997b). Sufficient evidence has indicated that this unit must be the size of a syllable in Mandarin Chinese, but can be a phonemic segment in English and Dutch.

Because previous studies in Mandarin Chinese have already consistently documented no onset preparation effect with an implicit priming task in speaking (Chen, Chen, & Dell, 2002; O'Seaghdha, Chen, & Chen, 2010), the present study examined typing only, but contrasted the findings with those reported for speaking base on the same materials. The OCH predicts that the onset segment of a Chinese word can be prepared during zhuyin typing, i.e., an onset preparation effect is predicted in an implicit priming task of zhuyin typing.

In addition to the syllable onset, the full syllable was also examined. If phonological encoding in zhuyin typing is segment-driven as predicted by the OCH, a syllable preparation effect that is a function of the number of segments in a syllable should be observed.

## Method

### Participants

Sixteen native Mandarin Chinese speakers from the student body of National Cheng Kung University were recruited for

the onset experiment, and another sixteen for the syllable experiment. They were all native and habitual zhuyin typists, i.e., they learned the zhuyin typing when they first learned typing and have been typing in zhuyin ever since. All the participants had normal or corrected-to-normal vision and they were paid for participation.

### Apparatus and Materials

The experiment was programmed in DMDX (Forster & Forster, 2003) and run on a personal computer (Intel® Core™2 Quad CPU, Q6600@2.40GHz) with a 20-inch LED screen (32bits, 1400x1050 pixels, 8-ms refresh rate) and a standard keyboard that included marks of the zhuyin letters.

The stimulus materials for the onset experiment were disyllabic words taken out of Experiment 5 of J.-Y. Chen et al. (2002). They consisted of four sets of prompt-target word pairs, with four pairs in each set. The prompt and the target in a pair bore clear semantic or associative relationship such that they could be learned easily. The target words were chosen such that they shared the same onset consonant of the first syllable in a set. Across the four sets, four different onset consonants were used (m, d, sh, l). These formed the homogeneous sets (see Set 1-4 in Table 1). The same target words were reshuffled to form the four heterogeneous sets such that within a set the target words no longer shared the onset consonant (see Set 5-8 in Table 1). The arrangement of the stimulus materials was identical to that of J.-Y. Chen et al. (2002) Experiment 5.

The stimulus materials for the syllable experiment were disyllabic words taken out of Experiment 3 of T.-M. Chen & J.-Y. Chen (2006) (see Table 2), and arranged in the same way. The target words in a homogeneous set shared the first tonal syllables.

Table 1: Target words arranged as homogeneous sets (1-4) and heterogeneous sets (5-8) for the onset experiment.

Homogeneous				
Set	1	2	3	4
Heterogeneous	mo1-cai3 摸彩 draw lots	da1-ing4 答應 promise	shu1-fa3 書法 calligraphy	luo1-suo1 囉唆 nagging
	ma2-que4 麻雀 sparrow	de2-kuo2 德國 Germany	shi2-yan4 實驗 experiment	li2-ge1 驪歌 farewell song
	mu3-dan1 牡丹 peony	du3-buo2 賭博 gambling	she3-qi4 捨棄 abandon	la3-ba1 喇叭 horn
	mi4-yue4 蜜月 honeymoon	di4-yu4 地獄 hell	shou4-ruo4 瘦弱 weak	lu4-shi1 律師 lawyer

Table 2: Target words arranged as homogeneous sets (1-4) and heterogeneous sets (5-8) for the syllable experiment.

Homogeneous				
Set	1	2	3	4
Heterogeneous	5	xi1-gua1 西瓜 watermelon	hong2-shui3 洪水 flood	jia1-fa3 加法 addition
	6	xi1-fan4 稀飯 porridge	hong2-guan1 宏觀 macroscopic	yi4-wen2 軼聞 anecdote
	7	xi1-guan3 吸管 straw	jia1-bin1 嘉賓 honored guests	yi4-wei4 異味 peculiar smell
	8	xi1-shui3 溪水 stream	hong2-mo2 虹膜 iris	jia1-shi4 家事 household duty
			jia1-yao2 佳餚 delicacy	yi4-ren2 藝人 entertainer
				yi4-chu4 益處 benefit

## Design and Procedure

The design and the procedure were identical to the experiments where we took the materials from. Each pair in a set was repeated four times (the Repetition factor) so that there were 16 pairs and they appeared in a random order within a block. Half of the participants received the homogeneous sets first and the other half received the heterogeneous sets first (the Sequence factor). The participants went through the round of homogeneous and heterogeneous sets (the Context factor) three times (the Round factor) and in the same sequence. The type of onset consonants or syllables constituted another factor (Onset). The Sequence factor was a between-subjects factor while the rest were within-subjects factors.

During the learning phase, the participants were shown the four pairs of words in a set. They learned the association between the two words in each pair until they had memorized the pairs well. Then the target words were cued one at a time by their associated prompt words. When the participants succeeded in reporting the target words correctly without hesitation, they proceeded to the testing phase. Otherwise, they repeated the learning phase.

During the testing phase, each trial began with a 1000-Hz warning tone and two short dashed lines flanking a blank space at the center of the screen. The tone and the dashed lines appeared for 200 ms. The prompt word appeared in the previously flanked space 600 ms later. The prompt word stayed on the screen for 150 ms. Another 1850 ms elapsed before the trial ended. The participants were told to type in zhuyin the target word upon seeing the prompt word, as quickly and accurately as possible. The participants entered the zhuyin letters in the English input mode. Accordingly, no homophonous characters were shown for selection after the zhuyin letters of a character have been entered. Response latencies were measured, to the accuracy of milliseconds, from the presentation of the prompt word to

the striking of the first zhuyin letter. If no response was initiated within 2000 ms of the presentation of the prompt word, a feedback tone of 500 Hz was sounded for 200 ms. The next trial began after another 200 ms. A practice session containing four trials was given before the experiment began. The participants were seated 60 cm from the screen. Each character measured 1.6 cm in height and 1.1 cm in width at that viewing distance.

## Results

### Onset Experiment

Error rates were 2% in the homogeneous condition and 4% in the heterogeneous condition. Response times ranged from 374 to 1946 ms for the homogeneous trials (mean: 825, SD: 190), and ranged from 354 to 1988 ms for the heterogeneous trials (mean: 894, SD: 195). No apparent outliers were noted. All response times (RTs) for the correct trials were then analyzed using a linear mixed model (Statistical Analytic System, the PROC MIXED procedure) with subjects and items as random-effect variables and context, sequence, round, repetition as fixed-effect variables. Most notable in the analysis was the significant main effect of context:  $F(1, 14) = 33.67, p < .0001$ . The mean RT was 824 ms in the homogeneous context and 894 ms in the heterogeneous context. The difference represents an onset preparation effect of 70 ms. The context effect varied with sequence:  $F(1, 1465) = 4.92, p < .03$ , being greater when the heterogeneous sets appeared first than when the homogeneous sets appeared first. The context by sequence interaction also varied with round:  $F(2, 1465) = 8.46, p < .0005$ . The three-way interaction is manifested as the context effect displaying an increasing trend when the homogeneous trials were done first and a decreasing trend when the heterogeneous trials were done first (see Table 2). The remaining effects are not enumerated here because they were either non-significant ( $p$ 's  $> .06$ ) if they involved the context factor, or significant but did not involve the context factor. Table 3 summarizes the results by presenting the mean RTs as a function of context, round, and sequence.

Table 3: Mean RTs (SEs in the parentheses) as a function of context, round, and sequence for the onset experiment.

Sequence	Round	Homo- geneous Context	Hetero- geneous Context	Prepara- tion Effect
Homo- geneous First	1	909 (18)	932 (24)	23
	2	824 (20)	875 (18)	51
	3	789 (18)	848 (19)	59
	<b>Overall</b>	<b>841 (12)</b>	<b>885 (12)</b>	<b>44</b>
Hetero- geneous First	1	835 (20)	964 (17)	129
	2	787 (19)	876 (18)	89
	3	796 (22)	866 (19)	70
	<b>Overall</b>	<b>806 (12)</b>	<b>902 (11)</b>	<b>96</b>

Figure 1: Cumulative response latency distributions for the homogeneous context and the heterogeneous context for the onset experiment.

Although the participants were told to complete all key presses without hesitation or pauses once a response was initiated, it is possible that the homogenous context might have encouraged a strategic behavior in them to start the first key press without having planned for the subsequent keys. If this was the case, the duration of a response should be longer in the homogeneous context than in the heterogeneous context. Unfortunately, response durations were not available to rule out this possibility. However, we plotted cumulative response latency distributions for the two conditions, following Damian and Stadthagen-Gonzalez (2009). As Figure 1 shows, the differences between the two distributions are relatively uniform across the entire spectrum of response latencies, suggesting that the strategy of immaturely starting responses on homogeneous trials was not used by our participants. The similar distributions of the two conditions also rule out the possibility that participants were able to locate the first key and initiate a response on homogeneous trials sooner than on heterogeneous trials, where the first keys were different and took time to locate.

### Syllable Experiment

Error rates were 2% in the homogeneous condition and 5% in the heterogeneous condition. Response times less than 250 ms were excluded, making up 0.8% of all trials, before they were subject to the same kind of analysis as in the onset experiment. The context effect was significant, with the homogeneous RTs being 255 ms faster, on the average, than the heterogeneous RTs (620 ms vs. 875 ms):  $F(1, 14) = 69.98$ ,  $p < .0001$ . The context effect did not vary with sequence ( $p > .8$ ), but it increased significantly across rounds ( $p < .01$ ). The three-way interaction involving context was not significant,  $p > .19$ . Table 4 summarizes the results of the syllable experiment.

The cumulative distribution plot of Figure 2 shows no clear evidence of strategic responding for the homogeneous

trials. To examine if the syllable preparation effect increased with the number of segments in the syllable (tone being counted as a segment), a by-item linear regression analysis was performed, which revealed a slope of 63ms. This is fairly close to the 70 ms onset preparation effect.

Table 4: Mean RTs (SEs in the parentheses) as a function of context, round, and sequence for the syllable experiment.

Sequence	Round	Homo- geneous Context	Hetero- geneous Context	Prepara- tion Effect
Homo- geneous First	1	669 (29)	906 (17)	237
	2	591 (29)	870 (16)	279
	3	584 (32)	858 (14)	274
	<b>Overall</b>	<b>615 (18)</b>	<b>878 (9)</b>	<b>263</b>
Hetero- geneous First	1	678 (13)	916 (12)	238
	2	619 (18)	857 (10)	238
	3	577 (19)	842 (12)	265
	<b>Overall</b>	<b>625 (11)</b>	<b>872 (7)</b>	<b>247</b>

Figure 2: Cumulative response latency distributions for the homogeneous context and the heterogeneous context for the syllable experiment.

### Discussion

Employing the implicit priming task, a widely used tool for studying word form encoding in spoken production, we examined whether words that shared the initial onset consonant could be typed with faster response times than words that did not share the initial onset consonant. The result of the experiment was clear. There was a significant and sizeable onset preparation effect when words to be typed shared the initial onset consonant (70 ms). This contrasted interestingly with the small and non-significant onset effect observed in our previous work when the task was speaking (J.-Y. Chen et al., 2002, Experiment 5 with the same material: -1 ms; O'Seaghdha et al., 2010, Experiments 1-4 and 7 with different materials: 3, -6, 3, 4, 2 ms). We also observed a large tonal syllable preparation

effect which varied with the number of segments in the syllable. The slope of 63 ms was similar to the 70 ms onset preparation effect, suggesting that the syllable preparation effect was likely segment-based. This also contrasted interestingly with the syllable preparation effect previously observed for speaking, which could be more unambiguously attributed to the syllable. Together, these results extended the previous findings of significant onset priming for typing (30 ms) but no significant onset priming for naming (-5.6 ms) when an unmasked priming task was employed (Chen & Li, 2011).

Speaking a Chinese word and typing it in zhuyin take the same input for processing, i.e., the concept of the word. They also require retrieving the same phonological representation of the word. However, the two tasks have different goals, aiming at different outputs. The findings of the present study as well as the earlier one (Chen & Li, 2011) suggest that the form of the output can constrain the internal organization/mechanism of the production system. Speaking, aiming at syllable-sized gestures, requires a syllable-driven word form encoding process. Typing, aiming at segment-sized gestures, involves segment-sized word form encoding process. Thus, all production systems are not organized in the same way. The kind of outputs a production system is designed to produce can flexibly and adaptively alter the way the system is organized and operates.

It has been suggested that the traditional priming paradigm and the implicit priming paradigm tap different levels of word form encoding process (Levelt et al., 1999; Cholin, Schiller, & Levelt, 2004). Traditional priming works to pre-activate the segments of a word, facilitating its phonological encoding process. Its effect takes place at the early stage of phonological encoding. Implicit priming is said to work at this early stage of phonological encoding as well as at the later stages of phonological encoding and phonetic encoding (i.e., online syllabification and possibly accessing the mental syllabary). Because onset priming in zhuyin typing was observed with both the explicit priming paradigm and the implicit priming paradigm, it may be concluded that the production system respects the form of its output and gets ready for that form at the stage as early as the beginning of the word form encoding process.

One caveat against the above conclusion is that typing is typically much slower than speaking, indicating low automaticity, and this is perhaps the reason that typing is less hierarchically organized than speaking (Berg, 2002). Future work will investigate this with professional typists.

The output constraint is not unique to the production system only, but finds an analog in the perception system too, where it is the input that constrains how the perception system is organized and operates. For example, research has shown that the structural and functional basis of word recognition and reading varies between an alphabetic writing system like English and a logographic writing system like Chinese (Perfetti, Liu, & Tan, 2005; Tan, Spinks, Eden, Perfetti, & Siok, 2005; Tzeng & Hung, 1981; Kuo, Yeh, Duann, Wu et al., 2001; Kuo, Yeh, Lee, Wu et al.,

2003; Siok, Niu, Jin, Perfetti, & Tan, 2008; Siok, Perfetti, Jin, & Tan, 2004).

When building a model of language processing, a universal one is always preferred. But, even a universal model needs to incorporate flexible parameters and constraints to accommodate the variations across languages and tasks. One source of such constraints might be sought from the input and output a particular language system is designed to process. This view carries the Gibsonian tradition of emphasizing the role of environment in perception (Gibson, 1986), but extends it to production.

## Abstract

By some accounts, speakers of classifier languages such as Mandarin or Japanese, which lack count-mass syntax, require classifiers to specify individuated meanings of nouns. This paper examines this view by testing how Mandarin speakers interpret bare nouns and use classifier knowledge to guide quantification in four studies. Using a quantity judgment task, Study 1 found that Mandarin speakers interpret nouns like English speakers, regardless of their syntactic status as mass or count in English. Study 2 showed that Mandarin speakers quantified broken objects like English adults, again suggesting that Mandarin nouns specify criteria of individuation. Studies 3 and 4 together showed that classifiers are not typically required for individuation, except when the reference of nouns is semantically ambiguous (e.g., *rock*, *string*) and can denote either objects or substances. In sum, we argue that individuation can be specified lexically in classifier languages like Mandarin, and does not depend on classifier syntax.

**Keywords:** individuation; quantification; nouns; classifiers; word learning; Mandarin; mass-count syntax.

## Introduction

Languages differ in how they express reference to kinds of things. In English and other Indo-European languages, countable things like dogs and cups are typically referred to using count syntax (e.g., *those are dogs*), whereas uncountable entities like milk and sand are expressed as mass nouns (e.g., *that is some milk*). However, other languages, like Mandarin Chinese, make no such syntactic distinction. Instead, nouns in Mandarin, and related classifier languages like Japanese and Tsotsil Mayan, act much like mass nouns in English (Allan, 1980; Chierchia, 1998). Nouns cannot co-occur directly with numerals (*\*san bi* ‘three pen’), but instead require classifiers (CLs) for counting (*san CL-zhi bi* ‘three pens’, is literally translated to ‘three CL-stick pen’). Based on this syntactic distinction, some researchers have argued that nouns in classifier languages may not specify individuation lexically. Instead, languages like Mandarin may rely on classifiers – i.e., words like “bit” and “piece” – to syntactically specify units of individuation, resulting in a fundamental difference in how nouns encode meaning cross-linguistically (e.g., Borer, 2005; Huang & Lee, 2009; Lucy, 1992).

For example, according to Lucy (1992), in classifier languages such as Yucatec Mayan, all lexical nouns “are unspecified as to unit since they all require supplementary marking (i.e., numeral classifiers) in the context of numeral modification” (p. 73). Similarly, in her discussion of Mandarin Chinese, Borer (2005) argues that, “the need for a classifier projection to license counting vs. the absence of

classifiers in the context of mass interpretation confirms the claim that in the absence of classifiers, [noun] predicates in Chinese are interpreted as mass” (p. 108). Under this account, classifiers do not merely reflect the meaning provided by the noun, but actually supply units of individuation and quantification, just as English mass nouns require unitizers like “piece” to specify the unit.

Several studies have provided evidence for the view that only count nouns in mass-count languages lexically specify units of individuation. In one study, using a word extension task, Lucy found that when presented with an entity (e.g., a cardboard box), and asked to judge which of two alternatives was more similar, English speakers preferred a shape-matched choice (e.g., a plastic box) whereas Yucatec Mayans divided their choices between the shape-matched choice and a substance-matched alternative (e.g., a piece of cardboard; see also Lucy & Gaskins, 2001). In a subsequent study, Imai and Gentner (1997) found a similar result in Japanese speakers who were more likely to extend novel words on the basis of substance than on the basis of object kind relative to English speakers.

In more recent work, Huang and colleagues (Huang & Lee, 2009; Huang, 2009) used familiar words to examine noun semantics in Mandarin-speaking adults and children. Using a picture verification task, they found that Mandarin-speaking adults judged sentences containing a bare noun (*yizi* ‘chair’) as acceptable when these nouns were used to refer to either a whole object or just a piece of an object (e.g., *yizi*, or ‘chair’, was acceptable for a whole chair or half of a chair). However, when a sortal classifier was added to the noun (*zhang yizi* ‘a chair’), adults rejected pictures depicting object parts, while children continued to accept them. Based on this finding, they concluded that, first, learning sortal classifiers “initiates children into learning how individuals and non-individuals are encoded in the language” (Huang, 2009: 150), and second, nouns do not have individuated meanings independent of classifiers (see also Borer 2005). Thus, on their view, the combination of a classifier and noun specifies criteria for individuation.

Huang and Lee’s interpretation of these findings is tempered, however, by the fact that many of the nouns they considered to be count in English were in fact syntactically flexible, and could be used as either count or mass in English. For example, the word ‘apple’ in English can refer to either individuals or nonindividuated stuff, depending on syntax (e.g., *some apple* vs. *some apples*). If we assume that noun meanings are the same cross-linguistically, Mandarin speakers might also be willing to accept whole and parts for the flexible nouns in a bare noun phrase because of the different meanings these nouns allow, just as English

speakers might be willing to accept either whole or parts depending on the syntax affixed to the flexible noun.<sup>1</sup>

In support of the view that noun meanings do not differ between mass-count and classifier languages, several recent studies show that count syntax is not necessary for individuation, and that both English mass nouns and bare nouns in classifier languages can specify individuation. First, several researchers have argued that English mass nouns are not limited to denoting non-individuals (e.g., Barner & Snedeker, 2005; Chierchia, 1998). Take, for example, the English mass noun ‘furniture,’ ‘a piece of furniture’ cannot refer to just a leg of a chair, but must denote a whole individual (e.g., a chair). Only ‘a piece of a piece of furniture’ can refer to the leg of a chair. This suggests that mass nouns like ‘furniture’ do provide natural atomic units for counting, namely anything that counts as a “piece” (Doetjes, 1997). This intuition has been supported by experimental studies that probe how mass-count syntax affects quantity judgments. When asked to decide which of two sets contains “more furniture,” participants base quantity judgments on number (e.g., judging that six tiny pieces of furniture are more furniture than two large pieces), despite basing judgments on volume for other mass nouns that denote substances (Barner & Snedeker, 2005). These findings show that English mass nouns can specify individuation, despite lacking overt count syntax.

Moreover, recent studies have found evidence that many nouns in classifier languages also supply criteria for individuation (Barner, Inagaki & Li, 2009; Li, Chen, Barner, & Carey, under review). In the absence of classifiers, speakers of both Japanese and Tsotsil Mayan based quantity judgments on number to the same extent as English speakers for words like ‘cup’, ‘furniture,’ and ‘ketchup’. For mass-count flexible nouns in English such as ‘string’ and ‘apple,’ English speakers quantified by number when the nouns were presented in count syntax (more apples) and by volume when in mass syntax (more apple). Japanese speakers, who received no syntactic cues, made quantity judgments in-between the count and mass groups of English speakers’ judgments, sometimes judging by number and sometimes by volume. This is consistent with the hypothesis that both count and mass readings are available to Japanese and English speakers for flexible nouns, and that syntax selects from universally available lexical meanings.

Subsequent studies have also found that cross-linguistic differences may be much smaller than first reported, are present only when entities are physically ambiguous, and can be made to disappear depending on testing context (e.g., Li, Dunham, & Carey, 2009). Importantly, several studies

have argued that cross-linguistic differences are more likely attributable to lexical statistics rather than to noun semantics. For example, English subjects may be more likely to infer that novel nouns denote object kinds because count nouns are more frequent than mass nouns in English. Speakers of classifier languages, however, need not make such syntactic inferences, and thus may rely more on the physical properties of novel referents to make their judgments, resulting in more variable responding for ambiguous entities (e.g., Imai & Mazuka, 2003; Colunga & Smith, 2006; Li & Gleitman, 2001; Barner et al., 2009).

In summary, a review of recent work on cross-linguistic individuation provides mixed evidence for the claim that, in absence of classifiers, nouns do not specify individuation in languages like Mandarin, Japanese, and Tsotsil Mayan. We believe, however, that the current body of evidence more strongly supports the position that noun semantics are not different cross-linguistically, and that some nouns in classifier languages do provide criteria for individuation just like nouns in mass-count languages. The current study provides even stronger evidence for this position. We assessed how speakers of Mandarin Chinese interpret familiar nouns (Study 1), whether they accept parts of broken objects as units for quantification (Study 2), and whether classifiers change how nouns are interpreted, or are instead semantically inert (Studies 3 and 4).

## Study 1

Using a quantity judgment task (Gathercole, 1985; Barner & Snedeker, 2005), we tested the hypothesis that bare nouns in Mandarin do not individuate unless classifiers are present. We reasoned that, if bare nouns do not individuate in absence of classifier syntax, Mandarin speakers should quantify by volume rather than by number, or quantify randomly across different types of nouns. On the other hand, if nouns can lexically specify individuation, even in absence of classifiers, Mandarin speakers should quantify by number for nouns denoting object kinds (e.g., chair), and by volume for nouns denoting substance kinds (e.g., mustard). For nouns that are used flexibly as either mass or count in English (e.g., string, apple), Mandarin judgments should fall in-between the mass and count judgments, and should vary from one item to the next, depending on the degree to which each word favors an individuated meaning cross-linguistically. To explore this, we tested subjects with two kinds of flexible words – those that continue to apply to a referent in both mass and count forms after the thing has been cut into pieces (e.g., string) and those that can only be used in mass syntax to name the cut referent (e.g., apple).

## Method

**Participants** Fifty-six participants were recruited from universities in Taiwan, with 14 participants assigned to one of the following four noun types (categorized according to their English syntax): count nouns, mass nouns, ‘apple’ type

<sup>1</sup> Other issues such as object functionality arise with Huang and Lee’s study. For example, subjects sometimes noted that the part of a depicted object could still potentially function as a whole individual of that kind (e.g., a torn pair of pants as *kuzi* ‘pants’ could still function as a pair of pants). Thus, it seems likely that results would have differed if they had tested subjects with only translations of English count nouns, using only pictures of clearly non-functional parts.

flexible nouns, and ‘string’ type flexible nouns.<sup>2</sup>

**Procedure** All participants completed a quantity judgment task. They were shown photographs of two characters: one had two large objects or two large portions of substances and the other had four small objects or four small portions of substances. The combined volume of the four small objects or portions was always less than that of the two large objects or portions. Participants were asked to choose which of the two had “more”. Instructions were written in Chinese above the photographs, and all questions were presented without classifiers (*Shui you bijiao duo* [noun]?; Who has more [noun]?).

There were eight nouns for each of the four noun types. For example, the ‘count’ condition included nouns such as ‘bag’ and ‘balloon,’ and the ‘mass’ condition included nouns such as ‘black pepper’ and ‘mustard.’ The two flexible noun lists differed with respect to the salience of their individuated meanings, and in particular, whether their count forms could be used to name pieces of their referents (e.g., half a rock, or half an apple). Eight words satisfied this criterion (e.g., apple, donut), and the remaining eight did not (e.g., rock, string). We will henceforth refer to the first flexible list as ‘Flexible A’ and the second as ‘Flexible B.’<sup>3</sup>

## Results and Discussion

An ANOVA comparing noun types (Count, Flexible A, Flexible B, vs. Mass), with percentage of judgments by number as a dependent variable, found a significant difference across noun types ( $F(3, 52) = 24.88, p < .001, \eta_p^2 = 0.59$ ;  $F(3, 28) = 1444.76, p < .001, \eta_p^2 = 0.99$ ). Pair-wise t-tests by subjects-analysis revealed that judgments based on number were most frequent for count nouns (100%), and least often for substance-mass nouns (0%): Count > Flexible A and Flexible B > Mass (Count vs. Flexible A:  $t(26) = 2.15, p < .05$ ; Flexible A vs. Flexible B:  $t(26) = .74, n.s.$ ; Flexible B vs. Mass:  $t(26) = 4.92, p < .001$ ). Replicating Barner et al. (2009)’s results with Japanese speakers, quantity judgments by number for mass-count flexible nouns were in-between count nouns and mass nouns (Flexible A: 75.0%; Flexible B: 62.5%). These results indicate that Mandarin speakers share the same conceptual distinction on the two kinds of flexible nouns as English speakers. Across languages, the referents of these flexible nouns can be represented either as objects or as the stuff that

forms them. English speakers rely on mass-count syntactic cues when making judgments; however, since Mandarin lacks such cues, speakers relied instead on each referent’s physical properties.

Next, we conducted an items-analysis to examine whether adults responded differently to the two types of flexible nouns. Since participants were more likely to stick to one way of responding throughout the study for flexible nouns, item-analysis was more sensitive to detecting differences across noun types. We found a similar pattern of results (Count > Flexible A > Flexible B > Mass), but the items-analysis also revealed that participants quantified more by number for Flexible A than Flexible B nouns (Count vs. Flexible A:  $t(22) = 13.13, p < .001$ ; Flexible A vs. Flexible B:  $t(14) = 5.58, p < .001$ ; Flexible B vs. Mass:  $t(14) = 53.46, p < .001$ ). Mandarin speakers were slightly more likely to quantify by number for flexible nouns if their English count-noun equivalent only applied to whole referents (e.g., apple, donut), relative to flexible nouns whose English count-noun equivalents applied equally well to a whole object or its parts (e.g., string, rock).

Overall, this set of data suggests that Mandarin noun meanings do not differ fundamentally from nouns in English, and that semantic criteria which predict mass-count usage in English predict the judgments of subjects tested in Mandarin. These data suggest that semantic differences in nouns drive syntactic usage in English, rather than syntax driving the creation of new meanings.

## Study 2

Study 1 provides one form of evidence against the claim that count syntax is necessary for individuation. In Study 2, we sought converging evidence for this claim using a different method. As noted by Huang and Lee (2009), if Mandarin nouns do not specify individuation, then Mandarin speakers should differ from English speakers with respect to how they refer to the parts of broken objects. Previous studies have shown that English-speaking children, unlike adults, often treat parts of objects as units for quantification (e.g., three pieces of a broken fork as being “more forks” than two whole forks; Brooks, Pogue, & Barner, 2011; Shipley & Shepperson, 1990). By some accounts, these failures suggest an inability to use the semantic criteria of nouns to guide quantification. Thus, if Mandarin nouns lack criteria of individuation, then adult speakers should resemble English-speaking children, and should treat pieces of broken objects as units of quantification.

In their study, Huang and Lee (2009) found that Mandarin adults often accepted bare nouns as labels for parts of broken objects. However, as mentioned above, their study included many flexible nouns, whose referents may also be construed as unindividuated by speakers of English when count syntax is not provided (e.g., some apple). In Study 2, we addressed this concern by using nouns that were unambiguously count in English. Also, we varied the syntactic framing of nouns by testing some subjects with

<sup>2</sup> English language is part of the school curriculum in Taiwan, and thus participants in our study would have received training in English. Although proficiency with English can potentially influence participants’ responses, our participants likely do not speak English fluently on a daily basis (see Yeh & Gentner, 2005).

<sup>3</sup> Most nouns were selected using the MacArthur Communicative Development Inventory (Fenson 1994). A group of 13 English speakers provided ratings that corroborated our categorization of whether the noun was a count noun, mass noun, or mass-count flexible noun. Another group of 12 English speakers verified the distinction between flexible A and flexible B nouns. They were asked to judge for each flexible noun whether cutting the thing in question would result in two (“Imagine one [noun]. Imagine that it is cut in half. Are there now two [noun]s?”).

classifiers and some without. If Mandarin nouns do provide criteria of individuation, then Mandarin speakers should behave like their English counterparts and quantify by whole objects regardless of whether a classifier is present. However, if nouns do not provide criteria of individuation, Mandarin speakers should only reliably choose the side with whole objects when a classifier is present.

## Method

**Participants** Twenty-one native Mandarin-speaking adults who had not participated in Study 1 were recruited from universities in Taiwan, and were assigned randomly to one of two conditions.

**Procedure** There were two tasks. In the quantity judgment task, one of the two characters always had two whole objects while the other character had one object cut into three pieces. The objects tested were named by count nouns in English (e.g., cup, ball, shoe), and were a subset of nouns from Study 1. In the counting task, participants saw either three or four objects, one of which was cut into three pieces. They were asked to count the set using a noun (e.g., How many [shoes] are there?) and to give a numerical response. The quantity judgment task was always presented before the counting task.

Participants were tested in Mandarin, and heard instructions containing either a bare noun phrase ( $n=10$ ) or a sortal classifier-noun phrase ( $n=11$ ). In the quantity judgment task, participants were asked, *Shui you bijiao duo* (CL) [noun]? (Who has more (CL) [noun]?). In the counting task, participants were asked, *Zheli you duoshuo* (CL) [noun]? (Here have how-many (CL) [noun]?).

## Results and Discussion

Participants overwhelmingly gave whole object responses in both tasks regardless of whether the sortal classifier was present. For both conditions, responses were near 100% on average for the quantity judgment task and at 100% for the counting task. For the quantity judgment task, there was no significant difference in how often participants gave whole object responses between the classifier (90.9%) and bare noun conditions (100%;  $t(19) = .95$ ,  $p = .35$ ).<sup>4</sup> The finding that adults counted and quantified whole objects in the bare noun condition suggests that judgments were guided by lexical criteria of individuation rather than by classifier syntax. This provides further evidence that nouns in Mandarin do provide criteria of individuation

## Study 3

Studies 1 and 2 show that sortal classifiers are not required to specify individuation for nouns in Mandarin. However, just as English count syntax can disambiguate meanings for flexible nouns, one might expect that sortal classifiers can do the same in Mandarin. To explore this, Study 3 tested

<sup>4</sup> Non-parametric tests using Mann-Whitney U revealed the same pattern of results and found no difference across the two conditions.

subjects using the flexible nouns from Study 1, and manipulated whether the words were presented with classifiers using a quantity judgment task. We predicted that, with the addition of a sortal classifier, Mandarin speakers should unambiguously quantify by number, just as English speakers do when presented with flexible nouns in count syntax.

## Method

**Participants** Sixty-four native Mandarin-speaking participants were recruited in Taiwan as in Study 1.

**Procedure** All participants completed a quantity judgment task. Half of the participants were tested on the Flexible A list, and half on the Flexible B list from Study 1; half of each group was assigned to the bare noun condition and half to the classifier condition, resulting in 16 subjects per group. In the classifier condition nouns were presented with a sortal classifier, whereas nouns in the bare noun condition were not. All else was identical to Study 1.

## Results and Discussion

An ANOVA with Noun Type (Flexible A vs. Flexible B) and Syntactic Frame (Bare vs. Classifier) as between subjects factors found a significant effect of Syntactic Frame ( $F(1,60) = 8.19$ ,  $p < 0.01$ ,  $\eta_p^2 = .120$ ;  $F(1, 14) = 47.15$ ,  $p < 0.001$ ,  $\eta_p^2 = .771$ ). Participants quantified significantly more by number in the classifier condition (85.2%) than in the bare noun condition (62.9%; see Figure 1). For the items-analysis, but not the subjects-analysis, there was a main effect of Noun Type,  $F(1,14) = 12.62$ ,  $p < 0.01$ ,  $\eta_p^2 = 0.47$ . Subjects quantified by number slightly more for the Flexible A list relative to the Flexible B list (80.8% vs. 67.3%). There was no interaction between Syntactic Frame and Noun Type.

Figure 1. Percentage of judgments by number for flexible A and B nouns across the three conditions - the bare noun and original classifier conditions (from Study 3), and the classifier emphasized condition (from Study 4).

To conclude, we found that classifiers did affect quantity judgment for flexible nouns, leading to more judgments based on number relative to the bare noun condition. However, somewhat surprisingly, the presence of a sortal classifier did not lead participants to choose by number

100% of the time, as one would expect if the classifier were the primary cue for specifying individuation in Mandarin. This finding also suggests that the possibility that adults in our study were implicitly adding the classifier they have come to associate with the noun when making quantity judgments in the bare noun condition seems unlikely.

## Study 4

Although it is possible that participants in Study 3 were relatively insensitive to classifiers when interpreting ambiguous nouns, it is also possible that subjects simply failed to notice their presence when reading the study stimuli. In Study 4 we addressed this concern by underlining the classifiers to emphasize their presence. We expected that when the classifiers are salient to subjects, they should use them to disambiguate the interpretation of flexible nouns.

## Method

**Participants** Twenty additional participants were recruited as in the previous studies.

**Procedure** Procedures were identical to Study 3, with the exception that classifiers were underlined in the written instructions.

## Results and Discussion

With the classifier emphasized, participants now quantified by number 100% of the time for both Noun Types (Flexible A: 100%; Flexible B: 99%; see Figure 1). An ANOVA with Noun Type (Flexible A vs. Flexible B) and Classifier Presentation (Original, Emphasized) as between subjects factors found a significant effect of Classifier Presentation ( $F(1,48) = 7.70, p < 0.01, \eta_p^2 = .138$ ;  $F(1,14) = 65.92, p < 0.001, \eta_p^2 = .825$ ). Participants quantified by number significantly more often when the classifier was underscored (99.4%) than when it was not (85.2%; see Figure 1). No other effects were found by the subjects-analysis. The items-analysis again revealed an effect of Noun Type ( $F(2,14) = 12.62, p < .01, \eta_p^2 = .474$ ). Also, there was a significant interaction between Noun Type and Classifier Presentation in the items-analysis ( $F(2, 14) = 5.23, p < .05, \eta_p^2 = .272$ ). This was driven by the fact that Noun Type only mattered for the original presentation (Study 3) but did not matter for the new presentation (Study 4), since participants were at ceiling in quantifying by number.

Underlining the classifiers led our subjects to quantify by number 100% of the time, suggesting that classifiers can disambiguate between ambiguous noun meanings in Mandarin, much like mass-count syntax in English. However, unlike English subjects who rarely ignore mass-count information, subjects in Study 3 sometimes ignored classifiers when reading instructions. This suggests that classifiers may add little information that is not already provided by the head noun, and typically act mainly as syntactic agreement. In the case of flexible nouns, subjects may draw on their knowledge of the relative frequency of individuated and unindividuated usages – e.g., quickly assuming that ‘apple’ should get an individuated

interpretation because it does most of the time in ordinary speech. Consistent with this idea, recent work on online sentence comprehension in Mandarin suggests that mensural classifiers (i.e., measure words) has a stronger influence on referential selection than sortal classifiers (Klein, Carlson, Li, & Tenenhaus, in press).

## General Discussion

Four studies investigated the claim that bare nouns in Mandarin Chinese do not specify criteria of individuation, and that individuation is introduced by sortal classifiers. Study 1 found that Mandarin speakers do not differ from speakers of English when making quantity judgments for familiar nouns. For example, Mandarin speakers based judgments almost exclusively on number for English count nouns. For mass-count flexible nouns such as ‘apple’ or ‘rock’, Mandarin speakers relied on lexical semantics to determine the units for counting, and made judgments that were roughly between those of English mass and count judgments, suggesting that across languages speakers can access both the individuated and unindividuated interpretations of flexible words. Overall, the current results were similar to those of English and Japanese speakers reported in Barner et al. (2009), and suggest that nouns in Mandarin individuate, despite lacking count syntax, and do so even when classifiers are not explicitly used.

Consistent with this, Study 2 found that Mandarin-speaking adults did not quantify parts of broken objects like English-speaking preschoolers (see Brooks et al., 2011; Shipley & Shepperson, 1990), which provides evidence against the claim that Mandarin nouns lack criteria of individuation. Together, the findings in Studies 1 and 2 suggest that Mandarin noun meanings are no different than noun meanings in English - Mandarin nouns like *yizi* ‘chair’ or *pingguo* ‘apple’ denote kinds of countable individuals.

If individuation is not specified by classifier syntax, what is the role of sortal classifiers in noun phrases? Are classifiers completely inert semantically, or can they sometimes contribute to the compositional semantics of a noun phrase? Findings from Studies 3 and 4 shed light on these questions by testing mass-count flexible nouns. Here, we found an effect of classifier syntax on quantity judgments; participants were more likely to base judgments on number when classifiers were added to flexible nouns. However, adding a classifier did not always have this effect; instead, as shown by Study 4, subjects attended systematically to classifiers only when their presence was made highly salient to subjects. Our suggestion is that subjects typically ignore classifiers because nouns normally provide the relevant content themselves. For adults, lexical meanings supply criteria of individuation, and may be supplemented by knowledge of the relative frequency of different meanings in everyday speech (e.g., the fact that ‘apple’ is frequently used to refer to whole apples rather than to apple-stuff).

The view that lexical semantics can provide the criteria of individuation for nouns in classifier languages such as

Mandarin and Japanese corroborates previous studies in English where English-speaking adults quantify over individuals when nouns such as ‘furniture’ or ‘jewelry’ are used in mass syntax (Barner et al., 2009; Barner & Snedeker, 2005). This suggests that syntax is not the only means that supplies criteria of individuation. In English, the individuation can be expressed syntactically, if the word is used in count syntax (e.g., apples) or through the lexical concept itself (e.g., furniture).<sup>5</sup> In languages that lack count syntax such as Mandarin, however, the lexical concept alone can determine individuation.

To summarize, the current studies provide strong evidence that nouns have similar semantic content cross-linguistically, regardless of variation in their syntactic expression. Nouns in classifier languages such as Mandarin and Japanese encode individuation like nouns in English, and can express this content without requiring the overt use of classifiers. Not only are classifiers unnecessary for individuation in Mandarin, but they also appear to be relatively weak cues to meaning. Unless their presence in a sentence is explicitly highlighted, Mandarin speakers often overlook them, and rely instead on the nouns themselves to determine interpretation. This suggests that in Mandarin, when the meaning of a noun phrase is ambiguous, speakers may rely on other contextual and pragmatic information rather than syntactic cues to disambiguate reference. In contrast, in mass-count languages like English, mass-count syntax often performs this disambiguating function. Outside these ambiguous cases, like string, apple, rock, etc., speakers of classifier languages converge on similar interpretations as speakers of mass-count languages, suggesting that nouns encode individuation in the same way across syntactically diverse languages.

<sup>5</sup> Interestingly, object-mass nouns such as furniture are often used in count syntax in other languages (e.g., French). This suggests that in languages where nouns are obligatorily marked as mass or count, individuation must be syntactically licensed.

# The Role of Preview and Incremental Delivery on Visual Search

Eric M. Chiu (echiu@ucmerced.edu)

## Abstract

Recent studies show that visual search often involves a combination of both parallel and serial search strategies. Consequently, computational models and theoretical accounts of visual search processing have evolved from traditional parallel or serial descriptions to a continuum from “efficient” to “inefficient.” In our first experiments (1a & 1b), we demonstrate with various conditions that search efficiency does not increase with *simultaneous* delivery of target features in a conjunction-search task. In the second experiment, we explore effects of *incremental* non-linguistic information delivery and discover improvement of search efficiency. We find a facilitatory effect when non-linguistic visual delivery of target features is concurrent with the visual display onset, but not when the target features are delivered prior to display onset. The results support an interactive account of visual perception that explains linguistic and non-linguistic mediation of visual search as chiefly due to the incrementality of target feature delivery once search has begun.

**Keywords:** visual search, incremental, conjunction, efficient

## Introduction

The present study is part of a research program that explores the degree to which the incremental processing of spoken words in a full sentence can interact with concurrent visual search processes.

Traditionally, two contrasting perspectives have plagued the field of attention in visual search. The *serial-processing* perspective claims that observers allocate complete attentional resources discretely and wholly to individual objects, one at a time (Treisman & Gelade, 1980; Treisman, 1988). Conversely, biased competition has been found to be mediated by neural mechanisms in the extrastriate visual cortex, which forms a persuasive line of reasoning not in favor of the serial-processing perspective but for the *parallel-processing* perspective, which claims attention is better characterized as a function of partially active representations of objects simultaneously contending for probabilistic mappings onto motor output (Desimone & Duncan, 1995; Reynolds & Desimone, 2001; Desimone, 1998). Single-feature visual search has been demonstrated to be relatively unaffected by the number of distractors, often inducing a perceptual “pop-out” effect. In contrast, two-feature conjunction-searches typically produce a linear increase in reaction time (RT) as the number of distractors increase. However, as we will demonstrate these apparent dichotomous perspectives may not be from two contrasting

fundamentals but rather a product of a single process better described as a graded enhancement of feature salience and supported by observations of improvement in visual search tasks (Olds, Cowan, & Jolicoeur, 2000a, 2000b, 2000c).

Olds and colleagues (2000a, 2000b, 2000c) observed, in a series of experiments, some facilitatory effects as a result of the very brief duration when search displays had only single-feature distractors. Although observers’ responses were not as fast as with pure “pop-out” displays, Olds and colleagues (2000a, 2000b, 2000c) illustrated a graded improvement of search efficiency, by presenting single-feature visual search pop-out displays for very brief durations (in some conditions less than 100 milliseconds) before transitioning them to conjunction-search displays. Findings like this “search assistance,” along with signal detection theory analyses of visual search data (Eckstein, 1998), and a lack of a bimodal search efficiency distribution (Wolfe, 1998), has replaced the serial-parallel dichotomy account with a continuum of search efficiency (e.g., Nakayama & Joseph, 1998).

Work by Spivey, Tyler, Eberhard, and Tanenhaus (2001) illustrates a different kind of “search assistance” phenomenon. Observers in an *Audio/Visual Concurrent* (A/V-concurrent) condition, where the conjunction-search display is presented concurrently with target identity via auditory linguistic queries (e.g. “Is there a red vertical?”), showed dramatically improved search efficiency compared to an *Auditory-First* control condition, where the same spoken query of target identity was provided prior to visual display onset. The findings suggest that upon hearing the first-mentioned adjective in the spoken query, visual attention is able to begin the search with only that feature, thus initiating the process more efficiently, resembling a single-feature search. Upon hearing the second adjective, several hundred milliseconds later, observers can then quickly find the target among the now attended subset of objects. Additionally, Reali, Spivey, Tyler, and Terranova (2006) implemented quantitative localist attractor simulations to extend the generalizability of the improvement in visual search efficiency when the identity of the conjunction target is delivered incrementally via a spoken target query while the stimulus display is visible, rather than prior to stimulus onset.

Subsequently, Gibson, Eberhard, and Bryant (2005) found with faster speech (4.8 syllables/second vs. 3.0 syllables/second) the A/V-concurrent condition no longer provides an enhanced efficiency effect on conjunction-

search tasks, indicating that improvement in visual search efficiency is affected by speech rate.

Though more recently, experiments by Jones, Kaschak, and Boot (2011) used eye-tracking to examine an alternative view to one that proposes search efficiency is increased due to language enhancing perceptual processing. Jones and colleagues (2011) observed patterns of eye movements suggesting increased efficiency with concurrent speech was not likely due to linguistic enhancement of perceptual processes but instead delaying the onset of target-seeking eye movements. They contend the findings by Gibson et al. (2005) are better explained by this “preview” of search display (when observers are presented with the search display prior to being notified of the target object’s identity) because slower speech provides observers with more search display viewing time, which provides additional information about potential target locations independently of the information conveyed by auditory linguistic speech stream.

The purpose of the present study was to, first, examine the role of preview of search display on visual processing and to, second, further understand exactly how language comprehension and visual search interact in real-time.

### Experiment 1a

In this experiment, we utilized visual cues to deliver simultaneously a two-feature target identity in a conjunction-search task.

#### Method

In this experiment we utilized three SOA, stimulus onset asynchrony, conditions (0-ms, 350-ms, and 750-ms) when identifying the target object. Participants were either presented with the target identifying visual cue simultaneously with the search display (0-ms SOA) or with either a 350-ms or 750-ms delay after onset of search display. All three SOAs appeared equally and randomly.

**Participants** One hundred and fifty-seven University of California, Merced undergraduate students received course credit for participating in this experiment. Participants who were unable to perform the task with an accuracy of 80% or better were removed from the analysis. Twenty-four participants did not meet this requirement thus were removed from the analysis. Additionally, all incorrect responses and trials with RTs greater than 2.5 interquartile ranges (IQR) from the median were also omitted (IQR was used for data culling because of its superior resistance to the influence of outliers).

**Stimuli and Procedure** Each stimulus bar subtended  $2.8^\circ \times 0.4^\circ$  of visual angle and neighboring bars were separated from one another by an average of  $2.0^\circ$  of visual angle. Target identifying visual cues were either red or green horizontal bars that appeared at the top and bottom of the search display or were red or green vertical bars that

appeared on the left and right of the search display. Dimensions of the visual cues were designed to resemble the dimensions of the stimulus objects but four times larger.

The first block was referred to as the “practice” block, consisting of 32 trials, and was followed by an experimental block with 96 trials. Participants were instructed to respond to each display as quickly and accurately as possible by pressing the labeled “YES” button on the keyboard if the target was present in the display and the labeled “NO” button if it was absent.

The target object was present or absent in half of the trials. Moreover, we utilized four set sizes of objects (5, 10, 15, and 20), which appeared equally and randomly. Given two target features (color: red or green, and orientation: vertical or horizontal) four unique targets appeared equally and randomly throughout the trials. The duration of the entire experiment was approximately fifteen minutes. Two 20” Apple iMacs were used to run the experiment. The experiment was programmed and executed using Mathwork’s MATLAB software.

### Results and Discussion

In this experiment we demonstrate with various conditions that search efficiency does not increase in a conjunction-search task when target features are delivered simultaneously, despite having time to preview the search display. The RT-by-set-size functions for target-present trials (filled symbols) are shown in Figure 1 and Figure 2 for target-absent trials (open symbols) in the three SOA conditions, 0-ms (circles), 350-ms (diamonds), and 750-ms (triangles). We should note at this time that RT’s were recorded from display onset, irrespective of condition, until a response was made. Next to each graph line is the best-fit linear equation and the proportion of variance accounted for ( $r^2$ ). Error bars indicate standard error of the mean. In the 0-ms SOA control condition, the RT-by-set-size function was highly linear in both target-present,  $r^2 = .994$ , and target-absent trials,  $r^2 = .984$ , as typically observed in standard conjunction-search tasks. Similarly, the RT-by-set-size functions for the 350-ms and 750-ms SOA conditions were highly linear in target-present trials,  $r^2 = .925$  and  $r^2 = .992$ , and target-absent trials,  $r^2 = .977$  and  $r^2 = .961$ , respectively.

Since our primary interest is to assess the effects of preview on visual search efficiency, analysis in this experiment compared the 350-ms and 750-ms SOA conditions to the 0-ms SOA control condition. Overall mean RTs, as well as y-intercepts, were significantly slower in the 350-ms and 750-ms SOA conditions because delivery of target identity was delayed by 350-ms and 750-ms, respectively, relative to the 0-ms SOA control condition for both target-present,  $t(132) = 2.38$ ,  $p = .017$ , and  $t(132) = 8.21$ ,  $p < .001$ , and for target-absent,  $t(132) = 4.05$ ,  $p < .001$ ,  $t(132) = 9.31$ ,  $p < .001$ , trials. Similar to previous observations, mean accuracy was 94.7% for all three conditions (Spivey et al., 2001; Reali et al., 2006).

For all experiments in this report the most important analysis is in comparison of the slopes of functions relating RT to set size. This slope value is an indicator of how efficient the search process is, that is, how much it resembles a serial process where each new distractor object increases RT by a sizeable fixed duration, or how much it resembles a parallel process where each new distractor object increases RT by little or no amount. The slopes of the RT-by-set-size functions reveal that 350-ms and 750-ms SOA conditions did not produce more efficient visual search compared with the 0-ms SOA control conditions (see fig. 1 & 2). Contrary to findings by Jones et al. (2011) an analysis revealed slopes for the 350-ms and 750-ms SOA conditions compared to the 0-ms SOA control condition were not significantly different for target-present trials (22.4 ms/item & 20.5 ms/item vs. 19.6 ms/item),  $t(132) = 0.61$ ,  $p = .543$ , and  $t(132) = 0.21$ ,  $p = .835$ , and target-absent trials (37.0 ms/item & 35.7 ms/item vs. 41.9 ms/item),  $t(132) = -0.99$ ,  $p = .323$ , and  $t(132) = -1.26$ ,  $p = .207$ .

Figure 1. Results from Experiment 1a shown separately for target-present trials.

Similar to Spivey et al. (2001) and Realí et al. (2006), we found a near 2:1 ratio between target-absent and -present trials in all three conditions (37.0-ms/item vs. 22.4 ms/item for 0-ms SOA, 35.7 ms/item vs. 20.5 ms/item for 350-ms SOA, and 41.9 ms/item vs. 19.6 ms/item for 750-ms SOA). This 2:1 ratio between target-absent and -present trials has been regarded as consistent with a standard serial search account.

The results of this experiment indicate that simply delivering target identity simultaneously in a conjunction-search task with a variety of SOAs so that observers are allowed preview time does not substantially affected search efficiency. The results observed in all three conditions are of the type that are traditionally interpreted as consistent with

the construction of a conjunction template of the target object followed by a serial process whereby discretely comparing each display object with the target template (Treisman & Gelade, 1980).

Figure 2. Results from Experiment 1a shown separately for target-absent trials.

## Experiment 1b

In this experiment we extended the methods in Experiment 1a to first, mimic the duration (1500-ms) of the auditory linguistic query, which identified the target object in previous work by Spivey et al. (2001) and to, secondly, explore the effects of a relatively long preview duration of search display on visual search processing.

## Methods

The method in the experiment follows that of Experiment 1a with the exception that only two SOAs (0-ms and 1500-ms) were used for the target identifying visual cue.

**Participants** Fifty-nine University of California, Merced undergraduate students received course credit for participating in this experiment. Five participants were unable to perform the task with an accuracy of 80% or better and were subsequently removed from the analysis. As with Experiment 1a, all incorrect responses and trials with RTs greater than 2.5 IQRs from the median were also omitted.

**Stimuli and Procedure** The same stimuli and target identifying visual cues from Experiment 1a were used in this experiment. Participants were presented with both SOAs equally and randomly in a within-subjects

experimental design. The same testing apparatuses and software were used in this experiment as the last.

## Results and Discussion

As with Experiment 1a, we continue to demonstrate with a slightly different condition that search efficiency does not increase with simultaneous delivery of target feature in a conjunction-search task, despite having time to preview the search display. Figure 3 shows the RT-by-set-size functions for target-present trials (filled symbols) and target-absent trials (open symbols) in the 0-ms SOA (triangles) and 1500-ms SOA (circles). In the 0-ms SOA control condition, the RT-by-set-size function was highly linear in both target-present,  $r^2 = .995$ , and target-absent trials,  $r^2 = .979$ , as typically observed in standard conjunction-search tasks. Similarly, the RT-by-set-size functions for the 1500-ms SOA condition was highly linear in target-present trials,  $r^2 = .975$ , and target-absent trials,  $r^2 = .958$ .

Figure 3. Results for Experiment 1b shown separately for target-present and -absent trials.

Overall mean RTs, as well as y-intercepts, were significantly slower in the 1500-ms SOA condition because delivery of target identity was delayed by 1500-ms relative to the 0-ms SOA control condition for both target-present,  $t(53) = -3.05$ ,  $p = .002$ , and target-absent,  $t(53) = -3.06$ ,  $p < .002$ , trials. Similar to previous observations, mean accuracy was 94.5% for both conditions.

The slopes of the RT-by-set-size functions reveal that the 1500-ms SOA condition did not produce more efficient visual search compared with the 0-ms SOA control

conditions (see fig. 3). An analysis revealed slopes for the 1500-ms SOA condition compared to the 0-ms SOA control condition were not significantly different for target-present trials (16.9 ms/item vs. 15.6 ms/item),  $t(53) = 0.22$ ,  $p = .825$ , and target-absent trials (36.4 ms/item vs. 42.4 ms/item),  $t(53) = -0.85$ ,  $p = .398$ .

Consistent with Experiment 1a, we found a near 2:1 ratio between target-absent and -present trials in both conditions (36.4 ms/item vs. 16.9 ms/item and 42.4 ms/item vs. 15.6 ms/item).

The results of this experiment continue to indicate that simply delivering target identity simultaneously in a conjunction-search task with a relatively long SOA (1500-ms). From Spivey et al. (2001) participants were unable to effectively utilize a noteworthy preview to improve search efficiency. Although a 1500-ms SOA mimics the overall duration of linguistic query it fails to simulate the incremental delivery of information characteristic of speech.

## Experiment 2

In this experiment, we explore effects of incremental non-linguistic information delivery on visual search processing by visually replicating the temporal characteristics of the auditory linguistic query that was used to identify the target object in previous work by Spivey et al. (2001).

## Methods

In this experiment, to simulate the auditory-first and A/V-concurrent condition in Spivey et al. (2001), we utilized two slightly different conditions. A *cue-first* condition similar to the auditory-first condition, delivered target identity incrementally via a visual cue prior to display onset, and a *cue-concurrent* condition similar to the A/V-concurrent condition, delivered target identity incrementally via the identical visual cue but concurrently with display onset. In Spivey et al. (2001) all participants failed to report experiencing any difference in display onset timing, thus auditory-first and A/V-concurrent conditions appeared randomly in a mixed trial design. Since in our experiment the difference between timing of display onset for cue-first and cue-concurrent trials was much more apparent, due to the unimodal nature of the task, we opted for a blocked trial design.

**Participants** Forty-six University of California, Merced undergraduate students received course credit for participating in this experiment. Eight participants were unable to perform the task with a minimum accuracy of 80% and were subsequently removed from the analysis. As with the previous experiments, all incorrect responses and trials with RTs greater than 2.5 IQRs from the median were also omitted from the analysis.

**Stimuli and Procedure** Stimulus objects were identical to experiments 1a and 1b. In order to visually simulate the incremental information delivery of the spoken query (e.g.,

“Is there a red vertical?” 500-ms to utter the first feature color, “red” or “green,” and 1000-ms to utter the second feature orientation, “vertical” or “horizontal”) in Spivey et al. (2001), target identifying visual cues began as all red or all green horizontal and vertical bars that appeared on all sides (top, bottom, left, and right) of the search display for 500-ms to identify the color of the target. To identify the orientation of the target, the visual cue then transitioned to grey horizontal or vertical bars that appeared either at the top and bottom or the left and right of the search display, respectively, for 1000-ms before disappearing. Dimensions of the visual cues were identical to the previous experiments.

Prior to participating in the experimental blocks observers participated in two practice blocks (one of each cue-first and cue-concurrent) consisting of 32 total trials and was followed by two experimental blocks with 64 trials each for a total of 128 trials. One experimental block contained cue-first trials only and the other contained cue-concurrent trials only. The order of the experimental blocks (cue-first first or cue-concurrent first) was randomly assigned to participants, each order was used equally. Participants were instructed to respond to each display as quickly and accurately as possible by pressing the labeled “YES” button on the keyboard if the target was present in the display and the labeled “NO” button if it was absent.

The target object was present or absent in half of the trials. Furthermore, we utilized four set sizes of objects (5, 10, 15, and 20), which appeared equally and randomly. Given two target features (color: red or green, and orientation: vertical or horizontal) four unique targets appeared equally and randomly throughout the trials. The duration of the entire experiment was approximately 20 minutes. Two 20” Apple iMacs were used to run the experiment. The experiment was programmed and executed using Mathwork’s MATLAB software.

## Results and Discussion

In this experiment we demonstrated a facilitatory effect when visual non-linguistic delivery of target features is presented concurrently with the visual display onset, but not when the target features are delivered prior to display onset. Figure 4 shows the RT-by-set-size functions for target-present trials (filled symbols) and target-absent trials (open symbols) in the cue-first (triangles) and cue-concurrent (circles) conditions. In both target-present and -absent trials the RT-by-set-size function was linear for both the cue-concurrent condition,  $r^2 = .768$ ,  $r^2 = .962$ , respectively, and the cue-first condition,  $r^2 = .314$ ,  $r^2 = .698$ , respectively, which is typically observed in standard conjunction-search tasks. Overall mean RT, as well as y-intercepts, were significantly slower in the cue-concurrent condition because delivery of target identity was delayed by 1500-ms relative to the cue-first control condition for both target-present,  $t(37) = 4.49$ ,  $p < .001$ , and target-absent,  $t(37) = -4.32$ ,  $p < .001$ , trials. Mean accuracy was 94.0% for both conditions.

Figure 4. Results from Experiment 2 shown separately for target-present and -absent trials.

The slopes of the RT-by-set-size functions reveal that the cue-concurrent conditions produced more efficient visual search compared with the cue-first control conditions (see fig. 4). An analysis revealed slopes for the cue-concurrent condition compared to the cue-first control condition were significantly different for target-present trials (5.6 ms/item vs. 14.0-ms/item),  $t(37) = -2.77$ ,  $p = .010$ , and target-absent trials (16.4 ms/item vs. 30.8 ms/item),  $t(37) = -2.75$ ,  $p = .006$ . Furthermore, we found a near 2:1 ratio between target-absent and -present trials in both cue-concurrent conditions (16.4 ms/item vs. 5.6 ms/item) and cue-first conditions (30.8 ms/item vs. 14.0-ms/item), regarded as consistent with a standard serial search account.

The results of this experiment indicate that visual non-linguistic delivery of target features presented incrementally and concurrently with the visual display onset has a facilitatory effect on visual search efficiency, but not when the target features are delivered prior to display onset. The results observed in the cue-first condition are of the type that are traditionally interpreted as consistent with the construction of a conjunction template of the target object followed by a serial process of sequentially comparing each display object with the target template (Treisman & Gelade, 1980). Conversely, the results in the cue-concurrent condition, which simply involved shifting the relative timing of display onset relative to target identity cue, are more consistent with a parallel or “partial parallel” (Maioli, Benaglio, Siri, Sosta, & Cappa, 2001) search process, which

is observed in the similarly shallower slopes in the RT-by-set-size functions.

## General Discussion

In a series of experiments we made strides toward understanding exactly how language comprehension and visual search interact in real-time. We demonstrated with various conditions that search efficiency does not increase with simultaneous delivery of target features in a conjunction-search task despite relatively lengthy previews of search display, 1500-ms in some conditions (Experiment 1a & 1b). We then explored the effects of incremental non-linguistic information delivery by visually simulating auditory linguistic queries and discovered an improvement of search efficiency where facilitatory effect only occurred when visual non-linguistic delivery of target features was concurrent with the visual display onset, and not when the target features were delivered prior to display onset.

In conclusion, our findings suggest that it is the incremental nature of target delivery (whether via speech perception or visual perception) that allows the visual search process to begin when only a single feature of the target identity has been heard. When the initial feature is identified the search proceeds in an efficient nearly-parallel fashion so when the second adjective is presented, a substantial amount of the target identification process has already been completed, and as a result the presence of multiple distractors is less disruptive. These results support an interactive account of visual perception that explains linguistic and non-linguistic mediation of visual search as chiefly due to the incrementality of target feature delivery once search has begun. Future research on understanding exactly how language comprehension and visual search interact in real-time will benefit greatly from the development of further experimental tests such as this.

## Acknowledgments

We are grateful to Andreas Kolling for help with the MATLAB code for the experiments. Additional thanks to Monica Yanez, Markie Johnson, Norma Cardona, Mauricio Cifuentes and Courtney Griffin-Oliver for help with collecting data.

# Determining Relevance: Close Enough is Good Enough

Sheldon J. Chow (schow55@uwo.ca)

Department of Philosophy, Stevenson Hall, The University of Western Ontario  
London, Ontario, N6A 5B8 Canada

## Abstract

Humans exhibit characteristic success in considering what is relevant in their cognitive tasks. Yet understanding how relevance is determined in cognition remains a problem. This paper seeks to make headway on this problem. The relevance problem is first introduced. Sperber and Wilson's influential theory of relevance is then discussed, but dismissed as inadequate. Some conditions are identified that an adequate definition of relevance might reasonably be expected to satisfy. A novel way to conceive of relevance is suggested which proves to be useful in understanding human cognitive performance.

**Keywords:** Relevance; concepts; file model; cognitive architecture.

## The Relevance Problem

A longstanding problem in philosophy and cognitive science is understanding how we determine what is relevant to our cognitive tasks. The cognitive systems paradigmatically responsible for general reasoning and decision-making—so-called central systems—admittedly allow for free exchange of information. A dream of a snake biting its own tail, for example, bore in interesting and important ways on Kekulé's theorizing of the benzene molecule. A consequence of such a free exchange of information, however, is that, provided an appropriate set of background beliefs, any representation held by an agent can *in principle* be relevant to a given cognitive task in central cognition. Who won tonight's football game is *prima facie* irrelevant to whether there is beer in your friend's fridge. But if you believe that your friend's favourite football team played tonight, and that your friend usually overindulges in beer consumption whenever his favourite team wins, then your belief about who won tonight's game actually *is* relevant to your belief about beer in your friend's fridge. Since relevance can be determined only with respect to one's background beliefs, there is no way to circumscribe *a priori* the subset of representations that are relevant in a given occasion of reasoning or inference. Let us express this problem thus:

**The relevance problem** How a cognitive system considers only what is (mostly) relevant, or equivalently, how a cognitive system knows what is relevant.

Despite the fact that the relevance problem introduces a computational problem of sifting through heaps of information to decide what bears on the task at hand, humans seem to determine what is relevant in their cognitive tasks quickly and rather easily. This is not to say that we always know and consider what is relevant. For we often fail to do so, especially

when cognitive demands are high and/or when cognitive resources are low. Nevertheless, humans characteristically exhibit reasonable levels of success at identifying representations which are relevant to the task at hand. Such reasonable levels of success cannot be ascribed to chance or luck. Therefore, we are left to explain how humans (seem to) solve the relevance problem, short of considering the totality of one's beliefs (Fodor, 1987, 2000).

However, the inquiry into how relevance is determined is constrained by how relevance is defined. Indeed, whether and the extent to which relevant representations are picked out and brought to bear on a cognitive task will depend on what property we are concerned with. Yet, defining relevance is not an easy task. In this paper I provide a cursory overview of what is arguably the most influential account of relevance to date, namely Sperber and Wilson's *Relevance Theory*. I will then be able to use their Relevance Theory as a basis from which to propose an understanding of relevance that is supported by a view of concepts and cognition which draws on current theories in cognitive science, as well as Fred Dretske's information-theoretic epistemology.<sup>1</sup> This will allow me to show how relevance, or something like it, can be understood as naturally arising from human cognitive architecture, thus enabling the characteristic performance we observe in human reasoning.

## Sperber and Wilson's Relevance Theory

Sperber and Wilson (1986/1995) developed their Relevance Theory in the context of communication and pragmatics. Humans tend to have an easy time communicating with each other, despite the fact that the meanings of utterances are enormously underdetermined. A simple example: Alice says to Bob, "Isn't that cute?" while nodding toward a chipmunk scurrying up a tree; Bob knows that by "that" Alice is referring to the chipmunk, and not to the birds in the other branches, the tree itself, or whatever else was within his perceptual field at the time of her utterance. According to Sperber and Wilson (SW henceforth), Bob understands that Alice was referring to the chipmunk because the stimulus of the

<sup>1</sup> It should be kept in mind throughout the discussion that I am not intending to develop a full theory of relevance. I therefore do not offer any claim of completeness. Such a task deserves a more extensive treatment than what I can provide in this short paper. My contribution might be understood as a useful preliminary discussion of how the problem of relevance might be stated, and an identification of some conditions that an adequate definition of relevance might reasonably be expected to satisfy. Nevertheless, I shall suggest a potential way to conceive of relevance which proves to be useful in understanding human cognitive performance.

chipmunk running up the tree was *relevant* (or at least more so than any other present stimulus).

Although SW's Relevance Theory is mainly concerned with verbal/ostensive communication and comprehension in particular, they claim that their theory can be extended to the inference processes of ordinary thinking (1986/1995, p. 67; p. 75). This is because SW ground their account of relevance in a fundamental and general view of human cognition. Specifically, SW claims that cognition always tends toward efficiency (i.e., maximizing gains and minimizing costs), and furthermore that human cognition succeeds in increasing its efficiency by having a tendency toward *maximizing relevance*. According to their Relevance Theory, the relevance of an input to a process is a function of *cognitive effect* on the one hand, and *processing effort* on the other.<sup>2</sup>

It should be obvious that relevance, assessed in terms of cognitive effect and processing effort, comes in degrees. In addition, some input may yield greater cognitive effects on some occasions and less effects on others, or, depending on circumstances related to fatigue or stress, the same input may be more or less easy to process at different times. Thus, relevance is a relative property—relative to an individual and to a time. SW therefore provide the following two definitive conditions for relevance:

1. *Ceteris paribus*, the greater the cognitive effects achieved by an individual by processing some input, the more relevant that input is to that individual at that time.
2. *Ceteris paribus*, the greater the effort expended by an individual by processing some input, the less relevant that input is to that individual at that time.

When SW claim that human cognition has a tendency toward maximizing relevance—which they assert as The Cognitive Principle of Relevance<sup>3</sup>—they mean that human cognition is geared toward allocating cognitive resources to processing available inputs (from the environment or from memory) so as to maximize expected cognitive effects for the least expected effort.

Sperber and Wilson (1995) make the point that an individual is not interested in cognitive effects *per se*, but only insofar as such cognitive effects contribute to achieving certain cognitive goals, or otherwise fulfilling its functions. For

---

<sup>2</sup>SW develop their account in terms of constructing an appropriate context within which to process inputs. A context is simply just a set of assumptions within which input can be processed. For simplicity, I will pass over this aspect of their account; no harm is done to the central points of the present paper.

<sup>3</sup>SW's Relevance Theory makes claims about human cognition in general, but an important consequence of their Cognitive Principle, and one that is the basis for their work in pragmatics, is the Communicative Principle of Relevance: *Every ostensive stimulus conveys a presumption of its own optimal relevance*. This Communicative Principle of Relevance is really the centerpiece of SW's Relevance Theory. However, since communication and pragmatics are not the focus of this paper, the Communicative Principle will not be discussed any further.

indeed, there may be cognitive effects that are not worth having, or that contribute negatively to the individual's cognitive functions or goals. Thus, SW define a *positive cognitive effect* as a cognitive effect that contributes to the cognitive goals or functions of the individual in a positive way. This is typically achieved by alterations in the individual's beliefs. In SW's words, positive cognitive effects produce an "epistemic improvement" (Sperber & Wilson, 1995, p. 266); they make a "worthwhile difference" to the cognitive functioning of the individual (Wilson & Sperber, 2006, p. 608).

Thus far I have given a brief outline of SW's Relevance Theory. Nevertheless, there are a number of ways in which Relevance Theory is inadequate. For brevity, I mention here only two inadequacies, but these are most damaging. First, it is grossly unclear how to quantify cognitive effect and effort so as to make sense of the ratio between the two in SW's definition of relevance. Second, SW's conception of cognition is strictly in terms of deduction—processes performed by a "deductive device" that is supposed to "model the system used by human beings in spontaneous inference" (Sperber & Wilson, 1986/1995, p. 94). Of course, there is wide consensus now that spontaneous inference is not strictly deductive, but is to a large extent non-demonstrative. SW's account of cognition completely excludes such non-demonstrative cognition, as well as other aspects of cognition such as perception.<sup>4</sup>

In light of these shortcomings, the remainder of this paper is devoted to offering the beginnings of a more adequate account of relevance in cognition. I will begin by outlining a psychologically plausible theory of cognition. We shall see that this will allow a more naturalistic understanding of SW's notion of "positive cognitive effects", but more importantly it has the potential to deliver a desired account of relevance.

## Concepts and Cognition

A number of cognitive scientists and philosophers have converged on an idea about the nature and function of mental representations (e.g., Evans, 1982; Fodor, 2008; Lawlor, 2001). The idea is a *file model* of cognition (Kahneman, Treisman, & Gibbs, 1992; Pylyshyn, 2003; Treisman, 1982; Treisman & Schmidt, 1982). There is no standard doctrine accepted by everyone who endorses the file model, but there is some common ground that can be identified.

According to the file model of cognition, one has a mental "file" for each object that one has beliefs about. Each mental file has a "label" that both picks out the file, and refers to the

---

<sup>4</sup>By the second edition of *Relevance* (1995), Sperber and Wilson had disavowed such a central systems architecture in favour of the massive modularity hypothesis. Though I note this only in passing, I believe that certain complications arise for their Relevance Theory within a massively modular architecture. This is a matter to be discussed on some other occasion, however. Sperber (2005) has recently suggested that cognitive efficiency, in terms of maximizing relevance, is achieved biologically—specifically, by optimally allocating energy in the brain. His proposal is to think of maximizing cognitive effects and minimizing effort in terms of noncognitive physiological processes. However, this entails an account of relevance entirely different from SW's Relevance Theory, and Sperber has not developed such an account in any detail.

object that is associated with the file. Further, each file holds a number of “notes” or “memos” that contain various kinds of information or beliefs, or representations more generally, about the given object.

It is important for the present purposes to understand that the file model can be conceived more particularly to be a theory of the structure of *concepts*. On this reading, a concept names a file that contains representations about the things in the concept’s extension. When thinking about cats, for instance, one calls upon one’s CAT file, which may contain such representations as *is a living thing, is a furry creature, is a quadruped, is grandma’s favourite animal*, etc.<sup>5</sup> Notice now that what is contained in the file—what notes there are in the file—name other concepts: LIVING THING, FURRY CREATURE, QUADRUPED, GRANDMA’S FAVOURITE ANIMAL, etc. This is not classical decomposition. Rather, concept files contain notes that convey information about the concept in question. Hence, unpacking the notes of one’s CAT concept file is unpacking one’s beliefs and other stored knowledge about cats, the representations of which invoke further concepts. Moreover, whatever is inferred from the unpacked representations may excite further concepts, thereby bringing to mind files and representational content of their own. Thus, such a conceptual system forms a vast network among the beliefs and other representations which are contained in concept-files.

A very important feature of this account is that concepts do not exist independently of one another. Rather, this is a view of concepts wherein vast connections exist between them in virtue of their content. Every representation is a part of an interconnected network, where activation can spread through the system depending on the strengths and the organization of the connections between representations in the network. In principle, the structure allows for any content to activate any other content, which is a hallmark of central cognition (cf. Viger, 2006b).

We might therefore see that the file model of cognition allows for the following sort of picture to underwrite thought and inference. When one is presented with a given cognitive task, the nature and content of the task initially activates and primes<sup>6</sup> a focused set of concepts and contents. Suppose, for instance, one is presented with the task of estimating whether it is likely or unlikely that there will be a plane crash within the month. This task would activate conceptual content concerning *planes, crashes, likelihoods, estimation, months, timeframes*, and more. Certainly, various parameters will constrain what conceptual content gets activated. Some parameters include those that are given by the language used (e.g., using “plane” rather than “jet”), as well as those that are suggested by the nature of the task (e.g., the task elicits a course-grained subjective likelihood assignment to a future event as opposed to, say, a fine-grained numerical subjective

probability). Other parameters will have to do with factors affecting long-term memory recall, such as which concepts an individual possesses, the relative strengths at which conceptual content is stored in long-term memory, the ease with which conceptual content is activated (perhaps based on past activations), and the existence and relative strength of connections between concepts and conceptual content established by past inferences. In addition to these constraints, limits on time and cognitive resources will restrict what and how many conceptualizations occur. Yet, even with these constraints, a considerable amount of conceptual content may still get activated.

This has been a brief overview of the file model of cognition. Before I continue, I should note that the file model is best viewed as a useful analogy for thinking about concepts and the relations among them and their contents. The model is advanced here merely as a gesture toward a possible cognitive conceptual architecture. If the file model is to become a viable basis for a definition of relevance, it will need much further development and theoretical refinement—a task that is beyond the scope of this paper. Nevertheless, the main proposal here does not depend on the truth of the file model, specifically. It requires only that there exist highly organized systems of knowledge or representations in cognition which bear certain connections to one another. The file model gives us a tentative idea of what these systems might be. Yet, that a number of cognitive scientists have converged on it to model various aspects of cognition is suggestive of its plausibility.<sup>7</sup>

## Reinterpreting Relevance

Let us now turn back to relevance. There is something intuitively right about the idea that relevance has something to do with what SW call “positive cognitive effects”. For indeed, it seems as if processing irrelevant information would not generally yield anything positive for the cognitive system. Yet, we would need a more precise understanding of positive cognitive effect which avoids the pitfalls of SW’s account, but which is somehow tied to relevance. The account of concepts and cognition in the previous section delivers this.

To see this, let us begin by drawing some lessons from Fred Dretske (1981). In developing his information-theoretic epistemology, Dretske commented that there is “a *relativization* of the information contained in a signal because *how much*

<sup>5</sup>The convention I adopt here is to represent concepts in small caps, contents in italics, and uses in quotes.

<sup>6</sup>For simplicity, I will often use “active”/“activated” to refer to both active/activated and primed content.

<sup>7</sup>Moreover, the file model lends itself to being interpreted within certain current neurological theories of conceptual cognition. For example, Barsalou’s (1999) *perceptual symbols systems* view of cognition, Patterson, Nestor, and Rogers’ (2007) theory of a *semantic hub*, and Damasio and Damasio’s theory of *convergence zones* (A. R. Damasio, 1989; H. Damasio, Tranel, Grabowski, Adolphs, & Damasio, 2004; Tranel, Damasio, & Damasio, 1997), each posits the existence of neurological sites that store and enact a “code” which specifies specific neural patterns to be (re)activated during mental representation. My preferred (albeit tentative) interpretation is to understand concept-files to be roughly analogous to the posited sites where the codes are stored; opening files can then be understood as instantiating the appropriate codes to (re)activate neural patterns for representation; and file labels can be understood as lexical terms that name concepts in natural language. (This last point was suggested to me by Chris Viger.)

information a signal contains, and hence *what* information it carries, depends on what the potential receiver already knows about the various possibilities that exist at the source” (p. 79). Although we might not know (or even cannot know) absolute measures associated with the amount of information generated by an event or carried by a signal, Dretske believes that *comparisons* can be made, “in particular comparisons between the amount of information generated by the occurrence of an event and the amount of information a signal carries about that event” (p. 54).

According to Dretske, our concepts are cognitive structures that enable us to extract and exploit certain information in the environment. Learning or enriching a concept provides us with the ability to encode (or digitalize) certain aspects of our (analog) sensory experience in such a way that we are able to cognitively respond in certain ways which we would not have been able to otherwise. Having the concept DAFFODIL, for example, enables one to see a daffodil *as* a daffodil (as opposed to a flower, or some green and white object), and thus allows one to have daffodil-thoughts and to cognize daffodil-stimuli in certain ways. Importantly, then, what information one can encode from stimuli crucially depends on what one already knows about the objects of the stimuli, or in the terms of the present account, on what and the way in which conceptual contents are coded in one’s conceptual architecture.<sup>8</sup>

A natural account of relevance follows from this picture in terms of the amount of information received from a source (such as a stimulus). More specifically, the greater the amount of information received, the greater the relevance of that information. For example, suppose that Alice and Bob are on a nature walk. Alice is a botanist, whereas Bob never cared for plant science. As Alice and Bob gaze upon the flora of the forest floor, they both cognitively extract a vast amount of information from their respective perceptual scenes. However, Alice’s conceptual knowledge is so rich that she is able to extract more specialized information than Bob does or even can, having to do with the various kinds of plants that they come across. In this way, the perceptual scene carries more information for Alice than for Bob. Of course, they both process the *same* information, but Alice can *cognitively extract* more information. Whereas Bob simply sees a plant, Alice sees Blindwood ivy; whereas Bob simply sees flowers, Alice sees daffodils. Importantly, certain information in Alice’s and Bob’s perceptual scene is very *relevant* to Alice but not so relevant to Bob. And the information from the perceptual

scene that Alice finds relevant is just that information she is able to extract via her conceptual knowledge. On the other hand, such information is not as relevant to Bob because he cannot represent the information in the same ways, since he lacks the conceptual wherewithal to do so.<sup>9</sup>

Therefore, I suggest that the relevance of a stimulus to a given cognitive system (or agent) depends on the amount of information received from that stimulus. Since the amount of information received depends on one’s conceptual wherewithal to attend to and code specific information in certain ways, whether and the extent to which something is relevant is dependent on the informational content of one’s concepts. But this is not the entire story, since relevance will also depend on the context and cognitive task. Suppose, for instance, that both Alice and Bob are botanists, but Alice is interested in finding a rare flower while Bob is interested in seeing a specific species of ivy. Both Alice and Bob could code the same information in the same ways, but because of their different goals and cognitive tasks, Alice will find flower information more relevant than Bob, and Bob will find ivy information more relevant than Alice.

This can be easily accounted for, however, once it is understood that, in setting up one’s goals and preparing for one’s cognitive task, one requisitely activates a number of concepts with specific conceptualizations and representations, as described above. This will in a sense serve as a filtering mechanism for focusing attention. Alice will thus be (cognitively/conceptually) geared to attend to specific information related to a specific flower whereas Bob will be (cognitively/conceptually) geared to attend to specific information related to ivies, as each will have prepared a set of concepts and representations upon embarking on their respective cognitive tasks. The set of concepts and representations that gets activated when one prepares for a given cognitive task will tend to be relevant, although this may not always be the case. What gets activated will depend on previous experience, past activations, and the extant relations and connections among the activations. These relations will constrain and guide inference.

Thus, on this view, the degree to which information is relevant is a matter of the *informativeness* of information. In other words, relevance is conceived to be a measure of how much information gets encoded given one’s cognitive wherewithal and preparation (i.e., the activations and connective relations among one’s conceptual representations). The same information can be more or less informative, and hence rele-

<sup>8</sup>According to information theory, and thus according to Dretske, a signal carries 0 information if one already knows the message the signal carries. I disagree, since for a signal to carry 0 information, one would have to be unable to extract and conceptualize any information from the source in question (cf. Gabbay & Woods, 2003). And such a thing does not seem to be likely, or even possible, in human cognitive practice. Processing information one already knows may be *redundant*, but it may also be useful to strengthen or reaffirm one’s beliefs. A corollary of this view is that a signal will always carry information for human cognitive systems; the *amount* of information in a signal will depend on what the receiver knows, or more specifically, on activated conceptual representations. More on this presently.

<sup>9</sup>We might consider here a situation in which Bob is trying to learn some botany, in which case the information received from the stimuli given by the forest floor would seem to be more relevant to Bob than Alice, since Alice already knows what Blindwood ivy is and looks like, etc. However, this situation is a shift in context from the scenario described in the main text. Specifically, Bob’s cognitive task has changed, and therefore so has his cognitive preparation. The difference in cognitive preparation, along with, say, Alice’s instruction, will entail a difference in the kinds and amounts of information extracted from the environment, and hence a difference in relevance. See below.

vant, depending on the agent and cognitive task. Understood this way, relevance is not just a property of information *per se*—not just a matter of what information gets processed—but a matter of *how information gets processed*.

If this is right, then positive cognitive effect can be understood in terms of the informativeness of information that is processed—processing information yields positive cognitive effects insofar as the results are informative. But this is just to refer to the degree of relevance of the information in question. This means that positive cognitive effect is yielded by processing relevant information. We therefore have our intuitive connection between positive cognitive effect and relevance borne out by the present account: Processed information has positive cognitive effect *because* it is informative; and the degree to which it is informative is the degree to which the information is relevant. Cognitive effects and effort therefore do not define relevance. Rather, concepts and the extant relations between their contents will facilitate cognitive effects and effort in processing information. Hence, it is structured concepts that deliver relevance, which in turn produces cognitive effects with little effort.

This account of relevance is definitely an improvement over SW's account. On the one hand, there is no problem of how to quantify cognitive effect and effort to make sense of the ratio between the two; instead, relevance is measured directly in terms of degree of informativeness. On the other hand, there is no conceiving cognition strictly in terms of deduction; the adopted view of cognition is amenable to deductive and non-demonstrative inference alike.

## How Do We Determine What is Relevant?

We are now in a position to see how the foregoing account of concepts and cognition can help to explain our characteristic levels of success in our reasoning. Given the present account, we have more constraints on our reasoning than we may know. Specifically, a certain kind of relevance is determined by the extant relations among the contents of our concepts. The kind of relevance I have in mind is *de facto* relevance (cf. Gabbay & Woods, 2003), in which information appears to be relevant due to the architectural characteristics of cognition. More specifically, and to continue the line of reasoning in the previous section, something is (more or less) *de facto* relevant if it appears to be (more or less) informative when processed against a given set of activated concepts. In this way, *de facto* relevance cannot be determined *a priori*, as should be expected. Instead, it simply arises out of the nature and structures of our concepts.

The *de facto* relevance established by the extant relations within and between activated conceptual contents appears to be enough for humans to get by on. The kind of relevance that matters to the relevance problem spelled out in the first section of this paper, on the other hand, is a kind of *objective* relevance which exists independently of cognizers. Many examples of objective relevance come from science. For example, the motions of terrestrial objects are relevant to the

motions of the planets, and this is an objective fact, but we did not know this until Newton came along.<sup>10</sup>

There will certainly be times when we fail to process objectively relevant information, or when we process information that is not very objectively relevant at all. In some cases we may end up processing some objectively *irrelevant* information. Moreover, inevitably there will be cases in which we fail to process *de facto* relevant information, due to cognitive limitations, fatigue, stress, or some other extraneous factor. Under satisfactory conditions, however, our activated concepts, with their contents and extant relations, provide a network that informs cognition of what is *de facto* relevant, and constrains and guides its processing accordingly. The situation may not be ideal, but it is good enough for us to get by on—indeed, such is to be expected from satisficing organisms. On the other hand, when we enter into certain high-stake arenas, such as science or philosophy, we alter our standards, and *de facto* relevance is no longer good enough. In such circumstances, objective relevance is sought, and this is likely why progress and getting things right are much more difficult to achieve in these endeavours.

At the same time, however, we might understand the foregoing account of concepts and cognition as contributing to how humans manage to solve, not the relevance problem stated above, but a more fundamental problem. To see what I mean, let us consider Daniel Dennett's (1984) example of fixing a midnight snack. He noticed that such a mundane task requires copious amounts of knowledge: "We know trillions of things; we know that mayonnaise doesn't dissolve knives on contact, that a slice of bread is smaller than Mount Everest, that opening the refrigerator doesn't cause a nuclear holocaust in the kitchen" (p. 136). Dennett also noticed that we must possess a system of representing this knowledge in such a way that it is accessible on demand. This would require a system that is organized in such a way that achieves the efficient representation and access we observe in humans. In his words: "A walking encyclopedia will walk over a cliff, for all its knowledge of cliffs and the effects of gravity, unless it is designed in such a fashion that it can find the right bits of knowledge at the right times, so it can plan its engagements with the real world" (pp. 140-1). From these considerations, we might say that humans solve a *representational relevance problem*:

**The representational relevance problem** How a cognitive system embodies the informational organization, and enables access to the relevant information, that seems to be required for human-like cognitive performance.

I believe that the present account of concepts and cogni-

<sup>10</sup>Notice that objective relevance also cannot be determined *a priori*; but rather than against a set of beliefs, relevance is determined against a background of facts and phenomena. The motions of terrestrial objects, for instance, are not objectively relevant *simpliciter*; it is objectively relevant with respect certain phenomena, such as planetary motion.

tion is precisely what enables humans to solve the representational relevance problem. For as I have illustrated, concepts are organized in such a way that the extant relations between their contents facilitates access to *de facto* relevant information. Such information may not be objectively relevant, but it will almost certainly be the kind of information that is needed to guide successful action, and this is all that is needed for human-like performance.

It is interesting to note, however, that it seems that much of the information that is *de facto* relevant turns out to be objectively relevant a lot of the time. This is evident from how humans get on in the world, and the success rate of many human inferential endeavours. I can only speculate why this is so: it is likely an outcome of some evolutionary process. This would explain our reasonable levels of success in bringing to bear objectively relevant information on our cognitive tasks. I admit that this is not a deep explanation. However, if we conceive our conceptual system to have evolved to track *things in the world*, then it should not be much of a mystery why our conceptual wherewithal reflects the organized structure of information in the world, including objective relevance relations. In this way, then, we can conceive *de facto* relevance to be built up by systems that track objective relevance. And, just like any cognitive system that tracks stuff in the world, sometimes things work out and sometimes things go awry; and sometimes cognitive systems track truths but not all the time (such as the perceptual systems; cf. Viger, 2006a). It seems, however, that *in the main* cognition tracks truths in the world, and is quite good at it. Thus, the *de facto* relevance embodied by the relations within and between concepts by and large reflects objective relevance in the world. This is what makes *de facto* relevance close enough to objective relevance; and close enough is good enough.

## Abstract

Children with Specific Language Impairment (SLIC) experience difficulties in processing Subject relative clauses (SRC). This has been interpreted as evidence that they lack syntactic representations for SRC. Our study investigates the spontaneous production of SRC in typically developing children (TDC) and SLIC in a structural priming paradigm, and compares their performance in a sentence repetition task. We demonstrate that SLIC are much more likely to produce SRC during priming than in sentence repetition; moreover, when primed, their performance matches TDC's baseline (unprimed) performance. Furthermore, we design two simple unsupervised Bayesian models, and predict the developmental group (SLI, TD) and priming condition (Primed, Non-Primed). Overall, this study shows that SLIC can spontaneously produce SRC when primed, suggesting their impairment is related to working memory, rather than a deficit in syntactic knowledge.

**Keywords:** specific language impairment; language development; syntactic priming; sentence repetition; Bayesian data analysis.

## Introduction

Subject relative clauses (SRC) such as *the cat that's on the table* are generally early acquired, at around 3 years in typically developing children (TDC; e.g., Crain et al. 1990). However, children with Specific Language Impairment (SLIC) display difficulties in producing subject (and object) relative clauses (Novogrodsky & Friedmann, 2006). Preschool SLIC show a delayed onset of relative clause production, and frequent omission of the complementizer in both elicitation and spontaneous production (Contemori & Garraffa, 2010). This difficulty extends to repetition of sentences involving SRCs. This is particularly interesting, because recent research has suggested that in TDC, prior exposure to even difficult structures can facilitate their subsequent production (e.g., Bencini & Valian 2008). Such effects have been identified as manifestations of syntactic priming, whereby an abstract syntactic representation is facilitated (Bock, 1986). In adults, syntactic priming appears to be implicated in sentence repetition (Potter & Lombardi, 1998). It is therefore striking that SLIC do not show facilitated production of SRC in sentence repetition, as we would expect a benefit from a syntactic priming effect, enhanced by lexical repetition.

Previous research has therefore proposed that SLIC do not have a syntactic representation of SRC (Conti-Ramsden et al., 2001). In this paper, we consider an alternative hypothesis, namely that SLIC's poor performance in sentence repetition does not reflect a lack of syntactic knowledge, but rather a task-specific difficulty, which may be related to working

memory demands. We investigate this hypothesis by comparing SLIC's and TDC's production of SRCs in tasks where they are explicitly elicited (in a sentence repetition task) and when they are implicitly elicited (in a picture-description syntactic priming paradigm). We use Bayesian Data Analysis to investigate our hypothesis, and design a series of Bayesian models to tackle it.

## Experiment

Substantial research has used a syntactic priming paradigm to demonstrate that people use abstract syntactic representations to process language (Bock, 1986; Pickering & Branigan, 1998). In such research, speakers show an increased tendency to use a particular structure after previously encountering the same structure (even with different lexical content). These effects have been argued to provide evidence about syntactic representation (Branigan et al., 1995). Recent research on TDC has therefore used syntactic priming to provide evidence for the early acquisition of TDC's syntactic representations, e.g., passive constructions (e.g., Bencini & Valian 2008): If children are more likely to produce a particular structure after previous exposure to it, it implies that they have an abstract representation for that structure, which can be facilitated through residual activation or implicit learning (Chang et al., 2006; Pickering & Branigan, 1998). The former may explain short term priming effects; the latter may explain long term and cumulative priming effects. We argue that a syntactic priming paradigm can similarly be used to examine whether SLIC have access to an abstract representation of SRC, whose availability can be incremented through priming.

To do this, we used a Snap priming paradigm (Branigan et al., 2005), in which SLIC and TDC engaged in a card game that involved three elements: 1) listening to the experimenter describe a picture (using either a simple noun or an SRC), 2) describing their own picture, 3) and deciding whether or not the two pictures matched<sup>1</sup>.

In the analysis, we assess whether the two groups (TDC, SLIC) differ in their production of SRC (Model 1); and test if any difference depends on the priming condition (i.e., whether the experimenter's description involved a simple noun or an SRC; Model 2). We expect TDC to have a higher production of SRC than SLIC. However, we expect SLIC to perform better in the primed than in the non-primed condi-

<sup>1</sup>On three quarters of trials, the pictures did not match, and on one quarter - Snap trials - they did match

tion. If so, this would provide evidence that SLIC have a syntactic representation of SRCs, whose retrieval is facilitated by prior exposure. This in turn would imply that SLIC's observed impairments in SRC production have a different source than lack of syntactic knowledge of SRCs.

We then compare the two groups' performance on Snap trials only (i.e., where the child's picture matched the experimenter's picture, and hence the child could repeat the experimenter's description verbatim), with their performance in a task where they were explicitly asked to repeat the experimenter's sentence <sup>2</sup> (Model 3). Thus we compare children's production of SRC sentences, when the children produce those sentences freely in response to a picture stimulus (priming) and when they produce them as part of an explicit repetition task (repetition). If their impairment is fundamentally syntactic, then SLIC are expected to be equally bad on both tasks, and the TDC equally good on both tasks. If instead the impairment has a non-syntactic source, then children may show differential performance on the two tasks. In particular, if SLIC have a working memory impairment, they may find it difficult to produce SRC in a task where they must retain in working memory the meaning to be communicated (as well as its syntactic form).

We then investigate cumulative priming, i.e., whether the likelihood of producing an SRC increases as a function of priming instances (Kaschak et al., 2011), which is assumed to reflect implicit learning. Given previous evidence that SLIC have impairments in implicit learning (Tomblin et al., 2007), we should observe no such cumulative effect benefit in SLIC.

Finally, we move on to possible applications of our study, and investigate the problem of classification, and the related issue of diagnostic statistics to assess impairment (here, SLI). We use Bayesian inference to built two classifiers: in the first (Model 5), we categorize the development group (SLI, TD) based on the number of SR produced; and in the second (Model 6), we use the same measure to categorize development group and priming (Primed, Non-Primed). The retrieval performance of the two Bayesian models is compared with logistic regression classifiers, binomial (Model 5), and multinomial (Model 6) on F-score, an aggregate measure of precision and recall.

## Method

We compared SLICs (and control TDCs) production in a syntactic priming paradigm using a picture description SNAP task. Thirty-eight (19 SLI, 19 TD) pre-school monolingual Italian children participated (mean = 5.4 years, Non-verbal IQ > 92). SLIC were selected on the basis of their general comprehension and expressive abilities, measured on MLU and on performance on standardized language tests (expressive abilities: Frog story; receptive lexicon: PPVT; receptive grammar: TCGB).

Children described target pictures after hearing the experimenter describe a prime picture with an SRC (*a cat that's on a wall*) or a simple noun (*a cat* in a within-participants manipulation (priming). There were 24 prime/target pairs (where the experimenter's and child's pictures, and hence necessarily

their descriptions, were different), and 8 'snap' pairs (where the experimenter's and child's pictures were identical, and they could therefore use identical descriptions).

The same groups of children took also part in a sentence repetition task, where they had to repeat, verbatim, 10 SRC sentences produced by the experimenter. We compare their performance in this task with their performance on the 'snap' trials (8 per participant), in which they described the same picture as the experimenter had just described (and hence could repeat the experimenter's utterance verbatim).

## Data Analysis

We adopt a Bayesian approach for the analysis of this study, with the aim of uncovering the parameters responsible for generating the observed data, (e.g., the performance of the two populations of children), infer their distribution, and have an estimate of the uncertainty in our hypothesis (Kruschke, 2010).

In the next sections, we describe four Bayesian models used to test our hypotheses. Then, we apply Bayesian analysis on a classification task and infer, in an unsupervised way, developmental group (SLIC, TDC) and priming condition (Primed, Non Primed) using the number of produced SRC as our dependent measure. We compare the performance of these two Bayesian classifiers with logistic regression models, which are trained on the same set of data. We report F-scores to assess the overall performance of the models, and precision and recall for the different classes to evaluate more in depth the classification performance.

## Models

All Bayesian analyses presented here are performed using OpenBugs as implemented by the R packages BRugs and R2WinBugs (Sturtz et al., 2009; Kruschke, 2011).

**Model 1: Group analysis** The first model estimates how different the two groups of children (TDC, SLIC) are in producing SRC. We model the occurrence of an SRC production through a Bernoulli process (e.g., coin toss) with a given probability of success, whereby the total number of occurrences in a series of trials follows a binomial distribution. For each group of children, the number of SRC produced is denoted by the vectors  $x$  and  $y$ , which represent independent samples from two different binomial distributions, in a total of  $N$  trials ( $N = 24$ ), with respective probabilities  $p$  and  $q$  underlying SR production. Each group consists of  $S$  observations, equal to the number of children in that group. The index  $i$  in  $x_i$  and  $y_i$  refers to subject  $i$  in each group. The likelihoods of the data are given by:

$$P(x_1, x_2, \dots, x_S | p) = \prod_{i=1}^S \binom{N}{x_i} p^{x_i} (1-p)^{N-x_i}, \quad (1)$$

in the case of the TDC group, and an analogous equation for the SLI group by replacing  $p$  by  $q$ . As prior knowledge, we assume that both  $p$  and  $q$  are independently drawn from  $\sim \text{Beta}[1, 1]$ . This allows us to independently estimate the underlying production rate for TDC and SLIC.

<sup>2</sup>Conducted on the same groups of children.

**Model 2: Effects of priming** In the second model, we compare the effect of priming on the production of SRC for the two groups of children. Here, our dependent measure is the number of SRC produced for each trial, i.e., we aggregated over participants. Every trial can belong to one of the two Priming states (Primed, Not Primed). So, each observation  $n_t, (t = 1, \dots, N)$  is the number of SRC produced in trial  $t$ , to which a particular state of priming  $c_t$  is associated:  $c_t = 1$  refers to a Non-Primed trial, and  $c_t = 2$  to a Primed one. Since trials are independent, and we know their priming status, given by the vector  $c$ , the likelihood of the performance of a group can be computed as a product over trials:

$$P(n_1, n_2, \dots, n_N | p, c) = \prod_{t=1}^N \binom{S}{n_t} p(c_t)^{n_t} (1 - p(c_t))^{S-n_t} \quad (2)$$

We assume a uniform prior for  $p(1)$ , and the relation  $p(2) = p(1) + \theta$ , where the difference parameter  $\theta$ , is also given a uniform prior,  $\theta \sim \text{Uniform}[0, (1 - p(1))]$ . We apply this model, independently to SLIC and TDC. In the former case,  $n$  is calculated from the performance of the SLIC; in the latter case,  $n$  is obtained from the TDC group. This model allows us to infer 4 parameters.

**Model 3: Sentence Repetition vs Priming** In this third model, adapted from Model 2, we explore more closely the role of working memory on the production of SRC by comparing SRC repetition on SNAP trials in the priming task<sup>3</sup>, where participants could repeat the experimenter’s sentence, with SRC elicited through sentence repetition.

Every trial can belong to one of the two tasks (Repetition, Priming). So, each observation  $n_t, (t = 1, \dots, N)$  is the number of SRC produced in trial  $t$  in Repetition ( $c_t = 1, N = 10$ ) or Priming ( $c_t = 2, N = 8$ ). As for Model 2, we assume a uniform prior for  $p(1)$ , and the relation  $p(2) = p(1) + \theta$ , where the difference parameter  $\theta$ , is also given a uniform prior,  $\theta \sim \text{Uniform}[0, (1 - p(1))]$ . This model is applied independently to SLIC and TDC.

**Model 4: Cumulative priming** Finally, in our fourth model, we quantify the rate at which cumulative priming occurs for the two groups of children. For this model, we represent the data as two matrices  $X_{S \times N}$  (TDC) and  $Y_{S \times N}$  (SLI), where each entry, for example  $x_{it} \in \{0, 1\}$  is a Bernoulli random variable denoting production or not of a relative clause for each subject ( $i = 1, \dots, S$ ), in each particular trial ( $t = 1, \dots, N$ ). We can calculate the likelihood of the data from each group, by using the following expression:

$$P(X | p_0, a, k) = \prod_{i=1}^S \prod_{t=1}^N p(t)^{x_{it}} (1 - p(t))^{1-x_{it}} \quad (3)$$

In this model, the probability of producing an SRC is given by  $p(t) = p_0 + ak(t)$ , and it increases linearly with the number of priming trials  $k(t)$  that have occurred up to trial  $t$ .

<sup>3</sup>Note that we exclude this data from any other model of priming.

Table 1: Observed production performances (in percentage) for the two groups on the repetition and priming task (also divided by Priming condition)

Group	Repetition	Priming SNAP	Primed	Non-Primed
TDC	90%	56%	57%	19%
SLIC	16%	39%	24%	0.9%

In analogy, for the SLI group we have  $q(t) = q_0 + bk(t)$ . We must estimate 4 parameters:  $p_0, a, q_0, b$ . As priors, we use non-informative uniform priors for the intercepts, e.g.  $p_0 \sim \text{Uniform}(0, 1)$ , and normal distributions for the slopes, e.g.,  $a \sim \text{Normal}(0, 1)$ . We expect to find a lower rate of cumulative priming for SLIC than for TDC ( $a > b$ ), due to their impairment of implicit learning.

All models are run for 50000 iterations with a thinning of 10. If the chains have not converged, and are highly auto-correlated, we keep updating until convergence. We discard the first 5000 iterations of the Monte Carlo Markov Chains (MCMC) sample as burn-in, to calculate the posterior distribution of the parameter values. A summary of the results is reported in Table 2.

## Results

Before going into the modeling results, we report the observed performance on the priming task, as well as on the repetition task for the two groups (refer to Table 1).

It is clear that during the repetition task SLIC are much more impaired than TDC in producing SRC. However, their production rates improves when we look at repetition during the priming (SNAP task) trials, where SLIC are twice as good compared to the sentence repetition result. When looking at the performance within the Priming task, we see an effect of priming on both TDC and SLIC. The production rate of SRC is more than doubled in Priming trials compared to the Non-Primed condition. These results are largely confirmed in our inferential analysis.

As expected, in Model 1 we find that  $p > q$ : TDC are more likely to produce SRC than SLIC (refer to Table 2). This result indicates that SLIC experience more difficulties, in fact twice more so ( $p/q \approx 2$ ), in producing SRC than TDC. However, in order to understand whether structural priming is actually increasing the production rate of SRC in SLIC, and quantify any difference with TDC, we included the priming variable in Model 2.

Here, we find that TDC are more likely to produce SRC, especially in Primed trials. Crucially, however, we also find a strong effect of Priming in SLIC. In fact, we observe that SLIC are 20% more likely to produce an SRC when primed than when not primed. Moreover, we see that the probability of producing an SRC by a SLIC who is primed becomes indistinguishable, if not higher, than that of a TDC who is not primed. This result demonstrates that the impairment displayed by SLIC cannot be attributed to a lack of syntactic knowledge, but rather to some other aspect of cognition. In fact, when the relevant structural representations are facilitated through syntactic priming, SLIC can spontaneously pro-

duce relatively complex structures such as SRC. To examine the possible role that working memory might play in SLIC's previously observed impairment in SRC production, in Model 3, we compared syntactic priming with a task that explicitly taps working memory, namely sentence repetition.

The result of Model 3 clearly shows that the SLIC perform very differently in the two tasks, Snap and repetition (see Table 2). This is especially evident when looking at the difference in probability between the two tasks: SLIC are much more likely to produce an SRC during the Snap task than during the repetition task, whilst for TDC, the difference  $p(2) - p(1)$  is almost negligible.

This result is intriguing as it implies that given a task in which the child has to actively retrieve syntactic material to communicate a contextually supported proposition (provided by the visual stimulus), their impairment is much less pronounced. This pattern is consistent with a working memory impairment in which SLIC children have difficulty in building, maintaining, and retrieving a representation of an entire sentence. In order to better explore the role of working memory on the production rate, we turn to cumulative priming. If implicit learning, which is hypothesized to underlie long term and cumulative priming effects, is impaired in SLIC, then we might observe a weaker, or almost null, effect of cumulative priming in that group.

Interestingly, the results of Model 4 show that the intercept parameter  $p_0$ , which indicates the baseline probability for TDC to produce an SRC, is markedly lower than the value observed in the previous model (refer to Table 2 for the list of models). The intercept  $q_0$ , instead, is reasonably similar in value across the two models. When we look at the slope parameters ( $a, b$ ), we observe a different rate for the two groups of children. In particular, TDC experience more cumulative priming in producing SRC, compared to SLI children. This result indicates that although cumulative priming occurs in both groups, this effect is more prominent in TDC. Moreover, it seems that cumulative priming plays a crucial role on the likelihood of producing SRC, as it emerges when comparing the estimates of this model with Model 1. The diminished effect of cumulative priming in SLIC is in keeping with evidence that SLIC have impaired implicit learning. At the intercepts, in fact, the two groups display a similar probability of producing SRC, and the difference becomes more prominent when previous exposure to SRC increases.

In the next section, we shift the focus from quantification to prediction, and apply Bayesian analysis to make inferences about our data. In particular, we implement two Bayesian classifiers to predict development group and priming in an unsupervised way, i.e., we assume there is no prior knowledge about such classification, and we want to infer it from the data. In order to validate the performance of such models, we compare the classification performance of the two Bayesian models with the output of logistic classifiers. We report the F-score, which is a measure of test's accuracy based on the weighted average of precision and recall:  $F = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}$ . Precision is the fraction of retrieved instances that are relevant, e.g., the number of correctly categorized children in a certain group,  $\frac{tp}{tp+fp}$ , and recall is the

Table 2: Mean and 95% Highest Density Intervals for the posterior distributions of parameters for the different models.

fraction of relevant instances that have been retrieved,  $\frac{tp}{tp+fn}$ , e.g., the correctly categorized children off the total number of possible children in that group; where  $tp$  (true positive) is the number of instances correctly retrieved,  $fp$  (false positive) are the instances wrongly retrieved and  $fn$  those instances which should have also been retrieved. We report precision and recall for each category to distinguish what the model found easier to classify, from what found it more difficult.

### Inference of developmental categories and priming

In the first Bayesian classifier (Model 5), our goal is to predict the development group of a child (SLI, TD) by considering blindly their SR production scores. Therefore, we don't assume a-priori that there is a division between TD and SLI, and mix the data between the two different groups. Our task is to infer correctly which data belongs to each category. We implement an extension of Model 1 as follows.

To each observation  $z_i$ , ( $i = 1, \dots, 2S$ ), corresponding to the

number of SR clauses produced by all subjects of the experiment, we assign a hidden state  $c_i \in \{1, 2\}$ , which refers to the subject being an SLI (1) or a TD (2). If the hidden state of each subject is known, the total likelihood of the data can be computed as:

$$P(z_1, z_2, \dots | c_1, c_2, \dots) = \prod_{i=1}^{2S} \binom{N}{z_i} p(c_i)^{z_i} (1 - p(c_i))^{1-z_i} \quad (4)$$

where  $p(1)$  is the probability of producing a relative clause in the SLI group, and  $p(2)$  of the TD group. This corresponds to a mixture model, where we infer the two distributions present in the data set (estimate  $p$ ) and the probabilities  $\pi_i(1)$  and  $\pi_i(2)$  that each observation  $z_i$  belongs to distribution 1 or 2 (estimate  $c$ ). We assume a Dirichlet prior for the category assignment and a uniform distribution for  $p$ , similar to previous models.

The final model (Model 6) is an extension of Model 5, where, beside the development group, we want to infer also the priming condition (Primed, Non Primed). So, the only real difference is that we assume four categories  $c_i \in \{1, 2, 3, 4\}$  where 1 is SLI-Non priming, 2 is SLI-Priming, 3 is TD-Non Priming and 4 is TD-Priming. Again, the model is blind to these categories, and our goal is to infer them from the data. We proceed as in Model 5 and we obtain a posterior (discrete) distribution for the categorical classification of each observation, namely what is the probability that an observation comes from category 1, 2, 3 or 4. The most likely category for each observation can be obtained by considering the median of such a posterior distribution, i.e. the category that obtains a probability higher than 1/2 for that observation.

**Model performance** We compare the categorization performance of these two unsupervised models against two fully supervised logistic classifiers, Binomial (BL) for Model 5, and multinomial (ML) for model 6. The logistic classifiers are built using the R libraries `glm` and `mlogit`. We first fit a generalized linear model, binomial with logit link, and a multinomial regression to obtain the regression coefficients. Our dependent measure is the number of SRC produced and the independent predictor is the category: group for the binomial logistic classifier, group and priming for the multinomial classifier.

From the regression coefficients, we derive the logits, which exponentiated give us the unscaled probabilities of observing a certain category, e.g., SLI, associated to a certain SR production score. The unscaled probabilities are normalized to range between 0 and 1<sup>4</sup>.

For the sake of completeness, we compare the estimates of the parameters for these two models, where categories have to be inferred, with those where such information was explicitly modeled (Model 1 and Model 2); see Table 2 for the actual values. We observe that the estimates are close between

<sup>4</sup>More details can be found on the online tutorial provided by UCLA: Academic Technology Services, <http://www.ats.ucla.edu/stat/r/dae/mlogit.htm>

Table 3: Classification Performance of the Bayesian Models and the Logistic classifiers: F-scores, precision (left value) and recall (right value) for the different categories (TD and SLI): where P (Primed) and N-P (Non Primed)

(a) Model 5 vs Binomial Classifier

Model	F-score	Categories	
		TD	SLI
Model 5	0.85	(0.8, 0.84)	(0.83, 0.78)
BL	0.85	(0.8, 0.84)	(0.83, 0.78)

(b) Model 6 vs Multinomial Classifier

Model	F-score	SLI N-P	SLI P	TD N-P	TD P
Model 6	0.55	(0.76, 0.88)	(0.42, 0.15)	(0.35, 0.26)	(0.53, 0.94)
ML	0.56	(0.65, 0.78)	(0.36, 0.47)	(0.4, 0.21)	(0.83, 0.78)

Model 1 and Model 5; whereas there is a more marked difference between Model 2 and Model 6. As the number of categories to be inferred from the data increases, the task becomes more challenging.

When comparing the classification performance, we find that Model 5 and BL are perfectly equivalent, both in terms of F-score, and on the precision and recall of the group category. Obviously, the main outstanding difference is that the Bayesian model is unsupervised, while the logistic classifier is fully supervised. Moreover, it is interesting to notice that SLIC and TDC are recognizable as separate populations, rather than being outliers of the same distribution.

On the multi-class task, in contrast, we find that ML is slightly better than Model 6 on the F-score. When looking at precision and recall for the different classes, we find both models achieving higher classification performances on the two most extreme classes (SLI Non Primed and TD Primed), with Model 6 having a better recall than ML, which instead has a better precision. It is interesting to notice that both models fail to account for the two categories SLI Primed and TD Non Primed. The reason is that SLIC Primed perform as well as TDC Non primed. This result confirms further our main hypothesis that SLIC have syntactic knowledge of SRC, and can achieve performance comparable to TDC when the relevant representations are facilitated through syntactic priming.

## General Discussion

Typically developing children are able to process SRC around the age of 3 years (Crain et al., 1990). Yet children with SLI show difficulties with these structures at the same age (Novogrodsky & Friedmann, 2006). In particular, the finding that SLIC cannot repeat verbatim SRC sentences produced by an experimenter has been taken as evidence that SLIC do not have a syntactic representation of relative clauses (Conti-Ramsden et al., 2001). To challenge this claim, we compared SLIC and TDC's production of SRCs in two different tasks, one of which implicitly elicited repetition of SRC sentences (syntactic priming in a 'Snap' task) and one of which explic-

itly elicited repetition of SRC sentences (sentence repetition task), in a series of Bayesian Models. We then used such models to infer developmental group and priming condition on a trial-by-trial basis by looking at the number of SRCs produced.

We found that although TDC display a higher production of SRC than SLIC (Model 1), SLIC nevertheless are more likely to produce an SRC when primed, i.e., after hearing an SRC (with different lexical content) than after hearing a simple noun (Model 2). This suggests that SLIC have an abstract representation of SRC that they can recruit during production, when it has been facilitated through previous use. Crucially, however, SLIC performed worse in a sentence repetition task than in 'snap' priming trials in which they could repeat verbatim the experimenter's sentence (Model 3). In other words, the same children who performed poorly in a task that required explicit repetition of sentences performed significantly better in a priming task, where implicit repetition could be realized through incremental production of a sentence and did not require the (meaning and structure of the) entire sentence to be maintained in working memory. This suggests that SLIC's impairment on these structures is related to working memory. Furthermore, we found that whereas TDC showed a large cumulative priming effect (i.e., were much more likely to produce an SRC after several exposures), SLIC showed a markedly reduced, if not negligible, cumulative effect (Model 4).

Taken together, our results suggest that SLIC's poor performance on SRCs may reflect a working memory impairment that affects on-line processing, rather than the absence of a syntactic representation for SRCs (i.e., a deficit in syntactic knowledge). In a task that implicates all stages of language production, and in which production can occur incrementally without the necessity of retaining in working memory a representation of the entire sentence, SLIC are able to spontaneously produce SRCs after being exposed to them; furthermore, their spontaneous production of SRCs in this context is less impaired than their elicited repetition of SRCs, relative to TDC. However, the finding that SLIC show reduced cumulative priming suggests that they may also have impaired implicit learning, which may have far-reaching implications for their acquisition of language. The classification performance of our Bayesian models demonstrates moreover that we can infer the developmental group of a child very accurately (Model 5) with the same accuracy as a Binomial Logistic Classifier, with the clear advantage that the Bayesian model is unsupervised. Crucially, our classification performance degrades when trying to infer the group and the Priming condition (Model 6), because SLIC Primed perform as well as TDC Non-Primed.

In conclusion, we suggest that modeling differences in syntactic performance in syntactic priming and other experimental paradigms has great potential for investigating the nature of impairments in syntactic representations versus other aspects of cognition in SLIC and other atypical populations.

## Abstract

We have proposed that visual narratives in comics are organized with a hierarchic narrative “grammar.” Inspired by classic “click” studies of syntax, we inserted blank “disruption” panels Before, At, or After the constituent boundaries of comic strips. In self-paced viewing, Experiment 1 found that blanks After the boundary were viewed slower than Before or At the boundary. Panels immediately following blanks were slower than corresponding panels in sequences without blank panels, but only when placed Before or After the boundary. Three ordinal panel positions following the boundary, panels following blanks At the boundary or with No-Blanks were viewed faster than panels following blanks After or Before the boundary. This supports constituency because disruptions had greater impact within, as opposed to between, constituents. Using ERPs, Experiment 2 found a larger anterior negativity to blanks within constituents (Before/After) than between constituents (At). This indicates disruptions of constituents are recognized before reaching a subsequent panel. A larger P600 appeared to blanks After the boundary than in the first constituent (Before/At). This positivity may reflect a reanalysis reflecting the inability to integrate all prior panels into a single constituent, since they are divided by the constituent boundary.

**Keywords:** Grammar; Constituent Structure; Discourse; Narrative; Comics; ERPs; Left Anterior Negativity.

## Introduction

Drawings have conveyed narratives through sequences of images for thousands of years, but in contemporary society they appear most prevalently in comics. In comparison with research on the structure and comprehension of verbal narrative, however, little is known about mechanisms of processing sequential images. For example, are narrative units integrated linearly across each adjacent relationship or they organized into hierarchic constituents?

## Background

Since the 1950s, research on language has stressed that sentences are organized into hierarchic constituents, rather than linear word-to-word connections (e.g., Chomsky, 1957).

An analogous distinction between local relationships and hierarchic segmentation has underlined research of text and discourse. Traditional approaches emphasize coherence relationships between individual sentences (Halliday & Hasan, 1976; Zwaan & Radvansky, 1998). Participants can intuitively segment texts into consistent groupings (Gee & Grosjean, 1984; Mandler & Johnson, 1977), suggesting that readers’ comprehension extends beyond adjacent relationships between individual sentences.

Some theories have formally described hierarchical relationships in narrative, such as “story grammars” (e.g. Mandler & Johnson, 1977; Rumelhart, 1975; Thorndyke, 1977), which use phrase structure rules to organize narratives around characters’ goal-driven events. Constituent structure in these models was examined using clustering models (Gee & Grosjean, 1984; Mandler, 1987; Mandler & Johnson, 1977), similar to those employed by early psycholinguistic research on syntactic relations (e.g. Levelt, 1970). Participants divided a narrative into logical groupings, and these intuitions were then submitted to the algorithms in hierarchic clustering models. These analyses yielded tree structures that closely correlated with the models predicted by the original theories.

As in verbal discourse, theories of visual narrative have also emphasized linear relationships between individual images (McCloud, 1993). However, beyond such linear relationships, participants also intuitively divide visual narratives into segments (Gernsbacher, 1985). Again, this suggests that comprehension may extend beyond adjacent relationships.

Recently, Cohn (2003, In Press) has proposed a theoretical model of narrative structure that formalizes the

constituent structure of visual narrative. Like story grammars' treatment of sentences, this model organizes panels into hierarchic constituents (though important differences distinguish this approach from story grammars, and this model could potentially provide an alternative approach for describing the structure of verbal discourse).

Figure 1 illustrates the narrative structure for a 6-panel *Peanuts* comic strip. This sequence depicts a baseball game that starts with Lucy hitting a ball, which allows Charlie Brown to run home and score, escaping a tag by Schroeder. The first panel shows Lucy tossing a ball. This panel functions as an Initial, initiating the interactions in the sequence. In the second panel, Lucy hits the ball, a narrative "Peak" as the culmination of the initiated action. Together, these two panels act as an Initial constituent that propels the rest of the sequence. A second constituent begins with Schroeder waiting for the ball—nothing happens here except a set-up of the characters (Establisher). The next Initial begins the new set of events, which climax in the penultimate Peak panel—Charlie interrupts the catch by sliding into the base. The last panel then resolves this interaction (Release). Together, these panels act as a Peak that is set up by the constituent-level Initial of the first panels. Thus, at a higher level of processing, the first constituent (Lucy hitting the ball) acts as an Initial, which facilitates the second constituent (Charlie scoring), a Peak. As a result, the narrative structure operates on both the panel level and the level of whole constituencies.

Figure 1: Narrative structure in a comic strip with markings Before, At, and After the narrative constituent boundary.

While clustering analyses have shown evidence for hierarchic structure in verbal discourse, no studies to date have examined constituent in sequential images. Furthermore, evidence that narrative constituent structure is used during *online* processing has yet to be explored in any modality. Here we describe two experiments to determine whether constituents are used when processing sequential images.

## Experiment 1: Self-paced Viewing

In a classic experiment on syntactic structure, Fodor and Bever (1965) pioneered a "click technique" where they played a verbal sentence in one ear of a participant, and then introduced short bursts of white noise ("clicks") in the other ear. They reasoned that, if clauses constitute the perceptual processing units of sentences, clicks that disrupt those units would be harder to discern than clicks occurring between clauses. They found that participants were better able to recall clicks that were placed at the clause boundaries than those before or after it. Also, participants tended to falsely recall clicks within constituencies as occurring within the constituency break. Subsequent studies found similar findings, with the overall interpretation that such disruptions reflect the psychological validity of a syntactic constituent structure (for review see Garrett & Bever, 1974).

In Experiment 1, we used an analogous "disruption" paradigm to determine whether the comprehension of visual sequences also draws upon a constituent structure in narrative sequences. We measured viewing times in graphic sequences where blank white "disruption" panels were inserted Before, At, or After the narrative constituency boundary.

## Methods

### Participants

60 self-defined comic readers (35 male, 27 female, mean age = 24.03) from the Tufts University student population and surrounding neighborhoods were paid for their participation.

### Stimuli

Novel 6-frame long sequences were created (160 sets) using individual panels culled from several volumes of Charles Schulz's *Peanuts*. Using Cohn's (In Press) model of visual narrative, we designed sequences that had two narrative constituents. This was confirmed using a behavioral task in which 20 participants drew lines to divide strips into two parts. Our final 120 strips had a 71% agreement on where constituent boundaries were located. Each sequence had constituent boundaries appearing after panel 2, 3, or 4 (40 of each type). Using these strips, we then inserted blank "disruption" panels Before, At, or After the constituency boundaries (as notated at the bottom of Figure 1), along with No-Blank control sequences. Because of the variation in position of the boundary, blank panels across all sequences could appear between the second and fifth panel positions, and items were counterbalanced across four lists such that each participant only viewed a sequence once. 15 fillers in each list had two successive blank panels and one-third of 75 additional no-blank fillers had violations of coherence.

## Procedure

Participants viewed comic panels one frame at a time on a computer screen, self-pacing their way through the sequence. After each sequence, they rated the coherence of the strip on a 1 to 5 scale.

## Results

Three-way ANOVAs showed that the position of the blank panel significantly impacted how fast it was viewed (see Figure 1),  $F(2,118)=12.93$ ,  $p<.005$ ,  $F(2,238)=7.26$ ,  $p<.005$ . This effect arose because blanks After the boundary were viewed significantly slower than blanks Before and At the boundary, (all  $t_s < -2.7$ , all  $p_s < .01$ ). There were no difference in viewing times between blanks appearing Before and At the boundary,  $t(59)=-.964$ ,  $p=.339$ ,  $t(119)=-1.09$ ,  $p=.280$ .

Figure 2: Viewing times to blank panels.

The placement of blank panels in a sequence also impacted the processing of subsequent panels. Viewing times to panels appearing immediately after the blank differed from corresponding panels in sequences that had No-Blank (i.e., Blank +1, see Figure 3). Overall, we found a main effect of Disruption (blank, no blank),  $F(1,59)=6.34$ ,  $p<.05$ ,  $F(2,119)=14.11$ ,  $p<.001$ , a main effect of Position (Before, At, After) in the subjects analysis,  $F(2,118)=3.11$ ,  $p<.05$ ,  $F(2,238)=.472$ ,  $p=.617$ , but no interaction between them,  $F(2,118)=1.3$ ,  $p=.276$ ,  $F(2,238)=1.57$ ,  $p=.210$ . Panels following blanks Before the narrative constituent boundary were viewed significantly slower than their corresponding No-Blank panels,  $t(59)=-3.11$ ,  $p<.005$ ,  $t(119)=-3.48$ ,  $p<.005$ , as were panels following blanks After the boundary, a trending difference in the items analysis,  $t(59)=-1.34$ ,  $p=.184$ ,  $t(119)=-1.8$ ,  $p=.074$ . Panels following blanks At the boundary were not slower than corresponding panels in No-Blank sequences,  $t(59)=-.878$ ,  $p=.383$ ,  $t(119)=-1.56$ ,  $p=.121$ .

Figure 3: Viewing times to panels immediately after the blank panel (Blank +1) compared with corresponding panels in sequences with No-Blanks.

Delayed effects were also found three panel positions after the narrative constituent boundary (Boundary+3, see Figure 4),  $F(3,177)=2.90$ ,  $p<.05$ ,  $F(3,357)=5.24$ ,  $p=.005$ . Panels following a blank After the boundary were viewed slower than panels following blanks At the boundary and panels in sequences with No-Blank, (all  $t_s > -3.36$ , all  $p_s < .05$ ). Panels following blanks Before the boundary were viewed slower than those following blanks At the boundary,  $t(59)=1.49$ ,  $p=.142$ ,  $t(79)=2.12$ ,  $p<.05$ , and trending to be slower than panels in sequences with No-Blanks,  $t(59)=-1.56$ ,  $p=.124$ ,  $t(79)=-1.77$ ,  $p=.081$ . However, viewing times did not differ between panels following blanks Before and After the boundary, or between panels following a blanks At the boundary and in sequences with No-Blank, (all  $t_s < -1.34$ ,  $p > .184$ ).

Figure 4: Viewing times to panels three positions after the narrative constituent boundary (Boundary +3) in all sequence types.

## Discussion

Blank panels were viewed slower when they appeared After compared to Before or At the narrative constituent boundary. Panels immediately following blanks were slower than corresponding panels in sequences without a preceding

blank panel, but only when placed Before or After the boundary. A delayed effect of this disruption appeared three panels after the narrative constituent boundary. At this position, panels following blanks At the boundary or with No-Blanks were viewed faster than panels following blanks After or Before the boundary. These results are consistent with the presence of constituent structure to visual narrative: a blank panel disruption had greater impact within (Before/After) as opposed to between (At) constituents.

## Experiment 2: Event-Related Potentials

Different ERP components have been associated with manipulations of semantic and syntactic constraints. For example, the N400 ERP component has been associated with semantic processing of words (Kutas & Hillyard, 1980), individual visual images (Holcomb & McPherson, 1994), and images in visual narratives images (Cohn, Paczynski, Jackendoff, Holcomb, & Kuperberg, 2012; West & Holcomb, 2002). The N400 effect has been suggested as indexing the spreading activation of a word or image's meaning as it integrates with its preceding context to the information stored in semantic memory (Kutas & Federmeier, 2011).

In contrast, two ERP components have been linked to violations of grammatical structure during sentence processing. First, the P600 is a positive deflection that peaks from 600-800ms (Osterhout & Holcomb, 1992). It is seen to syntactic anomalies and ambiguities and has been interpreted as reflecting a process of continued analysis and/or repair as structural and semantic information are integrated to make sense of a sentence (Friederici, 2002; Kuperberg, 2007).

Waveforms resembling the P600 have also been found in domains outside of language. For example, in studies using silent movie clips of everyday events, a P600 was seen to "action violation" endings in which a predicted action was carried out with an incongruous object (e.g. a person preparing to cut a piece of bread followed by an image of the person attempting to cut the bread with an iron). This suggested that the P600 effect may reflect the integration of structural and semantic information around an event beyond linguistic processing (Sitnikova, Holcomb, & Kuperberg, 2008).

Certain syntactic operations have also been tied to a left-anterior negativity (LAN), which falls in the same time window as the N400 (between 300 and 500ms), but is distributed over frontal and left lateralized regions (Neville, Nicol, Barss, Forster, & Garrett, 1991). This component has been associated with violations of syntactic constituent structure in sentences (Friederici, 2002).

Anterior negativities outside of language have also been associated with violations of hierarchic structure in music. Patel and colleagues (1998) found a P600 to structural violations in musical sequences (e.g., a nearby key chord or a distant-key chord appearing after an otherwise in-key musical sequence). Another negative-going effect, distributed over right anterior and temporal sites, also

appeared between 300 and 400 milliseconds. This (*early right anterior negativity*) has led researchers to argue for overlap in the neural resources used to process structure in both music and language (Koelsch, Gunter, Wittfoth, & Sammler, 2005; Patel, et al., 1998).

Only one study has previously hinted at a LAN during the processing of visual sequences. Cohn et al. (2012) manipulated the presence or absence of narrative structure and semantic relatedness between panels in visual narratives. A larger negativity was found to sequences of scrambled panels (which had no semantic relations and no narrative structure) than to sequences with only narrative structure but no semantic theme (i.e., the sequence followed a narrative arc, but used panels from various sequences which had no meaningful relationship with each other). However, this negativity only appeared in a localized left anterior region, and was larger in participants with higher comic reading expertise. This left anterior effect was distinguished from a more widespread N400 effect that was greater in magnitude in these sequences that lacked semantic relations than to panels in sequences with no narrative structure, but with semantic relations to a general theme (like baseball), and to semantically and narratively congruous Normal sequences. We suggested that the left localized negativity—distinguished from the N400—might be analogous to the left anterior negativity effect seen to violations of structure in language. However, because this study did not directly introduce violations to narrative structure, this interpretation was speculative.

In Experiment 2, we predicted that violations of constituency in visual narratives would elicit similar ERP effects as violations of structure during sentence processing: P600 and LAN effects. We used the same set of stimuli from Experiment 1 and measured ERPs directly at blank panels.

## Methods

### Participants

24 self-defined comic readers from Tufts University (8 male, 16 female, mean age = 19.9) participated in the study for compensation.

### Stimuli

The same stimuli were used in Experiment 2 as in Experiment 1.

### Procedure

Participants viewed each sequence one panel at a time on a computer screen while ERPs were measured to all panels. After each sequence, participants rated its coherence on a 1 to 5 scale.

## Results

At the blank panel, between 500 and 700 milliseconds, repeated measures ANOVAs revealed significant interactions between Disruption Position, Region, and

Electrode Site at midline regions, and interactions between Disruption Position, Region, and Hemisphere at peripheral regions of the scalp (all  $F_s > 3.24$ , all  $p_s < .05$ ). Follow-ups showed a larger negativity to blank panels that appeared Before the boundary than to those appearing At the boundary at left anterior regions (F3, FC5, F7). Blanks appearing After the boundary evoked a larger negativity than those At the boundary again in left anterior regions (F3, FC5, F7) as well as at FPz and FP2. ERPs to Blank panels appearing Before or After the boundary did not differ in amplitude.

Figure 5: Amplitudes for blank panels at left anterior (F3) and posterior (O2) sites. Scalp map shows the contrast between blank panels After and At the boundary from 500 and 700ms.

At posterior sites, a larger P600 appeared to blank panels placed After the boundary (within the second constituent) than those placed Before or At the constituency boundary. The contrast between the After and At conditions revealed a significant effect at O1, Oz, and O2, and between the After and Before conditions showed an effect at O2.

## Discussion

A larger negativity was found to disruption blank panels that appeared within constituents (Before/After) than to blanks that appeared between constituents (At). This negativity localized to anterior, and somewhat left lateralized, locations. This is consistent with the lateralized anterior distribution of negativity effects shown to violations of syntax in sentences (Neville, et al., 1991) and music (Koelsch, et al., 2005; Patel, et al., 1998). It is important to note that it is only possible to confirm or verify that a blank panel has actually disrupted a narrative constituent once the subsequent panel is reached. However, we still saw a larger anterior negativity where the disruption occurred Before than At the boundary on the blank panel itself, prior to confirmation on the subsequent panel. This suggests that the brain may make online predictions about the building of constituent structure as a narrative progresses.

In addition to the anterior negativity effect, we also saw a P600 effect to blank panels appearing After (versus Before or At) the boundary. Because this positivity appeared to blanks only after a new constituent had been reached, we suggest that it reflected the failure of integrating all of the prior panels into a single constituent. This blank followed a panel after the constituent boundary, meaning that the preceding panel would be unable to be integrated into a single constituent with the other prior panels, thereby evoking a reanalysis of starting a new constituent (Friederici, 2002; Kuperberg, 2007).

## General Discussion

The results of Experiment 1 suggest that the introduction of a blank panel into a sequence has a greater impact on viewing times of subsequent panels if it falls within a narrative constituent (Before/After a narrative boundary) than between narrative constituents (At a narrative boundary). This provides evidence that comprehenders use narrative boundaries during the processing of visual sequences. The results of Experiment 2 support this interpretation. Moreover, because effects were seen on the blank panel itself, this further suggests that comprehenders of visual sequences make active predictions about narrative constituent structures.

Taken together, these results show that disruptions within a narrative constituent have a greater impact on processing than disruptions between narrative constituents. This suggests that the comprehension of sequential images draws upon a narrative structure that is organized into constituents, analogous to grammatical structure in language.

# Framing attention in American and Japanese comics

Neil Cohn (neilcohn@emaki.net), Amaro Taylor-Weiner, Suzanne Grossman

Department of Psychology, 490 Boston Ave  
Medford, MA 02155 USA

## Abstract

Research has shown that Americans focus more on focal objects of a scene while East Asians attend to the surrounding environment (Nisbett, 2003; Nisbett & Miyamoto, 2005). The panels of comic books—the sequential frames of images—highlight aspects of a scene comparably to how attention focuses on parts of a spatial array. Thus, comparison of American and Japanese comics can inform cross-cultural cognition by looking at the expressive mediums produced by these cultures. We compared the framing of figures and scenes in the panels of two genres of American comics (Independent and Mainstream) with mainstream Japanese “manga.” Both genres of American comics focused on whole scenes as much as individual characters, while Japanese manga individuated characters and parts of scenes. We argue that this framing of space in comics simulates a viewer’s integration of a visual scene, and is consistent with cross-cultural differences in the direction of attention.

**Keywords:** Cultural Psychology; attention; comics; Japan; manga.

## Introduction

Cross-cultural research shows that East Asians and Westerners differ in their direction of attention (Nisbett, 2003; Nisbett & Miyamoto, 2005). Beyond studying attention through perception, cognition can also be compared through cultural production (Morling & Lamoreaux, 2008), as in artistic expression (Masuda, Gonzalez, Kwan, & Nisbett, 2008). Comic books provide an ideal place to analyze the direction of attention, because panels act like windows onto a scene (Cohn, 2007). Thus, analysis of panels in Asian and American comics provides a place to look for cultural differences in cognition through creative expression.

## Attention across Cultures

Over the past decade, various research has shown that Asians and Americans direct their perception to aspects of visual scenes in different ways (Nisbett, 2003; Nisbett & Miyamoto, 2005). On the whole, Americans focus more on focal objects and characters with agency than on aspects of the background, while Asians attend to aspects of the whole environment or to characters’ relationship to the contextual environment.

These findings have been consistent across numerous behavioral paradigms. After viewing video scenes, Americans mostly describe the salient objects, while Asians

describe significantly more aspects of the surrounding context (Masuda & Nisbett, 2001). Americans also tend to notice changes to focal objects in animations that feature slight changes to a single scene, while Asians pick up on changes to the broader environment and relations between objects (Masuda & Nisbett, 2006). When recalling scenes where the background is changed from its original context, Americans are unaffected while Asians’ memory appears impaired (Masuda & Nisbett, 2001), and Americans’ eye movements fixate sooner and longer on focal objects, while Asians make more saccades to elements of the background (Chua, Boland, & Nisbett, 2005). Additionally, when viewing photographs of objects, fMRI studies show that Americans have stronger activation than Asians in brain regions associated with the storing of semantic information about object properties (Gutchess, Welsh, Boduroglu, & Park, 2006). All of this work supports that Americans focus more on focal objects while Asians attend more to aspects of environments and relationships.

Research has also suggested that preferences for attention permeate into artistic representations. Masuda, Gonzalez, Kwan, and Nisbett (2008) looked at a corpus of artwork, and found that Western paintings emphasized the focal objects and figures, while East Asian paintings emphasized the broader context and environment. This trend was reinforced in drawings and photographs of figures and scenes produced by individuals from these cultures. Thus, these cognitive preferences for attention extend into artistic expression, and other contemporary media produced by these cultures might be expected to show further evidence of these trends.

## Comic Panels as Units of Attention

Comic books are an ideal place to examine attention in artistic expression. Because comic panels act as windows on a visual story, they can serve as graphic equivalents of a “spotlight of attention” for the fictitious scene. To this end, Cohn (2007) has described comic panels as “attention units” that highlight parts of a scene in different ways. Within a sequence of images, a scene may have two types of elements: *Active entities* are those that repeat across panels by engaging in the actions and events of the sequence, while *inactive entities* are elements of the background. Panels can be categorized related to these elements (and depicted in Figure 1):

1. *Macro* – depict multiple active entities
2. *Mono* – depict single active entities
3. *Micro* – depict less than one active entity (as in a close up)
4. *Amorphic* – depict no active entities (i.e., only inactive entities)

In one of the first comparisons of American and Japanese comics, McCloud (1993, pp. 77-81) coded types semantic relationships between juxtaposed panels. He found that American and European authors primarily used transitions showing actions with clear temporal change, followed by shifts between characters and locations. Manga similarly showed shifts in actions, characters, and locations.

Figure 1: Framing of attention in visual narrative.

These categories are distinguished by the amount of information they contain, which decreases successively: Macros contain more active information than Monos, which show more than Micros, which show more than Amorphic panels. These ways of highlighting attention are similar to, though not the same as, types of film shots. For example, a Macro may involve a long shot to capture the most information possible, but a panel showing only the hands of individuals exchanging a piece of paper would be a Macro (because they involve multiple characters) that uses a close up shot. In this way, close ups are also not always Micros, but they vary based on how much information they window.

### Cross-cultural Comparison of Comics

With the growing influx of Japanese manga (“comics”) into America over the past several decades, many comparisons have been made between the techniques of Japanese and American authors (Cohn, 2010, 2011; McCloud, 1993, 1996). Japanese manga come from a different cultural context than that of American comics. While comics in America have historically appealed to a particular subculture, manga in Japan are treated much the same as movies, television, or textual books. Manga are widely read by all ages, have many genres, and, in fact, are so popular that they constitute nearly one-third of all printed material (Gravett, 2004; Schodt, 1983). Though Japanese manga were influenced by American authors early in their historical development (Gravett, 2004), they developed largely in isolation over the past 60 years. With increased importation of manga into America starting in the 1980s, the differences between narrative techniques that emerged from these separate traditions have become quite salient to readers, authors, and scholars of comics in America.

However, unlike American and European books, manga also transitioned to different aspects of the environment of a scene. McCloud attributed these differences to an “artistic culture” of Japan that focused on “being there over getting there.”

This hypothesis extended McCloud’s (1993, pp. 77-81; 1996) larger proposal that

manga allow a reader to take more of a subjective viewpoint on a story than American and European comics. He based this on the greater focus on environmental aspects in storytelling, more “subjective” types of motion lines (where a reader appears to move at the same pace as a moving object, as opposed to seeing it move in front of them), and subjective viewpoints in panels, which show the viewpoint of a character in the narrative. In order to test this broad claim directly, Cohn (2011) coded a corpus of comics and manga for this last type of subjectivity, where panels depict the viewpoint of a character in the narrative. More subjective panels were used in Japanese manga than American comics. This provided evidence that manga do indeed use more subjective viewpoints, at least across one measurable dimension.

Cohn’s (2011) study also examined the attentional types of panels described above. Nearly 60% of American panels were Macros, with only 35% Monos and 5% Micros (Amorphics were not yet theorized as a category, and were likely mixed in Monos and Micros). However, Japanese manga used almost as many Macros (57%) as Monos (43%), and more Micros (10%) than American comics. Because manga featured less than the whole scene in over half of all panels, it implies that the Japanese are as interested in the component parts of a scene as much as the whole scene. These results also suggest that the narrative structure of manga demands the inferential construction of whole scenes more than American comics (Cohn, 2010). These findings of more Micros in Japanese manga are also consistent with claims by Toku (2001, 2002) that manga influences Japanese children’s drawings. She found that Japanese children draw far more variable viewpoints than American children, particularly “exaggerated” close-ups.

While these studies have indicated that comic panels differ between cultures, variability may exist by looking within cultures. Obvious variability can be found in the diversity of American graphic styles compared to the far more uniform drawing style in manga. Graphic styles are

particularly pronounced between genres, which in America differ greatly between the more “serious” graphic novels and mainstream comics. Styles in genres of Japanese comics also vary, but mostly conform to a stereotypical style of big eyes, pointy chins and noses, and big hair. The diverse styles used in American comics have been likened to types of “dialects”, compared with “accents” in manga genres, which vary on a common schema (Cohn, 2010).

Variation between genres may apply to the level of panels as well, and can thereby inform about the framing of attention. In an early study, Neff (1977) found that panels use types of film shots differently between various genres of American comics. Wide shots (Long and Medium) far outnumbered Close shots (Close and Close ups) in panels for all genres. However, there were far less Close shots in Adventure and Romance comic panels than in Mystery and Alien Beings comics. These findings imply that different genres of American books do highlight different aspects of a visual scene. However, the sample size in this study was somewhat limited in scope—only two pamphlet-sized comics were analyzed per genre—making the results hard to generalize.

Given these precedents, the present study examined comic panels both within and between cultures by manipulating country of origin and genre. We compared the panels of “mainstream” Japanese manga with the two major populations of American comics: Mainstream and Independent (“Indy”) books. Mainstream books from both America and Japan were chosen because they are the most popular and most stereotypical instances of their respective comic cultures. American Indy books were chosen because they feature a different artistic movement in America that contrasts the Mainstream genres (discussed below). Thus, if variation occurs between the structures of comics from America, we may expect it between Mainstream and Indy comics.

If panel types of all three populations differ, it would imply sub-cultural “artistic” contexts vary related to narrative techniques of particular traditions. If Japanese panel types are similar to Mainstream comics yet different from Indy comics, it would imply that the framing of a scene differs based on genre, even cross-culturally. In contrast, if American genres do not differ from each other, yet both differ from Japanese manga, it would imply cultural differences beyond the contexts of genre.

To this end, if both American genres do differ from Japanese panels, we would predict the results to reflect the findings of Masuda et al. (2008) for art and photographs by Asians and Americans. Similar results would expect American comics to focus more on focal objects through Monos and Amorphics. Meanwhile, Japanese panels should show the opposite: here we would predict more Macros to focus on the relationships between characters in whole scenes.

## Methods

### Materials

Thirty graphic books were chosen at random from a corpus of over 200 comics donated from various comic companies. We coded 300 panels in each book for the properties of attentional panel type and shot type. 10 books were chosen from each of three populations: “mainstream” Japanese Manga, Mainstream American comics, and Indy American comics. In order to operationalize how these populations are identified, it is useful to discuss their differences.

Mainstream and Indy books differ greatly in graphic styles, genres, formats, publishers, and often readership. Mainstream comics primarily feature drawing styles common to superhero comics (dynamic linework, muscular figures, brighter colors), and focus on the genres of superheroes, horror, and science fiction. Mainstream books are also often produced by specific publishers and are serialized in pamphlet style formats that are only sometimes afterwards collected into books. Mainstream comics are sold primarily through specialty comic books stores. In contrast, Indy books use more variable graphic styles (particularly more cartoony and “artistic” styles) with more “serious” or dramatic genres (such as memoir, drama, etc.). Different publishers are known for producing Indy books and Mainstream comics, and they appear mostly in book formats (“graphic novels”). Indy books are often sold in comic books stores, but also have a much higher distribution into regular bookstores.

While some overlap in readership does exist between Mainstream and Indy comics, they largely appeal to different groups of people. Readers of Mainstream comics often read serializations that appear each month. They often are very devoted to their favorite comics, and American comics often target the writing with this consistent readership in mind, evident through frequent references to previous storylines. Indy comics have more varied readership because they are not serialized volumes. Often, Indy books are produced in single editions, and thus do not have consistent readership (though readers may follow particular authors’ works). Readers of Japanese manga are often more similar to Mainstream American comics—they have their favorite comics which are released weekly in large anthologies. While readership of manga is larger on the whole in Japan than America, there is no reason to believe that comics in either country are explicitly made with any expectation that readers will be more or less proficient in understanding them.

Additionally, while some crossover exists in readership between American genres, most authors of Mainstream and Indy books remain independent to their genres. Mainstream and Indy books are also created with a slightly different process. Mainstream comics are largely made by an industry-line style committee (Duncan & Smith, 2009) consisting of a writer, penciler, inker, colorist, etc. While an editor coordinates their efforts and oversees the plotline, for the most part these creators are free to follow their own

styles of writing and artwork. In contrast, Indy comics are more often drawn and written by individual authors. Japanese manga typically combine these methods. They are usually attributed to a sole author, who then employs a team of uncredited assistants who complete the more menial aspects of the drawings, like shading or drawing backgrounds (Schodt, 1983). While these creative processes may vary between countries/genres, the finished products largely reflect the intuitions of the authors or creative teams.

In this study, we distinguished American Mainstream and Indy books by criteria of graphic style, genre, and publishers. Mainstream books ranged in publication date from 1992 to 2005 with a mean of 2002, while Indy comics were published between 1991 to 2008, with a mean at 2003. Japanese books featured more consistent visual styles, following the stereotypical “standard graphic dialect” of Japanese comics (Cohn, 2010). However, since genres in Japan do not align neatly with those in America (Shonen “boys comics,” Shojo “girls comics,” and Gekiga “serious comics”), books were chosen that reflected the genre closest to Mainstream American comics—those focusing primarily on action/adventure themes (Shonen “boys comics”). Only English translations of manga were analyzed in the study due to their availability in our donated corpus, though manga were attributed to their original Japanese publication dates, from 1984 to 2005 with a mean of 1999.

Thus, our analysis contrasted either genre or country of origin. American Mainstream books shared a similar overall genre (action/adventure) with Japanese manga, though they came from the same country of origin as American Indy comics. All of the chosen books were widely read and popularly distributed throughout comic readership, and from major publishers—i.e., none of the books were obscure or minimally distributed. Books analyzed are provided online at [http://www.emaki.net/CTG\\_FramingAppendix.html](http://www.emaki.net/CTG_FramingAppendix.html).

## Areas of analysis

All books were coded for their attentional Panel Type—the way in which panels highlight attention in the various types of attentional categories previously discussed (Macro, Mono, Micro, Amorphic). Panels that could not be recognizably coded into these categories were identified as “Ambiguous.” Two researchers independently coded each book’s properties, and were consistent in their codings ( $Kappa=.785$ ,  $p<.01$ ). Final analyses used the mean between coders’ scores for each book.

Populations were fairly similar in the number of pages/book and panels/page analyzed. Indy comics averaged

56.6 pages/book and 5.99 panels/page, while Mainstream comics averaged 62.6 pages with 5.12 panels/page. Manga used 65.2 pages/book with 4.75 panels/page.

Figure 2: Relative proportion of panel types across American Mainstream comics, American Indy comics, and Japanese Manga.

## Results

### Panel Type

The analysis of attentional framing of panels found main effects for Panel Type,  $F(3,81)=89.71$ ,  $p<.001$ , with a Panel Type by Group interaction,  $F(6,81)=5.68$ ,  $p<.001$ . Main effects between Groups were not significant,  $F(2,27)=1.37$ ,  $p=.269$ .

As depicted in Figure 2, Indy and Mainstream comics used many Macros and Monos, with minimal Micros and Amorphics. Within Indy comics, overall differences were found between panel types,  $F(3, 27)=27.34$ ,  $p<.001$ , as well as between each pair of types (all  $t>5.81$ , all  $p<.001$ ), except the near equal means for Macros with Monos, and Micros with Amorphics. Mainstream panels also differed between all types,  $F(3,27)=30.05$ ,  $p<.001$ . These books featured only slightly more Macros than Monos, which was not statistically significant. Micros and Amorphics numbered far fewer overall, though there were almost twice as many Micros as Amorphics,  $t(9)=2.14$ ,  $p=.06$ . All other panel types featured significant contrasts (all  $t>5.55$ , all  $p<.001$ ).

Finally, Manga also showed main effects between panel types,  $F(3,27)=64.00$ ,  $p<.001$ . Monos far outnumbered other types, with roughly half as many Macros, and far fewer Micros and Amorphics. All types differed from each other, (all  $t>3.16$  or  $<-7.3$ , all  $p<.05$ ), except Micros and Amorphics.

Across the three populations, differences were found between each Panel Type (all  $F_s>2.8$ , all  $p_s<.01$ ). Indy and Mainstream comics showed no differences for any of the panel types (all  $t_s<1.8$ , all  $p_s>.11$ ). Indy panels differed

from Manga for all types (all  $t_s > 2.6$ , all  $p_s < .05$ ) except Monos, while Mainstream panels differed from Manga on all types (all  $t_s > 2.9$ , all  $p_s < .01$ ) except with regard to Micros.

## Discussion

This study analyzed how various cultures' comic panels frame a fictitious scene as a way to gain insight on how these cultures may direct attention. We compared Mainstream and Indy genres of American comics with "mainstream" Japanese manga. Even more than in Cohn's (2011) study, Japanese panels highlighted individual elements of scenes more than American books. Japanese manga were found to have far more Monos than any other type of panel, followed by Macros, and small proportions of Micros and Amorphics. Both Mainstream and Indy American comics had near equal proportions of Macros and Monos, again with small proportions of Micros and Amorphics.

In the analysis of panels types between cultures, manga used significantly more Monos, Amorphics, and Micros than did both types of American comics. American comics did not vary in their panel types between genres, despite surface stylistic differences. Thus, though Japanese manga and Mainstream American comics were similar in terms of "mainstream" appeal and action/adventure themes, this similarity did not influence the framing of scenes. These results suggest that the primary difference between these populations of comics are that of country of origin: The framing of entities in American comic panels differ from Japanese panels, though American comic genres do not differ substantially from each other.

What can these results offer to our understanding of cross-cultural attention and cognition? On the whole, the framing of attention in both genres of American comics focused more on detailing a whole scene as much as, if not more than, individual characters, as indicated by the prevalence of Macros over Monos. In contrast, Japanese manga directed attention toward details in the scene through Monos, Micros, and Amorphics, in lieu of actually showing full scenes in Macros.

These results seem to run counter to the cross-cultural research on attention. As suggested by the analysis of art and photographs in Masuda, Gonzalez, Kwan, and Nisbett (2008), wouldn't we expect American comic panels to focus more on the primary objects of a scene (i.e., Monos) because of a preference for objects over environments? Shouldn't Japanese panels focus more on scenes as a whole (i.e., Macros)? If these results are to be taken directly, they provide counter-evidence for the claims made by Nisbett and Masuda with regard to the manifestation of attention in popular culture.

One interpretation of these results is that cross-cultural panel framing has nothing to do with attention, but rather reflects the expertise of each cultures' readers. Manga are far more prevalent in Japan than in America, and thus Japanese may have a greater expertise in general in reading

sequential images. American comics may be geared towards less experienced readers, and thus they need to be constantly reminded of the elements in a scene with more Macros. On the other hand, more experienced readers in Japan may be able to retain or construct the whole scene without being presented with it.

Thus, under this interpretation, attention is not a factor at all. We find this explanation to be unfeasible. Manga do indeed have wider readership across the country of Japan compared with the readership of comics across America. However, American comics, particularly Mainstream comics, are targeted towards a consistent readership. These readers are often serious and devout fans, and would have as much if not greater fluency in their visual language than casual manga readers in Japan. Thus, attributing these findings to expertise alone seems unlikely.

Though these results on the surface appear to contrast previous findings on attention, we suggest another interpretation of these results that is indeed more consistent with the research by Nisbett and Masuda. Comic panels are not isolated images like the photos and drawings, but are instead meant to be read (and are created) in a sequence. A sequence of images in comics act as a simulation of how an individual might view a fictitious visual scene in front of them (a similar argument for film shots is made by Levin & Simons, 2000). This simulation of attention across sequential images is different from the treatment of attention in individual images, like in the study by Nisbett and Masuda (2003).

Like in attention, readers track only the most important aspects of a sequence to establish the continuity of the narrative. Non-relevant information may then go unattended by the "spotlight of attention" across panels, as happens in change blindness paradigms (Levin & Simons, 2000). There are thus two strategies a comic author can use when creating comic. They can either show a full scene (Macro) and rely on the reader's attentional intuitions to discern the most important parts, or they can use panels to directly highlight only those salient parts directly (Monos, Micros, Amorphics), omitting what is unimportant altogether. This use of panels would heighten the "subjective viewpoint" of panels simulating attention.

These and previous data suggest that American comics more consistently use the first option: letting the reader direct their own attention across panels to find the most relevant aspects of continuity, while letting less important elements simply go unattended. This is suggested by the larger amounts of Macros found in American comics of both genres. In contrast, Japanese manga do more to simulate the perception of a reader's attention, evident in greater use of Monos, Micros, and Amorphic panels. That Japanese manga use a strategy that is more subjective of the way attention may be directed is consistent with McCloud's (1993, 1996) claim that manga allow a reader to take more of a subjective viewpoint on a story. It also is supported by previous corpus analysis showing that "subjective panels"—panels that directly show the viewpoint of a character in the

narrative—are more plentiful in Japanese manga than American comics (Cohn, 2010).

These different strategies of depicting actions by simulating attention also reflect the way in which attention may be different between readers of different cultures. Manga panels highlight individual elements of a scene or environment because that would be how Japanese readers' attention would fall on elements of a visual array, and out of this information would need to integrate these parts into a coherent whole. In contrast, because American readers will naturally pick out the focal characters of the scene, American comics can use more Macros, assuming attention will be directed to the important elements of interest automatically. In this way, panels from comics and manga reflect how a Japanese or American reader might look at a visual scene if the whole array were in front of them, thereby echoing the differences in cultural windowing of attention.

By analyzing comics with a clearly defined categorization system, we have shown that visual narratives are bound by cultural conventions that create patterns in the ways that Japanese and American comic authors window attention onto visual scenes. We propose that these results are consistent with the cross-cultural research showing differences in how Asians and Americans perceive and attend to their visual environment (Nisbett, 2003; Nisbett & Masuda, 2003; Nisbett & Miyamoto, 2005), and lend further support to efforts to study cognitive process through creative cultural expression.

## Acknowledgments

Thanks go to the Tufts Center for Cognitive Studies for funds supporting this research and to these publishers for their generous donation of books: Dark Horse Comics, Drawn & Quarterly, First Second Books, IDW Publishing, Oni Press, Top Cow, and Viz Media. Early drafts benefited from feedback from Ray Jackendoff, Igor Grossman, and Taka Masuda and the Culture and Cognition Lab at the University of Alberta.

## Abstract

In typical development, word learning goes from slow and laborious to fast and seemingly effortless. Typically developing 2-year-olds are so skilled at learning noun categories that they seem to intuit the whole range of things in the category from hearing a single instance named – they are biased learners. This is not the case for children below the 20<sup>th</sup> percentile on productive vocabulary (*late talkers*). This paper looks at the individual vocabularies and word-learning biases of late- and early-talking toddlers. Experiment 1 shows that neural networks trained on the vocabularies of individual late talkers learn qualitatively different biases than those trained on early talker vocabularies. Experiment 2 confirms the novel predictions made by the simulations about word learning biases in late- vs. early-talking children. The implications for diagnosis and intervention are discussed.

**Keywords:** Late talkers; early talkers; computational models; neural networks, word learning.

## Introduction

There is extraordinary variability in the vocabularies of very young children. A two-year-old in the lower 10<sup>th</sup> percentile may produce around 10 words whereas a two-year-old in the top 10<sup>th</sup> percentile will produce well over 300 (Fenson, Dale, Reznick, Thal, Bates, Hartung, Pethick, & Reilly, 1993). In general, the course of word learning proceeds from slow, effortful learning of nouns and of the range of things that belong in a category, to very rapid learning of object names. Indeed, typically developing 2-year-olds are so skilled at learning new nouns that they seem to intuit the whole range of things in a named category from a single naming experience. This is not necessarily the case for children below the 15<sup>th</sup>-20<sup>th</sup> percentile on productive vocabulary, or *late talkers*. Why do some children learn words quickly and early and others learn words slowly, maybe even showing effects that persist into adolescence? This paper looks at two possible contributing, and interrelated, factors: noun vocabulary composition and word learning biases

The evidence suggests that children are skilled noun learners because they know about the different kinds of properties that are relevant for categorizing different kinds of things. Typically-developing children show word learning biases that are specific to different kinds of things: they generalize names for solid objects by shape and names

for non-solid substances by material (e.g., Soja, Carey, & Spelke, 1991).

The evidence also suggests that children learn how to learn nouns – and learn how different kinds of properties are relevant for different kinds of things – as a consequence of learning names for things. Each noun the child learns appears to teach the child something general about how to learn new nouns that name things of that same kind, and critically, at the same time, this learned general knowledge constrains and facilitates the types of nouns the child will learn next. Through computational models and a study with toddlers, we show that even before they turn 2, late- and early-talker toddlers show different word learning biases.

## Vocabulary composition and word learning biases

The relationship between vocabulary composition and word learning biases has been typically characterized in one of two ways: abstract knowledge guides, facilitates and indeed allows word learning (e.g., Soja et al, 1991; Gelman & Bloom, 2000) or the words that have been learned give rise to, create, and in fact constitute generalized knowledge about word learning (e.g., Colunga & Smith, 2005, Samuelson, 2008). We would like to bypass the debate on whether word-learning biases are the egg to the vocabulary chicken or the other way around and focus instead on the interrelationship between these two factors.

In the domain of names for objects and substances, and in typical development, vocabulary structure and abstract knowledge in the form of kind-specific generalizations appear to be tightly coupled. First, the tendency to attend to shape in the specific context of naming artifacts emerges as children learn nouns, becoming particularly robust around the time children have between 50 to 150 nouns in their productive vocabulary (Gershkoff-Stowe & Smith, 2004). Second, the order of development of these word learning biases reflects the statistical structure of early noun vocabularies, (Samuelson & Smith, 1999; Colunga & Smith, 2005). Third, changing 17-month-olds' vocabulary composition by intensively teaching them names for artifacts yields an early bias to generalize names for artifacts by shape *and accelerates learning of object names outside of the lab*, causing a dramatic increase in vocabulary size for children in the experimental training group but not for those in the control groups (Smith, Jones, Landau, Gershkoff-Stowe & Samuelson, 2002). Fourth, computational models

trained on the structure of the average 30-month-old vocabulary, show word learning biases like those of young children when processing new objects (Colunga & Smith, 2005), and further the structure of the training set affects subsequent training, facilitating the learning of some sorts of categories but hindering others (Colunga, in prep). Altogether, these results suggest a developmental feedback loop between learning object names, developing biases to attend to the relevant properties for artifacts, and the learning of more object names.

## Late Talkers

Children below the 15<sup>th</sup>-20<sup>th</sup> percentile on normative measures of productive vocabulary size, so-called late talkers, are not a homogenous group in terms of their developmental outcomes: some catch up, and some show persistent delays (Rescorla, 2002, Rescorla, Roberts, & Dahlsgaard, 1997). However, Rescorla and colleagues argue against considering late talkers and typically developing children as distinct groups, and argue instead for conceptualizing them in terms of a “language endowment spectrum.” Importantly, although there is continuity in vocabulary measures at the group level, the outcome for individual children cannot be accurately predicted on the basis of vocabulary production or comprehension (e.g., Desmarais, Meyer, Bairati & Rouleau, 2008).

The literature briefly reviewed above suggests that, in typical development, the words a child knows and what the child knows about learning words in general go hand in hand, and that learning names for categories of things organized by shape speeds up learning nouns. However, this may not be the case for all children. Unlike typically developing children, late talkers do not systematically extend the name of a novel solid object to other objects that match it in shape, and in fact, in one study, almost half of the late talkers systematically extended the novel name of a solid object to others matching in texture rather than shape (Jones, 2003). Recent evidence suggests that the vocabularies of children of different language abilities may be structured differently (Colunga & Sims, 2011; Beckage, Smith & Hills, 2011). These findings suggest that late talkers may not just be limited in their production of object names (the measure that defines them as late talkers) but also deficient in the processes that subserve the acquisition of new words and in their knowledge about those categories. The crucial question, then, is whether these differences in vocabulary composition are differences that matter. Do the different nouns late- and early-talkers know yield different word learning biases? In two experiments we test the relationship between vocabulary composition and word learning biases, first in neural networks (Experiment 1) and then with 1-year-old toddlers in the lab (Experiment 2). For the purposes of this paper we will focus on contrasting the vocabularies of children on the two opposite ends of the spectrum, late talkers and early talkers.

If the differences in vocabulary structure can, to some extent, explain the differences in language ability, we would expect late talker vocabularies to yield different word

learning biases than early talker vocabularies. More specifically, we would expect early talker vocabularies to yield word learning biases that would facilitate the learning of a vocabulary structured like the MCDI – highlighting shape similarities for solids and material similarities for non-solids. In contrast, we would expect networks trained on late talkers’ vocabularies to generalize more variable word learning biases, and perhaps even biases that would be unhelpful in learning early vocabularies.

## Experiment 1

### Method

**Materials.** The vocabulary measure used was the Bates-MacArthur Communicative Developmental Inventory toddler version (MCDI) both to select children and to measure vocabulary composition. This is a parent checklist that asks parents to indicate the words that their child *produces* and although it is imperfect as a measurement instrument (Fenson, et al, 1994) it appears to be reliable and to be systematically related to children’s performances in a variety of laboratory measures of word learning, including especially their word-learning biases in the Novel Noun Generalization (NNG) task (e.g., Landau, et al, 1988).

**Participants.** The vocabularies of 15 late talkers and of 15 early talkers were selected out of a pool of 148 parent-filled MCDI forms for children between 18-30 months of age. The criterion for inclusion was that there existed a vocabulary form from a child matching in age to within 5 days in both the late talker and the early talker groups. Late talkers fell under the 25<sup>th</sup> percentile; early talkers were above the 75<sup>th</sup> percentile according to the MCDI norms.

The ages for the two language groups ranged from 18.49 months to 28.26 months ( $M=23.14$  and  $23.15$  for late and early talkers respectively). Vocabulary sizes for the late talker group ranged between 15 and 425 words ( $M=132.53$ ); for the early talker group vocabulary size was between 158 and 664 words ( $M=457$ ).

The noun vocabularies for each individual child were characterized by looking at the proportion of nouns they knew for each of the following categories: 1) solid things alike in shape (e.g., spoon), 2) solid things alike in material (e.g., chalk), 3) solid things alike in both shape and material (e.g., penny), 4) non-solid things alike in shape (e.g., bubble), 5) non-solid things alike in material (e.g., milk), 6) non-solid things alike in both (e.g., jeans). Nouns in children’s vocabularies were classified as falling in each of these categories according to adult judgments made for each of the nouns in the MCDI reported in Samuelson & Smith, 1999. The training sets were then constructed to mimic the vocabulary composition of each child (see below).

**Architecture.** The computational models are a modified version of the ones Colunga & Smith, 2005. The main difference is that these networks were trained using the Leabra algorithm, an algorithm that combines Hebbian and error driven learning (O’Reilly, 1996), instead of Contrastive Hebbian Learning as in the original simulations.

The networks are organized as follows: Words are represented discretely (as single units) and are input on the Word Layer (Figure 1). Referents are represented as distributed patterns over several dimensions on the Perception Layer. For example, the shape and material of an object (say the roundness of a particular ball and its yellow rubbery material) are represented by an activation pattern along the Perception layer. Solidity and Non-solidity are represented discretely; one unit stands for Solid and another for Non-Solid. Finally, there is a hidden layer that is connected to all the other layers and to itself. These networks have been shown to model performance in an analog of the NNG Task when trained on vocabularies structured as those of the average 30-month-old.

**Figure 1: Architecture of the network and example input patterns.**

**Training.** The networks are trained with categories presenting the same correlational structure as each individual child's noun vocabulary. On each training trial, a word is paired with a referent. The patterns associated with each word are determined by adult judgments of the early noun corpus. For example, adults judged balls to be similar in shape but different in material. To simulate this, we randomly selected an input vector to represent ball shape. Then on individual training trials, we paired that pattern with the label ball and a randomly selected material pattern (Figure 1). We do this for each noun in the training set. Each network was trained in this way for its simulated vocabulary until they reached asymptotic (and near perfect) performance. This part of the simulation is intended to put into the networks the lexical knowledge that the individual child would bring to the laboratory NNG task.

Because we are interested in the consequences of different vocabulary structures regardless of their size, all networks were trained to learn 24 nouns, proportionally structured like their corresponding child's vocabulary. Thus, the only difference between networks were the differences in vocabulary composition for each individual child.

**Testing.** The question is what sort of word learning bias will the networks learn given different vocabulary structures. We address this question in a virtual version of the NNG task. On each test trial of the virtual NNG task, we presented the network with three novel entities (one at a time) on the perception layer – an exemplar, and two choice items, one matching the exemplar in shape only and one matching in material only. For each of these three inputs, we recorded the resulting pattern of activation on the hidden layer. This is a measure of how the network represents these items. If the network emphasizes the shape of the item then the similarities of the internal representations for the exemplar and its shape matching choice should be *greater* than the similarity of the internal representations for the exemplar and the material matching choice. If, however, the internal representations highlight the material of the items, then the similarity of the internal representations for the exemplar and the shape matching choice should be *less* than the corresponding similarity of the exemplar and the material matching choice. We used these similarities along with Luce's choice rule to calculate probability of choice using these similarity measures in order to predict performance in the novel noun generalization task.

In previous work these models have been used to demonstrate the plausibility of the idea that the correlations in the early noun lexicon are sufficient to create second order generalizations – knowledge that any solid thing should be named by shape, and any non-solid thing should be named by material. The present simulations extend this work to variable vocabularies of individual children in the bottom and top ends of the language endowment spectrum.

## Results

The networks' predictions for each of the fifteen vocabularies of early talkers and late talkers are shown in Figure 2. In short, using a cut-off of at least two standard deviations above or below the 50% chance level mark, all networks in the early talker group show a shape bias for solids, and 12/15 early talker networks show a material bias for non-solids as well. In contrast, 12/15 late talker networks show a shape bias for solids and only 3/15 show a material bias for non-solids. Interestingly, 6/15 late-talker networks show a shape bias for *non-solids*, a novel prediction that has not been empirically tested so far. To further analyze the networks' performance, networks were classified according to the observed generalization patterns: *correct* if they showed a shape bias for solids and a material bias for non-solids, *half-right* if they showed the appropriate shape bias for solids but no consistent bias for material, or *wrong*, if they showed an incorrect overgeneralized shape biased to non-solids. A chi-square test showed these types of word learning biases were distributed differently in late talker and early talker networks,  $X^2(2,15)=14.743$ ,  $p=.0006$  (Yates'  $p=0.004$ ).

**Figure 2. Predicted proportion of shape choices for each of the early talker and late talker networks**

## Discussion.

The results of the simulations suggest that the differences in noun vocabulary composition between late- and early-talking children may result in differences in word learning biases. The word learning biases learned by these networks can be interpreted as predictions at the group level. First, the networks make a novel prediction about early talkers. A majority of the early talker networks show material biases for non-solids. Previous findings have shown that children at this age (18- to 30-month-olds) show a material bias for non-solids only when offered extra cues. For example, Soja (1992) showed older 2-year-olds have a material bias when offered supporting syntactic and visual cues, and Colunga & Smith (2005) showed an early material bias for non-solids that were presented in simple shapes for older 1-year-olds. However, children in general do not show a robust material bias for non-solids until around age 3 (Samuelson & Smith, 1999). Thus, this is a novel prediction that warrants testing: the networks predict that early talkers, unlike the general population, will show an early material bias for non-solids even without supporting cues.

The networks also make predictions about the patterns of novel noun generalizations one should expect to see in late talkers between 18 and 30 months of age. As a group, late talkers should show a shape bias for solids, with about half of them overgeneralizing this shape bias to non-solids as well. In Experiment 2 we test these predictions with late- and early-talker toddlers in the lab. Additionally, we run neural network simulations based on the composition of the

individual vocabularies of these children to replicate the pattern found in Experiment 1.

## Experiment 2

### Method

**Participants.** Nine late talkers (5 girls) and 8 early talkers (4 girls) between the ages of 18 and 22 months ( $M=19.4$ ) were selected out of 32 children recruited as part of a larger study. As in Experiment 1, the criterion for inclusion was scoring at or below the 25<sup>th</sup> percentile for late talkers and at or above the 75<sup>th</sup> percentile for early talkers. MCDI scores ranged from 5<sup>th</sup> to 20<sup>th</sup> percentile ( $M=8.9$ ) for the late talkers and between 75<sup>th</sup> and 99<sup>th</sup> percentile for early talkers ( $M=91$ ). Vocabulary sizes for the late-talker group ranged between 9 and 82 words ( $M=33$ ) and between 151 and 526 words ( $M=376.3$ ) for the early-talker group.

**Stimuli.** The stimuli consisted of a warm up set, a solid set and a non-solid set. The warm up set had an exemplar, a red plastic ball, two other balls (a tennis ball and a green and blue rubber ball), a plastic spoon, a toy carrot, and a toy cat.

The solid set consisted of an exemplar, an orange fuzzy round container, and 5 test items: two items matching the exemplar in shape alone (iridescent green bumpy round container and golden glittery round container), two items matching the exemplar in material (fuzzy blue irregular ring and fuzzy orange hook-like shape, and one matching in color (orange mesh polyhedron). The non-solid set was similarly structured and consisted of an exemplar (purple craft sand mixed into Noxzema in a rounded elongated x-like shape), two material matches (green sand + Noxzema in an asymmetric s-like shape and red sand + Noxzema in a lollipop-like shape), two shape matches (elongated x-like shapes made out of sawdust or purple shaving cream), and a color match (purple hair gel in an hourglass shape). All non-solids were presented on flat, square, plastic foam boards.

**Procedure.** In the warm-up phase, the experimenter presented all six toys to the child and allowed him or her to look at them and handle them for 30 seconds. Then the objects were removed and immediately placed back on the table outside of the child's reach. The child was then shown the exemplar ball and told, "look at this ball." Then they were asked to "get a ball" or get "another ball." If the child failed to retrieve a ball, the child was asked one more time, and finally was told "here's another ball," handed the ball, and allowed to get it one more time on request. If the child got one of the non-ball distracter items, they were told, "that's not a ball, that's a \_\_\_\_\_", then the distracter was replaced on the table, and the child was asked again for it.

The procedure during the test phase with the solid and non-solid novel sets was the same, except that no feedback was offered. Children were shown the exemplar and told, "Look at this dax" and then asked to "get a dax" or "get another dax" for the solid set or "get more dax" or "get some dax" in the non-solid set. Children were asked to get another (or more) until they indicated that there were no more. Thus, solids were presented with count syntax supporting an object construal and non-solids were

presented with mass syntax supporting a substance construal (Soja, 1992). The solid set was always presented before the non-solid set, and there was a 5-minute break and a change in testing rooms in between the two test sets.

**Coding.** To incorporate order information into children's choices, and because all children made at least three choices for each test set, their choices were coded as follows: 3 points for the item that was 1<sup>st</sup> choice, 2 points for the 2<sup>nd</sup> choice, 1 point for the 3<sup>rd</sup> choice, and 0 points for other.

## Results

**Simulations.** The simulations based on individual children's vocabularies showed patterns comparable to the ones in Experiment 1. For the early talker networks, 6/8 showed shape and material biases, and the other two showed only a shape bias and no robust material bias. None of the early talker networks showed incorrect biases. For the late talker networks, all eight networks showed a shape bias for solids, but only one showed a material bias for non-solids<sup>1</sup>. In addition, 4/8 late talker networks showed an overgeneralized shape bias for non-solids. A chi-square test showed these types of word learning biases were distributed differently in late talker and early talker networks,  $X^2(2,8)=7.77$ ,  $p=.02$  (Yates'  $X^2=4.54$ ,  $p=0.103$ ).

**Figure 3. Scores for shape and material matches for solids and nonsolids for early- and late-talking toddlers.**

**Word learning biases.** The simulations in Experiment 1 predicted that early and late talkers would show different word learning biases, and predict specific patterns of novel noun generalizations for solids and non-solids for these two groups of children. We first look at the data of all children together and then evaluate the predictions for each language group. We submitted both groups of children's scores for the shape and material test items for the solids and non-solid sets to a 2 (language group: early, late) x 2 (solidity: solid, nonsolid) x 2 (dimension: shape, material) mixed ANOVA. Figure 3 shows the average score for the items that matched the exemplar in shape or material for the solid and nonsolid sets for both language groups. There was a main effect of dimension,  $F(1,29) = 4.77$ ,  $p = .045$ ,  $\eta^2 = .24$ ; overall shape matches had higher scores than material matches. There was

<sup>1</sup> One late talker child had no nouns, so no network was ran for that child. Thus, only 8 late talker networks were ran.

also a significant interaction between solidity and dimension,  $F(1,15) = 15.6$ ,  $p=.001$ ,  $\eta^2 = .51$ . Post-hoc tests showed that across both language groups, children were more likely to choose the shape over the material match for the solid set,  $t(16) = 4.03$ ,  $p=.001$ , but not for the nonsolid set,  $t(16) = -.613$ , n.s. The three-way interaction between language group, solidity, and dimension was marginally significant,  $F(1,15) = 4.33$ ,  $p=.055$ ,  $\eta^2 = .22$ .

The language-group-specific predictions made by the models were tested by analyzing the two groups separately. First, the prediction that early talkers would show a robust shape bias for solids and a robust material bias for nonsolids was confirmed by a 2 (solidity) x 2 (dimension) ANOVA revealing a two-way interaction between solidity and dimension,  $F(1,7) = 26.15$ ,  $p = .001$ ,  $\eta^2 = .78$ . Furthermore, planned comparisons (all two-tailed) showed that this interaction came from early talkers' shape bias for solids ( $t(7)=3.06$ ,  $p=.018$ ) and material bias for non-solids ( $t(7)=-4.46$ ,  $p=.003$ ). Second, a similar analysis on late talkers' scores revealed a main effect of dimension,  $F(1,8) = 5.5$ ,  $p=.047$ ,  $\eta^2 = .41$ , and no other main effects or interactions. Planned comparisons showed that late talkers had a shape bias for solids,  $t(8) = 2.57$ ,  $p=.033$ , but did not overgeneralize the shape bias to non-solids as a group,  $t(8) = 1.1$ , n.s. However, 4 out of the 9 late talkers in the study showed a shape bias for non-solids (a difference score of more than 3), and none of the early talkers did.

## Discussion

The results of Experiment 2 confirm the predictions of the simulations in Experiment 1. Early talkers show a shape bias for solids and a material bias for non-solids; late talkers show a shape bias for solids that can be over-generalized to non-solids. It is important to note that these predictions work at the group level and not at the level of individuals. For example, although four late talkers showed an overgeneralized shape bias for nonsolids in both the behavioral tasks and in the network simulations, these were not the same children; only two children showed this bias in both the simulations based on their vocabularies and their performance in the behavioral task. The behavioral task, and probably the vocabulary measure as well, lack the finesse to make predictions at the individual level based on a single data point. We return to this point in the general discussion.

The results of experiment 2 are in line with previous work noting a relationship between the number of nouns in a child's vocabulary and their word learning biases, but they extend it in important ways. The finding that early talkers show robust word learning biases for both solids and non-solids at not even two years of age is new. Although one might have predicted this pattern of results a priori from either the empiricist or the rationalist sides of the word learning debate, or even just from the idea that early talkers might excel across tasks, the prediction came from the models. Harder to predict without the networks, however, is the pattern found for the late talkers. In fact, at first glance it seems to contradict what we know about late talkers; that 2- to 3-year-old late talkers lack a shape bias while their same-

aged peers already have a well-established bias. However, the prediction from the networks, and our findings on the patterns of word learning biases in very young late talkers, before the age of 2, can help us understand the processes underlying word learning in general.

Gershkoff-Stowe and Smith (2004) followed eight children as they learned their first 100 nouns, looking at their word learning biases for solids and their vocabulary growth every three weeks. Their results show that as children's noun vocabulary increases, so does their attention to shape. They set the emergence of the shape bias at around the time children acquire 50 nouns. Our results suggest that this relationship may be different for late talkers. None of the late talkers in Experiment 2 reached the 50-noun mark (though a couple were on the cusp), and yet they overall showed a robust preference for shape for the solid set in our task. Curiously, although attention to shape increased with vocabulary size in Gershkoff-Stowe's study, the lower vocabulary group did show a preference of shape over material. This suggests an intriguing possibility: These models do not make a distinction between naming and non-naming contexts. It is possible that the shape preference for solids here is not a true shape bias, but rather an overgeneralized heightened attention to shape. The fact that about half of the late talkers showed an overgeneralized shape bias for non-solids suggests that this may be the case.

## General Discussion

The work presented here makes two main contributions. First, the findings of these two studies show that late talkers and early talkers know different sorts of nouns that lead to qualitatively different word learning biases. Importantly, these differences are shown within a computational model that has been previously shown to capture various aspects of novel noun learning, suggesting a promising use for process-level computational models. Efforts to tease apart the contributions of different factors to outcomes in late talkers have come up with some characteristics that put children at higher risk, but the underlying mechanisms are not well understood. The work of Ziegler and colleagues in the domain of dyslexia offers a good example of the potential for using computational models – and specifically models that operate at the mechanistic level – in simulating individual differences and further understanding subtypes in atypical development (Ziegler, Castel, Pech-Georgel, George, Aario, & Perry, 2008). Thus, the models presented here are a promising first step in leveraging computational models to aid in the understanding of why some late talkers catch up and others do not.

Second, these models represent an important extension over previous word-learning modeling efforts in that they go beyond modeling the performance of the mythical average child to making predictions about the performance of individual children, and of children who are both at the top and at the bottom of the vocabulary spectrum. In so doing, the simulations presented here make novel and testable predictions. The relationship between vocabulary

composition and word learning biases modeled here – the words you know determine the way you learn new words, which constrains and facilitates the words you will know next, and so on – opens a new way of thinking about computational models, to capture not only averages and not only individuals, but individual *trajectories*. If we can build computational models that can successfully capture this self-constructing developmental loop, the implications for early diagnosis, designing early interventions, and understanding the mechanisms that underlie word learning in typical and atypical development are far-reaching.

## Abstract

The nature of the connection between musical and spatial processing is controversial. While pitch may be described in spatial terms such as “high” or “low”, it is unclear whether pitch and space are associated but separate dimensions or whether they share representational and processing resources. In the present study, we asked participants to judge whether a target vocal note was the same as (or different from) a preceding cue note. Importantly, target trials were presented as video clips where a singer sometimes gestured upward or downward while singing that target note, thus providing an alternative, concurrent source of spatial information. Our results show that pitch discrimination was significantly biased by the spatial movement in gesture. These effects were eliminated by spatial memory load but preserved under verbal memory load conditions. Together, our findings suggest that pitch and space have a shared representation such that the mental representation of pitch is audiospatial in nature.

**Keywords:** mental representation; pitch perception; music; gesture; spatial representation; metaphor

## Introduction

Musical and spatial processing are interlinked, but the exact nature and extent of the connection is controversial. People with amusia (i.e., an impaired ability to discriminate pitch) have corresponding spatial deficits in some reports (Douglas & Bilkey, 2007), but others have failed to replicate the association (Tillman et al., 2010; Williamson, Cocchini, & Stewart, 2011). People have been found to map musical pitch to vertical spatial locations (Pratt, 1930; Rusconi, Kwan, Giordano, Umiltà, & Butterworth, 2006), but they are also willing to map it to psychophysical luminosity and loudness (Hubbard, 1996; McDermott, Lehr, & Oxenham, 2008), and to words denoting emotion, size, sweetness, texture and temperature (Eitan & Timmers, 2010; Walker & Smith, 1984). Thus, while pitch may be described in spatial terms such as “high” or “low”, it remains unclear whether pitch and space are merely two amongst many associated dimensions or whether the representation of pitch is fundamentally spatial.

Pitch is a psychoacoustic property that corresponds to waveform frequency; its representation involves the primary auditory cortex but the full neural specification of pitch processing is still not well understood (e.g., Bendor, 2011). Space is a physical property of the three-dimensional body we occupy and the world through which we move, and is represented in a multimodal or supramodal system that takes input from vision, touch, and other perceptual modalities in

order to create a common spatial code (Bryant, 1992; Giudice, Betty, & Loomis, 2011; Lacey, Campbell, & Sathian, 2007). Numerous studies have shown that activating pitch also activates space along the vertical axis. A high-pitch prime leads people to explicitly relate it to a high spatial location (Pratt, 1930), and to implicitly attend to a visual target (Walker et al., 2010) or make a manual response (Rusconi et al., 2006) in a high spatial location. However, the above findings cannot distinguish between an *associative mapping* explanation, where representations of pitch and space are separate but linked, and a *shared representation* explanation, where pitch and space share common representational and processing resources.

According to an associative mapping explanation, the representation of musical pitch is purely auditory in nature. An individual's perception of a note's pitch would essentially comprise a modality-specific auditory representation of its sound frequency, and one would recall its pitch as a simulation (i.e., a partial replay of the neural activation that arose during experience: Barsalou, 1999) of that frequency. Perceiving a high pitch note rapidly activates a high spatial location because the two representational dimensions are directly associated, as are the dimensions of pitch and loudness (McDermott et al., 2008) or pitch and happiness (Eitan & Timmers, 2010). Notwithstanding these associations, pitch perception and discrimination itself remains an exclusively auditory matter. Conversely, a shared representation explanation for pitch/space effects would hold that the representation of musical pitch is audiospatial in nature. Here, an individual's perception of a note's pitch would comprise an audiospatial representation of both its sound frequency and its height on the vertical axis. One would then recall its pitch as an auditory and spatial simulation of that frequency and height. People may therefore be willing to map musical pitch to other dimensions because they all share a common spatial grounding (i.e., are mediated by space): for example, both loudness (Eitan, Schupak, & Marks, 2010) and emotional valence (Meier & Robinson, 2004) show similar effects to pitch in vertical space. Pitch perception and discrimination, therefore, is obligatorily audiospatial.

In the present studies, we aimed to distinguish between these two explanations by using a basic psychophysical task of pitch discrimination, where participants must judge whether a target vocal note is the same as (or different from) a preceding cue note. Importantly, target trials were presented as video clips where a singer sometimes gestured upward or downward while singing that target note, thus

providing an alternative, concurrent source of spatial information. Signal detection analysis then allowed us to isolate the response criterion of pitch discrimination (i.e., underlying bias towards the belief that pitch has or has not changed), for which the two accounts produced differing predictions. An associative mapping explanation of the pitch/space relationship would predict that a concurrent spatial stimulus should have no effect on response criterion. Because pitch representations are purely auditory, people can discriminate pitch on the basis of auditory frequency, regardless of what other processing might be taking place in the spatial system. Only in the shared representation account, where the audiospatial representation of musical pitch cannot be disentangled from the visuospatial representation of vertical gesture, would a criterion shift emerge. Because pitch representation is audiospatial, people cannot discriminate pitch without being biased by concurrent spatial movement.

### Experiment 1: Biasing Pitch

In this and the following experiments, participants watched target trials of an actor gesturing while singing a particular musical note. Gestures frequently and effectively communicate spatial information to recipients that goes beyond what is conveyed in speech (Graham & Argyle, 1975; Holler, Shovelton, & Beattie, 2009). Our nonlinguistic combination of gesture and pitch stimuli therefore allowed us to embed spatial information in a naturalistic context to which people are sensitive, but in a less obtrusive manner than pairing pitch with (for example) geometric shapes.

Our hypotheses were simple. If the shared representation explanation is correct and pitch representations are audiospatial, then spatial information in concurrent gesture should influence pitch discrimination in two specific ways. First, the spatial movement of gesture should bias participants towards the belief they had perceived a pitch movement (i.e., that the target note was different to the cue). Furthermore, participants should be sensitive to the direction of spatial movement, where downward gestures would make pitch appear lower in frequency, and upward gestures would make pitch appear higher in frequency. On the other hand, if the associative mapping explanation is correct, then none of these effects would appear.

### Method

**Participants** Thirty-two native speakers of English from the University of Manchester took part in the experiment. Five were replaced when funnel debriefing indicated they were aware of the potential effect the gestures could have had on their pitch discrimination judgements. All were right-handed, had no hearing impairment, and were non-musicians (i.e., not musically trained). They received course credits or £4 for participation.

**Materials** Target notes consisted of 16 vocal notes, sung by professional actors/singers on a major scale from A2 (110 Hz) to A3 (220 Hz) for the male actor, and from A3 (220

Figure 1: Stills from video stimuli, showing a singer gesturing downward, at rest with no gesture, and gesturing upward. Arrows indicate extent and direction of movement.

Hz) to A4 (440 Hz) for the female actor. The fundamental frequency of these vocal notes was a maximum of 17 cents (17% of a whole tone) away from the intended pitch. Each actor was filmed moving the right hand downward or upward for the duration of the note, (i.e., downward or upward gesture), or resting their hands naturally on the lap (i.e., no gesture) (see Figure 1). In order to ensure stimulus consistency in gestural and vocal behaviour, we overdubbed the best gesture videos with the best target notes, and ensured each final stimulus was a seamless synchronization of mouth movement, gesture movement, and sung vocal. All 48 target videos lasted 1.4 seconds.

Cue notes consisted of synthesized notes at the same fundamental frequencies as the target notes, created with Garageband software with the Classical Ensemble voice (which sounded like a mixed choir of male and female vocalists). We chose to use synthesized human voices in order to avoid the spatial pitch characteristics associated with musical instruments (e.g., horizontal for a piano, vertical for a clarinet), and to give cue notes a similar timbre to target notes while still allowing us to use the same type of cue for male and female actors' notes. We then edited the synthesized cue notes in Audacity to replicate the target sung notes' frequency exactly (same pitch), or to shift it one semitone up (higher pitch) or down (lower pitch).

Cue and target stimuli were paired so that each target note (accompanied by a downward gesture, no gesture, or upward gesture) was preceded by a cue note of the same pitch, higher pitch, or lower pitch. We divided these 144 pairs into two materials lists, where both lists included all 48 same-pitch pairs, and the remaining stimuli were distributed so each list had 24 higher-pitch and 24 lower-pitch pairs (i.e., an equal number of same and different pitch).

**Procedure** Participants were instructed that they should watch videos of professional actors singing musical notes, and, in each case, judge as quickly and accurately as possible whether the actor's sound was the same pitch as an earlier musical note. The experiment was run with Superlab 4.0 on a MacBook laptop, with videos displayed onscreen at approximately 14 x 10.5 cm. Participants were randomly assigned to one of the two material lists and were tested individually in a lab cubicle. In each trial, they first saw a fixation cross for 500 ms, then heard the synthesized note, and immediately afterwards saw the target note video. After

the video, a screen appeared with the prompt “SAME DIFFERENT”, and participants were asked to press the left-hand key on a response box if they thought the actor's sound was the same pitch as the earlier musical note, or the right-hand key if they thought it was a different pitch to the earlier musical note (left/right mapping to same/different responses counterbalanced). If participants pressed the “different” key, another screen appeared with the prompt “HIGHER LOWER”, and participants were asked to press the left-hand key if they thought the actor's sound was a higher pitch than the earlier musical note, or the right-hand key if they thought it was a lower pitch (left/right mapping to higher/lower responses counterbalanced). There was a blank of 500 ms between trials.

Within each lost of materials, stimuli were arranged into six blocks so that each of the 16 target notes appeared once per block (gestures counterbalanced). The order of blocks was fixed but presentation of trials within a block was randomized per participant. Participants performed 4 practice trials before the main experiment, and the whole procedure lasted for about 15 minutes.

**Design & Analysis** We ran two stages of analysis of variance, each with a single within-participants factor of gesture (downward, no-gesture, upward) and effect sizes reported as partial eta-squared ( $\eta_p^2$ ). First, signal detection analysis examined performance on the same/different judgments to determine if gesture affected people's response bias and sensitivity in pitch discrimination. “Different” responses to different-pitch targets constituted hits, and those to same-pitch targets constituted false alarms. For each participant, we then calculated criterion  $c$  (criterion or bias) and  $d'$  (sensitivity) statistics for each gesture condition (e.g., Stanislaw & Todorow, 1999).

Second, we examined the trajectory of error to determine whether downward gestures made notes seem lower than they really were (and upward gestures higher). Each error in the same/different and higher/lower judgments represented an upward or downward response trajectory: for example, a downward trajectory was one where (1) a same-pitch target was judged to be lower in pitch, (2) a higher-pitch target was judged to be the same pitch, or (3) a higher-pitch target was judged to be lower in pitch. For each participant, we calculated the proportion of downward errors out of all errors in each gesture condition. Four participants with empty cells (i.e., perfect accuracy in one or more conditions) were excluded from trajectory analysis.

## Results & Discussion

People found the pitch discrimination task moderately difficult, with overall accuracy of 71.1%. Signal detection analysis supported the shared representation prediction that the spatial movement in gesture would affect pitch discrimination. There was a criterion difference between gesture types,  $F(2, 62) = 4.57$ ,  $p = .014$ ,  $\eta_p^2 = .129$ , as shown in Figure 2 (left panel). Most trials showed a bias towards “same” responses (i.e.,  $c > 0$ ), but planned comparisons showed this bias was weaker for downward ( $p$

$= .006$ ,  $\eta_p^2 = .187$ ) and upward ( $p = .011$ ,  $\eta_p^2 = .156$ ) gestures compared to when notes were unaccompanied by gesture. Upwards and downward gestures had the same response bias ( $p = .999$ ). Participants' increased propensity to make “different” responses in the presence of gesture did not affect their overall sensitivity in pitch discrimination,  $F(2, 62) = 2.04$ ,  $p = .139$ ,  $\eta_p^2 = .062$ , with equivalent performance in no-gesture ( $d' = 1.79$ ), downward ( $d' = 1.99$ ) and upward ( $d' = 1.83$ ) gesture conditions.

Analysis of error trajectory also followed predictions (see Figure 3, left panel). The nature of errors that people made was influenced by gesture,  $F(2, 54) = 9.23$ ,  $p < .001$ ,  $\eta_p^2 = .255$ . Specifically, planned comparisons showed that, relative to the no-gesture condition, downward gestures increased the number of downward trajectory errors ( $p = .007$ ,  $\eta_p^2 = .205$ ) while upward gestures reduced them ( $p = .043$ ,  $\eta_p^2 = .105$ ).<sup>1</sup>

## Experiment 2: Spatial Memory Load

If the shared representation explanation of pitch/space effects is correct, then the criterion shift and error trajectory in Experiment 1 emerge from an overlapping spatial representation of gestural movement and pitch. A spatial memory load should therefore attenuate these effects by occupying resources required for audiospatial pitch discrimination. Holding a spatial load in memory should remove the biasing effect of spatial movement on pitch discrimination, meaning that people will remain quite liberal in their tendency to assume that notes are the same. Consequently, the direction of spatial movement should no longer drive the trajectory of error to the same extent.

## Method

**Participants** Thirty-two new participants took part under the same criteria as Experiment 1. Five participants were replaced for awareness of the gesture effect. All had adequate recall of the spatial memory load (i.e., correctly recalled four or more out of six grids, see Materials).

**Materials** Stimuli were as per Experiment 1. In addition, items in the spatial memory task consisted of six different 3-by-3 grids (plus one for practice) in which five random cells had been filled with an X.

**Procedure** Instructions were identical to Experiment 1 except that participants were asked to hold in memory a visually-presented spatial grid during each block of the task. Before each of the six blocks, participants saw a spatial grid onscreen and could study it until they were satisfied they had memorised it. At the end of the block, participants were

<sup>1</sup>Although our participants were not musically trained, this fact did not preclude some level of knowledge about music; at the end of the experiment, we therefore gave participants a questionnaire to probe their exposure to music instruction (e.g., experience of playing a musical instrument, ability to distinguish pitch differences in staff notation). Musical knowledge was unrelated to either global response criterion  $r(30) = -.055$ ,  $p = .765$ , or downward error trajectory  $r(26) = -.182$ ,  $p = .354$ , though it did correlate positively with overall sensitivity  $r(30) = .597$ ,  $p < .001$ .

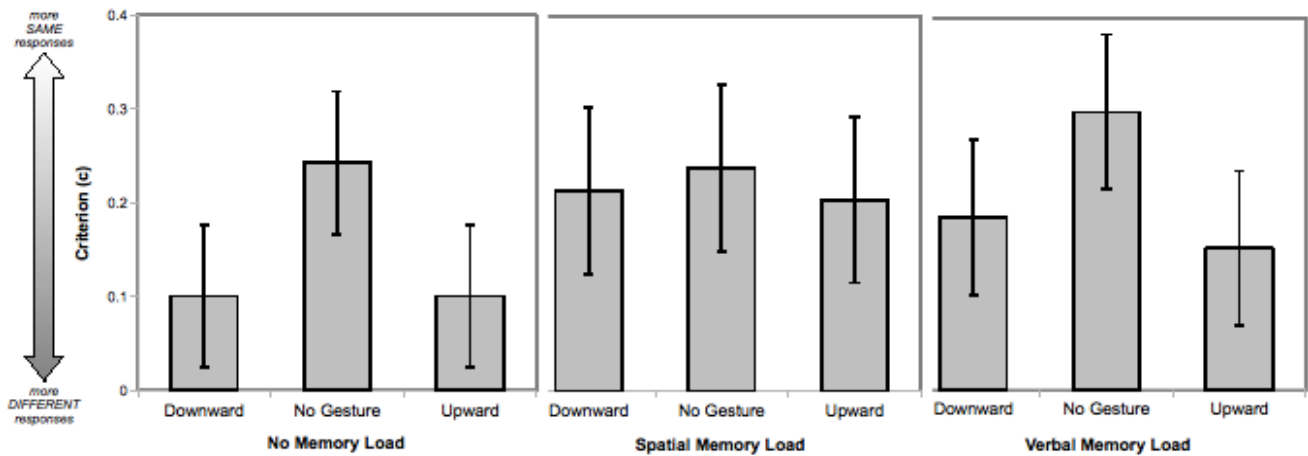

Figure 2: Response criterion in pitch discrimination (i.e., bias towards belief that target note was same as / different to cue) per gesture condition in Experiment 1-3. Error bars show within-participants 95% CI.

Figure 3: Proportion of pitch discrimination errors that expressed a downward trajectory (i.e., where participants thought the note was lower in pitch than reality) per gesture condition in Experiments 1-3. Error bars show within-participants 95% CI.

asked to recall the grid by drawing the positions of the Xs on a blank grid; these were later coded for accuracy (a grid must be perfectly recalled to qualify as an accurate response). The experiment lasted approximately 20 minutes.

**Design & Analysis** As in Experiment 1. Six participants with perfect accuracy in one or more conditions were excluded from trajectory analysis.

## Results & Discussion

Overall accuracy was similar to Experiment 1 at 73.8%. Signal detection analysis confirmed the predictions of the shared representation account that a spatial memory load would eliminate the biasing effect of spatial movement on pitch discrimination. There was no longer any criterion difference between gesture types,  $F(2, 62) = 0.15$ ,  $p = .856$ ,  $\eta_p^2 = .005$  (see Figure 2, centre panel): a similar bias towards “same” responses appeared for downward, upward and no-gesture conditions (all  $p$ s  $> .3$ ,  $\eta_p^2$ s  $< .009$ ). Sensitivity of pitch discrimination was unaffected by gesture,  $F(2, 62) = 1.11$ ,  $p = .176$ ,  $\eta_p^2 = .054$ : no-gesture  $d'$

$= 2.01$ , downward gesture  $d' = 1.92$ , upward gesture  $d' = 1.88$ .

Analysis of error trajectory showed attenuated effects compared to Experiment 1 (see Figure 3, centre panel). Spatial movement in gesture had an influence on the direction of error,  $F(2, 50) = 3.61$ ,  $p = .034$ ,  $\eta_p^2 = .191$ . Downward gestures led to more downward trajectory errors than no gesture ( $p = .034$ ,  $\eta_p^2 = .127$ ), but upward gestures did not reduce their occurrence relative to no gesture ( $p = .406$ ,  $\eta_p^2 = .002$ ).<sup>2</sup>

## Experiment 3: Verbal Memory Load

While the results of Experiment 1 support the shared representation account of pitch/space effects, it is possible that participants were silently labelling the pitch of the target notes as “higher” or “lower” in preparation for the discrimination task. The spatial movement in gesture could then have interacted with the representation of this verbal

<sup>2</sup> Musical knowledge was again unrelated to response criterion  $r(30) = -.196$ ,  $p = .282$ , and error trajectory  $r(24) = .084$ ,  $p = .984$ , and correlated with overall sensitivity,  $r(30) = .546$ ,  $p = .001$ .

label rather than inducing a bias in pitch discrimination itself. We therefore examined the origin of the criterion shift by replicating the task while participants held a verbal load in memory to block a linguistic labelling strategy. If the shared representation explanation is correct, then the criterion shift of Experiment 1 should emerge unscathed. Furthermore, if the criterion shift re-emerges under a verbal memory load, it will verify that the cancelled effects in Experiment 2 were not due to generic processing difficulties under memory load conditions but rather were specific to spatial content.

## Method

**Participants** Thirty-two new participants took part under the same criteria as Experiment 1. Three participants were replaced for inadequate recall of the verbal memory load (i.e., anyone who recalled fewer than four out of six diphone sequences, see Materials).

**Materials** Stimuli were as per Experiment 1. In addition, items in the verbal memory task consisted of six different sequences of three nonsense diphones (e.g., [tɛ kæ vo]); one further sequence was used for practice. Each sequence was recorded by a male native speaker with clear enunciation.

**Procedure** Instructions were identical to Experiment 1 except that participants were asked to hold in memory an auditorily-presented diphone sequence during each block of the task. Before each of the six blocks, participants listened to a diphone sequence three times and repeated it back to the experimenter (second author); if there were any errors in repetition, the experimenter enunciated the sequence again until participants got it right. At the end of each block, participants recalled aloud the memorised diphone sequence to the experimenter who transcribed it and later coded it for accuracy (a sequence must be perfectly recalled to qualify as an accurate response). Participants were familiarised with diphone recall during the practice session. The experiment took approximately 20 minutes to complete.

**Design & Analysis** As in Experiment 1. Three participants with perfect accuracy in one or more conditions were excluded from trajectory analysis.

## Results & Discussion

Overall accuracy was similar to Experiment 1 at 69.3%. Signal detection analysis replicated the findings of Experiment 1, and confirmed that the biasing effect of spatial movement on pitch discrimination was not due to a verbal labelling strategy. Figure 2 (right panel) shows the criterion difference emerged between gesture types,  $F(2, 62) = 3.39, p = .040, \eta_p^2 = .098$ . As before, the bias towards “same” responses was weaker for downward ( $p = .040, \eta_p^2 = .095$ ) and upward ( $p = .009, \eta_p^2 = .168$ ) gestures compared to when notes were unaccompanied by gesture. Upwards and downward gestures had the same response bias ( $p = .549$ ). Since these “different” responses were distributed across both correct and incorrect trials,

sensitivity of pitch discrimination did not change with gestural movement,  $F(2, 62) = 1.78, p = .176, \eta_p^2 = .054$ , with equivalent performance in no-gesture ( $d' = 1.68$ ), downward ( $d' = 1.89$ ) and upward ( $d' = 1.84$ ) gesture conditions.<sup>3</sup>

Analysis of error trajectory again replicated Experiment 1 (see Figure 3, right panel). The nature of errors in pitch discrimination was influenced by the spatial movement in gesture,  $F(2, 56) = 6.62, p = .003, \eta_p^2 = .191$ . Downward gestures marginally increased the frequency of downward trajectory errors compared to no gesture ( $p = .052, \eta_p^2 = .092$ ) while upward gestures reduced their occurrence ( $p = .034, \eta_p^2 = .115$ ).

## General Discussion

In the present paper, we show that concurrent visuospatial movement biases pitch discrimination. Viewing upward and downward gestures biased people towards believing they had perceived a change in pitch, despite an underlying tendency to assume that all notes were the same. Indeed, when we examined the pattern of errors that people made, we found that the direction of gesture was also driving the direction of error: downward gestures made notes seem lower in pitch than they really were, and upward gestures made notes seem higher in pitch than they really were. These effects were not due to a verbal labelling strategy as they were preserved under verbal memory load. However, their disappearance under spatial memory load conditions indicates that the biasing effect is spatial in origin. Together, these findings support the shared representation explanation for the relationship between pitch and space.

When people hear a musical note, its pitch is not just represented in the auditory modality. Rather, its representation is audiospatial, in that it comprises both an auditory and spatial representation of the note's frequency. However, things become more complicated when people watch someone singing a note. On the one hand, if the singer remains still, then the same story applies: the audiospatial representation still reflects the note's pitch. But, on the other hand, if the singer gestures with an upward or downward movement, then both the visual gesture and auditory note require representational resources in the vertical spatial axis. Hence, the spatial information in the gesture is co-perceived with that in the note, and results in an audiospatial representation of the note's pitch that has been modulated by the direction of spatial movement in the gesture.

While many previous studies have examined the relationship between pitch and vertical space, they could not determine the nature of pitch representation because both associative mappings and shared representations would lead a pitch stimulus to prime its associated spatial location and facilitate motor responses to that location (e.g., Rusconi et al., 2006). However, a mapping from high pitch to high spatial location would be static, and could not explain why

<sup>3</sup> Musical knowledge was again unrelated to response criterion  $r(30) = -.040, p = .828$ , or error trajectory  $r(27) = .044, p = .820$ , and correlated with overall sensitivity,  $r(30) = .394, p = .026$ .

the spatial movement in gesture biased participants towards believing they had perceived a movement in pitch. A dynamic, shared representation of pitch and space, where pitch is represented not only in terms of spatial position but also movement and direction, is consistent with our results.

There are several possibilities as to how and why musical pitch is represented in vertical space, and not in some other spatial dimension. When speaking, producing a pitch higher than normal voice frequency moves the larynx upward in the throat, and producing a lower pitch moves it downward. Furthermore, breathing from the top of the lungs by raising and lowering the shoulders tends to produce higher-pitch vocal notes, while breathing from the bottom of the lungs by tensing and relaxing the thoracic diaphragm tends to produce lower-pitch, resonant notes. Thus, cumulative experience of our own voices provides a possible vertical grounding for vocal pitch, which could then generalize to pitch of other people's voices or musical instruments, and so on. While some have claimed the appearance of pitch/space effects in young infants means the connection between domains is innate (Walker et al., 2010), even 3-4 month old babies have considerable experience of vocalisation. A conservative estimate of one hour per day crying, fussing etc. (e.g., Michelsson, Rinne, & Paajanen, 1990) provides a 4-month old infant with over 100 hours experience of vocal pitch under various body configurations. Since infants of that age can learn statistical regularities in the environment with only a few minutes' exposure (Kirkham, Slemmer & Johnson, 2002), it seems premature to assume they could not have learned to represent pitch spatially.

Future research will need to determine whether pitch/space effects emerge from a learned or innate mechanism, but, whatever its origin, the present paper demonstrates that pitch is fundamentally audiospatial. The nature of the link between musical and spatial processing is one of shared representation.

## Abstract

Previous research has shown that people use both embodied perceptual simulations and linguistic distributional knowledge during conceptual processing, with linguistic information especially useful for shallow tasks and rapid responding. Using two conceptual combination tasks, we show that this linguistic shortcut is evident in both shallow and deep conceptual processing of novel stimuli. Specifically, in both shallow sensibility judgement and deep interpretation generation tasks, people use the linguistic shortcut as a “quick and dirty” guide to whether the concepts are likely to combine in a coherent situated simulation. Linguistic distributional frequency predicts both the likelihood and timecourse of rejecting a novel word compound as nonsensical or uninterpretable. However, it only predicts the timecourse of successful processing in shallow sensibility judgement because deeper interpretation generation requires conceptual processing in the simulation system.

**Keywords:** conceptual combination; linguistic distributional information; embodied cognition; simulation.

## Introduction

The embodied simulation view of conceptual representation holds that the same neural systems that are responsible for representing information during perception, action, and introspection are also responsible for representing (or *simulating*) the same information during conceptual thought (e.g., Barsalou, 1999; Glenberg, 1997). Furthermore, concepts do not exist in a representational vacuum, but rather are situated within a broader situational context that includes perceptual, motor, affective and social information on how that concept has been experienced in the past (e.g., Barsalou & Wiemer-Hastings, 2005; Lynott & Connell, 2010a). A *cactus*, for example, can potentially include visual information (e.g., its green colour and prickly surface), tactile information (e.g., the sharpness of its spines), and affective information (e.g., negative valence for anyone who has spent days picking spines from skin), all situated relative to other concepts (e.g., in a desert location or as a pot plant on a kitchen windowsill).

However, the simulation system does not act alone. People are sensitive to distributional, statistical patterns in language and the wider environment, and this sensitivity provides a powerful generalised learning mechanism from early infancy (Aslin et al., 1998; Kirkham et al., 2002). Even in adults, the linguistic system contains statistical

distributional information in a dynamic web of word-to-word (and phrase-to-phrase) associations that is powerful enough to support superficial strategies in a broad range of linguistic and conceptual tasks (e.g., Barsalou, Santos, Simmons & Wilson, 2008; Louwerse & Jeuniaux, 2008; Lynott & Connell, 2010a). The linguistic and simulation systems are closely interconnected and mutually supportive; linguistic information can activate simulation information, which may in turn activate further linguistic information, and so on. For example, when the word “cactus” is encountered, closely related linguistic tokens such as “prickly” and “sharp” will be activated, which will in turn begin to activate their relevant grounded representations in the simulation system, thus drawing attention to the visual and haptic modalities. Because their structures are both based on experience, the linguistic and simulation systems mirror each other to a certain extent, which suggests that information from language alone can approximate the perceptual, motor, affective, etc. content of concepts. Supporting this view, Louwerse and Connell (2011) have shown that linguistic distributional information is capable of distinguishing words on the basis of their perceptual modality. Words like *rustling*, *glistening*, and *freezing* refer to object properties in particular perceptual modalities (i.e., auditory, visual, and haptic) and occur in language with particular usage patterns. Louwerse and Connell showed that statistical analysis of these distributional patterns (based on 5-gram co-occurrence frequencies from a large corpus) produced three clusters that corresponded to auditory, visuohaptic and olfactogustatory modality groups. In other words, although auditory words were distinct, distributional information could not distinguish vision from touch, nor smell from taste. These three “linguistic modalities” (i.e., modality-specific clusters within the linguistic system) of auditory, visuohaptic and olfactogustatory words are therefore a coarse-grained approximation of the perceptual reality of five modalities. Linguistic distributional information is, at best, a blurred mirror of the simulation system.

The essential difference between the two systems is that the linguistic system is best for “quick and dirty” judgements, while the simulation system is best for deeper conceptual processing. When a word such as “cactus” is heard or read, both systems are kickstarted but the linguistic system peaks in activation (e.g., spreads activation to other

tokens “prickly”, “sharp”, and so on) before the simulation system peaks (e.g., forms a visual, haptic, affective situated simulation of a *cactus*). The linguistic system thus has the potential to act as a shortcut and provide a response before the relatively more expensive simulation system is fully engaged. Support for this idea comes from Louwerse and Connell (2011), who compared the abilities of the linguistic and simulation systems to predict modality switching costs in property verification tasks. Switching costs refer to the finding that people are slower to confirm that a perceptual property is true of an object (e.g., auditory *leaves can be rustling*) when it follows a property from a different modality (e.g., visual *dew can be glistening*), and this processing cost is assumed to arise from the re-allocation of attention between modality-specific areas during perceptual simulation of the object property in question (Pecher, Zeelenberg & Barsalou, 2003). When Louwerse and Connell examined whether switching costs were best predicted by “linguistic modalities” (i.e., auditory, visuohaptic, and olfactogustatory word clusters) or actual perceptual modalities (i.e., auditory, gustatory, haptic, olfactory, and visual categories, based on human ratings), they found that the linguistic shortcut was the best predictor of fast responses, whereas perceptual simulation of five modalities was the best predictor of slow responses. In short, the linguistic system offers a fuzzy approximation that can provide an adequate heuristic in certain tasks, whereas the simulation system provides representational precision for more complex and precise conceptual processing.

## The Current Study

Although Louwerse and Connell's (2011) study offers important evidence for the role of the linguistic shortcut conceptual processing, it is based on the retrieval of familiar information that is always expected to be successful. Most of human cognition is not like that, however. In order to function in a normal environment, we must be able to represent new concepts and process unfamiliar information, and work within the constraint that our conceptual processing is not always successful. Indeed, one of the key issues of a cognitive system with limited resource capacity is that not everything *should* be processed; a cognitive triage mechanism – an automatic means to determine whether it is worth expending precious representational and executive resources on a particular conceptual task, or whether it should be abandoned pending further clarification / information – would offer an invaluable aid to efficient functioning. A strong test of the linguistic shortcut hypothesis would therefore predict that use of the shortcut should be evident in the processing of (1) novel stimuli, (2) for successful responses in relatively shallow conceptual tasks, and (3) for apparent failures where a process is halted as not worth the effort, regardless of the depth of processing ostensibly involved in the task.

In the present experiments, we examined the role of the linguistic shortcut in conceptual combination using both shallow and deep processing tasks. Conceptual combination

is the process of understanding novel word compounds such as *cactus beetle* or *elephant complaint*, and is predicated upon the inherently constructive nature of cognition that allows us to represent new concepts by mentally manipulating old ones. For example, a *cactus beetle* may be represented as a beetle that feeds on cacti, or as a green and prickly beetle; both are equally valid end products of a successful combination process. Recently, Lynott and Connell (2010a) proposed the Embodied Conceptual Combination (ECCo) theory, which argues for a distinct role for the linguistic system during conceptual combination that complements that of the simulation system. Specifically, if the two nouns in a compound have little shared statistical, distributional history from language use, then the linguistic system offers people a reasonable heuristic for rejecting the compound as incomprehensible without expending much cognitive effort in attempting to combine the concepts. In contrast, if the nouns have frequently been encountered in close proximity to one another, then the linguistic system offers people a reasonable heuristic for accepting that the concepts can probably be combined in a shared, situated simulation.

Both sensibility judgement and interpretation generation tasks are commonly used in conceptual combination studies, but they differ in the required depth of processing (Lynott & Connell, 2010a). Sensibility judgement (Experiment 1) is relatively shallow because it simply asks people whether or not a particular compound makes sense. Interpretation generation (Experiment 2) is relatively deep because it asks people whether or not they can think of a meaning for a particular compound, and, if so, to specify the meaning. We therefore expected the linguistic system to play a differential role in conceptual combination according to task requirements: as a shortcut for both accepting and rejecting compounds in sensibility judgements, but only for rejecting compounds in interpretation generation because successful processing requires detailed representation in the simulation system.

## Experiment 1: Sensibility Judgement

In this experiment, we presented people with novel noun-noun compounds in a forced-choice sensibility judgement task, where they pressed “yes” if they thought the compound phrase made sense, and pressed “no” if they thought it was nonsense. Similar methods have been used in a number of previous conceptual combination studies (e.g., Gagné & Shoben, 1997; Estes, 2003; Tagalakis & Keane, 2006). We measured response times to press both “yes” (i.e., accept as sensible because of successful combination) and “no” (reject as nonsense because of failed combination) keys. Following ECCo's proposal regarding the nature of the linguistic shortcut in sensibility judgements, we predicted inverse effects for acceptance and rejection of compounds. Linguistic distributional frequency (i.e., how frequently the two nouns have shared a context) should be *negatively* related to acceptance rates and times because high-frequency compounds will quickly appear sensible: the

linguistic shortcut allows people to assume the concepts in question can combine merely because their two nouns have been frequently juxtaposed. In contrast, linguistic distributional frequency should be *positively* related to rejection times because low-frequency compounds will quickly appear nonsensical: the linguistic shortcut allows them to be dismissed out of hand rather than attempting a costly and potentially pointless combination effort in the simulation system.

## Method

**Materials** Forty one noun-noun compounds were used in this study: 27 novel test items and 14 lexicalised filler items. Test items comprised novel noun-noun compounds (e.g., *octopus apartment*, *elephant complaint*, *whale knife*) with a British National Corpus phrase frequency greater than 20 (BNC, 2001), and featured a range of concept types (i.e., artifacts, natural kinds, abstract concepts). Filler items were lexicalised noun-noun compounds (e.g., *hospital wing*, *guerrilla warfare*) with a BNC frequency greater than 20, and were included to provide a baseline of highly sensible combinations to ensure that participants attended to the task.

In order to approximate the linguistic distributional information available to novel compounds, we carried out a corpus analysis using the Web 1T 5-gram corpus (Brants & Franz, 2006), which contains over a trillion tokens culled from Google indices and thus allows extensive analysis of linguistic distributional patterns<sup>1</sup>. For each compound, we calculated the cumulative 5-gram frequency of occurrence between the modifier and head nouns (e.g., the summed count of *octopus ... apartment* with zero, one, two and three intervening words: for a similar approach, see Louwerse & Connell, 2011). Finally, frequencies were log-transformed as  $\ln(f + c)$ , where  $f$  is the raw frequency and  $c$  is a constant (minimum non-zero frequency) added to all values to enable log calculations of zero counts.

All novel compounds were potentially sensible because they had been successfully interpreted by a majority of participants in previous studies (Lynott & Connell, 2010b). Critical to our present purposes, data from an offline pretest (i.e., an open-response task under no time constraints:  $N = 20$ ) showed no reliable relationship between items' linguistic distributional frequency and success rate of interpretation,

<sup>1</sup>Note that a broader co-occurrence measure like LSA (Landauer & Dumais, 1997) is not the same as the 5-gram frequency count we use here. LSA measures co-occurrence over a broad paragraph-length window before reducing the total matrix to approximately 300 dimensions, so distance between words can be calculated as the cosine of the angle between two points in this high-d space. LSA scores between words therefore reflect a broad linguistic similarity, such that synonyms, which often occur in the same general contexts, should receive a high score. In contrast, n-gram frequencies measure co-occurrence within a narrow window of local context (i.e., with 0-3 intervening words for 5-grams). N-gram frequencies between words therefore reflect whether words are used in close proximity with one another. They do not reflect similarity of meaning because synonyms, which occur within 0-3 words of each other only rarely, should receive a low score.

$r(25) = .170$ , one-tailed  $p = .198$ .

**Participants** Twenty-four native speakers of English completed the experiment for a nominal sum. One participant was excluded for judging a majority of lexicalised filler items as nonsensical.

**Procedure** Participants were told that they would be presented with two-word phrases onscreen; some of these phrases would be familiar to them, while others would not. They were instructed to press the key labelled “Yes” to indicate that the phrase made sense or to press the key labelled “No” to indicate the phrase was nonsense. All responses were made with the participant’s dominant hand.

Each trial began with the word “Ready” appearing on the screen for 2000 ms, followed by the compound which remained onscreen until the participant made a decision. Response times were recorded in seconds from the onset of the compound until the participant’s keypress (“Yes” or “No” button). There was a blank screen interval of 1000 ms until the start of the next trial. Each participant saw all compounds presented in a different random order. The experiment took less than 10 minutes to complete.

**Design & Analysis** Response decision data (i.e., whether a compound was accepted or rejected) were analysed in a mixed-effects logistic regression model (logit link function) with crossed random factors of participants and items. The inclusion of items was empirically validated because it improved model fit over participants alone,  $\chi^2(1) = 38.31$ ,  $p < .0001$ . Linguistic frequency (i.e., log 5-gram frequency per compound) acted as a fixed predictors variable. Response time data were analysed in a mixed-effects linear regression model with participants as a random factor. Items were not included as a crossed random factor because it did not further improve model fit,  $\chi^2(1) = 2.55$ ,  $p = .111$  (Baayen, Davidson & Bates, 2008). Response decision (i.e., yes or no) and linguistic frequency (i.e., log 5-gram frequency per compound) acted as fixed interacting predictors variables. The primary advantages of mixed effects analysis as regards the present experiment is that it can determine the effect of item-level predictors while simultaneously taking participant variability into account, and that it offers greater power than analysing aggregated responses over participants or items (Baayen et al., 2008; Locker, Hoffman & Bovaird, 2007). Regression coefficients are reported as unstandardized  $\beta$  values. Effect size  $r$  for each predictor was calculated from  $t$  (Cohen, 1988).

## Results & Discussion

Data points more than 2.5 standard deviations from each participant’s mean time per response decision were removed as outliers: 1.6% for “yes” responses and 2.4% for “no”.

**Acceptance / Rejection Rates** Overall, 31.6% of novel compounds were judged as sensible and 68.4% as nonsense. As predicted, the likelihood of accepting a noun-noun

compound as sensible increased with linguistic distributional frequency,  $t(606) = 4.63$ ,  $p < .0001$ ,  $\beta = 0.251$ ,  $r = .185$ . Even though all the compounds were novel stimuli with no pre-specified definition, the fact that two nouns had been relatively frequently juxtaposed was enough to allow their combination to seem sensible.

**Acceptance / Rejection Times** Sensibility acceptance times ( $M = 2.625$ ,  $SE = 0.096$ ) were generally slower than rejection times ( $M = 2.364$ ,  $SE = 0.144$ ),  $t(557.1) = 3.03$ ,  $p = .003$ ,  $\beta = 1.151$ ,  $r = .127$ . Linguistic frequency had a marginally positive effect on overall response times,  $t(556.5) = 1.89$ ,  $p = .059$ ,  $\beta = 0.084$ ,  $r = .080$ ; but critically interacted with response decision to produce a negative effect on acceptance times,  $t(556.8) = -2.70$ ,  $p = .007$ ,  $\beta = -0.187$ ,  $r = .114$ . Separate analysis of “yes” and “no” responses showed the predicted inverse effects (see Figure 1). The time taken to accept a novel compound as sensible decreased with greater linguistic frequency,  $t(162.9) = -2.62$ ,  $p = .005$ ,  $\beta = -0.140$ ,  $r = .201$ , whereas the time to judge a compound as nonsense increased with linguistic frequency (i.e., low frequency compounds were rejected quickly, high frequency compounds were not),  $t(376.8) = 1.77$ ,  $p = .039$ ,  $\beta = 0.077$ ,  $r = .091$ .

In other words, the linguistic shortcut acts to facilitate shallow conceptual combination by providing an heuristic of sensibility. Higher linguistic distributional frequency facilitates acceptance of a novel stimulus: words that often share a local context are quickly and frequently judged to be a sensible phrase, which constitutes successful (albeit “quick and dirty”) processing of the combination. Lower

linguistic frequency, however, facilitates rejection: words that rarely share a context are quickly and frequently judged to be a nonsensical phrase, which may appear to constitute a failed conceptual combination process, but is perhaps better regarded as successful avoidance of a potentially costly but fruitless cognitive effort. Of course, participants do not have to rely solely on this linguistic shortcut just because it exists, and are free to base their sensibility judgements on the simulation system. Nevertheless, the results of this experiment demonstrate a statistical tendency to use linguistic distributional information as a sensibility heuristic, even when individual differences between participants and items are partialled out. We return to this issue in the general discussion.

## Experiment 2: Interpretation Generation

While the previous experiment examined a relatively shallow form of conceptual combination (i.e., judging whether a noun-noun compound made sense, but without having to specify why), this experiment focuses on a deeper form of processing by asking people to provide an actual interpretation for each compound. As before, we used a forced-choice task, where participants pressed “yes” if they could think of a meaning for the compound phrase (and then told us the meaning they had generated), and pressed “no” if they could not. Because the interpretation generation task invites deeper processing than sensibility judgement by asking people to think of a meaning, previous research has found it leads to more liberal use of “yes” decisions to novel compounds (Tagalakakis & Keane, 2006). We therefore expected a larger proportion of items to be accepted than in

Figure 1: Regression plots of linguistic distributional frequency against model predicted response times for rejection (“no” decision) and acceptance (“yes” decisions) of novel noun-noun compounds in Experiment 1’s sensibility judgement and Experiment 2’s interpretation generation tasks. Dotted lines represent 95% confidence intervals around the mean. All fits except “yes” responses in interpretation generation are significant at  $p < .05$ .

Experiment 1, but, as for sensibility judgement, we expected this acceptance rate to be positively related to linguistic distributional frequency. The linguistic shortcut should quickly make high-frequency compounds appear interpretable, and – because most people can generate meanings for these items when they try – their subsequent combination in the simulation system is likely to succeed. Acceptance times thus reflect the latency of full conceptual combination, and as such should not be predicted by mere linguistic frequency. Rejection times, on the other hand, should show the same positive relationship with linguistic frequency that we saw for sensibility judgement: words that seldom appear in the same contexts will be quickly and frequently rejected as uninterpretable because the linguistic shortcut suggests their concepts may not combine.

## Method

**Materials** As per Experiment 1.

**Participants** Eighteen native speakers of English completed the experiment for a nominal sum.

**Procedure** Instructions were identical to Experiment 1 except that participants were asked to press the key labelled “Yes” to indicate that “Yes, I can think of a meaning” (whereupon a screen appeared for them to type in the interpretation just generated), or to press the key labelled “No” to indicate that “No, I cannot think of a meaning”. The experiment took approximately 20 minutes to complete and had a short, self-paced, break halfway through.

**Design & Analysis** Data were analysed with crossed random factors because model fit improved with the inclusion of items for both logistic regression of response decision data,  $\chi^2(1) = 69.95$ ,  $p < .0001$ , and linear regression of response time data,  $\chi^2(1) = 6.17$ ,  $p = .013$ . All other details were the same as Experiment 1.

## Results & Discussion

2.2% of “yes” responses to novel compounds resulted in blank or invalid interpretation (e.g., “a”, “I don’t know”) and were excluded from analysis as they did not represent successful combination. Data points more than 2.5 standard deviations from each participant’s mean per response decision were removed as outliers: 1.3% for “yes” responses and 2.8% for “no”.

**Acceptance / Rejection Rates** Overall, 68.5% of compounds were accepted and successfully interpreted and 31.5% were rejected as uninterpretable. Each compound had a variety of different, coherent interpretations, such as a *whale knife* as “A knife that has a picture of a whale on it” or “knife used by whalers”, or an *elephant complaint* as “a large complaint” or “a complaint about elephants in the area”. As predicted, the likelihood of successfully interpreting a noun-noun compound increased with linguistic distributional frequency,  $t(439) = 2.10$ ,  $p = .019$ .  $\beta$

$= 0.145$ ,  $r = .100$ .

**Acceptance / Rejection Times** Interpretation times ( $M = 3.348$ ,  $SE = 0.110$ ) were marginally faster than rejection times ( $M = 3.713$ ,  $SE = 0.194$ ),  $t(413.7) = 1.77$ ,  $p = .077$ ,  $\beta = 0.974$ ,  $r = .087$ . Linguistic frequency had an overall positive relationship with response times,  $t(117.0) = 2.14$ ,  $p = .034$ ,  $\beta = 0.209$ ,  $r = .194$ ; but, critically, it negatively interacted with response decision,  $t(413.8) = -2.44$ ,  $p = .015$ ,  $\beta = -0.259$ ,  $r = .119$ . Results for separate analysis of “yes” and “no” responses were as predicted (Figure 1). The time taken to accept and interpret a novel compound was unaffected by linguistic distributional frequency,  $t < 1$ . Like sensibility judgements, however, the time to reject a compound as uninterpretable increased with linguistic frequency,  $t(120.7) = 2.74$ ,  $p = .007$ ,  $\beta = -0.256$ ,  $r = .242$ .

In both shallow sensibility judgement and deep interpretation generation tasks, people use the linguistic shortcut as a “quick and dirty” guide to whether the concepts are likely to combine in a coherent situated simulation. Building a representation that is detailed enough to provide an interpretation is a function of deep conceptual processing in the simulation system, and took some 700 ms longer than accepting a compound as sensible. This extra depth of processing meant that successful interpretation times were no longer predicted by information from the linguistic system. Rejection times were also slower for interpretation generation than for sensibility judgement, and the 1300 ms difference suggests that at least some “no” responses resulted from tried-and-failed conceptual combination in the simulation system. However, the fact that rejection times were still strongly predicted by linguistic distributional frequency shows that the linguistic shortcut offered an important heuristic for avoiding this resource-wasting event.

## General Discussion

There are three novel findings in the present paper. First, we show that linguistic distributional frequency can predict not only the timecourse of successful conceptual processing (i.e., “yes” responses in sensibility judgement), but also the timecourse and likelihood of failure (i.e., “no” responses). Second, use of this linguistic shortcut extends beyond simple retrieval into the processing of novel stimuli in conceptual combination. The more often two words have appeared in close proximity to one another, the faster people are to accept the compound as sensible and the slower they are to reject it as uninterpretable nonsense. Third, we show that the influence of such linguistic shortcuts is not restricted to shallow conceptual tasks, but is also useful in deeper conceptual processing as a form of cognitive triage. The less often two words have appeared in close proximity, the faster people reject their compound as uninterpretable rather than risk costly failure in the simulation system. These findings support theories that argue for complementary roles of the linguistic and simulation systems in conceptual combination (Lynott & Connell,

2010a) and conceptual processing more generally (Barsalou et al., 2008; Louwerse & Jeuniaux, 2008).

But isn't all this just standard *word frequency effects*? In a word, no. We can't observe the above range of effects in conventional psycholinguistic tasks such as lexical decision or word naming. Firstly, responses in lexical decision and naming tasks are either correct or incorrect (e.g., correctly rejecting a non-word), whereas novel compounds do not necessarily have a "correct" interpretation. Rather, an individual's processing of a compound is either successful or unsuccessful, and even an "unsuccessful" outcome may represent the most efficient use of cognitive resources. Secondly, lexical decision and naming tasks rely solely on the recognition of known concepts, while conceptual combination tasks require the processing of new conceptual entities. Thus, the paradigm in this paper allows us to examine the conceptualisation of novel stimuli at two depths of processing, and demonstrate how the linguistic shortcut offers a useful heuristic in both shallow and deep tasks.

Of course, participants do not have to rely solely on a linguistic shortcut just because it exists. An individual may double-check apparently sensible or apparently uninterpretable compounds within the simulation system by actually attempting to combine the concepts. Indeed, it is possible that some particularly cautious individuals may even base every sensibility judgement on whether the concepts can combine into a coherent simulation. However, an easy shortcut is hard to refuse. Because the linguistic shortcut is faster and computationally cheaper than basing a judgment on the simulation system, and because on-the-fly conceptual processing does not have to be perfect (only "good enough": Ferreira, Bailey & Ferraro, 2002), participants can safely exploit it most of the time.

# Exploring Decision Rules and Sampling Dynamics in Recognition Memory

Gregory E. Cox (grcox@indiana.edu)

Richard M. Shiffrin (shiffrin@indiana.edu)

Department of Psychological and Brain Sciences, Indiana University  
1101 E. Tenth St., Bloomington, IN 47405 USA

## Abstract

Cox and Shiffrin (2012) introduced a dynamic model of recognition memory that was capable of making simultaneous predictions for accuracy and mean response time. The present paper extends that work by investigating the assumptions underlying the model's decision process, in particular those pertaining to the process by which features are sampled at test and the processes by which evidence for an "old"/"new" recognition decision accumulates. These assumptions are tested against empirically collected response time distributions. Evidence is found that sampling dynamics can change in response to instructions, and that competition between accumulators for "old" and "new" evidence is not necessary to capture at least the recognition data presented here.

**Keywords:** Recognition memory; response time; memory models.

## Introduction

Cognitive scientists have long understood the utility of timing information for making inferences about the cognitive processes underlying behavior. Yet, the field of recognition memory has only made limited use of this rich source of data. This is partially because of a lack of available data to constrain dynamic models of recognition, and partially because most theories of recognition are themselves static: Recognition decisions are presumed to operate on a fixed value of "familiarity", which is a signal indicating the presence or absence of an item in memory. If the familiarity is above a particular criterion, a participant declares the item "old", otherwise it is considered "new". Most extant models of memory are concerned purely with how this familiarity value is calculated for different items. Some of these models assume that an item is compared to many individual memory traces (e.g., Hintzman, 1988; Shiffrin & Steyvers, 1997; McClelland & Chappell, 1998), to an aggregate of several memory traces (Murdock, 1982), or to the present context (e.g., Dennis & Humphreys, 2001; Howard & Kahana, 2002).

We have recently proposed (Cox & Shiffrin, 2012) that taking a dynamic, as opposed to static, approach to recognition will shed light on many previously vexing issues. Our original work was concerned with the problem of criterion setting in the case of widely-varying stimulus materials, where the absolute value of familiarity may fluctuate wildly between different test items. Although, in principle, criteria might be learned over time (c.f., Turner, Van Zandt, & Brown, 2011), we showed that the problem of learning stimulus-specific criteria is bypassed entirely if one treats recognition decisions as inherently dynamic in nature. In this case, rather than basing a decision on a fixed asymptotic level of familiarity, recognition can make use of the *changes in* familiarity over time as information is gathered from the test stimulus. The shape of

the "familiarity profile" generated by this gradual accrual of information is invariant to many of the factors that would result in different levels of asymptotic familiarity, e.g., amount of prior exposure to the stimulus and degree of encoding.

Although the model proposed by Cox and Shiffrin (2012) was originally motivated to address the criterion setting problem, it has potential application as a general model of recognition. We showed that the predictions of the model for accuracy and mean response times were in accord with published data on recognition memory, but left many questions unanswered. For example, we assumed that the decision took the form of a race between two parallel accumulators, one leading to an "old" response and the other to a "new" response. This decision mechanism was not explicitly compared to other possible mechanisms, e.g., those with non-independent accumulators like a random walk or diffusion process (e.g., Ratcliff, 1978). Further, we assumed that the times between sampling events—i.e., sampling a feature from the test stimulus—were drawn independently and identically from an exponential distribution, but made no attempt to investigate whether this sampling process might differ between study and test and between conditions.

At the level of mean RT, these sets of predictions would be difficult to disentangle from those arising from other assumptions regarding correlated accumulators or different sample time distributions. Thanks to the generous contributions of Chris Donkin and Andrew Heathcote, we are now able to test the assumptions of our original dynamic recognition model regarding the decision mechanism and sampling dynamics. In so doing, we have taken yet more steps toward developing a general theory of recognition that is able to account for both accuracy and response time.

## The Model

The modeling framework used in this paper is a direct outgrowth of the dynamic recognition model proposed by Cox and Shiffrin (2012), which is itself based on the REM model (Shiffrin & Steyvers, 1997). The central tenet of the dynamic recognition model is that information about a test item is sampled over time and added to a memory probe. When the probe is compared to the contents of memory at time  $t$ , it produces a particular familiarity value,  $\phi(t)$ . How this value changes over time constitutes evidence for an old/new recognition decision: decrements in  $\phi(t)$  (relative to  $\phi(t-1)$ ) are evidence that the item is new, because additional item information *reduces* its familiarity. Contrariwise, increases in  $\phi(t)$  are evidence that the item is old, because new item information *increases* its familiarity. We now give a more detailed exposi-

tion of the model, although the reader is directed to Cox and Shiffrin (2012) for additional information.

## Representations and Encoding

An episodic memory trace for an item is represented as a vector of features, each of which is binary with an equal *a priori* probability of being “0” or “1”. These features are divided into two kinds: *content* features which arise from the item itself, which may include information about its sensory characteristics or semantics, and *context* features which arise from the situation in which the item was encountered. Episodic memory is presumed to consist of a (very large) set of such traces from across the life span, although for practical purposes, we restrict ourselves to modeling just a subset of these traces (see below). In addition, we assume that two traces of the same item need not be encoded using the same features. For example, a particular apple might be encoded primarily with features pertaining to its physical appearance on one occasion, but on another the apple might be encoded primarily with features pertaining to its taste. This encoding variability is captured in the model by a parameter  $\alpha$ , the probability that any one feature is shared between two traces of the same item (independent of whether a *value* is stored for that feature). Likewise, the parameter  $\gamma$  denotes the probability that a feature is shared between two traces of *different* items. The exact values of these parameters will depend on the kinds and varieties of items presented during study and test and are at least partially under the decision maker’s control.

A memory trace is formed whenever an item is encountered, e.g., on a study list<sup>1</sup>. Memory traces are formed by copying into long-term memory a short-term memory representation of the item. The short-term memory representation is built up over time. Context features are presumed to be already present in the representation, since they are persistent in the environment. Content features are gradually sampled from the test item and added to the short-term memory representation. Such features are sampled at random, with replacement, and are copied into the STM representation correctly with probability  $c$ , otherwise a random value (either “0” or “1”) is copied. Note that, because the sampling occurs with replacement, a new sampled value can replace one that was previously present in the STM representation, even if the new value was copied incorrectly. Finally, due to capacity limitations, we assume that at most  $N_c$  content features and  $N_x$  context features are available to enter into STM.

At study, the sampling process is terminated at stimulus offset after some specified time,  $T_s$ . We assume that the dynamics of the sampling process are governed by a homogeneous Poisson process, that is, the time between feature samples is exponentially distributed with rate  $\rho_s$ . Thus, the number of samples obtained at study (which may involve “overwriting” a previously sampled feature value) after  $T_s$  time

units is Poisson distributed:

$$\Pr(k \text{ samples}; \rho_s, T_s) = \frac{(\rho_s T_s)^k}{k!} \exp(-\rho_s T_s).$$

At that point, the STM representation of the study item, comprised of the current context features plus whatever content features were sampled from the item in the time available, is copied into a long-term memory trace. Again, any one feature may be incorrectly copied from the STM representation into LTM with probability  $c$ , otherwise a random value is stored. Thus, a memory trace consists of  $N_x$  context features, some of which may have been copied incorrectly, and  $N_c$  content features, some of which have (correctly or incorrectly) sampled values and others of which are “blank”, indicating that no value was sampled for that feature.

At test, the STM representation of the test item serves as a probe that is compared to the contents of memory. This comparison is made after each sampling event  $t$ , resulting in a familiarity value,  $\phi(t)$ . The change in  $\phi(t)$  from one sampling event to the next constitutes the evidence for making a recognition decision. We now turn to the details of how the comparison between the probe and memory is made and how  $\phi(t)$  is calculated.

## Computing Familiarity

To compute a familiarity value, after each sampling event, the STM representation of the test item is used as a probe and is compared, in parallel, to all traces in episodic memory. Each comparison results in a measure of the similarity between the probe and a given trace, denoted  $\lambda_i(t)$  (where  $i$  indexes the trace in memory). The similarity measure takes the form of a likelihood ratio: the likelihood that the probe and the trace encode the *same* item versus the likelihood that they encode *different* items.

**Likelihood Calculation** The evidence that goes into computing these likelihoods comes from the features that have been sampled thus far and added to the probe (by time  $t$ ) and from the features that had been stored in the trace at study. For any one feature, there are five possible outcomes of the comparison:

1. The probe and trace both have a value stored, and the value matches ( $M$ ).
2. The probe and trace both have a value stored, and the values do not match ( $N$ ).
3. The probe has a value stored, but the trace does not ( $P$ ).
4. The trace has a value stored, but the probe does not ( $T$ ).
5. Neither the trace nor the probe have a value stored.

Although the full model described in Cox and Shiffrin (2012) makes use of all these possible outcomes, for present purposes we are only concerned with the first two. This is because outcomes  $P$  and  $T$  are only indicative of a non-match if traces of the same item are more likely to share features than are traces of different items (i.e., if  $\alpha > \gamma$ ). In the simulations reported here, we deal only with items that are of the

<sup>1</sup>A memory trace would also be formed after each test trial. We do not attempt to model this here, but the formation of memory traces at test may be necessary to explain several phenomena in recognition memory (Criss, Malmberg, & Shiffrin, 2011).

same type (namely, nouns) and so we assume that the degree of encoding variability is uniform, i.e.,  $\alpha = \gamma$ .

Although the reader is referred to Cox and Shiffrin (2012) for the details of these derivations, the following are the conditional probabilities needed to compute a match:

$$\begin{aligned}\Pr(M|\text{Same}) &= c + (1 - c)\frac{1}{2} & \Pr(M|\text{Different}) &= \frac{1}{2} \\ \Pr(N|\text{Same}) &= (1 - c)\frac{1}{2} & \Pr(N|\text{Different}) &= \frac{1}{2}.\end{aligned}$$

Because features are sampled independently, these probabilities are multiplied together for as many feature comparisons result in a  $M$  or  $N$  outcome, as appropriate to obtain the likelihood under each hypothesis, *same* or *different*. Letting  $N_M$  and  $N_N$  denote the number of feature-value matches and mismatches, respectively, the likelihood ratio for a trace  $i$  can thus be written:

$$\begin{aligned}\lambda_i(t) &= \left[ \frac{\Pr(M|\text{Same})}{\Pr(M|\text{Different})} \right]^{N_M} \left[ \frac{\Pr(N|\text{Same})}{\Pr(N|\text{Different})} \right]^{N_N} \\ &= (1 + c)^{N_M} (1 - c)^{N_N}.\end{aligned}\quad (1)$$

**Familiarity Calculation** A likelihood ratio  $\lambda_i(t)$  is produced, in parallel, for all traces in memory. However, the vast majority of traces in memory will be an extremely poor match to the probe and produce very low likelihood ratios, either because these traces encode different items (differ in content features) or because they were encoded in vastly different situations (differ in context features). Thus, we assume that only some traces in memory are “active” at any one time. For a trace to be activated in response to a probe, it must produce a likelihood ratio greater than a threshold  $\theta$ . For simplicity, we fix  $\theta = 1^2$ . We denote the set of active traces, i.e., those for which  $\lambda_i(t) > \theta$  by  $A(t)$  (of size  $|A(t)|$ ). Only those traces in  $A(t)$  contribute to the familiarity value  $\phi(t)$ . Because traces that fail to match on either content (i.e., they encode the same item) or context (i.e., they were encoded under similar circumstances, e.g., in a memory study list) are extremely unlikely to pass threshold and entire  $A(t)$ , we only model storage of the  $N$  items from the study list plus  $K$  traces of the test item from different contexts.

Having computed a match value  $\lambda_i(t)$  for each trace in memory and selected the set of activated traces  $A(t)$ , the familiarity value,  $\phi(t)$ , is simply the average likelihood over all active traces, i.e.,

$$\phi(t) = \frac{1}{|A(t)|} \sum_{i \in A(t)} \lambda_i(t). \quad (2)$$

## Decision Mechanism

Our model assumes that recognition decisions are based not on the absolute value of familiarity, but rather on how this value changes over time. Because the likelihood ratio scale is

<sup>2</sup>The full model assumes that  $\theta$  depends on the ratio  $\frac{\alpha}{\gamma}$ , but these are assumed equal in the subsequent simulations and so play no role in the setting of the activation threshold.

highly skewed, we first take the logarithm  $\log \phi(t)$  (this transformation does not alter the underlying logic of the model); the evidence for recognition decisions is then  $\nabla \log \phi(t) = \log \phi(t) - \log \phi(t - 1)$ . Positive values of  $\nabla \log \phi(t)$  are considered evidence that the test item is “old” while negative values are treated as evidence that the item is “new” (i.e., has not been encountered in the current context).

In our original model, positive and negative changes in familiarity feed into two parallel, non-interacting accumulators,  $B^+(t)$  and  $B^-(t)$ . That is,

$$\begin{aligned}B^+(t) &= \sum_{\tau=0}^t \begin{cases} \nabla \log \phi(\tau) & \text{if } \nabla \log \phi(\tau) > 0 \\ 0 & \text{if } \nabla \log \phi(\tau) \leq 0 \end{cases} \\ B^-(t) &= \sum_{\tau=0}^t \begin{cases} \nabla \log \phi(\tau) & \text{if } \nabla \log \phi(\tau) < 0 \\ 0 & \text{if } \nabla \log \phi(\tau) \geq 0 \end{cases}.\end{aligned}$$

The final recognition decision is, then, a race between these two accumulators: the predicted response is given by whichever accumulator reaches its threshold first ( $\beta^+$  or  $\beta^-$  for  $B^+(t)$  and  $B^-(t)$ , respectively).

The predicted response time is related to the number of sampling events  $t$  needed for the first of the accumulators to reach its threshold. In our previous work, we assumed, as is common in many models that posit sequential independent feature samples from a test stimulus (e.g., Brockdorff & Lamberts, 2000; Mewhort & Johns, 2005), that the times between sampling events were exponentially distributed with a fixed, uniform rate  $\rho_t$  (which may be different than the sampling rate at study,  $\rho_s$ ). This has the consequence that the observed response time, given that  $t$  samples were needed for one of the accumulators to reach threshold, is drawn from a Gamma distribution (the convolution of  $t$  independent and identically distributed exponential distributions).

## Simulations

Although our previous work on a dynamic model for recognition memory included predictions for mean response times, a much stronger test of the model is to compare its predictions to empirically collected *distributions* of response times. Unfortunately, empirical RT distributions in recognition memory are still somewhat rare (despite the fact that one of the leading models of response time, the diffusion model of Ratcliff, 1978, was originally developed to account for RT distributions in recognition memory!). Thus, we once again express our gratitude to Chris Donkin and Andrew Heathcote for providing us with empirical RT distributions against which to compare the predictions of our model. This comparison affords special insight into two features of our model that had to be simply assumed in our earlier work: first is the distribution of times between samples at test. Second is the assumption of independence between the two accumulators.

In obtaining a correspondence between the model and data, we fixed most of the parameters involved at the values given in Table 1. Our primary goal in these simulations was not

Table 1: Summary of the fixed parameters of the model, along with their values used in the present simulations.

Parameter	Value	Description
$N_c$	30	Maximum number of content features.
$N_x$	30	Number of context features.
$c$	0.85	Probability of correct feature copy.
$K$	200	Number of history traces of a test item available to be activated.
$\theta$	1	Minimum likelihood needed to enter the set of active traces.
$\rho_s$	60	Feature sampling rate at study.

Figure 1: Observed group performance and RT quantiles (10%, 30%, 50%, 70%, 90%) are shown in black, with model predictions using the independent accumulator mechanism in blue.

to obtain the best quantitative fit possible, which could potentially require all model parameters to be freely varied. Rather, we wished to capture the qualitative features of the data whilst varying only a small number of parameters, thereby allowing a more direct interpretation of the model’s predictions.

## Sampling Dynamics

Heathcote and Donkin (2012) recently collected both accuracy and response times in a recognition memory paradigm. Participants studied lists of 25 words each. At the conclusion of each study list, participants were tested in a standard old/new recognition paradigm. The test lists were unbiased (i.e., composed of an equal number of studied and unstudied words). On half of the test lists, participants were instructed to try to be as accurate as possible without taking too long to make their response (“accuracy focus”), while on the other half, participants were instructed to be as fast as possible without sacrificing accuracy (“speed focus”). The resulting group mean accuracy and RT quantiles (along with model fits) are plotted in Figure 1.

To replicate this procedure in our model, we assumed that 25 items were studied for  $T_s = 1$  time unit, fixed the other model parameters at the values given in Table 1, and simu-

Table 2: Best-fitting parameter values for the independent accumulator mechanism, given the Heathcote and Donkin (2012) recognition data.

Parameter	Condition	Value
$\beta^+$	Accuracy	13
	Speed	6
$\beta^-$	Accuracy	-17
	Speed	-9.4
$\rho_t$	Accuracy	158 samples per second
	Speed	105 samples per second
$T_n$	Accuracy	297 ms
	Speed	266 ms

lated 1000 study/test lists. To fit the model to the observed RT distribution data, we wished to optimize four parameters, which we allowed to vary between the speed and accuracy focus conditions: The first two of these are the thresholds for the old and new accumulators,  $\beta^+$  and  $\beta^-$ , respectively. We assume that participants can adjust their decision criteria in response to instructions, with lower thresholds leading to faster but potentially more error-prone responses. Two additional variables were allowed to vary between condition: the sampling rate at test,  $\rho_t$ , and the amount of “non-decision time” per trial,  $T_n$ . Non-decision time is introduced to account for any processes that are not being explicitly modeled, e.g., the time required to initially attend to the test stimulus and the time required to actually execute the motor response. Just as we assume that participants are able to adjust their decision bounds, we assume that instructions can induce participants to devote more resources toward particular components of the recognition process. For example, speed instructions may lead to faster execution of the motor response—leading to reduced non-decision time—but the added time pressure may result in less efficient extraction of information from the test stimulus—and therefore a lower average sampling rate.

Indeed, this is the pattern found in the fitted parameters, shown in Table 2 (which achieved an adjusted  $R^2 = .98$  between predicted and observed RT quantiles). The thresholds are farther apart in the accuracy condition than in the speed condition, as one would expect. In addition, non-decision time is slightly lower in the speed condition, which may be attributed to a slight decrease in the time needed to execute the response resulting from practice in the blocks of speed trials. Most interesting, however, is that although response thresholds are lower—and responses correspondingly faster—in the speed focus condition, the sampling rate is estimated to be substantially lower in the speed condition<sup>3</sup>. In other words, although participants appear willing to make responses on the basis of less evidence when encouraged to produce fast responses, participants appear to be collect this evidence less efficiently. One possible explanation for this is, to paraphrase Starns, Ratcliff, and McKoon (2012), that the additional metacognitive demands in the speed condition (e.g., the need to monitor response time and avoid pure guessing)

<sup>3</sup>In addition, both estimated sampling rates at study are faster than the sampling rate assumed at study, which was fixed at 60 samples per second.

Figure 2: Collapsing thresholds (dashed lines) relative to the mean familiarity value for targets (blue line) and foils (red line). Light regions around the mean familiarity show the area between the 2.5% and 97.5% quantiles of the familiarity distribution at each time.

divert resources from processing the test stimulus itself.

### Correlated Accumulators

Another feature of our model that was previously untested is the assumption of independence between the positive and negative accumulators. This independence places our model in a different class than random walk or diffusion models (e.g., Ratcliff, 1978), which assume that evidence in favor of one option (e.g., “old”) is equivalent evidence *against* the other option (e.g., “new”). A random walk model may thus be seen as a model with two perfectly anti-correlated accumulators.

The primary reason for choosing an independent accumulator structure in our original work was the nature of the evidence on which we presume recognition decisions are based. In particular, because there is a maximum number of features that may be sampled, there is also a maximum (and minimum) value of familiarity that could result from a test item. Consider the case where, by a lucky happenstance, all the features sampled and added to the probe at time  $t$  perfectly match a single trace stored in memory. Further assume that this single trace is the only activated trace. Then, from equations 1 and 2,  $\phi(t) = (1 + c)^{N_c + N_x}$ . Because  $N_c$  and  $N_x$  are fixed, this is the maximum possible familiarity value. Clearly, any subsequent feature samples can only lead to a zero or negative change. Thus, if the threshold on the positive counter has not yet been reached, and the positive and negative counters are anti-correlated, the “old” threshold will never be attained because no further positive changes are possible.

Thus, if the accumulators are to be perfectly anticorrelated, as in a random walk, their thresholds cannot be fixed across time. This is not merely a feature of this particular model, but any model that places a limit on the amount of evidence that may be accrued over time. Thus, we introduce a rule by which the accumulator thresholds may collapse over time (for examples of collapsing thresholds in other domains, see Balakrishnan & Macdonald, 2011; Frazier & Yu, 2008). This rule is but one of many possible rules, but is based on the principle that the thresholds should be reduced in proportion to the amount of information that remains to be

Figure 3: Observed group performance and RT quantiles (10%, 30%, 50%, 70%, 90%) are shown in black, with model predictions—using the correlated accumulators with collapsing thresholds—in blue.

sampled from the stimulus. On any feature sampling event, each of the  $N_c$  content features has an equal chance of being sampled. Thus, the probability that any one feature has *not* been sampled after  $t$  sampling events is  $\left(1 - \frac{1}{N_c}\right)^t$ . Imagine that the decision maker has a number of features  $N_{max}$  that they consider sufficient for making a recognition decision (Diller, Nobel, & Shiffrin, 2001). Then, the probability that  $N_{max}$  features have been sampled after  $t$  sampling events is  $\sigma(t) = \left[1 - \left(1 - \frac{1}{N_c}\right)^t\right]^{N_{max}}$ . Thus, given initial thresholds  $\beta^+(0)$  and  $\beta^-(0)$ , the thresholds collapse toward one another in a symmetric fashion:

$$\beta^+(t) = \beta^+(0) - \sigma(t) \left( \frac{\beta^+(0) - \beta^-(0)}{2} \right) \quad (3)$$

$$\beta^-(t) = \beta^-(0) + \sigma(t) \left( \frac{\beta^+(0) - \beta^-(0)}{2} \right). \quad (4)$$

Different choices of  $N_{max}$  can lead to very different threshold behavior, however both our own investigations (not reported here for space) and the empirical work of Balakrishnan and Macdonald (2011) suggest that thresholds begin rather far apart and thereafter converge relatively quickly. Such behavior is consistent with low values of  $N_{max}$ ; in the absence of explicit evidence otherwise, we choose here  $N_{max} = 1$ . The resulting behavior of the thresholds relative to the mean familiarity value for targets and foils is shown in Figure 2.

Using this new decision rule, we again fit the model to Heathcote’s data, the only difference being that now the *initial* threshold value, rather than a constant threshold, for each accumulator was varied. The resulting best-fitting parameter values are shown in Table 3, with model fits in Figure 3 (adjusted  $R^2 = 0.89$  between predicted and observed RT quantiles). It is apparent that this new mechanism, more akin to

Table 3: Best-fitting parameter values for the correlated accumulator mechanism.

Parameter	Condition	Value
$\beta^+(0)$	Accuracy	8.6
	Speed	3.2
$\beta^-(0)$	Accuracy	-16
	Speed	-9
$\rho_t$	Accuracy	99 samples per second
	Speed	138 samples per second
$T_n$	Accuracy	357 ms
	Speed	367 ms

that of a random walk model, while capable of fitting accuracy just as well as the independent accumulator model does not fit RT quantile data as well, at least when assuming that the time between samples in exponentially distributed. As with the independent accumulator model, initial thresholds are have lower absolute value under speed focus relative to accuracy focus. However, in this case, non-decision time is estimated to be roughly equal between the two conditions, with increased sampling rate in the speed focus condition, as might be expected if speed instructions encouraged greater attention to the stimulus. Although the degree of fit is poorer when using correlated accumulators, the fit is certainly not too bad, not enough to rule out this mechanism as a plausible one for recognition decisions.

## Discussion

Our original work on a dynamic model for recognition memory (Cox & Shiffrin, 2012) represents one of the few attempts to link a full-fledged model of memory (in this case, an extension of the REM model; Shiffrin & Steyvers, 1997) to a decision mechanism capable of predicting both accuracy and response time. By comparing the model's predictions against entire RT distributions, we have been able to show that while the original assumptions of the model are viable, there are other possible routes to explore. These include the effect of task instruction (speed vs. accuracy focus) on sampling dynamics at test as well as a correlated counter mechanism, although a more thorough investigation of these mechanisms and the meaning of their parameters is in order.

Our model is admittedly complex, however, and incorporates many sources of variability. A correlated accumulator mechanism could produce superior predictions given different parameters for the underlying memory process. Indeed, our ongoing work in fitting our own data and data from (Starns et al., 2012) strongly suggests correlation between accumulators, even if the current data of Heathcote and Donkin (2012) do not require them. Just as task demands may influence sampling dynamics, they may also lead to different ways of balancing evidence in favor of "old" and "new" responses. Further, the dynamics of the sampling process may themselves be non-stationary, with the sampling rate changing over time (Hockley & Murdock, 1987) or different features being detected at different rates (Brockdorff & Lamberts, 2000). Finally, although the current paper is primarily

exploratory, we expect that additional models of the recognition process will be developed. As part of this venture, more attention must be paid to the flexibility of such models, and we believe that exercises such as those in this paper can help illuminate the space of possible mechanisms available to modelers of recognition memory. The complexity of the models presented here is balanced by the range of data they may be expected to explain, and the present work represents just one of many forays that will be necessary to develop a general theory of recognition memory.

## Abstract

Two studies are presented that explore the interpersonal effect of emotion displays in decision making in a social dilemma. Experiment 1 ( $N=405$ ) showed that facial displays of emotion (joy, sadness, anger and guilt) had an effect on perception of how the person was appraising the social dilemma outcomes (perception of appraisals) and on perception of how likely the person was to cooperate in the future (perception of cooperation). Experiment 1 also showed that perception of appraisals (partially and, in some cases, fully) mediated the effect of emotion displays on perception of cooperation. Experiment 2 ( $N=202$ ) showed that manipulating perception of appraisals, by expressing them textually, produced an effect on perception of cooperation thus, providing evidence for a causal model where emotion displays cause perception of appraisals which, in turn, cause perception of cooperation. In line with Hareli and Hess' (2010) findings and a social-functions view of emotion, we advance the reverse appraisal proposal that argues people can infer, from emotion displays, how others are appraising a situation which, in turn, support inferences that are relevant for decision making. We discuss implications of these results and proposal to decision and emotion theory.

**Keywords:** Emotion Displays, Decision Making, Social Dilemma, Appraisal Theories, Reverse Appraisal

## Introduction

Recent decades have seen growing interest on the interpersonal effect of emotion in decision making (e.g., Van Kleef, De Dreu, & Manstead, 2010). Complementing research on the impact of emotion in one's own decision making (for a recent review see Blanchette & Richards, 2010), this research explores how one's emotion displays impact another's decision making and emphasizes that emotional expressions are not simple manifestations of internal experience; rather, expressions are other-directed and communicate intentions, desired courses of actions, expectations and behaviors (Frijda & Mesquita, 1994; Keltner & Kring, 1998). The expression of emotion has also been argued to play a significant role in emergence of cooperation in social dilemmas (Boone & Buck, 2003; Frank, 1988). Social dilemmas, such as the prisoner's dilemma, are situations where people must choose between pursuing their own self-interest and collect a short-term reward or trust another person to reach mutual cooperation

and maximize joint long-term reward (Kollock, 1998). Empirical evidence confirms that facial displays of emotion can impact cooperation (e.g., de Melo, Carnevale, & Gratch, 2012; Schug, Matsumoto, Horita, Yamagishi, & Bonnet, 2010). However, the mechanism by which such social effects of emotion are achieved is less well understood.

In this paper we address this issue and look at appraisal theories of emotion to understand what is the information people retrieve from emotion displays and how is that accomplished. In appraisal theories, emotion displays arise from cognitive appraisal of events with respect to an agent's goals, desires and beliefs (e.g., is this event congruent with my goals? Who is responsible for this event?). According to the pattern of appraisals that occurs, different emotions are experienced and displayed. Since displays reflect the agent's intentions through the appraisal process, it is also plausible to ask whether people can infer from emotion displays the agent's goals by reversing the appraisal mechanism. We refer to this proposal as *reverse appraisal*. The intuition is that if appraisal, abstractly, is a function that maps from <event, mental state> to emotion, reverse appraisal is a function that maps from <event, emotion> to mental state. Empirical evidence is still scarce but in a recent study Hareli and Hess (2010) showed that people could, from expressed emotion, make inferences about the character of the person displaying emotion. For instance, a person who reacted with anger to blame was perceived as being more aggressive, self-confident but also as less warm and gentle than a person who reacted with sadness. Moreover, the results showed that such inferences were mediated by appraisal variables. In our case, reverse appraisal predicts that people infer, from emotion displays, how the counterpart is appraising the social dilemma outcomes; then, from these *perceptions of appraisal*, people infer how likely the counterpart is to cooperate in the future, which we refer to as *perceptions of cooperativeness*. This causal model is shown in Figure 1. The goal of the paper is to establish this causal model.

Figure 1: Causal model for the effect of emotion displays in cooperation in a social dilemma.

In a previous study (de Melo, Carnevale, & Gratch, 2011) we began gathering evidence for this causal model. Participants played the iterated prisoner’s dilemma with two computer players, or *agents*, that, even though following the same strategy to choose their actions, showed emotion displays that reflected different social value orientations (e.g., cooperative or competitive). Computer agents that show emotion have been argued in the past to be a useful research tool for basic human-human interaction research (Blascovich et al., 2001). In our case, following the intuition from appraisal theories that what matters is not the emotion display in itself but the appraisals that elicited it, the agents differed only in the context in which joy was expressed. For instance, a cooperative agent showed a smile in mutual cooperation, whereas a competitive agent showed a smile when the agent exploited the participant. As predicted by appraisal theories, the results showed that people interpreted the same smile differently and cooperated more with the cooperative than the competitive agent. In the present paper we go further and study whether the information people retrieve from emotion displays pertains to how the counterpart is appraising the interaction and, if such perceptions of appraisals lead to inferences about the counterpart’s likelihood of cooperation. To accomplish this, in a first experiment we asked participants to imagine playing the prisoner’s dilemma with different agents; participants were always told the same outcome occurred but were shown videos of different emotional reactions from the counterpart and were, then, queried about how they thought the counterpart was appraising the situation and how likely it was to cooperate in the future. We hypothesized that: following previous findings, emotion displays would impact perceptions of the counterpart’s cooperativeness (H1); and, according to reverse appraisal, emotion displays would impact perceptions of the counterpart’s appraisals (H2). A statistical analysis of mediation (Preacher & Hayes, 2008) was also conducted to test whether appraisal variables (conduciveness to goals or blameworthiness) mediated the effect of emotion displays on people’s perception of the counterpart’s cooperativeness. The hypothesis was that appraisal variables would mediate, at least partially, the interpersonal effect of emotion (H3). To further test the mediating role of appraisals, a second experiment explicitly manipulated appraisals and measured the effect on people’s perception of how cooperative the counterpart was. The manipulation consisted of having the agents, instead of showing facial displays of emotion, express how they were appraising the outcome through text (e.g., “I really don’t like this outcome and I blame you for it”). The hypothesis was that, in line with reverse appraisal, expression of appraisals would lead to effects on perception of the counterpart’s cooperativeness that were consistent with findings in the previous experiment (H4). This experiment, thus, establishes the remaining link (ii, Figure 1) in the proposed causal model. Therefore, Experiments 1 and 2, together, provide experimental evidence for the proposed model (Spencer, Zanna, & Fong, 2005).

## Experiment 1

### Method

**Scenarios.** Participants imagined playing the iterated prisoner’s dilemma with agents that displayed emotion. Each scenario pertained to the first round (of a 5-round game) and corresponded to a particular outcome of the game. Participants were then shown a video of the agent reacting emotionally to the outcome. Following the approach by Kiesler, Waters and Sproull (1996), and similarly to our previous study (de Melo et al., 2011) the game was recast as an investment game.

**Design.** The experiment followed a mixed design with two factors: Outcome (between-participants) with 4 levels (one for each possible outcome of the game); and, Emotion (repeated-measures) with 5 levels (Neutral vs. Joy vs. Anger vs. Sadness vs. Guilt). Building on experience from previous studies, we only explored 4 emotions and did not consider, for the time being, a full factorial design but, rather, only pairings of outcome and emotion that produced effects in those studies, as shown in Table 1. Considering only this subset of the possible pairings had, at least, two advantages: (1) each participant experienced at most 3 pairings (as opposed to 5 if all were considered), which constrained total participation time and, thus, reduced fatigue and boredom effects; (2) pairings that did not have a clear intuitive interpretation (e.g., displaying sadness or anger in mutual cooperation) were excluded from analysis.

Table 1: Emotions explored in Experiment 1.

		<i>Agent</i>	
		Cooperation	Defection
<i>Participant</i>	Cooperation	Neutral, Joy	Neutral, Joy, Guilt
	Defection	Neutral, Anger, Sadness	Neutral, Joy, Anger

**Emotion displays.** In this experiment, participants watched videos of agents expressing facial emotion displays. Three agents were used—Ethan, William and David—and the respective facial displays are shown in Figure 2. These facial displays were validated elsewhere (de Melo et al., 2012). The agents were referred to by their names throughout. Each participant saw a different agent in each condition, and they were randomly assigned to conditions.

Figure 2: The emotion facial displays used in Experiment 1.

**Measures.** After watching the video of the agent's emotional reaction, we asked participants the following questions (the questions referred to the agents by their respective names): How much did the agent experience each of the following emotions: a) Joy b) Sadness c) Anger d) Guilt? (scale goes from 1, *not at all*, to 7, *very much*).

Even though several appraisal theories have been proposed (Ellsworth & Scherer, 2003), there tends to be agreement on which appraisals predict the emotions we consider in this experiment: joy occurs when the event is conducive to one's goals; sadness occurs when the event is not conducive to one's goals; anger occurs when the event is not conducive to one's goals and is caused by another agent; guilt occurs when the event is not conducive to one's goals and is caused by the self. Thus, two appraisal variables are of relevance here: (a) *conduciveness to goals*, which measures whether the event is consistent or inconsistent with the individual's goals; and, (b) *blameworthiness*, which measures whether the self or another agent is responsible for the event. After watching the video of the agent's emotional reaction, participants were asked the following questions about how was the agent appraising the outcome (Ellsworth & Scherer, 2003):

1. How pleasant for him was it to be in this situation?
2. At the time of experiencing the emotion, do you think he perceived that the consequences of the event did or would bring about positive, desirable consequences for him (e.g., helping him reach a goal, or giving pleasure)?
3. Was the situation obstructive or conducive to his goals?
4. Was what happened something that he regarded as fair?
5. How much did you think he blamed himself for the event?
6. How much did you think he blamed you for the event?

Following the appraisal perception questions, we asked the participant one question about perception of the agent's cooperativeness (scale goes from 1, *not at all*, to 7, *very much*): How likely is he to *cooperate* in the next round? (where "cooperate" was replaced by the respective action in the investment game).

**Participants.** We recruited four-hundred and five ( $N=405$ ) participants online using Amazon Mechanical Turk. This resulted in approximately 100 participants for each outcome. Gender distribution was as follows: *males*, 47.4%; *females*, 52.6%. Age distribution was as follows: *18 to 21 years*, 14.1%; *22 to 34 years*, 59.5%; *35 to 44 years*, 13.6%; *45 to 54 years*, 7.9%; *55 to 64 years*, 4.2%; *65 years and over*, 3.0%. Most participants were from the United States (57.8%) and India (29.6%). The education level distribution was as follows (current or expected degrees): *high school*, 15.8%; *college*, 57.5%; *Masters*, 23.0%; *Ph.D. or above*, 3.7%. Education majors and profession were quite diverse. Participants were paid USD \$1.02 and average participation time was 23 minutes.

## Results

**Effects on perception of cooperativeness.** For each outcome, we conducted a repeated-measures ANOVA to analyze the effect of emotion display on perception of cooperativeness. The means, standard deviations, significance levels and effect sizes are shown in Table 2. In the table, "Participant exploits" corresponds to the outcome where the agent cooperated but the participant defected. "Agent exploits" corresponds to the outcome where the participant cooperated but the agent defected.

Table 2: Effects on perception of cooperativeness.

<i>Mutual cooperation (n=103)</i>		<i>Participant exploits (n=101)</i>	
Neutral	3.18 (1.613)	Neutral	3.67 (1.715)
Joy	4.70 (1.739)	Anger	2.81 (2.077)
-	-	Sadness	2.99 (1.841)
Sig. (r)	.000* (.542)	Sig. (partial $\eta^2$ )	.000* (.078)
<i>Agent exploits (n=98)</i>		<i>Mutual defection (n=103)</i>	
Neutral	3.11 (1.716)	Neutral	3.55 (1.856)
Joy	2.37 (1.755)	Joy	3.47 (1.835)
Guilt	4.56 (2.081)	Anger	3.53 (2.100)
Sig. (partial $\eta^2$ )	.000* (.286)	Sig. (partial $\eta^2$ )	.920 (.001)

\*  $p < .05$ .

**Effects on perception of appraisals.** Questions 1 to 4 were highly correlated ( $\alpha = .850$ ) and, thus, were collapsed (averaged) into a single measure called *conduciveness to goals*. For each outcome, we conducted a repeated-measures ANOVA to analyze the effect of emotion display on conduciveness to goals, self-blameworthiness (question 5) and participant-blameworthiness (question 6). Means, standard deviations, significance levels and effect sizes are reported in Table 3.

Table 3: Effects on perception of appraisal.

	Conduciveness to Goals	Self-Blame	Participant-Blame
<i>Mutual cooperation (n=103)</i>			
Neutral	3.68 (0.896)	2.97 (1.620)	3.23 (1.746)
Joy	5.51 (0.852)	2.64 (1.652)	2.57 (1.551)
Sig. (r)	.000* (.853)	.067 (.181)	.000* (.362)
<i>Agent exploits (n=98)</i>			
Neutral	4.19 (1.089)	2.80 (1.699)	2.88 (1.633)
Joy	5.92 (0.823)	3.05 (2.078)	2.83 (1.759)
Guilt	3.23 (1.179)	4.39 (1.672)	2.84 (1.558)
Sig. (partial $\eta^2$ )	.000* (.671)	.000* (.224)	.950 (.000)
<i>Participant exploits (n=101)</i>			
Neutral	3.56 (1.038)	2.85 (1.676)	2.79 (1.768)
Anger	2.19 (0.868)	3.49 (1.659)	5.20 (1.588)
Sadness	2.40 (0.901)	4.56 (1.590)	3.92 (1.730)
Sig. (partial $\eta^2$ )	.000* (.545)	.000* (.248)	.000* (.466)
<i>Mutual defection (n=103)</i>			
Neutral	3.72 (0.757)	2.92 (1.453)	3.12 (1.635)
Joy	5.32 (0.856)	2.29 (1.493)	2.39 (1.523)
Anger	2.69 (0.856)	3.36 (1.726)	5.02 (1.621)
Sig. (partial $\eta^2$ )	.000* (.733)	.000* (.119)	.000* (.477)

\*  $p < .05$ .

**Mediation analysis.** In this subsection we present a causal steps approach multiple mediation analysis (Preacher & Hayes, 2008) of perceptions of appraisal on the effect of emotion displays on perception of cooperativeness. This method is an extension to multiple mediators of the single-mediation analysis proposed by Baron and Kenny (1986). Figure 3 summarizes the mediation model. The independent variables (IVs) were the classification questions for perception of joy, anger, sadness and guilt. The dependent variable (DV) was perception of cooperativeness. The proposed mediators were the perception of appraisal variables: conduciveness to goals, self-blame and participant-blame. According to this approach, there is

Table 4: Mediation analysis of perceptions of appraisals on the effect of emotions on perception of cooperativeness.

		IV → Mediators (a paths)			Mediators → DV (b paths)			Total Effect (c path)	Direct Effect (c' path)	Indirect Effect (ab paths)			
		Cn	SB	PB	Cn	SB	PB			Tot	Cn	SB	PB
mutual coop	Joy	.457* (.000)	-.015 (.793)	-.125 (.037)	.305* (.026)	-.023 (.820)	-.124 (.221)	.372* (.000)	.217* (.011)	.155* (.011)	.139* (.025)	.000 (.862)	.016 (.285)
	Anger	.501* (.000)	-.140* (.002)	-.360* (.000)	.234 (.067)	.254* (.001)	-.070 (.332)	-.023 (.675)	-.129 (.103)	.107 (.076)	.117 (.066)	-.036* (.020)	.0251 (.332)
mutual defect	Joy	-.411* (.000)	.235* (.000)	.624* (.000)	.153 (.122)	.261* (.001)	-.131 (.099)	.049 (.395)	.131 (.089)	-.083 (.127)	-.063 (.122)	.061* (.004)	-.081 (.098)
	Anger	.496* (.000)	-.149* (.003)	.065 (.132)	-.597* (.000)	.204* (.000)	-.152* (.023)	-.336* (.000)	-.001 (.993)	-.336* (.000)	-.296* (.000)	-.030* (.021)	-.010 (.206)
agent exploits	Joy	-.480* (.000)	.469* (.000)	-.033 (.548)	-.467* (.000)	.127* (.038)	-.127 (.055)	.521* (.000)	.232* (.003)	.288* (.000)	.224* (.000)	.060* (.043)	.004 (.565)
	Guilt	-.136* (.000)	.393* (.000)	.153* (.004)	.576* (.000)	.014 (.842)	.075 (.226)	*.076 (.143)	-.015 (.798)	-.061 (.060)	-.078* (.001)	.005 (.841)	.012 (.260)
human exploits	Sad	-.196* (.000)	.034 (.500)	.543* (.000)	.568* (.000)	-.002 (.977)	.109 (.127)	-.112* (.038)	-.060 (.350)	-.052 (.198)	-.111* (.000)	-.000 (.977)	.059 (.127)
	Anger												

Note. Cn = Conduciveness to goals; SB = Self-Blame; PB = Participant-Blame; CP = Coping Potential.

Values correspond to unstandardized regression coefficients (*p* values in parentheses).

\* *p* < .05.

mediation by a specific mediator  $M_x$  if: (1) the path,  $a_x$ , from the IV to the mediator is significant; (2) the path,  $b_x$ , from the mediator to the DV, when controlling for the IV, is significant; (3) the indirect effect,  $a_x b_x$ , from the IV to the DV, when controlling for the mediator, is significantly different than zero and greater than zero by a non-trivial amount. Moreover, there is mediation of the *set* of mediators when the sum of the indirect effects of all mediators is significantly different than zero. Furthermore, there is full mediation when the direct effect,  $c'$ , of the IV on the DV, when controlling for all the mediators, is non-significant. Table 4 shows the analysis: the shaded cells on the *a*, *b* and *ab* path columns represent that the causal-step requirement on the respective path has been passed.

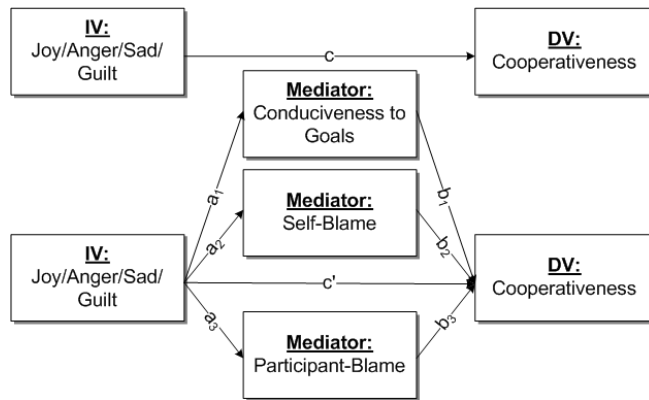

Figure 3: The multiple mediation model.

## Discussion

The results in Table 2 show that emotion displays impacted perception of the counterpart's cooperativeness: in mutual cooperation, participants perceived the happy agent to be more likely to cooperate than a neutral agent; when the participant exploited, participants perceived the angry or sad

agents to be less likely to cooperate than the neutral agent; finally, when the agent exploited, participants perceived the guilty agent to be more likely to cooperate than the neutral agent which, in turn, was more likely to cooperate than the happy agent. Notice these effects are compatible with findings in the literature (e.g., Van Kleef et al., 2010). Hypothesis H1 was, thus, confirmed. The results in Table 3 show that emotion displays impacted perception of appraisals in a way that was consistent with appraisal theories (Ellsworth & Scherer, 2003). For instance, happy agents were perceived to find the outcome conducive to their goals; sad or guilty agents were perceived to blame themselves for the (negative) outcome; and, angry agents were perceived to blame the participant for the (negative) outcome. Therefore, hypothesis H2 was also confirmed. Finally, the results in Table 4, show that appraisal variables, partially and sometimes fully, mediated the effect of emotion displays on perception of cooperativeness. For instance, in mutual cooperation, conduciveness to goals partially mediated the effect of joy; and, when the agent exploited, conduciveness to goals and self-blame fully mediated the effect of joy and partially mediated the effect of guilt. Hypothesis H3 was, thus, confirmed.

## Experiment 2

Spencer et al. (2005) argue that showing mediation statistically, as proposed by Baron and Kenny (1986), is no substitute to showing mediation experimentally. As an alternative to the statistical approach, they propose the experimental-causal-chain design, where each link of the proposed causal model is shown experimentally. Applying the experimental-causal-chain approach to our case means showing, experimentally, each of the causal links in the proposed causal model (Figure 1). The effect of emotion displays on perception of appraisals (causal link i) was already shown, experimentally, in the previous experiment.

In turn, the goal of Experiment 2 was to show experimentally the effect of perception of appraisals on perceptions of cooperativeness (causal link ii).

## Method

Experiment 2 used the same design and scenarios as Experiment 1. However, the manipulation consisted, instead of emotion displays, of textual expression of the appraisals. The mapping of emotion to appraisals followed predictions from appraisal theories (Ellsworth & Scherer, 2003) and is shown in Table 5. Participants were still introduced to the agents they imagined playing with, however, only a static image was shown of the (neutral) face. The textual expression of appraisals was simulated by typing at the bottom of the screen, as if simulating a chat interface.

Table 5: Mapping of emotions to expression of appraisals.

Emotion	Appraisal Expression
Neutral	I neither like, nor dislike this outcome
Joy	I like this outcome
Anger	I do NOT like this outcome and I blame YOU for it
Sadness	I do NOT like this outcome
Guilt	I do NOT like this outcome and I blame MYSELF for it

Regarding measures, after watching the video of the agent's reaction, we asked participants the same question about perception of cooperativeness as in Experiment 1.

We recruited two-hundred and two ( $N=202$ ) participants online using Amazon Mechanical Turk. This resulted in approximately 50 participants for each outcome. Gender distribution was as follows: *males*, 51.0%; *females*, 49.0%. Age distribution was as follows: *18 to 21 years*, 10.4%; *22 to 34 years*, 56.4%; *35 to 44 years*, 12.9%; *45 to 54 years*, 12.4%; *55 to 64 years*, 5.9%; *65 years and over*, 2.0%. Most participants were from the United States (66.3%) and India (22.8%). The education level distribution was as follows (current or expected degrees): *high school*, 15.3%; *college*, 62.9%; *Masters*, 18.3%; *Ph.D. or above*, 3.5%. Education majors and profession were quite diverse. Participants were paid USD \$1.02 and average participation time was 25 minutes.

## Results

For each outcome, we conducted a repeated-measures ANOVA to analyze the effect of emotion display on perception of cooperativeness. The means, standard deviations, significance levels and effect sizes are shown in Table 6. If we collapse the data from the two experiments, it becomes possible to analyze whether there was any interaction between Sample (Experiment 1 vs. Experiment 2) and Emotion (Neutral vs. Joy vs. Anger vs. Sadness vs. Guilt). Because the argument is that appraisals are part of the information retrieved from emotion displays, we expected there to be no interactions. Table 6 also shows these interactions.

## Discussion

The results in Table 6 show that expression of appraisals impacted perceptions of cooperativeness: in mutual cooperation, participants perceived the happy agent to be more likely to cooperate than a neutral agent; when the participant exploited, participants perceived the angry or sad agents to be less likely to cooperate than the neutral agent; finally, when the agent exploited, participants perceived the

guilty agent to be more likely to cooperate than the neutral agent which, in turn, was more likely to cooperate than the happy agent. Notice these are the same patterns as in Experiment 1 and, thus, our hypothesis H4 was confirmed. Finally, notice the Sample x Emotion interaction was not significant for any of the outcomes.

Table 6: Effects on perception of cooperativeness.

<i>Mutual cooperation (n=52)</i>		<i>Participant exploits (n=48)</i>	
Neutral	3.27 (1.693)	Neutral	3.65 (1.839)

## General Discussion

This paper presents insight into the mechanism for the social effects of emotion in a social dilemma. Two experiments were described that suggest a causal model (Figure 1) where emotion displays lead the receiver to infer how the sender is appraising the ongoing interaction and, these perceptions of appraisal, in turn, lead to inferences about the sender's propensity for cooperation in the dilemma. The experiments support this model by establishing experimentally both links in the model (Spencer et al., 2005) and by providing statistical evidence that perceptions of appraisal mediate the effect of emotion displays on perceptions of cooperativeness (Preacher & Hayes, 2008). We refer to the mechanism suggested by this causal model as reverse appraisal.

**Implications for emotion theory.** The results presented in the paper provide further evidence that emotions serve important social functions (Frijda & Mesquita, 1994; Keltner & Kring, 1998). For instance, whereas anger signaled a willingness to punish a non-cooperator with non-cooperation, guilt signaled regret for one's non-cooperation and a willingness to cooperate in the future. The paper further proposes that reverse appraisal is a useful framework for the social functions of emotion. Reverse appraisal suggests that an important component of the information retrieved from emotion displays refers to how the counterpart is appraising the ongoing interaction. This information is then used to infer the counterpart's mental states, such as his or her propensity for cooperation in a social dilemma. Finally, reverse appraisal can potentially generalize beyond social dilemmas and be viewed as a general mechanism for interpretation of emotion displays. This is, in fact, a promising line of future inquiry.

**Implications for decision-theory.** Van Kleef et al. (2010) argue emotion displays can influence people's decision

making through affective processes (e.g., emotional contagion) or inferential processes. Regarding the latter, Van Kleef et al. suggest that “each discrete emotion has its own antecedents, appraisal components, relational themes, and action tendencies” (p.48) and, thus, “observing a particular emotion in another person provides relatively differentiated information about how that person regards the situation” (p.53). This paper provides empirical evidence for such “differentiated information” in emotion displays which, as suggested by the results, pertains to perceptions of appraisal. Our results also reinforce findings regarding the importance of context for the interpretation of emotion (de Melo et al., 2011; Hareli & Hess, 2010; Van Kleef et al., 2010). For instance, the results showed that people reacted differently to the same smile when it was shown after mutual cooperation or after the agent exploited them. Finally, the results support Schug et al.’s (2010) contention that people are capable of identifying non-cooperators from emotion displays and punish accordingly.

**Limitations and future work.** Since the results from our experiments were promising, we plan in the near future to repeat both experiments with the complete factorial design. Such design will clarify the effect of emotion in pairings that were left unexplored (e.g., expression of anger in mutual cooperation). Moreover, complementing this paper’s focus of comparing the effect of emotion within the same outcome, the factorial design will allow us to study the effect of emotion *across* outcomes. Another limitation we intend do address is that the current causal model does not predict what will people decide after making inferences about the counterpart’s likelihood of cooperation. Notice the link between perceptions of cooperation and the decision to cooperate is not simple. For instance, whereas a pro-social might cooperate, a pro-self might exploit the cooperator (Steinel & de Dreu, 2004). Finally, to understand how reverse appraisal generalizes beyond the prisoner’s dilemma, it is important to assess whether perceptions of appraisal also mediate the effects of emotion displays in more social decision making tasks such as other social dilemmas (e.g., public goods), trust games and negotiation.

# Neural correlates of social perception: The posterior superior temporal sulcus is modulated by action rationality, but not animacy

Ben Deen (bdeen@mit.edu) and Rebecca R. Saxe (saxe@mit.edu)

Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology

## Abstract

Recent research has investigated the neural basis of social perception, the ability to make high-level social inferences from perceptual information. The right posterior superior temporal sulcus (pSTS) has been identified as a candidate region for this ability, but the specific processes to which the pSTS contributes remain unclear. In the present study, we investigated the neural correlates of social perception using simple animated geometric shape stimuli, separately manipulating the perceived animacy, goal-directedness, and path rationality in the animations. We did not find an increased pSTS response to animate or goal-directed animations. However, we found that across conditions, the pSTS response tracked path rationality, with stronger responses to irrational paths. This is consistent with prior neuroimaging research on the perception of human actions, and supports the claim that the pSTS is involved in action understanding.

**Keywords:** social perception, fMRI, superior temporal sulcus

## Introduction

Humans have a remarkable ability to infer the dispositions and intentions of other agents from perceptual information, and specifically from motion patterns such as hand and body motion, gaze shifts, and facial motion. This ability, termed social perception, comprises a number of subprocesses: the detection of agents in an environment, perceptual analysis of their motion, inference about social properties from the agent's actions and their context, and prediction of future actions based on these properties.

Recent research has begun to probe the neural basis of these processes, although the relevant brain regions and their specific functional role is still debated. One line of research has pointed to the right posterior superior temporal sulcus (pSTS) as a critical region for social perception (Allison, Puce, & McCarthy, 2000). This region responds more strongly to (human) biological motion than motion of inanimate objects (e.g. Grossman et al., 2000; Pelphrey et al., 2003). These responses might relate to the detection or perceptual analysis of biological motion, to higher-level processing of the intentions underlying the actions, or to some combination thereof.

Another set of studies indicates that the pSTS response to human actions is modulated by inferred intentions. Specifically, actions that violate inferred intentions in a given context, such as twisting empty space next to a gear rather than a gear itself, elicit a stronger pSTS response than the expected actions, across a range of contexts and specific actions (Brass, Schmitt, Spengler, & Gergely, 2007;

Pelphrey, Morris, & McCarthy, 2004; Pelphrey, Singerman, Allison, & McCarthy, 2003; Saxe, Xiao, Kovacs, Perrett, & Kanwisher, 2004; Vander Wyk, Hudac, Carter, Sobel, & Pelphrey, 2009). Such actions have been referred to as incongruent, irrational, or unexpected.

This effect has been interpreted as evidence that the pSTS is sensitive to the goals or intentions underlying human motion. For instance, Pelphrey et al. (2004) argued that the pSTS is involved in predicting actions in a given context based on an "intentional stance," in which actions are determined by a goal state and an assumption that the agent will choose the most efficient means to achieve the goal given situational constraints. They proposed that when this prediction is violated, the pSTS must engage in extra processing to explain the observed action in other terms, which would explain its stronger response to unexpected actions.

Another line of research supporting the role of pSTS in action understanding as employed animations of simple geometric shapes as stimuli (Castelli, Happé, Frith, & Frith, 2003; Gobbini, Koralek, Bryan, Montgomery, & Haxby, 2007). These studies have found a stronger pSTS response to animations depicting social interactions between animate shapes, compared with animations of shapes moving as inanimate physical objects. This demonstrates that the role of the pSTS extends to animations that lack the form and motion kinematics of humans, but imply intentional action. However, such comparisons have been largely visually uncontrolled, and could also reflect one of a number of processes: detecting agents, processing of their motion or intentions, or processing of interactions between multiple agents.

The present study aimed to investigate the neural correlates of social perceptual processes, using geometric shape stimuli. In particular, we use dot-chain stimuli perceived as slithering snakes or worms, which provide a strong percept of animacy without the need for multiple, interacting agents (Gao, New, & Scholl, 2011). This ensures that any effects observed do not relate to processing interactions between agents (c.f. Centelles, Assaiante, Nazarian, Anton, & Schmitz, 2011). To investigate each of the subprocesses listed above, we separately manipulated the perceived animacy, goal-directedness, and path rationality (or expectedness) of the animations. We first performed a behavioral study, eliciting judgments about these animations on various dimensions. The animations were then used as stimuli for an fMRI experiment, to investigate the response of the pSTS, as well as motion-sensitive area MT+, as a control region.

## Methods

### Experiment 1: Behavioral study

**Participants** For the behavioral study, responses were gathered using Amazon Mechanical Turk. There were 16 types of animation per condition, and 15 responses were elicited for each animation, yielding a total of 240 responses per condition. Participants were constrained to be from the United States, and to have a minimum 95% approval rating from prior Turk studies. The survey included several foil questions (e.g., what is the color of the dots?), and responses with incorrect answers to these questions were rejected.

**Stimuli** The stimuli consisted of a set of 4s-long animations of dots (i.e. circles) and dot-chains moving within a square-shaped environment, with walls present in some conditions as obstacles. For the head dot of the snake, motion was determined using the chase-subtlety algorithm from Gao, Newman, & Scholl (2009). In this algorithm, the velocity of the dot has a fixed magnitude, with a direction that updates periodically (every 5 frames or .167s, in the present study). The direction is chosen probabilistically: if the angle that directs the dot toward its goal is denoted  $\alpha$  and the subtlety parameter is denoted  $\gamma$ , the new direction is chosen from a uniform distribution over the interval  $[\alpha - \gamma, \alpha + \gamma]$ , where  $\gamma = \pi/12$  in this study. This results in a dot that takes a slightly winding path toward a goal. Tail dots in the chain, if present, followed the path taken by the head dot with a slight lag.

Conditions 1-4 were intended to manipulate animacy and goal-directedness in a 2x2 design (see figure 1 for a schematic depiction of each condition). Animacy was modulated by the presence or absence of six tail dots, leading to the percept of a worm or snake. Goal-directedness was modulated by the presence of a goal-dot at the end of the trajectory.

Conditions 5-8 were intended to manipulate path rationality. Stimuli in conditions 5-7 were considered animate and goal-directed, but involved trajectories with a bend, which was either around a wall or around nothing. These conditions were 5) rational (full wall), 6) semi-rational (half of a wall), and 7) irrational (no wall). As a visual control, walls were added to conditions 1-4 and 7-8, which were not relevant to the paths. In condition 8 (wander), the dot-chain had no goal and increased subtlety ( $\gamma = \pi/4$ ), leading to a percept of a randomly wandering snake, intended as a highly irrational, unexplainable action.

For each condition, 4 specific animations were designed with distinct trajectories; these stimuli were rotated 0°, 90°, 180°, and 270° to create 16 animations per condition. Two visual confounds should be noted: the animate condition had more dots and therefore more motion than the inanimate condition; and the wander condition had more changes in motion than all other conditions. These issues are further discussed below.

Figure 1: Schematic illustrations of the animation stimuli (not to scale). Note that the actual trajectories were not straight lines, but winding paths (see Methods section).

**Behavioral measures** Participants viewed the animations and were asked to respond to the following questions on a seven-point scale: 1) How much did the moving dot look like a living, animate thing, as opposed to an inanimate physical object? 2) To what extent did the moving dot appear to have a goal or goals? 3) To what extent did the dot's path seem strange or irrational? Additionally, several foil questions were asked to ensure meaningful responses.

**Data analysis** We performed several planned unpaired two-sample *t*-tests to test the specific effects of interest. We first tested the effect of having a tail (conditions 3 and 4 versus 1 and 2) on animacy ratings. We then tested the effects of having a goal dot (2 and 4 versus 1 and 3), of path irrationality (7 versus 5), and of wandering over irrationality (8 versus 7), on both goal-directedness and irrationality ratings. Additionally, we performed a post-hoc test for the effect of having a goal dot for animations with a tail (4 versus 3) on animacy ratings.

### Experiment 2: fMRI study

**Participants** 20 subjects (aged 19-28, mean 23.1; 10 female) were recruited for the fMRI study. All participants had normal or corrected-to-normal vision and no history of neurological or psychiatric disorders, and gave written, informed consent in accordance with the requirements of the MIT institutional review board.

**Stimuli** The animations used in the fMRI experiment were the same as those used in the behavioral study. Stimuli were presented in a jittered, event-related design, with a variable inter-stimulus interval of 0-15 seconds, during which a central fixation cross was presented. The experiment comprised 8 blocks lasting 9 minutes and 44 seconds, each containing 8 stimuli per condition, for a total of 64 stimuli per condition. Participants performed a one-back task on animations during the scan, to maintain attention; repeat trials were not included in the analysis.

Additionally, each subject received a localizer scan intended to define the pSTS and motion-sensitive area MT. This consisted of three conditions in a blocked design: biological motion (point-light displays [PLDs] depicting human motion; cf Grossman et al. 2000), scrambled motion (PLDs with initial dot positions scrambled), and static luminance change (static dots changing in luminance). Each subject received 2 or 3 runs lasting 7 minutes and 24 seconds each, and comprising 6 12s-long blocks per condition separated by a 12s interstimulus interval. Participants performed a one-back task on individual animations within the blocks, to maintain attention.

**fMRI Data Acquisition** Data were acquired on a 3T Siemens Tim Trio scanner, with a 32-channel head coil. Following high-resolution anatomical scans, functional images were acquired with an echo planar imaging pulse sequence sensitive to blood-oxygen-dependent (BOLD) contrast (repetition time [TR] = 1s, echo time [TE] = 30ms, flip angle = 70°, voxel size 3x3x3mm, matrix 64x64, 16 axial slices). Because of our interest in specific brain regions, we used a sequence with limited coverage (of visual cortex and the STS), but a TR of 1s for increased power and temporal resolution. The first four volumes of each acquisition were discarded to allow the system to reach steady state. For localizer scans, a similar pulse sequence was used, but with TR=2 and full brain coverage (32 axial slices).

**fMRI Data Analysis** Preprocessing and analysis of fMRI data was carried out using the FMRIB Software Library (FSL) version 4.1.8, supplemented with Freesurfer 4.5. Preprocessing steps included rigid-body motion correction, correction for interleaved slice timing, brain extraction, spatial smoothing (5mm FWHM Gaussian kernel), and highpass temporal filtering (100s cutoff). Functional images were registered to anatomical images using Freesurfer's bbrgister; anatomical images were in turn normalized to MNI space using FSL's nonlinear registration image registration tool (FNIRT).

For data analysis, whole-brain general linear model-based analyses were initially performed for the main task and localizer, for the purpose of defining regions-of-interest (ROIs) in individual subjects. Regressors were defined as boxcar functions with nonzero values during the duration of the stimuli; these were then convolved with a canonical double-gamma hemodynamic response function. FSL's FILM prewhitening was applied to account for residual autocorrelation. Statistical maps were thresholded with an initial cutoff of  $Z > 2.3$ , followed by Gaussian random field theory-based thresholding with a cluster-wise threshold of  $P < .05$ , to correct for multiple comparisons.

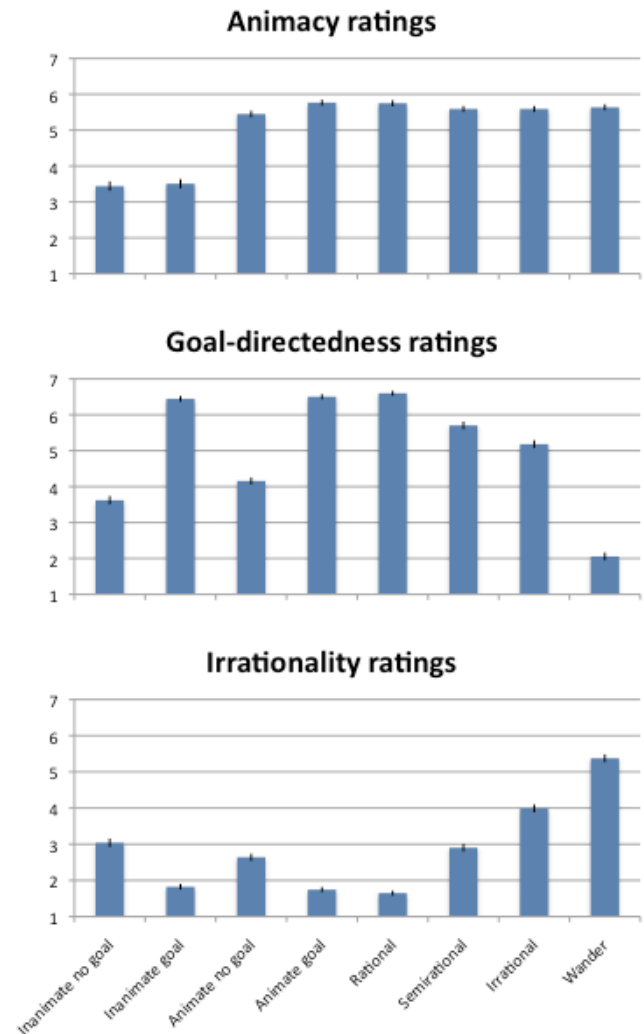

Figure 2: Behavioral responses. Plot of responses to three questions—regarding animacy, goal-directedness, and irrationality—for the eight conditions. Error bars give standard error.

To define the right pSTS, the main task was used rather than the localizer, because the latter did not consistently yield pSTS responses in individual subjects. The contrast of all conditions versus rest in the main task was used to define the pSTS, because this contrast is orthogonal to any balanced between-condition comparison. As a control, we investigated responses in right MT+, a motion-sensitive region thought include retinotopic areas MT, MST, and possibly others (Amano, Wandell, & Dumoulin, 2009). This was defined using the localizer scan, by contrasting scrambled motion with static luminance change. Regions were defined as all active voxels within a 7.5mm-radius sphere around the peak coordinate within an anatomical search space, intersected with a gray matter mask derived using Freesurfer. The search spaces consisted of the STS (for pSTS), and lateral occipito-temporal cortex (for MT+).

Mean betas values across the ROI were extracted for each subject. Planned, paired two-sample *t*-tests were performed

for each ROI, testing for effects of 1) animacy (conditions 3 and 4 vs 1 and 2), 2) goal-directedness (2 and 4 vs 1 and 3), 3) irrationality (7 vs 5), and 4) wandering over irrationality (8 vs 7). Responses were averaged when combining two conditions. Additionally, a post-hoc test assessed the effect of goal-directedness for animations with a tail (condition 4 versus 3) on the pSTS response.

## Results

### Behavioral results

The behavioral results are shown in figure 2. As predicted, the presence of a tail or dot-chain significantly increased the percept of animacy ( $t[958] = 19.43, p < 10^{-70}$ ). In spontaneous post-scan self-reports from subjects who participated in the fMRI experiment (a separate group of subjects), many described the dot-chain stimuli as either a “worm,” “snake,” or “tadpole,” that was “swimming” or “wiggling.” Additionally, we observed that for stimuli with tails, animations that contained a visible goal dot were rated as more animate than those without. A post-hoc test of this difference was significant ( $t[478] = 2.56, p < .02$ ).

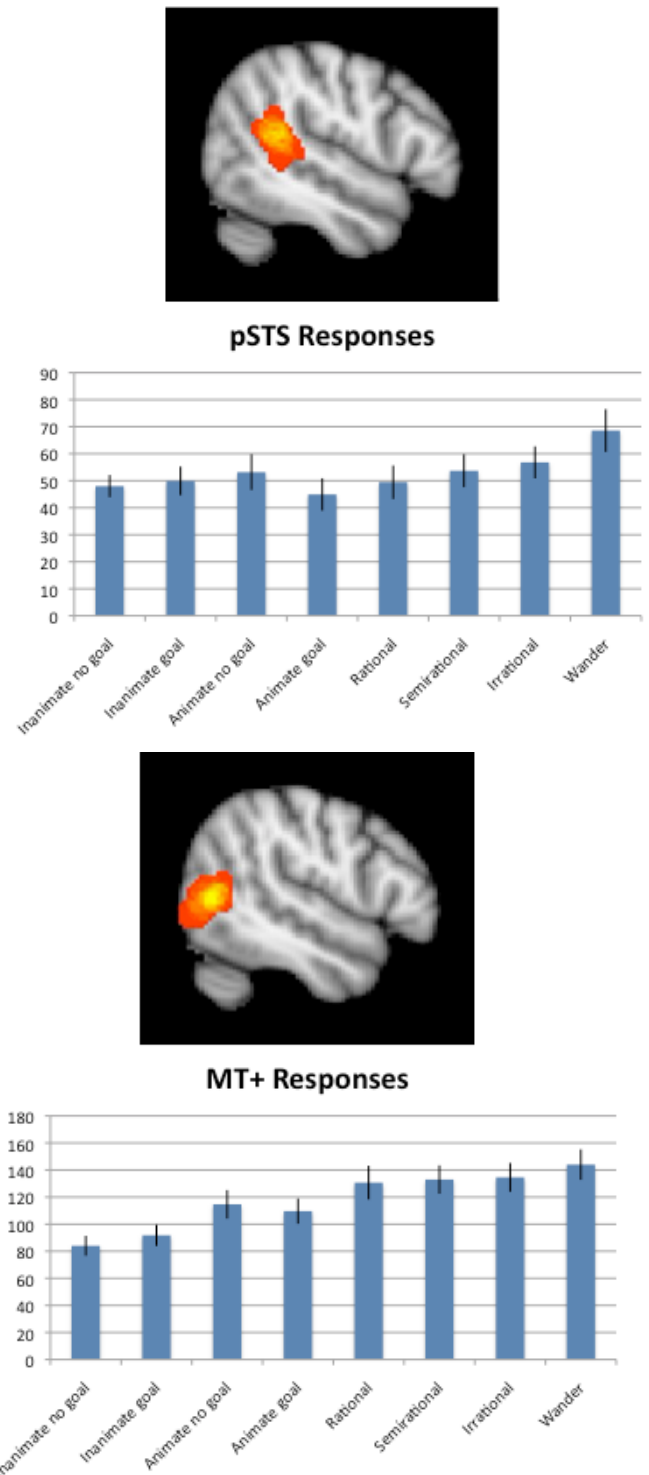

Ratings of goal-directedness were increased by the presence of a goal dot, as expected ( $t[958] = 25.40, p < 10^{-108}$ ). Additionally, goal-directedness ratings were lower for irrationality than rational stimuli ( $t[478] = -13.86, p < 10^{-36}$ ), and for wandering than irrational stimuli ( $t[478] = -24.79, p < 10^{-87}$ ).

Ratings of irrationality were higher for irrational than rational paths, as expected ( $t[478] = 18.00, p < 10^{-54}$ ). Additionally, they were higher for wandering than irrational paths ( $t[478] = 8.96, p < 10^{-17}$ ). The presence of a goal dot also influenced irrationality ratings, with higher ratings for stimuli without a visible goal ( $t[958] = -11.27, p < 10^{-27}$ ). Thus, we found an inverse relationship between ratings of goal-directedness and irrationality: namely, animations depicting an efficient path toward a clear goal were rated as highly goal-directed and rational, while paths that lacked a clear goal or used an inefficient trajectory were rated as less goal-directed and more irrational.

### fMRI results

Results from the right pSTS ROI analysis are shown in figure 3. The ROI was found in 19 out of 20 subjects. We found no effect of the animacy manipulation ( $t[18] = -.03, p = .98$ ), nor the goal dot manipulation ( $t[18] = -1.17, p = .26$ ). However, the pSTS did respond more strongly to irrational than rational stimuli ( $t[18] = -2.25, p < .05$ ), and to wandering than irrational stimuli ( $t[18] = 3.03, p < .01$ ).

Additionally, we observed that among animate stimuli, or stimuli with a tail, the pSTS had a lower response to animations with a visible goal dot. A post-hoc test for this comparison was significant ( $t[18] = -2.30, p < .05$ ). Thus, the pSTS response to animate stimuli tracked behavioral ratings of irrationality, but did not correspond to ratings of animacy or goal-directedness.

Figures 3 (above) and 4: Mean beta values extracted from right posterior superior temporal sulcus (pSTS, figure 3) and right MT+ (figure 4) regions of interest (ROIs). Error bars give standard error. The images above the bar plots show the locations of ROIs across subjects: for each voxel, the value plotted is the fraction of subjects whose ROI contained this voxel.

Results from the right MT+ ROI analysis are shown in figure 4. The ROI was found in 19 out of 20 subjects. For this ROI, there was a main effect of the animacy manipulation ( $t[18] = 5.57, p < 10^{-4}$ ). This is to be expected for a retinotopic region, insofar as the dot-chain stimuli occupied more of the visual field than the individual dot stimuli, and therefore this difference may not reflect the processing of animacy.

There was no effect of goal-directedness ( $t[18] = .52, p = .61$ ) or irrationality ( $t[18] = .97, p = .34$ ) on the MT+ response. These comparisons were tightly controlled for the magnitude and direction of motion, so no differences relating to motion processing were expected.

There was an effect of wandering over irrational stimuli in MT+ ( $t[18] = 2.71, p < .02$ ). This effect may also result from motion processing. Although the magnitude of motion is equated across wander and irrational conditions, the direction and derivatives thereof are not controlled. A larger number of changes in motion direction in the wander condition may have lead to decreased adaptation of direction-specific neural responses in MT+, and therefore an increased BOLD signal.

## Discussion

We have shown behaviorally that dot-chain stimuli governed by a simple motion algorithm can evoke a strong percept of animacy, and in certain conditions, goal-directedness, replicating and extending the findings of Gao et al. (2011). Furthermore, we found that the right pSTS response to these stimuli is not stronger for stimuli rated as animate or goal-directed. However, this response was modulated by path irrationality: for conditions 3-8 (the conditions rated as highly animate), pSTS activity corresponds well with irrationality ratings, as can be seen by comparing figures 2 and 3. By comparison, activity in right MT+ was not generally modulated by irrationality, instead tracking the amount of motion and change in motion in the stimuli, as expected.

Several results of interest came from our behavioral analysis. We found that ratings of goal-directedness and path irrationality had an inverse relationship. Straight paths without goal dots were rated as more irrational than those with visible goals, and inefficient trajectories toward a goal were rated as less goal-directed than efficient trajectories. Thus, these ratings may have both derived from a common implicit quantity, perhaps corresponding to the extent to which an action can be explained in terms of perceptible goals and environmental constraints (e.g. Gergely & Csibra, 2003).

Furthermore, we found that for dot-chain stimuli, which were perceived as highly animate, the presence of a goal dot had a small but significant influence on ratings of animacy. This is consistent with the hypothesis that goal-directedness provides a cue to animacy (e.g. Shultz and McCarthy, 2011). This result was unexpected and assessed with a post-hoc test, and thus should be independently replicated; however, we note that we have another, unpublished dataset

consisting of Mechanical Turk responses to similar stimuli, in which this effect was also observed.

Our imaging results show that with these stimuli, the pSTS response is not modulated by a large difference in perceived animacy between dot-chain and individual dot stimuli. This result appears inconsistent with claims that the pSTS is generally involved in the detection of agents or animate beings (e.g. Gobbini et al., 2011; Shultz and McCarthy, 2011). This finding is not directly inconsistent with any prior empirical result in the literature, to our knowledge, because prior contrasts involving animacy (e.g. faces versus nonfaces, biological motion versus scrambled motion, Heide-Simmer animations versus control animations) have been confounded with other factors (such as specific static or dynamic visual properties, the presence of a human, or the presence of an interaction), and thus cannot be considered pure animacy contrasts.

Another interpretation of these data is that the pSTS is involved in the detection of animacy, but relies on local cues such as the motion of individual dots in our animations, which are similar for the animate and inanimate conditions. This interpretation must invoke other processes to explain the large behavioral difference in animacy judgments for dots and dot-chains. However, this explanation appears inconsistent with the fact that the pSTS response to human motion is modulated by global form, and not just local cues (e.g. Grossman et al. 2000), unless this modulation relates to a process separate from agent detection.

The pSTS response in our data was also not increased by perceived goal-directedness. This is consistent with findings that the right pSTS responds similarly to intentional and externally caused human movements (Morris, Pelphrey, & McCarthy, 2008), and to goal-directed and non-goal-directed actions by robots (Shultz and McCarthy, 2011). This result might be interpreted as evidence against a role of pSTS in processing action goals. However, given the inverse relationship observed between ratings of goal-directedness and irrationality, there is another potential explanation. This region may apply an assumption that actions by animate beings are intentional, and attempt to explain all such actions. In this case, actions with a visible goal may be easier to explain, and thus evoke a weaker pSTS response, as observed for animate stimuli.

While the pSTS response in the present study did not increase with animacy or goal-directedness, it did track the perceived irrationality of the actions depicted. This is consistent with prior findings of irrationality effects during the perception of human actions, as described above, and extends these results to nonhuman agents depicted by simple geometric shape animations. Thus, whatever computations underlie this irrationality effect are likely similarly applied to the actions of human and nonhuman agents.

We note that animations in the rational, irrational, and semirational conditions were perfectly controlled for visual motion; therefore motion cannot be driving the differences observed. The wander condition did have a motion change

confound, as noted above. However, given the similar pSTS response to animate and inanimate conditions, which had a substantial difference in visual motion, we consider it implausible that the high response to the wander condition in this region results from motion properties.

As discussed above, the irrationality effect has been interpreted as supporting a role of the pSTS in action understanding, or inferring goals of actions and predicting future actions based on these goals. There are a number of interpretations of the irrationality effect consistent with this claim. For instance, this response might relate to the inference of a more complex goal structure underlying irrational actions. On this hypothesis, the pSTS tries to rationalize all actions, including ostensibly irrational ones, and simply requires a more complex explanation for the latter, perhaps positing extra goals that weren't immediately inferred from the context. Another possible interpretation is that this response constitutes an error detection signal for actions. On this hypothesis, the pSTS response doesn't reflect a reappraisal of the causal structure behind an irrational action, but simply reflects a signal indicating that the inferred structure was not correct. Future research should attempt to distinguish between these hypotheses.

Another question is of the specificity of this effect to actions. Does the right pSTS respond to any unexpected event, or more specifically, to unexpected visual motion events? While our current data doesn't speak to this question, Saxe et al. (2004) showed that while the pSTS responds more strongly when a walking human pauses behind a bookshelf than when he walks without pause, this isn't the case for gliding objects. This provides some preliminary evidence that this effect is specific to intentional actions, but this question should be followed up in subsequent studies.

In sum, we have shown that the pSTS response to animations of geometric shape motion is not increased by animacy or goal-directedness, but is modulated by action rationality. Future research should explore the computations that underlie this effect, and their precise contribution to action understanding.

## Abstract

How do words affect categorization? According to one theoretical account, even early in development, labels are category markers and are different from other features. According to another theory, early in development, labels are part of the input and are no more than other features. The current study addressed this issue by examining the effects of labels on category learning in 8- to 12- month infants. Infants were familiarized with exemplars from one category in either label-defined or motion-defined condition and then tested with prototypes from learned category and novel category. Eye tracking results indicated that infants exhibited better category learning in the motion-defined than in the label-defined condition. These results provide little evidence for the idea that labels are category markers that facilitate category learning.

**Keywords:** Cognitive Development, Categorization, Attention, Label, Psychology, Human Experimentation.

## Introduction

The ability to form categories is an important component of human cognition (see Murphy, 2002, for a review). It has been well established that this ability appears early in development, with young infants capable of forming categories at an early age (Eimas & Quinn, 1994; Oakes, Madole, & Cohen, 1991), and a substantial body of experimental evidence suggest that linguistic labels affect this process (Balaban & Waxman, 1997; Waxman & Markow, 1995; Fulkerson, Waxman, & Seymour, 2006; Waxman & Booth 2003; Robinson & Sloutsky, 2007). However, the mechanisms underlying the role of labels remain unclear, which has generated considerable debate. Some have argued that words denoting categories have the special status of category markers and, as such, they facilitate category learning at the earliest stages of word learning. At the same time, others have argued that early in development words are akin to other features, but they may become category markers in the course of development.

According to the former theory, early in development, young infants have general assumptions that words but not other kinds of auditory inputs are category markers which

denote categories and “infants embark on the task of word learning equipped with a broad, universally shared expectation, linking words to commonalities among objects” (Waxman, 2003). According to this view, linguistic labels refer to category information and facilitate infants’ category learning. There is much evidence consistent with this view. First, some researchers have demonstrated that labels may facilitate infants’ categorization above and beyond other kinds of auditory input (Balaban & Waxman, 1997; Fulkerson & Haaf, 2003; Fulkerson et al., 2006; Ferry, Hespos, & Waxman, 2010). Second, facilitative effects of linguistic labels were demonstrated for basic-level as well as superordinate or global categories (Balaban & Waxman, 1997; Waxman & Markow, 1995; Waxman & Booth, 2003). Finally, effects of labels have been shown to affect infants’ performance on a variety of cognitive tasks, such as inductive inference (Graham, Kilbreath, Welder, 2004; Welder & Graham, 2001) and object individuation (Xu, 2002; Xu, Cote, & Baker, 2005).

There are challenges, however, to the idea that linguistic labels are category markers that facilitate categorization early in development. There are theoretical proposals arguing that, at least early in development, labels are features of items (similar to color or shape) rather than category markers (Sloutsky & Lo, 1999; Sloutsky & Fisher, 2004; Sloutsky, Lo, & Fisher, 2001) and the contribution of linguistic labels is driven by attentional rather than conceptual factors (Napolitano & Sloutsky, 2004; Sloutsky & Napolitano 2003). There is also evidence that auditory input overshadows (or attenuates processing of) corresponding visual input (Lewkowicz, 1988a, 1988b; Napolitano & Sloutsky, 2004; Robinson et al., 2005; Robinson & Sloutsky, 2004a, 2004b; Sloutsky & Napolitano, 2003). Furthermore, many of the studies examining the effects of labels on infants’ category learning compared the effects of labels with those of unfamiliar sounds, but not with a silent condition. When a salient baseline was introduced (e.g., Robinson & Sloutsky, 2007), labels did not facilitate infants’ category learning above the

silent baseline (see also Robinson & Sloutsky, 2008, for similar findings on individuation tasks).

There is also recent evidence by Deng and Sloutsky (2012) who demonstrated that labels function the same way as other features for young children, but they may become category markers in the course of development. In particular, Deng and Sloutsky used a variant of Yamauchi & Markman's (1998, 2000) paradigm and pitted category label against a highly salient visual feature. They found that unlike many adults who relied on category label, children relied on the salient feature.

If labels are not category markers for preschoolers, how they can be category markers attracting attention to within-category commonalities for infants (e.g., Balaban & Waxman, 1997; Ferry, Hespos, & Waxman, 2010; Waxman & Markow, 1995)? Although there is evidence that labels do little above and beyond a silent condition (Robinson & Sloutsky, 2007), none of the studies claiming that labels are category markers compared effects of labels with those of highly salient visual features. How do labels affect (a) patterns of attention and (b) the outcome of category learning? And how do these effects differ from those of highly salient visual features? The goal of this research is to answer these questions by using a combination of eye tracking and a more traditional novelty preference paradigm.

## Overview of Current Study

The goal of the study reported here was to examine the role of labels in category learning in infancy. The experiment consisted of two between-subjects conditions: label-defined condition and motion-defined condition. In both conditions, infants were familiarized with the exemplars from one category and then tested with the prototype of this category and that of the contrast category. Infants saw the same testing stimuli in both conditions and neither label nor motion was provided during testing. Eye gaze data were collected from infants while being trained and tested in both conditions. If labels are category markers and are able to direct attention to the category-relevant information, then infants should learn better when labels are provided. This should not be the case, however, if labels are part of input rather than category markers.

## Method

### Participants

Thirty-eight infants (16 boys and 22 girls) ranging in age from 8 to 12 months ( $M = 10$  months, 14 days;  $SD = 1$  month, 27 days) participated in this experiment. Data provided by 2 infants were excluded from analyses due to fussiness and 6 infants were excluded for not looking at a single test trial.

### Apparatus

A Tobii T60 eye-tracker with the sampling rate of 60 Hz (i.e., 60 gaze data points per second for each eye) was used

Figure 1. Prototypes of stimuli from Categories A and B.

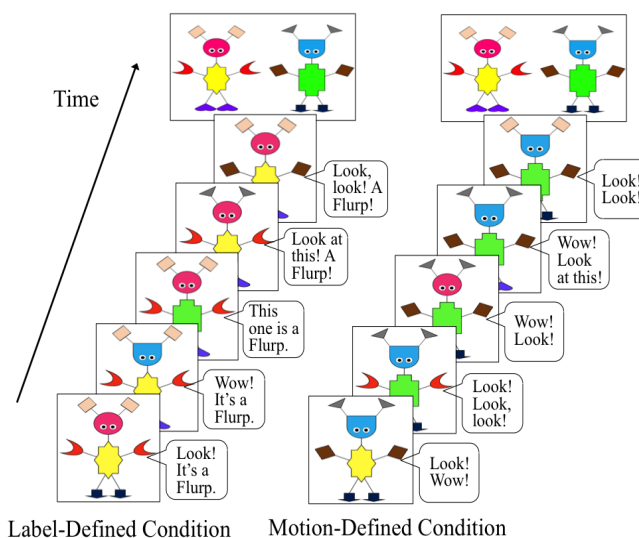

Figure 2. Example Stimuli.

to collect eye gaze data. The eye-tracker is integrated into a 17-inch computer monitor and located on a table inside a booth enclosed by black curtains. A trained experimenter monitored the experiment using Tobii Studio gaze analysis software installed on a 19-inch Dell OptiPlex 755 computer outside the booth. A video stream displaying participants' activities was projected onto a 9-inch black and white Sony SSM-930 CE television for experimenter's online monitoring. Two Dell speakers were located behind a black curtain on each side of the eye-tracker.

### Materials and Design

The materials were colorful drawings of artificial creatures and novel labels "flurp" and "jalet". The items had five features varying in color and shape and two categories were formed by different feature values (see Figure 1). As shown in Table 1, the two categories have a family-resemblance structure, which was derived from two prototypes (A0 and B0) by modifying the values of one of five features – head, antenna, hands, body, or feet. For example, to produce the

Table 1. Category structure used in learning.

Category A							Category B						
Stimuli	Head	Body	Hands	Feet	Antenna	Label/ Motion	Stimuli	Head	Body	Hands	Feet	Antenna	Label/ Motion
A1	1	1	1	1	0	1	B1	0	0	0	0	1	0
A2	1	1	1	0	1	1	B2	0	0	0	1	0	0
A3	1	1	0	1	1	1	B3	0	0	1	0	0	0
A4	1	0	1	1	1	1	B4	0	1	0	0	0	0
A5	0	1	1	1	1	1	B5	1	0	0	0	0	0
A0	1	1	1	1	1	1	B0	0	0	0	0	0	0

Note. The value 1 = any of five dimensions identical to "Flurp" (see Figure 1). The value 0 = any of five dimensions identical to "Jalet" (see Figure 1). A0 and B0 are prototypes of each category.

stimulus A1, the value of the antenna was changed from 1 to 0 so that it had four features consistent with the prototype A0 and one feature consistent with the prototype B0. See Figure 2 for example of stimuli.

There were two between-subjects conditions (label-defined vs. motion-defined). In the label-defined condition, the value of label did not vary across the exemplars; whereas in the motion-defined condition, a pattern of motion did not vary across the exemplars. In particular, one of the features (the feet) was animated to be highly salient using Macromedia Flash MX software and all the members of a given category had feet with the same pattern of motion. For "flurps", the feet were purple, heart-shaped, and stretched up and down; whereas, for "jalets", the feet were dark blue, arrows-shape, and moved sideways.

## Procedure

Infants were seated on parents' laps approximately 60 cm away from the eye-tracker. Parents were instructed not to interact with infants and not to point or label any of the stimuli. Prior to the experiment, infants completed a 5-point calibration sequence. The calibration points consisted of dynamic kitten images appearing in different locations on the screen, with "bounce" sound. After successful calibration, a colorful picture of a baby playing with several different toys was presented on the screen to keep infants' attention.

When infants and parents were ready to begin, an experimenter started the experiment by pressing the space bar. The picture of baby disappeared and infants were presented 20 familiarization trials and 4 test trials. The trials were mixed and pseudo-randomly assigned into 4 blocks, with 5 familiarization trials followed by 1 test trial in each block. On each familiarization trial, infants saw a creature produced from the structure of one category shown in Table 1 with a white background lasting for 8000 msec and heard a phrase starting at the onset of each trial. In label-defined condition, a labeling phrase (e.g., "Look! This is a Flurp") was presented in each trial and lasted for approximately 2800 msec. However, in motion-defined condition, the phrase was not labeled (e.g., "Look at this one!"). The feet of the creature moved after the phrase and the motion lasted for 3000 msec. The onset of motion in motion-defined condition was approximately the same as that of label in

label-defined condition. After familiarization, infants were tested with preference trial (in each block). Each test trial consisted of the prototype of the category that infants were trained with in familiarization and the prototype of the contrast category, and presented without either label or motion for 8000 msec. A dynamic bouncing ball was presented as an attention-engager between trials within each block. A short cartoon video was presented between blocks in order to let infants have a rest. All gaze data were recorded by the computer using Tobii Studio gaze analysis software.

## Results

Analyses presented below primarily focused on the percentage looking to the prototype of novel category at test and on the patterns of attention during familiarization phase and testing phase. Gaze data were exported from the computer using Tobii Studio gaze analysis software. Scenes were created for every trial (both familiarization and test) and eighteen areas of interest (AOIs) for fixations were defined: one rectangle surrounding the creatures on familiarization trials, two rectangles surrounding two prototypes respectively on test trials, and fifteen ellipses surrounding each feature of the creatures on both familiarization and test trials. These data were used to calculate (1) novelty preference score based on the proportion of looking time to the prototype of novel category as compared to the total looking time to both of the prototypes at test; and (2) patterns of attention based on the proportion of looking time to different features on both familiarization and test trials.

## Novelty Preference Scores

To examine how labels or patterns of motion affected infants' categorization, a novelty preference score was calculated for each test trial: accumulated looking time to the prototype from novel category divided by the overall looking time for both stimuli. The main results are presented in Figure 3. The data were submitted to a 4 (block: 1 vs. 2 vs. 3 vs. 4) by 2 (condition: label-defined vs. motion-defined) mixed ANOVA, with block as a within-subjects factor and condition as a between-subjects factor. There was a significant main effect of condition,  $F(1, 28) = 11.51$   $MSE = 0.24$ ,  $p < .01$ ,  $\eta_p^2 = 0.291$ , with infants looking substantially

Figure 3. Infants' novelty preference score at test in 4 blocks for label-defined and motion-defined conditions.

Figure 4. Infants' novelty preference score averaged across four blocks at test.

Figure 5. Infants' proportion of accumulated looking time to each feature averaged across 4 blocks at familiarization.

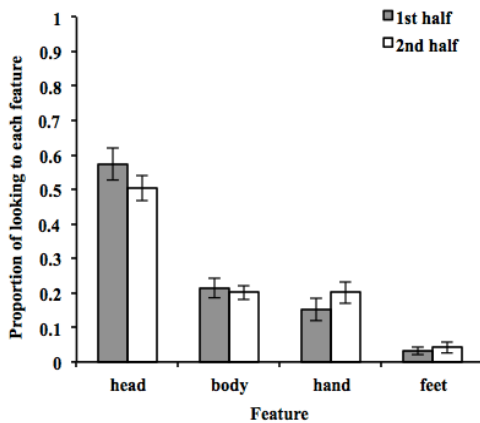

Figure 6. Infants' proportion of looking time to each feature in 1<sup>st</sup> and 2<sup>nd</sup> half familiarization trial in label-defined condition.

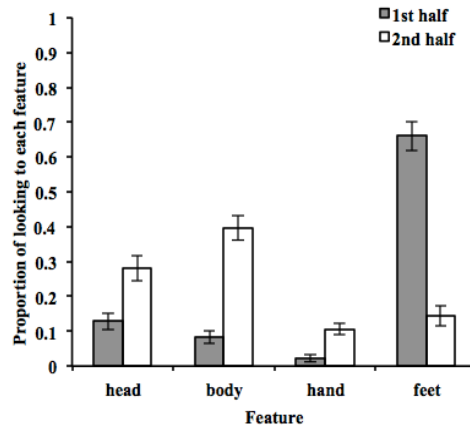

Figure 7. Infants' proportion of looking time to each feature in 1<sup>st</sup> and 2<sup>nd</sup> half familiarization trial in motion-defined condition.

Figure 8. Infants' proportion of accumulated looking time to each feature averaged across 4 blocks at test.

longer to the novel category in motion-defined condition compared to the label-defined condition. However, neither the main effect of block ( $p = .45$ ) nor the interaction between block and condition ( $p = .34$ ) was found. Therefore, data were collapsed across blocks for each condition and the results are presented in Figure 4. As shown in Figure 4, infants looked significantly longer to the novel category in motion-defined condition than in label-defined condition, independent sample  $t(28) = 3.71$ ,  $p < .01$ ,  $d = 1.44$ . In addition, infants' novelty preference score was significantly higher than chance in motion-defined condition

one-sample  $t(11) = 3.27$ ,  $p < .01$ ,  $d = 0.94$ ; whereas in label-defined condition, infants' looking to the novel category was not different from chance,  $p = .19$ .

### Patterns of Attention

To determine if moving feet served as an engager and pushed infants' attention to other features, we compared the accumulated looking time to the stimuli on familiarization trials in two conditions. The gaze data (accumulated looking time) were submitted to a 4 (block: 1 vs. 2 vs. 3 vs. 4) by 2 (condition: label-defined vs. motion-defined) mixed

ANOVA, with block as a within-subjects factor and condition as a between-subjects factor. Results revealed a main effect of block,  $F(3, 84) = 12.87$ ,  $MSE = 0.00$ ,  $p < .01$ ,  $\eta_p^2 = 0.315$ , with infants' accumulated looking time decreasing through blocks. However, infants' accumulated looking time did not differ between label-defined and motion-defined conditions,  $p = .44$ .

Because the comparable accumulated looking during familiarization trials resulted in different outcomes of category learning in two conditions, we deemed it necessary to examine how attention was distributed among different features of the stimuli at both familiarization and test. The proportion of looking time to different features on both familiarization (averaged across five trials within each block) and test trials (averaged across old and new prototypes) were calculated and the data were submitted to two separate 4 (feature: head<sup>1</sup> vs. body vs. feet) by 4 (block: 1 vs. 2 vs. 3 vs. 4) by 2 (condition: label-defined vs. motion-defined) mixed ANOVAs, with feature and block as within-subjects factors and condition as a between-subjects factor. For familiarization trials, because there was no main effect of block ( $p = .16$ ), these data were collapsed across four blocks. As shown in Figure 5, there was an interaction between feature and condition,  $F(3, 84) = 44.74$ ,  $MSE = 0.80$ ,  $p < .01$ ,  $\eta_p^2 = 0.615$ . Infants' accumulated more looking to the head in label-defined condition compared to motion-defined condition, independent sample  $t(27.7) = 6.46$ ,  $p < .01$ ,  $d = 2.25$ ; whereas they looked significantly longer at the feet, independent sample  $t(13.4) = 9.9$ ,  $p < .01$ ,  $d = 4.45$ , and the hands, independent sample  $t(25.2) = 3.40$ ,  $p < .01$ ,  $d = 1.14$ , in motion-defined condition than in label-defined condition. Infants accumulated comparable looking to body in both conditions,  $p = .91$ . Since the label and the moving feet were not presented for the entire 8-second trial in training, we further examined infants' pattern of attention by comparing their accumulated looking to each feature in the first half of the trial to that in the second half of the trial. Data were submitted to two 4 (feature: head vs. body vs. hands vs. feet) by 2 (time course: 1<sup>st</sup> half vs. 2<sup>nd</sup> half) repeated measures ANOVAs for the label-defined and motion-defined conditions respectively. As shown in Figure 6, in the label-defined condition, there was a main effect of feature,  $F(3, 51) = 43.25$ ,  $MSE = 1.63$ ,  $p < .01$ ,  $\eta_p^2 = 0.718$ , and an interaction between feature and time course,  $F(3, 51) = 5.74$ ,  $MSE = 0.02$ ,  $p < .01$ ,  $\eta_p^2 = 0.253$ . Infants looked significantly longer at the head in both of the 1<sup>st</sup> and 2<sup>nd</sup> half of the familiarization trial, Bonferroni  $ps < .01$ , but shorter at the feet,  $ps < .05$ . In the motion-defined condition, as shown in Figure 7, there was a main effect of feature,  $F(3, 33) = 42.63$ ,  $MSE = 0.46$ ,  $p < .01$ ,  $\eta_p^2 = 0.795$ , and an interaction between feature and time course,  $F(3, 33) = 57.67$ ,  $MSE = 0.79$ ,  $p < .01$ ,  $\eta_p^2 = 0.840$ . In contrast to infants who biased to the head in the label-defined condition, infants' looking was more widely distributed in the motion-defined condition: they looked longer at the moving feet during the first 4-second familiarization trial,

Bonferroni  $ps < .01$ , but they looked longer at the body and head during the latter half of familiarization trial (looking time: body > head > feet > hand; only for the last pair, Bonferroni  $p < .01$ ).

Similar analyses were conducted to examine the patterns of attention on test trials (recall that neither labels nor motion was presented during these trials). Since there was no main effect of block ( $p = .42$ ), the data were collapsed across blocks and results are presented in Figure 8. Similar to familiarization, there was an interaction between feature and condition,  $F(3, 84) = 4.94$ ,  $MSE = 0.18$ ,  $p < .01$ ,  $\eta_p^2 = 0.150$ . Infants looked longer at the head in label-defined condition compared to motion-defined condition, independent sample  $t(28) = 2.87$ ,  $p < .01$ ,  $d = 1.11$ . However, there was little evidence that infants in motion-defined condition just focused on feet to categorize; their looking instead was more widely distributed across the features,  $ps > .24$ .

## Discussion

In the study reported here, we investigated the role of labels in infants' categorization by comparing effects of labels with those of highly salient visual features. By using a combination of eye tracking and a more traditional novelty preference paradigm, we examined the patterns of attention and the outcome of category learning.

The current study reveals several important findings. First, infants exhibited better category learning when they saw a salient visual feature (i.e., moving feet) compared to when they heard a label. Second, although infants accumulated comparable looking during learning in motion-defined condition compared label-defined condition, their attention was more distributed among different features when there was a salient visual feature whereas they spent most of their time looking at the head when they heard a label. Third, there was little evidence of labels facilitating category learning in infants.

Many studies have examined the role of labels in infants' categorization and there is little agreement on the role of labels being category markers or features. However, none of the studies examining the effects of labels on categorization in infancy demonstrated that these effects are greater than those of highly salient features. By comparing the outcome of category learning and examining the patterns of attention in label-defined and motion-defined conditions, the current study has provided new evidence as to how labels may affect category learning in infancy. The results indicate that a pattern of motion has a greater facilitative effect on category learning than the label.

The current study raises an interesting question about the role of labels in infants' categorization by comparing the effects of label to those of a salient feature and the results suggest the labels may start out as features rather than category markers. Future research will examine whether labels merely fail to facilitate category learning or they actually hinder infants' category learning in infancy.

<sup>1</sup> Antenna are combined with head as one level of feature.

# Learning Deterministic Causal Networks from Observational Data

**Ben Deverett**

ckemp@cmu.edu  
Carnegie Mellon University

## Abstract

Previous work suggests that humans find it difficult to learn the structure of causal systems given observational data alone. We show that structure learning is successful when the causal systems in question are consistent with people’s expectations that causal relationships are deterministic and that each pattern of observations has a single underlying cause. Our data are well explained by a Bayesian model that incorporates a preference for symmetric structures and a preference for structures that make the observed data not only possible but likely.

**Keywords:** structure learning, causal learning, Bayesian modeling

Causal networks have been widely used as models of the mental representations that support causal reasoning. For example, an engineer’s knowledge of the local electricity system may take the form of a network where the nodes represent power stations and the links in the network represent connections between stations. Causal networks of this kind may be learned in several ways. For example, an intervention at station A that also affects station B provides evidence for a directed link between A and B. Networks can also be learned via instruction: for example, a senior colleague might tell the engineer that A sends power to B. Here, however, we focus on whether and how causal networks can be learned from observational data. For example, the engineer might infer that A sends power to B after observing that A and B are both inactive during some blackouts, that B alone is inactive during others, but that A is never the only inactive station.

A consensus has emerged that causal structure learning is difficult or impossible given observational data alone. For example, Fernbach and Sloman (2009) cite the results of Steyvers, Tenenbaum, Wagenmakers, and Blum (2003), Lagnado and Sloman (2004), and White (2006) to support their claim that “observation of covariation is insufficient for most participants to recover causal structure” (p 680). Here we join Mayrhofer and Waldmann (2011) in challenging this consensus. We show that people succeed in a structure learning task when the causal systems under consideration are aligned with intuitive expectations about causality. Previous studies suggest that people expect causal relationships to be deterministic (Schulz & Somerville, 2006; Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2008), and expect that any pattern of observations tends to be a consequence of a single underlying cause (Lombrozo, 2007). We ask people to reason about systems that are consistent with both expectations, and find that structure learning is reliably achieved under these conditions.

A previous study by White (2006) asked participants to learn the structure of deterministic causal systems from observational data alone. The structures involved were five-node

networks where the nodes represented population levels of five different species. White’s task proved to be difficult, and performance was poor even when White gave his participants explicit instructions about how to infer causal structure from observational data. Here, however, we demonstrate that both structures considered by White can be reliably learned in the context of the experimental paradigm that we develop.

Given that humans perform well on the structure learning tasks that we consider, it is natural to ask how this performance is achieved. Mayrhofer and Waldmann (2011) propose that learners rely on a “broken link” heuristic and identify the structure that minimizes the number of cases where a cause is present but an effect is absent. They contrast their heuristic-based approach with Bayesian accounts of structure learning that rely on patterns of conditional independence between variables. We propose a Bayesian account that falls in between these two alternatives. Like Mayrhofer and Waldmann, we believe that models which track patterns of conditional independence are often too powerful to capture the inferences made by resource-bounded human learners. Unlike Mayrhofer and Waldmann, we argue that a Bayesian approach is nevertheless useful for explaining why humans succeed in the tasks that we consider. In particular, we show that human inferences are influenced by two factors that are naturally captured by the prior and the likelihood of a Bayesian model—a preference for symmetric structures, and a preference for structures that explain the observed data without needing to invoke coincidences. We demonstrate that incorporating these factors allows a Bayesian model to account for our data better than an approach that relies on the broken-link heuristic alone.

## Bayesian Structure Learning

The causal systems that we consider are simple activation networks. Each network can be represented as a graph  $G$  which may include cycles. Figure 1a shows one such graph and a data set  $D$  generated over the graph. Each row  $d_i$  in the data set  $D$  represents an observed pattern of activation—for example, the first row represents a case where nodes A, C and D are observed to be active and node B is observed to be inactive. We will assume that each row  $d_i$  is generated by activating a randomly chosen node then allowing activation to propagate through the network. For example, Figure 1b shows that if A is the randomly activated node, the final pattern of activation will match the first row of matrix  $D$  in Figure 1a.

The activation networks that we consider have three important properties. First, all causal links are generative, and these generative links combine according to an OR function. For example, node C in Figure 1a will be active if node A is

Figure 1: (a) A simple activation network and a data set  $D$  generated over the network. Each row of matrix  $D$  is an observation which indicates that some of the nodes in the network are active. (b) The first observation in (a) is generated when node A spontaneously activates and activation propagates through the network.

active or if node B is active. Second, all causal links are deterministic. Third, spontaneous activations are rare: at most one node in the network can spontaneously activate at any time, which means that each observed pattern of activation can be traced back to a single root cause. For example, the spontaneous activation of node A is the root cause of the activation pattern in the first row of matrix  $D$  in Figure 1a. Our assumptions that causes are rare and have deterministic effects are conceptually related to the work of Lu et al. (2008) on “sparse and strong” priors for causal learning. Note, however, that our notion of rarity is different from their notion of sparsity. Their notion captures the expectation that each node in a causal graph is expected to have at most one strong cause, but ours captures the idea that each pattern of observations  $d_i$  is expected to have a single underlying cause. For example, the activation network in Figure 1a is inconsistent with their notion of sparsity, since A and B are both strong causes of C. This network, however, is consistent with our notion of rarity as long as the base rates of A and B are both very low, which means that at most one of these nodes will spontaneously activate at any time.

Because the networks we consider may include cycles, they are different from standard Bayesian networks. If desired, however, our activation networks can be represented as dynamic Bayesian networks where the cycles are unrolled in time (Rehder & Martin, 2011). For our purposes, however, it will be simplest to work with graphs that may include cycles.

Given a data set  $D$  generated from an unknown network  $G$ , a probability distribution over the possible networks can be computed using Bayes’ rule:

$$P(G|D) \propto P(D|G)P(G) = \left[ \prod_i P(d_i|G) \right] P(G), \quad (1)$$

where we have assumed that the rows  $d_i$  in the matrix  $D$  are independently generated over the graph. We will consider two versions of the prior  $P(G)$  and two versions of the likelihood term  $P(d_i|G)$ .

The first version of the likelihood term assumes that observation  $d_i$  resulted from the spontaneous activation of a single node in the graph. We sum over all nodes  $n$  that may have activated spontaneously:

$$P(d_i|G) = \sum_n P(d_i|G, n)P(n). \quad (2)$$

$P(d_i|G, n)$  is either 1 or 0 depending on whether  $d_i$  is the ob-

servation pattern produced by activating node  $n$  then allowing activation to propagate through the graph. The prior distribution  $P(n)$  is uniform, which captures the assumption that all nodes are equally likely to activate spontaneously. We refer to Equation 2 as the *probabilistic* likelihood.

The second version of the likelihood term depends only on whether observation  $d_i$  is consistent with  $G$ , and will be called the *logical* likelihood:

$$P(d_i|G) = \begin{cases} 1 & \text{if } d_i \text{ is consistent with } G \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

Observation  $d_i$  is consistent with  $G$  if  $d_i$  can be produced by activating some node in  $G$  and allowing activation to propagate through the graph.

The first version of the prior  $P(G)$  in Equation 1 corresponds to a uniform distribution over the full space of graphs. The second version captures a preference for graphs that are symmetric. Perceptual research has documented a preference for symmetric stimuli, and this preference can be viewed as an instance of a more general preference for stimuli that display “good form.” We hypothesized that a graph shows “good form” if many of its nodes play similar roles. For example, nodes A and B in Figure 1a play similar roles, and exchanging the labels on these nodes leaves the structure of the graph unchanged. The symmetry score of a graph can be formally defined as the number of graph automorphisms, or the number of node permutations that leave the structure of the graph unchanged. For a given number of nodes, the graph with no edges and the fully connected graph will share the highest possible symmetry score, because all possible node permutations leave the structure of these graphs unchanged. We used these symmetry scores to define a prior  $P(G) \propto s(G)$ , where  $s(G)$  is the symmetry score of graph  $G$ .

Combining the two likelihoods and the two priors produces a total of four different models. The “logical uniform” (LU) model produces a posterior distribution  $P(G|D)$  that assigns equal probability to all graphs  $G$  that are consistent with the data. The LU model is consistent with the broken link heuristic described by Mayrhofer and Waldmann (2011), which assesses how well graph  $G$  accounts for data  $D$  by counting the number of times that a parent node is active and a child node is inactive. In our setting, a graph is deemed consistent with data  $D$  if and only if the graph has a broken link count of zero. When applied to our experimental stimuli, the LU

model therefore makes identical predictions to a model which assumes that people choose a graph that minimizes the broken link count, and that people are indifferent among graphs that satisfy this criterion.

Like the LU model, the “probabilistic uniform” (PU) model assigns nonzero probability only to graphs that are consistent with the data. The PU model, however, allows for cases where a data set  $D$  is consistent with two graphs but better explained by one graph than the other. Consider a three-node problem where  $D$  includes 6 observations and where each observation indicates that nodes A, B and C are all active. The data are consistent with a causal chain where A sends an arrow to B and B sends an arrow to C. The data, however, are not typical of a chain, since the chain hypothesis requires the assumption that A spontaneously activated 6 times in succession, which seems like a big coincidence. The data are also consistent with a fully connected graph, and now no coincidence must be invoked, since all nodes end up active regardless of which node activates first. As this example suggests, comparing the logical models with the probabilistic models will allow us to evaluate whether people’s inferences depend on probabilistic factors like “degree of coincidence” that go beyond consistency with the data.

The “logical symmetry” (LS) and “probabilistic symmetry” (PS) models are directly comparable to the LU and PU models, except that they incorporate a preference for symmetric graphs. Comparing the symmetry models and the uniform models will allow us to evaluate whether people bring *a priori* expectations about the underlying structure to the task of structure learning.

## Structure learning experiment

We designed an experiment to explore whether humans are capable of learning the structure of an activation network given observational data alone, and to evaluate the four models just presented.

**Participants.** 36 members of the CMU community participated in exchange for pay or course credit.

**Design.** The experiment included 34 blocks, each of which included one or more observations generated over an unobserved network. 32 of the blocks involved networks with three nodes, and the final two blocks involved networks with five nodes. The *characteristic data set* for a network is a set of observations that result from spontaneous activations of each node in the network. Given any network with three nodes, there are 64 possible graphs, but the characteristic data sets for these graphs include only 9 qualitatively different types. Representatives of each type are shown in Figures 2a through 2i. Among the blocks of three-node networks, these nine types were each presented twice, making 18 blocks with three observations each. An additional nine blocks with six observations each were created by including two copies of a characteristic data set per block. Five additional blocks each had two or fewer observations, and are shown in Figures 2j through 2n. These 32 blocks were presented in random or-

der, followed by two final blocks for the five-node networks (Figure 5). These five-node networks are identical to causal structures previously studied by White (2006). The observations within all blocks were shown in random order.

**Materials and Procedure.** The nodes in each network appeared as rectangles on screen, and active and inactive nodes had different colors. Participants were told that these rectangles were detectors that “detect a rare type of particle called the mu particle.” Participants were told that the detectors were connected by directed satellite links, and that an “active detector always activates all detectors that it points to.” To reinforce this information, participants were given an example like Figure 1 where they observed a single detector activating and activation subsequently propagating over the network.

Participants then worked through the 34 blocks. Within each block the observations were presented one at a time. After seeing all observations for a given block, participants drew a graph on screen to indicate their best guess about the structure of the underlying network and rated their confidence in their guess on a seven point scale. To minimize memory demands, all observations within a block were retained on screen after being presented, which means that all observations were visible when participants reached the graph-drawing stage. Each previous observation appeared as a panel with detectors, and every edge that participants added during the graph drawing stage was simultaneously added to each of these panels. This design choice was intended to make it as easy as possible for participants to see whether the graph that they had drawn was consistent with all observations for that block.

**Results.** We focus first on results for the three-node networks. The first nine panels in Figure 2 show the most popular graphs for the nine characteristic data sets, and the remaining panels show results for the blocks with two or fewer observations. In each case the most common response is consistent with the data set, indicating that participants understood the task and were successfully able to discover causal structure given observational data alone. In particular, note that all 36 participants discovered the common effect structure in Figure 2d and the common cause structure in Figure 2f. Steyvers et al. (2003) found that these structures are difficult for learners to distinguish in a probabilistic setting, but our data suggest that they are easy to learn in our deterministic setting.

Figure 2 also includes predictions of the PS model, and correlations between the model and the data are shown. Results for all four models across the first 32 blocks of the experiment are shown in Figure 3. The first correlation in each panel shows the performance of a model across the entire set of blocks, and the correlation in parentheses shows the average single-block correlation. The PS model performs best overall, suggesting that the probabilistic likelihood and the symmetry prior are both required in order to capture human judgments. A bootstrap analysis indicates that the overall and average single-block correlations achieved by the PS model are reliably higher than the correlations achieved by the PU

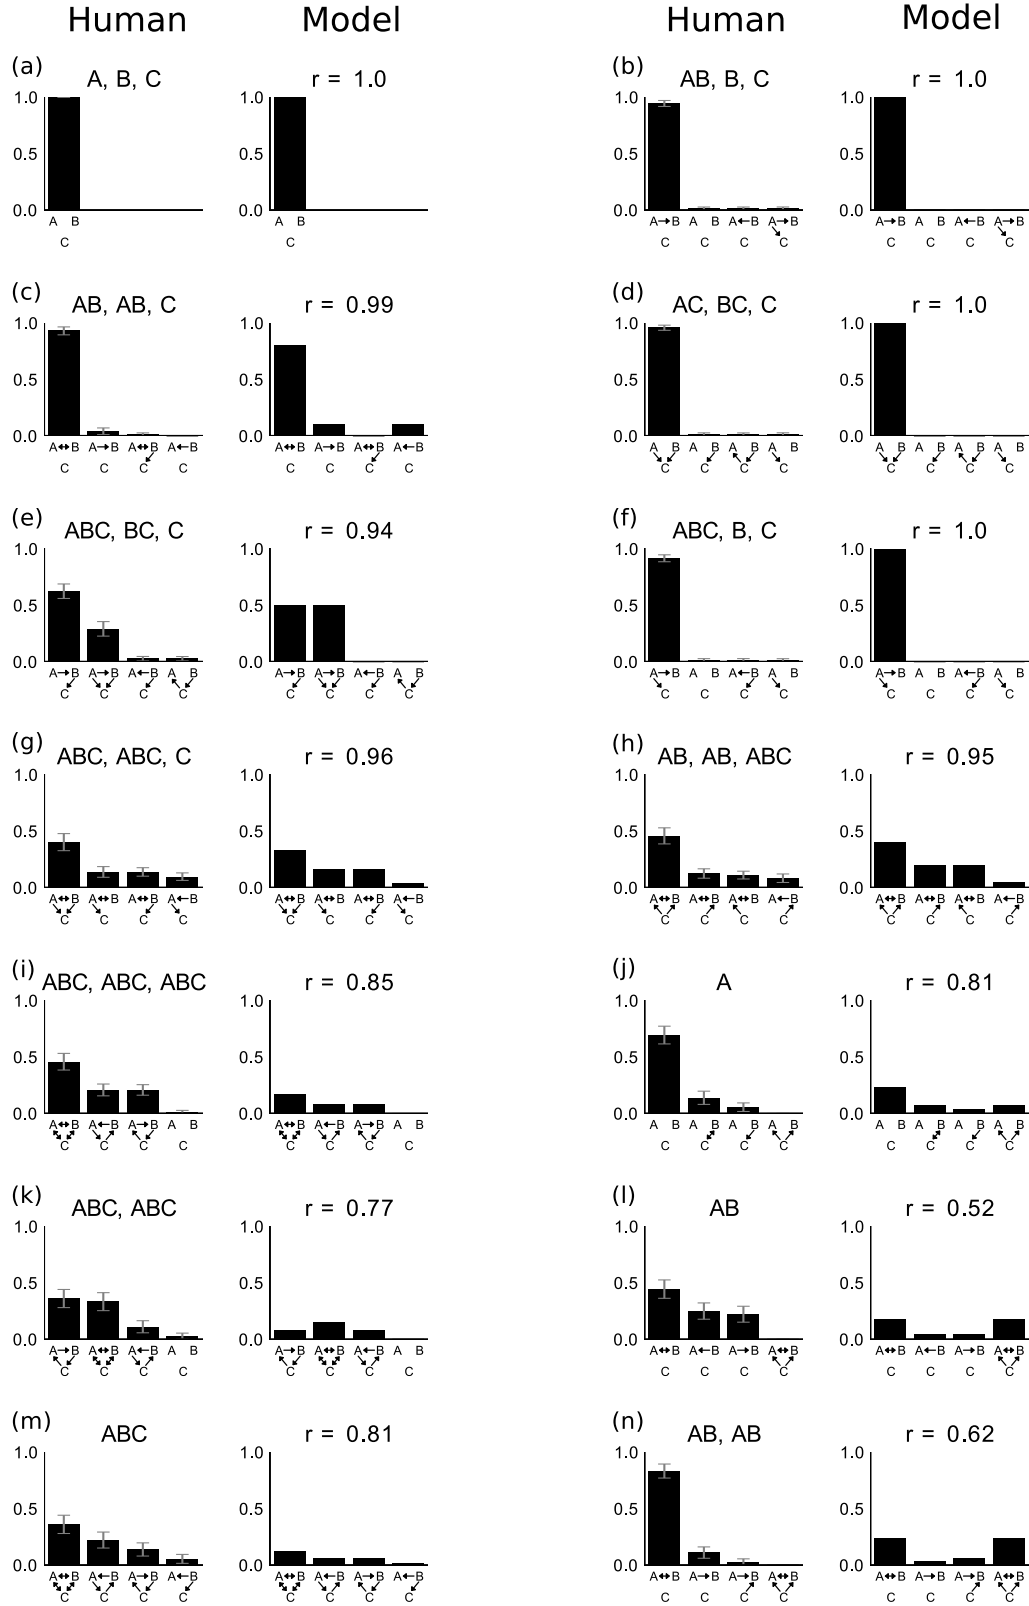

Figure 2: Participant responses and predictions of the PS model for 14 patterns of observations. The observed data are shown above the left plot in each panel, and the correlation between model predictions and human responses is shown above the right plot. The four structures in each plot always include the top two structures chosen by humans and the two most probable structures according to the model.

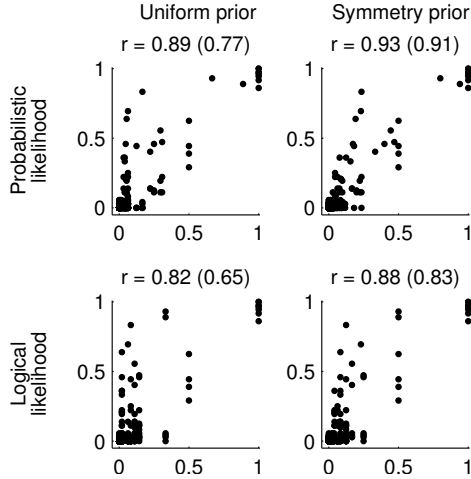

Figure 3: Comparison of the complete set of responses for the first 32 experiment blocks with the predictions of four models. The first correlation in each panel shows correlations based on the complete set of responses, and the correlation in parentheses shows the average correlation across the 32 individual experiment blocks.

and LS models ( $p < 0.01$  in all cases).

The main shortcoming of the logical likelihood is that it leads to predictions that are too diffuse. The structure preferred by participants is typically one of the most probable structures according to the LU model, but the model often assigns the same probability to many other structures. For example, after observing “ABC” three times in succession, the LU model assigns the same probability to all 51 structures that can generate the observation “ABC,” including causal chains over these variables. In contrast, the PU model assigns highest probability to the 18 structures that can *only* generate the observation “ABC.”

Although the PU model performs better than the LU model, its predictions are still more diffuse than the human responses. As just mentioned, the PU model predicts that 18 different structures are equally likely after observing “ABC” three times, but participants overwhelmingly prefer the top three structures shown in Figure 2i. The symmetry prior allows the PS model to capture this preference: note that the fully connected graph is the most symmetric structure that can only generate “ABC,” and the two cycles are the next most symmetric structures that meet this criterion.

To further evaluate the difference between the probabilistic and the logical likelihood, we examined the learning curves that result when the same observation is presented multiple times. The 34 blocks in the experiment include blocks where observation “ABC” is presented once, twice, three times, and six times. Figure 4b shows model predictions for these four blocks, where each bar represents the probability mass assigned to structures that can only generate “ABC.” The learning curves for the LU and LS models are flat—these models

Figure 4: Inferences after observation ABC is presented one, two, three or six times. (a) Proportion of structures chosen by humans that can only generate observation ABC (top); Average confidence ratings (bottom). (b) Probability assigned to structures that can only generate ABC by four models.

are sensitive to whether or not a structure is consistent with an observation, but the number of times that the observation appears is irrelevant. In contrast, the PU and PS models become increasingly confident that the underlying structure can only generate the observation “ABC.” Figure 4a indicates that participants show a similar learning curve, and become increasingly confident in their responses as the number of observations increases. Bootstrap analyses indicate that the differences between the first and the final bars are statistically significant for both plots in Figure 4a ( $p < 0.001$ ).

Figure 5 shows the most popular graphs chosen for the two five-node blocks. Each set of observations is consistent with only one structure, and participants were reliably able to discover these structures. Figure 6 compares our results to those reported by White, who found that relatively few participants were able to discover these five-node structures. There are at least two reasons why these tasks may have produced different results. First, our particle-detector scenario may be more intuitive than White’s task which required inferences about changes in the populations of species over time. Second, we asked participants to reason about the five-node structures following 32 inferences about three-node structures, which means that practice and familiarity with the task may have contributed to their performance. Future studies are needed to isolate the critical differences between these paradigms, but for now we can conclude that there are conditions under which people reliably discover White’s five-node structures from observational data alone.

Taken overall our results support two general conclusions. First, humans succeed at structure learning when causes are strong and when each observation has a single root cause. Because our cover story made these conditions quite clear, our data suggest that people reason accurately about deterministic systems where causes are rare, but not that people sponta-

Figure 5: Data sets, human responses and model predictions for the final two experiment blocks. All four models make the same prediction, because in both cases only one structure is consistent with the observations.

Figure 6: Comparison between our results and results reported by White (2006). The bars show the proportion of participants who successfully learned the five-node structures S1 and S2.

neously bring these assumptions to causal learning problems. Previous studies, however, suggest that both the determinism assumption and the rarity assumption may both apply more generally (Lu et al., 2008; Lombrozo, 2007)

The second general conclusion is that structure learning in our task cannot be adequately characterized as a search for a structure that is consistent with the observed data. At least two additional factors play a role: humans are sensitive to whether or not the observed data are typical of a given structure, and humans have *a priori* preferences for certain kinds of structures including symmetric structures. The PS model illustrates that these factors can be captured by the likelihood and prior of a Bayesian model, and demonstrates the value of the Bayesian approach to structure learning.

## Conclusion

Previous studies have found that structure learning from observational data is difficult. In contrast, our data suggest that humans find structure learning relatively easy in settings where causes act deterministically and where each observation has a single root cause. Future studies can consider relaxations of these conditions and explore whether humans still succeed at structure learning when causes are strong but not fully deterministic, and when most but not all observations

have a single root cause.

Our data are consistent with the recent work of Mayrhofer and Waldmann (2011), who also report positive results for learning from observational data. Mayrhofer and Waldmann (2011) argue that humans succeed at structure learning by relying on simple heuristics, but we found that their “broken link” heuristic accounted less well for our data than a Bayesian model that incorporates a probabilistic likelihood term and a symmetry-based prior. There may be alternative heuristics that can implement the computations required by our Bayesian model, but we believe that any successful account of our data will need to incorporate an *a priori* preference for symmetric structures, and a preference for structures that make the observed data not only possible but likely.

**Acknowledgments.** We thank Alan Jern for assistance with the experiment. This work was made possible by a training program in Neural Computation that was organized by the Center for the Neural Basis of Cognition and supported by NIH R90 DA023426.

## Abstract

Task-irrelevant stimuli are later recognized at enhanced levels providing that they had previously appeared with a task-relevant target (Dewald & Sinnett, submitted; Seitz & Watanabe, 2003, 2005). The present investigation explores this notion in the auditory sensory modality. Participants listened to a stream of auditory sounds and spoken words with the instruction to detect repetitions in only the sound stream (i.e., ignore the words). A surprise test measured recognition for the previously played words. Overall, when comparing target-aligned and non-aligned information in a later recognition task, facilitation was observed for words that had been aligned with target repetitions, despite equal presentation frequency and being irrelevant to the primary repetition task. This enhancement was mediated by the sensory modality of presentation in the surprise recognition task. Congruent auditory presentations between the exposure and recognition tasks yielded improved performance, and under cross-modal presentations the magnitude of the enhancement was greatest.

## Introduction

An emerging body of research has explored how unattended information (explicitly or implicitly presented) that appears simultaneously with a task-target in a separate task is later recognized in a subsequently presented surprise recognition test (Dewald, Sinnett, & Doumas, 2011; Seitz & Watanabe, 2003, 2005; Swallow & Jiang, 2010, 2011; Tsushima, Sasaki, & Watanabe, 2006; Tsushima, Seitz, & Watanabe, 2008). These investigations have generally consisted of a primary task involving visually presented task-relevant and previously irrelevant stimuli, with a later surprise recognition test for the irrelevant stimuli. Collectively, the findings suggest that the task-irrelevant stimuli are indeed processed, as long as they were previously aligned with a task-relevant target. However, two opposing patterns have been observed, with facilitatory (see for example Seitz & Watanabe, 2003; Watanabe, Nañez, & Seitz, 2001) or inhibitory (see for example Tsushima et al., 2006, 2008) effects for the previously aligned, but irrelevant material, seemingly dependent on whether it had originally been presented below or above, respectively, the threshold for conscious awareness.

Seitz and Watanabe (2003) required participants to identify differently colored target letters in a rapid serial visual presentation (RSVP) of the letters. Importantly, an array of randomly moving dots (irrelevant to the task) was

presented in the background during the letter identification task, of which a small subset moved coherently. Despite the coherent motion being implicit (i.e., participants were unable to reliably detect the coherent motion), participants were proficient at discriminating the motion (still presented below threshold) in a later discrimination task as long as it had previously been exposed simultaneously with the presence of a differently colored target letter during the identification task.

It is important to note that the initial motion presentation was implicit. This is a key point, as when presenting the coherent motion above threshold (i.e., 50% of the dots moved coherently), Tsushima et al (2008) showed an inhibition for target-aligned motions. Thus, it appears that facilitatory and inhibitory effects might be dependent on whether the initial presentation was presented below or above threshold, respectively.

As the majority of this research has used a relatively non-complex and simple stimuli (e.g., coherent motion in an array of moving dots), we recently examined (see Dewald et al., 2011) how a more salient stimulus, but irrelevant to the primary task, might affect later processing during an adapted inattention blindness (IB) task (see for example Rees, Ruth, Frith, & Driver, 1999; Sinnett, Costa, & Soto-Faraco, 2006). Participants were required to monitor a stream of pictures that had written words superimposed on top of each image, and respond to immediate repetitions in the picture stream while ignoring the word stream. A subsequently presented surprise recognition test for the previously ignored words demonstrated that words that had been temporally aligned with the presence of a task-target (i.e., an immediately repeating picture) were recognized significantly below chance levels (i.e., inhibited), while words that had been temporally aligned with non-targets (i.e., a non repeating picture) were recognized at chance levels.

It is important to note that the highly salient stimuli (written words) were presented for 350 ms (i.e., more than enough time for explicit perception). However, the aligned words were nonetheless inhibited in a later surprise recognition test. This finding dovetails with the earlier described findings by Tsushima et al (2008), who used target-aligned coherent motion as a stimulus and observed an analogous inhibition of motion discrimination for target-

aligned motions. That is, the coherent motion was also presented above threshold.

Other experimental paradigms have utilized different approaches to further investigate the way that the temporal alignment of task relevant and irrelevant information affects the later recognition of the irrelevant stimuli. Interestingly, despite the explicit presentation of their stimuli, the opposite findings, have been demonstrated, with a facilitation being observed for seemingly analogous conditions that elicited an inhibition. For instance, Swallow and Jiang (2010; see also Lin et al, 2010) completed a series of experiments suggesting an “attentional boost” (i.e., facilitation) for simultaneously presented, suprathreshold information in a dual-task paradigm. Participants monitored a stream of pictures of various scenes, while a series of items (small black superimposed shapes) was simultaneously paired with the presentation of each picture. The task was to remember as many of the presented scenes as possible, in addition to monitor the distractor stream of shapes for the presence of a color change. In a subsequent forced choice recognition test for the picture scenes, an enhanced recognition for pictures that had been previously presented simultaneously with the presence of a target (i.e., differently colored shape) in the distractor stream was observed.

Of particular note to Swallow and Jiang’s (2010) findings is that participants were required to attend to *both* streams of information simultaneously. Recall that in the paradigms utilized by Dewald et al (2011) and Tsushima et al (2006, 2008), participants were instructed to detect a target in one stream, but explicitly instructed not to attend to the other stream of irrelevant information, which constituted the information to be recognized in the subsequent surprise test. The division of attention between both streams of information in Swallow and Jiang’s paradigm could be the reason why a facilitation was observed in their results, rather than an inhibition.

A recent investigation by Dewald and Sinnett (submitted) aimed to more closely align their paradigm with the original procedure used by Tsushima et al (2006; see also, Seitz & Watanabe, 2003; Watanabe et al, 2001). In their experiment the exact same motion was paired with all of the target letters. This is different from the paradigm used by Swallow and Jiang (2010) or Dewald et al (2011), where a number of different pictures or words (irrelevant items in the primary task, but the items of interest in the subsequent recognition test), respectively, were aligned with targets in the primary task. In fact, the initial paradigm used by Dewald et al (2011) had 50 different words serving as the irrelevant stimuli during the picture repetition detection task. Therefore, in our subsequent work (Dewald & Sinnett, submitted) this relatively infrequent exposure rate (each of the 50 aligned words was presented only four times) was increased to an exposure rate more similar to Tsushima et al (2006, 2008). Accordingly, only a single word was aligned with all of the targets from the primary task of detecting picture repetitions. This enabled the number of instances that this task-irrelevant word was presented to be greatly

increased (from two times per word per participant, to 120 times). If the premise is that explicit information is later inhibited during a recognition task if it had been aligned with a task-relevant target, then an inhibition should have been observed for these items, especially given that the paradigm better replicated the original work demonstrating such an inhibition by Tsushima et al (2006). However, a facilitation for aligned words was seen, suggesting that the relationship between inhibition and facilitation is more complex than just whether the previously aligned stimuli were explicitly or implicitly presented. It is likely possible that the salience of the stimuli is also important, as an ignored written word is arguably processed to a higher level (i.e., semantically) than the ignored coherent motion of a moving array of dots.

Assuming that the facilitatory effect for explicitly presented, but ignored, stimuli is driven by whether the irrelevant stimulus is temporally aligned with the presence of a task-relevant target, it is important to extend these results to other sensory modalities. Despite vision being the dominant sense in humans (Chandra, Robinson, & Sinnett, 2011; Colavita et al., 1974; Posner et al., 1980; Sinnett et al., 2007), it is clear that the human perceptual experience is a result of multisensory information. Thus, it is important to explore if these inhibitory and facilitatory effects extend to other sensory modalities, as this will further inform how information is processed both within, and across modalities. For instance, Sinnett et al. (2006) demonstrated that when attentional reservoirs were depleted by a primary task, inattention blindness for spoken word perception was interrupted to the same degree as visual word recognition, however performance improved under multimodal conditions. Furthermore, a recent investigation by Dewald and Sinnett (2011a) extended this finding to the auditory modality by including an additional analysis for items that had previously appeared simultaneously with targets in the separate task. In this case, an inhibition for spoken words (explicitly presented) was observed. However, it should be noted that this investigation also used a large number of auditory words as irrelevant stimuli (i.e., identical to the visual paradigm incorporated in Dewald et al., 2011), therefore it is unknown if the inhibition for target-aligned stimuli will extend to conditions with an increased exposure rate (i.e., similar to the visual condition of Dewald & Sinnett, submitted; see also Tsushima et al., 2006, 2008).

Addressing precisely this, we adapted the same paradigm utilized in Dewald & Sinnett (submitted) to an auditory presentation, with the primary task to detect target repetitions in the sound stream, and the secondary task to subsequently recognize the previously ignored words that had been played simultaneously with the sounds. Critically, only one specific spoken word was presented to participants. This increased exposure rate lead to an enhanced performance rather than inhibited (i.e., akin to the attentional boost observed by Swallow & Jiang, 2010). If visual findings (Dewald & Sinnett, submitted) extend to the auditory modality, then we predict that the higher exposure

rate of the irrelevant spoken word will lead to a later facilitation in recognition for that word, as long as it had appeared simultaneously with an attended target in the previous task<sup>1</sup>.

A separate but equally important aspect of this research explores the modality in which the surprise test is presented. The use of dual task paradigms is pervasive in the cognitive sciences. For instance, seminal studies on dichotic listening (Broadbent, 1958; Treisman, 1964) presented participants with orthogonal messages to each ear, with the instruction to only direct their attention to a single channel of information. After this initial task, an unexpected test was given to assess the ability to recognize or recall the information that had been presented previously at the ignored ear. Of key importance here is the consideration of the sensory modality that the surprise test was presented in, respective of the initial exposure during the primary task. For instance, in these classic studies, the surprise test that probed participants' ability to process the originally presented irrelevant information was always given in the same modality as the original presentation during exposure in the primary task (auditorily).

To the best of our knowledge, this congruency in modality presentation between exposure and recognition tests has never been systematically manipulated. Therefore, given the recent interest in extending inattention blindness (see Sinnett et al., 2006) and target-alignment findings (see Dewald & Sinnett, 2010, 2011a,b) to the auditory modality and across modalities, it is important to explore how presenting the surprise test in a congruent modality would affect results, if at all. Thus, in addition to the aforementioned goals of extending this paradigm to the auditory modality and incorporating a higher exposure rate, we also presented the surprise recognition test in the same or different sensory modality, or across modalities. If primary and secondary task modality congruence is a factor, then we would expect improved results for congruent matchings vs. incongruent matchings, and potentially an additional enhancement for multimodal presentations given that performance is generally enhanced for multisensory presentations (see Driver & Spence, 2004).

## Method

**Participants.** Fifty-one participants were recruited from the University of Hawai'i at Manoa in exchange for course credit. Each participant completed the same auditory repetition detection task, but were divided across three different types of surprise recognition tests: visual only ( $n=18$ ), auditory only ( $n=17$ ), or cross-modal ( $n=16$ ). Participants were naïve to the experiment and had normal or corrected to normal hearing.

**Materials.** A total of 16 one to two syllable, high-frequency English words (average length of 5 letters, range

of 4-6 letters) were selected from the MRC psycholinguistic database (Wilson, 1988). The overall average frequency of the 150 selected words was 120 per million, ranging between 28 and 686. A native English speaker's voice was recorded reading the list three times, after which three blind listeners chose the best exemplar of each spoken word (a fourth listener was recruited in order to break a tie when needed). The selected recordings were edited to have the same length of presentation (350 ms) and average amplitude. The sound stimuli were extracted from a database of 100 familiar sounds and were also edited to 350 ms and similar average amplitude (see Sinnett et al., 2006). A stream of 960 sound-word concatenated items was created. Repeated sounds acted as the task relevant-targets. The presentation stream was broken into eight blocks of 120 trials in which an immediate sound repetition occurred on average one out of every eight trials, equating to 15 task-relevant target repetitions per block.

Eight spoken words (of the original 16) were randomly selected to overlay the 960 trial sound stream. This was done to parallel the quantity of items and exposure to irrelevant stimuli (see Dewald & Sinnett, submitted; Tsushima et al., 2006) as well as the dependent measure employed by Dewald and Sinnett (submitted; i.e., the analogous experiment in the visual domain). The presentation was pseudorandomized so that on average one out of every eight trials was an immediate sound repetition (and therefore the presentation of the same superimposed task-irrelevant target word). Critically, only one superimposed spoken word was aligned with all of the immediately repeated sounds for each participant. This single word was randomized between the eight words between participants, so as to control for any possible differences that may have existed regarding the saliency of any particular word. Lastly, it is important to note that both aligned and non-aligned words were exposed to participants in equal amounts.

A surprise recognition test for the presented words was administered after the completion of the repetition detection task. The test consisted of a total of sixteen words from which half came from the previously heard sound stream, while the other half consisted of foil words that had never been heard before (average frequency of 236 per million with a range of 165-399). The word recognition tasks were randomized and presented by DMDX software (<http://www.u.arizona.edu/jforster/dmdx.htm>) one at a time, in either the visual or auditory modality, or across modalities. For the visual presentation the words were written in bold, capitalized letters in Arial font at a size of 24 points, and remained on the screen until a response was made. For auditory presentations the words were spoken just as they were in the initial repetition detection task, albeit without the accompanying sounds. The sound stream and relevant surprise tasks were presented from two external speakers, equidistant to the computer screen. Cross-modal presentations involved the written word on the screen with the spoken word presented simultaneously.

<sup>1</sup> Note, target aligned and non-aligned words were themselves exposed in equal proportions. The higher frequency relates to comparisons to previous, but analogous research (see Dewald et al., 2011; Dewald & Sinnett, 2011, submitted).

**Procedure.** Participants were required to attend to the sound stream (i.e., they were explicitly instructed to ignore the simultaneously presented, overlaid spoken words) and respond to immediate sound repetitions by pressing the ‘G’ key on the keyboard of the computer. Each item in the sound-word presentation was presented for 350 ms with a 150-ms inter-stimulus interval (ISI; silence) for a stimulus onset asynchrony (SOA) of 500 ms. Before the first experimental block, a training block of eight trials was given and repeated until participants were familiar and comfortable with the task.

Immediately after the repetition detection task, the surprise word recognition test was administered to all participants (modality type of surprise task dependent on condition). Participants were instructed to press the “B” key if they had heard the word during the repetition detection task or, instead, the “V” key if they had not heard the word before.

## Results

To assess whether recognition performance was modulated by target alignment or the modality of presentation of the surprise task, a two-way, repeated measures ANOVA was conducted, with surprise test modality (auditory, visual, or cross-modal) as a between-subjects factor, and target alignment (target-aligned or non-aligned) as a within subjects factor. A main effect for target alignment confirmed that, overall, word recognition performance was significantly better for *target-aligned* words (72.5%) when compared to *non-aligned* words (58.8%) ( $F(2, 48) = 3.54, p = .03$ ). No main effect was found for modality of presentation ( $F(2, 48) = 1.58, p = .211$ ). Additionally, and of key importance to this analysis, an interaction was observed between target-alignment and modality of presentation ( $F(2, 48) = 3.08, p < .05$ ), suggesting that the modality of presentation in the recognition task played a role in recognition performance between *target-aligned* and *non-aligned* words. To further explore this interaction, each surprise recognition condition (auditory, visual, or cross-modal) is individually analyzed below.

**Visual surprise recognition test (VR):** Overall task performance for the surprise test was 65.8%, which was statistically different from chance ( $t(46) = 3.08, p = .001$ ). More importantly, the recognition for the *target-aligned* words (61.0%,  $SE=.11$ ) was not statistically different from *non-aligned* words (61.5%,  $SE=.57; t(17) = .03, p = .97$ ; see Figure 2). Note that the overall performance was higher due to increased performance on correctly rejecting foils. The correct rejection of foil words was compared with overall performance for *target-aligned* and *non-aligned* words. There was a significant difference between recognition for *target-aligned* words and correct rejections (*target-aligned*: 61.0%,  $SE=.11$  vs. *CR*: 79.6%,  $SE=.04, t(17)=2.14, p = .02$ ) as well as a significant difference between correctly recognizing *non-aligned* words and correct rejections (*non-aligned*: 61.5%,  $SE=.57$  vs. *CR*: 79.6%,  $SE=.04, t(17)=2.47, p = .02$ ). Lastly, confirming that participants were able to successfully perform the initial repetition task, the target

repetitions were significantly detected (**Hits**: 68%  $SE=.18$  vs. **Misses**: 28%  $SE=.04, t(17)=9.42, p < .001$ ).

**Auditory surprise recognition test (AR):** Overall task performance was 71.0%, which was statistically different from chance ( $t(45) = 4.47, p = .001$ ). Contrary to the visual condition, recognition for *target-aligned* words (76.4%,  $SE=.10$ ) was significantly better than *non-aligned* words (58.8%,  $SE=.05, t(16) = 2.37, p = .05$ ; see Figure 1). Again, unlike the first experiment, there was no difference in performance between *target-aligned* word recognition and correct rejections of foils (*target-aligned*: 76.04%,  $SE=.10$  vs. *CR*: 77.7%,  $SE=.06, t(16)=0.09, p = .967$ ). However, there was a significant difference between *non-aligned* word recognition and correctly rejecting foil words (*non-aligned*: 58.8%,  $SE=.05$  vs. *CR*: 77.7%,  $SE=.06, t(16)=2.35, p = .03$ ). Lastly, participants accurately detected target repetitions (**Hits**: 73%  $SE=.10$  vs. **Misses**: 23%  $SE=.11, t(16)=8.47, p < .001$ ).

**Cross-modal surprise recognition test (CR):** Overall word recognition was 69.2%, which was statistically better than chance ( $t(43) = 4.28, p = .001$ ). Recognition for *target-aligned* words (81.2%,  $SE=.10$ ) was significantly better than *non-aligned* words (55.7%,  $SE=.05; t(15) = 2.59, p = .05$ ; see Figure 1). There was no difference in performance between *target-aligned* word recognition and correct rejections of foils (*target-aligned*: 81.2%,  $SE=.10$  vs. *CR*: 70.8%,  $SE=.06, t(15)=0.82, p = .422$ ). Again, however, there was a significant difference between *non-aligned* word recognition and correctly rejecting foil words (*non-aligned*: 58.7%,  $SE=.05$  vs. *CR*: 70.8%,  $SE=.06, t(15)=2.07, p = .05$ ). Additionally, participants accurately detected immediate sound target repetitions in the primary task (**Hits**: 75%  $SE=.13$  vs. **Misses**: 24%  $SE=.03, t(15)=9.23, p < .001$ ).

## Discussion

The present findings extend investigations exploring how above threshold, but unattended information is processed when it appears simultaneously with an attended target. We demonstrate that in all conditions, the overall recognition of the words in the surprise task was better than chance, despite attention not being directed to the words. This finding is contrary to what can be predicted from inattention blindness investigations in that the overall recognition of the words should have been at chance, or perhaps even inhibited for the irrelevant stimulus (Dewald et al, 2011; Rees et al, 1999; Sinnett et al, 2006). It is likely that the increased exposure to (i.e., fewer items) to the irrelevant stimuli drove this effect. More importantly, the interaction between target-alignment and the modality of the surprise test was significant, driven by performance for *target-aligned* words being statistically better than non-aligned words in the **auditory recognition** (76% vs. 58%) and **cross-modal recognition** (81% vs. 55%) conditions. Note, when comparing the magnitude of the enhancement between these two conditions, there was (no) additional improvement for cross-modal conditions. Accordingly, this suggests that, at least in the present case, temporally aligning explicitly presented, irrelevant, auditory stimuli with relevant auditory target stimuli facilitates subsequent recognition of the irrelevant stimuli, but only if the recognition test is presented in the same modality as the initial task, or across modalities. Thus, an “attentional boost” (see Swallow & Jiang, 2010) for irrelevant stimuli was observed, as long as they were initially presented simultaneously with a target in the picture repetition task, despite not receiving direct attention.

Interestingly, when the surprise recognition task was presented in an incongruent modality from the exposure (i.e., the visual surprise recognition task) there was no difference between *target-aligned* and *non-aligned* words. Previous findings have demonstrated an inhibition for both visually aligned (Dewald et al., 2011) and auditorily aligned words (Dewald & Sinnett, 2011a) in a dual-task paradigm, despite not controlling for task modality congruence (i.e., the visual example presented information in the congruent modality, while the auditory example also presented the surprise test in the visual modality). However, it should be noted that both of these examples used a much lower exposure rate (i.e., 50 words had been aligned in the repetition detection task rather than only one that was repeated 120 times). This could possibly explain why we failed to observe a difference in the visual task condition here.

Further complicating the matter, Dewald and Sinnett (submitted) observed an enhancement for target-aligned words under nearly isomorphic conditions as utilized here, with the only difference being that the initial repetition detection task was presented in the visual modality. In fact, all research conducted thus far, exploring the fate of irrelevant auditory words either target-aligned or not, has presented the words in the visual modality during the

subsequent recognition task (Dewald & Sinnett, 2011a; Sinnett et al, 2006; see Dewald & Sinnett, 2011b for a cross-modal example). It is possible that the incongruence between the modality of presentation and subsequent recognition may in some way affect the recognition of the previously unattended items. Thus, further research should explore whether the observed enhancement for visually aligned words when tested with a visually presented surprise task extends to incongruent task modality presentations (or across modalities).

In the present experiment the cross-modal presentation lead to the greatest magnitude of enhancement for the previously aligned words in the surprise recognition test. This aligns well with previous investigations of attentional allocation across sensory modalities in perceptual and recognition tasks, suggesting that cross-modal presentations generally lead to superior to performance when compared to unimodal presentations (Dewald & Sinnett, 2011b; Duncan, Martens, & Ward, 1997; Sinnett et al, 2006; Toro, Sinnett, & Soto-Faraco, 2005).

The possibility that the presentation modality of the surprise test could modulate performance has yet to be fully explored. The resulting recognition performance, observed when the surprise task was incongruent to the initial exposure, necessitates an investigation into the nature of modality congruence in dual-task paradigms. Clearly, the current findings establish that attention must be paid to future methodologies utilizing a dual-task paradigm and the implications of modality congruence between the primary and secondary task. Furthermore, previous investigations that employ incongruent modalities between exposure and recognition must be revisited (Dewald et al, 2011, Sinnett et al, 2006).

Combined, the present findings and previous research offer insight into how irrelevant information is processed when it is presented simultaneously with an attended target. Under certain circumstances, as demonstrated here (see also Dewald et al., 2011 Dewald & Sinnett, submitted; Seitz & Watanabe, 2003; Tsushima et al., 2008), unattended stimuli can be perceived and affect behavior. Here we extend findings from previous research into the auditory sensory modality, and show a facilitation (i.e., attentional boost) for a highly exposed stimulus that was aligned with a target in the previous task when compared with items that were not aligned. More importantly however, we demonstrate that careful consideration must be given to the modality of presentation of dual-task paradigms in general.

## Abstract

The widespread occurrence of ideophones, large classes of words specialized in evoking sensory imagery, is little known outside linguistics and anthropology. Ideophones are a common feature in many of the world's languages but are underdeveloped in English and other Indo-European languages. Here we study the meanings of ideophones in Siwu (a Kwa language from Ghana) using a pile-sorting task. The goal was to uncover the underlying structure of the lexical space and to examine the claimed link between ideophones and perception. We found that Siwu ideophones are principally organized around fine-grained aspects of sensory perception, and map onto salient psychophysical dimensions identified in sensory science. The results ratify ideophones as dedicated sensory vocabulary and underline the relevance of ideophones for research on language and perception.

**Keywords:** semantics; sensory vocabulary; ideophones; sensory perception; mental lexicon

## Introduction

Ideophones are marked words that depict sensory imagery, like *sinisinisini* 'closely woven' and *saaa* 'cool sensation' in Siwu, a language of Ghana (Dingemanse, 2011a), or *gorogoro* 'rolling' and *pikapika* 'shiny' in Japanese (Kita, 1997). These highly specific renditions of sensory perceptions — the precise texture of an object felt, the manner of motion of a figure, the visual appearance of a surface — are a common feature of many of the world's languages, with some languages having ideophone inventories numbering into the thousands (Doke & Vilakazi, 1953; Kakehi, Tamori, & Schourup, 1996); but they are underdeveloped in English and other Indo-European languages (Nuckolls, 2004).

The widespread occurrence in natural languages of large classes of words specialized for depicting sensory perception is of significance to research examining the relation between language and perception. Yet, so far, ideophones have been a secret well-kept from cognitive science, studied mostly in lesser known languages by field linguists and anthropologists (Nuckolls, 1996; Voeltz & Kilian-Hatz, 2001). Although the tight link between language and perception in ideophones has long been recognized (Westermann, 1927), the study of their semantic structure has lagged and important questions remain unanswered. What is the link between ideophones and sensory imagery? How should native speakers' knowledge of these sensory words be characterized? What aspects of sensory perception are involved in their representation in the mental lexicon?

Previous semantic classifications of ideophones fail to answer such questions because they usually do not represent native speaker knowledge but reproduce the linguistic categories of the analyst. An example is Alexandre (1966), who classified ideophones in Bulu (a Bantu language from Cameroon) into the five-senses folk model of his own native language: "auditive, visual, tactile, gustative, and olfactive". However, since sensory science shows a larger taxonomy of the senses (Moller, 2002) — including not just the external senses but also interoception (sensitivity to inner physiological conditions) and proprioception (sense of balance and body posture) — we cannot assume the universal relevance of a Western folk model of perception to the classification of ideophones. Other studies of the semantic structure of ideophones have used evidence from lexical collocations, inferring for instance the sensory modes of ideophones from the verbs with which they co-occur (Diffloth, 1976; Awoyale, 1983). Such methods are likely to provide more insight than classifications based on analysts' intuitions, but since the verbs may underspecify the semantic space and since not all ideophones appear in regular collocation with verbs, they may provide an incomplete picture.

Recently, some studies have begun to investigate the semantic structure and sound-symbolic nature of ideophones in Japanese. In a learning study with infants, Imai et al. (2008) built novel words on the template of Japanese ideophones ('mimetics') for manners of motion, and found that these sound-symbolic forms facilitate early verb learning. Osaka (1990) investigated Japanese ideophones of crying, laughing, and talking using a similarity judgment task and found they could be arranged on sensory scales of intensity. In a follow-up study, Osaka and Osaka (2005) focused on laughter ideophones using fMRI, and found they activated striatal reward areas, which they connect to the image-evoking qualities of ideophones. Although interesting in their own right, none of these studies address the domain of ideophones as a whole, nor do they articulate what the principles of organization within this domain might be. Here we study a representative set of ideophones from Siwu, a Kwa language spoken in Ghana, West Africa — a linguistic region known for its extensive ideophone systems (Blench, 2010). The aim was to explore the semantic structure of the domain by capturing native speakers' intuitions.

How might ideophones be organized in the mental lexicon? One possibility is that ideophones are organized in terms of sensory perception (Kita, 1997). Another possibility is that they are organized in terms of semantic dimensions like activity, potency and evaluation, factors

commonly found in multidimensional scaling analyses of affective vocabulary (Osgood, Suci, & Tannenbaum, 1957; Osaka, 1990). A third possibility is that both principles operate, with dimensional and categorical properties working in parallel, perhaps at different levels of granularity. In order to test these hypotheses, we obtained similarity judgments of ideophones using a pile-sorting task.

Another matter of investigation concerns the nature of ideophones as sensory vocabulary. Work in the domain of touch for instance has identified psychophysical dimensions such as rough-smooth, hard-soft, springiness, and firmness (Yoshida, 1968). We considered how the distinctions encoded by ideophones map onto these dimensions, and what this may reveal about ideophones as sensory words and about the construction of sensory vocabularies in general.

## Methods

We used a pile-sorting task (Bernard, 2006; Weller & Romney, 1988) to collect similarity data for a frequency-based selection of 58 ideophones. Sorting tasks have been conducted with a wide variety of items, from English nouns (Miller, 1969) and texture words (Bhushan, Rao, & Lohse, 1997) to Navaho food concepts (Perchonock & Werner, 1969). Hierarchical clustering and multidimensional scaling were used to analyze the similarity data to uncover the underlying dimensions used to categorize the items.

## Participants

Fourteen participants (ten men), with a mean age of 37.1 years, took part in the sorting task. All were native speakers of Siwu. All were literate in Siwu and in Ewe, a regional language of wider communication.

## Materials and design

Ideophones are a class of words distinct from nouns and verbs in the Siwu language. They are formally identifiable in terms of phonotactics, word forms, expressive morphology, syntax, and prosody (Dingemanse, 2011b, pp. 133–160). There are at least 400 ideophones in Siwu. It would clearly be difficult to investigate all ideophones in a single sorting task. A selection of ideophones was therefore made using frequency as a criterion, since this is one measure of the representativeness of the ideophone inventory.

A total of 58 ideophones were selected as follows: a first selection included all ideophones which occurred at least twice in a corpus of five hours of naturally occurring conversations recorded in informal situations (Dingemanse, 2011b). There were 38 such ideophones. A second selection included ideophones which occurred more than three times in responses to elicitation tasks probing different perceptual domains (Majid & Levinson, 2007, 2011). There were 26 such ideophones. Discounting overlaps between the two sets left 20 new ideophones, bringing the total at 58 (Table 1). Each of the 58 ideophones was printed on a 105x35mm card in Siwu orthography.

## Procedure

The cards were presented to participants in a 6x10 array arranged according to a fixed random order. While laying the cards out, the ideophones were read out-loud to make sure they were familiar to participants. Three items, *belele*, *lelele*, and *melemele*, were not always recognized immediately. When this happened, the ideophones were presented in an example sentence from the conversational corpus. Participants were always able to recognize the words in context.

Instructions were given in Siwu: participants were asked to arrange the cards into groups of similar items. The instruction was to “place together words that belong together, words that are akin” (*atɔ̃mɛ wa lõkote, wa lõde manyibi*). Participants were given no explicit criteria for judging similarity and were told they could create as many piles as they liked with as many items per pile as they wished. For three participants who asked for clarification, the sorting procedure was demonstrated using ideophones not included in the set.

Cards were not literally piled but grouped together on a flat surface so all items were kept in view. Participants took between 30 and 70 minutes to group all 58 ideophones. Once participants had completed their groupings, they were debriefed and asked to describe each group.

Table 1: Siwu ideophones used in the sorting task

## Results

Dissimilarity matrices were created for each participant and then summed to create the equivalence matrix used for statistical analysis.

### Cluster analysis

Hierarchical cluster analysis of the data was performed using the average-linkage-between-groups method, which does not presuppose a particular type of structure in the data. Figure 1 below shows the dendrogram for the cluster analysis.

Figure 1: Dendrogram using average linkage

All clusters with a relatively high internal similarity (distances of 10 or lower) can be identified in terms of aspects of sensory perception: SWEET, TASTE, SURFACE APPEARANCE (including COLOUR), VIOLENT IMPACT (including COLLISION), TOUGHNESS, ROUGH, SMOOTH, SOFT, ROUND, ELONGATED, WET CONSISTENCY, SILENCE, EXTENT,

MANY and SMALL. Many of these clusters also join to form coherent higher-order groups. Such higher-order clusters (distances of 20 or lower) include MOUTH-FEEL (merging SWEET and TASTE), SOUND, STRENGTH, HAPTIC TOUCH (merging GRAININESS, SURFACE TEXTURE, and MALLEABLE), SHAPE (merging ROUND and SPATIAL EXTENT), and four clusters that are extended with one member each: WET CONSISTENCY, QUIET, QUANTITY, and SIZE. There is a small residue of words that were rarely grouped with other words, or grouped in very different ways by participants.

The cluster analysis showed two main things. First, it showed that sensory perception is the most salient organizing principle in the domain. This is confirmed by the descriptions given by participants in the debriefing; participants explained their groupings in terms of sensory modalities or acts of sensory perception. Second, it identified a number of coherent sensory categories (and interrelations between categories) at a finer grain than traditional five-senses classifications, providing insight into the different kinds of sensory imagery encoded by ideophones.

### Multidimensional scaling

Multidimensional scaling was used to test whether similarity judgments from ideophones were organized in terms of the three well-known dimensions of affective meaning: activity, evaluation and potency (Osgood et al., 1957; Osaka, 1990). A three-dimensional MDS solution showed an RSQ of .80 and a Kruskal stress value of .21 (for 2 dimensions stress was .27, while for 4 dimensions it was only slightly lower at .20). Within the MDS analysis, the major groups identified by the cluster analysis remain largely intact. This lends additional credibility to the sensory categories identified there and to the interpretation that aspects of sensory perception are an important organizing principle in the domain of ideophones.

Does the MDS analysis additionally support a dimensional interpretation? Dimension 1 features TASTE and SHAPE on opposite poles, reinforcing the strong internal coherence of these clusters and their mutual incompatibility in terms of sorting decisions. It does not easily yield a simple dimensional interpretation. Dimension 2 pulls apart a cluster of SOUND ideophones on one side with SURFACE APPEARANCE on the other. While this might be construed as an opposition of events versus states, suggestive of the dimension of activity, it is more plausible that, just as in Dimension 1, these particular clusters are pulled apart simply as a result of their high internal coherence coupled with their semantic incompatibility. The cluster analysis supports this interpretation.

The connotative dimensions of evaluation (good/bad) and potency (strong/weak) do not seem to play a role either. For instance, if evaluation were relevant, we might expect ideophones like *buàà* 'tasteless' and *nyanyarĩĩ* 'dirty' to cluster together, and to be far apart (on one dimension) from ideophones like *mêrêmêrê* 'delicious' and *nyêkênyêkê* 'intensely sweet', but this is not the case. If potency were

relevant we might expect ideophones that differ mainly in terms of intensity to be distant from one another, but they are not.

The nature of the clusters identified both in the cluster analysis and the MDS analysis provides a likely explanation of why the generic connotative dimensions may be absent. The clusters concern aspects of sensory experience from a diverse range of modalities. The sensory modalities differ in discrete, qualitative ways, and this appears to be reflected in our findings.

## Discussion

### Ideophones as dedicated sensory words

Our results suggest that sensory perception is the main organizing principle in the lexical domain of ideophones, despite other plausible organizing principles. As noted, one might expect generic dimensions commonly found in semantic differential studies to be apparent in this domain. Alternatively, sorting could be done on the basis of other principles, such as word length (grouping *saaa* ‘cool sensation’ with *kpoo* ‘silence’ or *tagbaraa* ‘long’ with *pəkəsəə* ‘slow’) or similarity in sound or spelling (*giligili* ‘circular’ with *gelegele* ‘shiny’). Neither the generic dimensions nor the non-semantic features play an appreciable role in the similarity data. This provides independent confirmation of claims made in the anthropological and linguistic literature that ideophones are dedicated sensory words. It also meshes well with empirical findings on the use of ideophones. Data from a corpus of everyday conversations shows that Siwu speakers use ideophones to demonstrate expertise (communicating very precisely about perceptual qualities) and also to share in sensory spectacles in storytelling (Dingemanse, 2011b, pp. 251–300). Both uses rely on the nature of ideophones as marked words that depict sensory imagery.

Previous explorations of the semantic domain of ideophones have mostly relied on informal judgments by the analyst. There is a danger that they do little more than reproduce folk models of the analysts’ metalanguage. In contrast, the sorting task allows us to capture a semantic-perceptual space based on native speaker judgments. The fine-grained categories that emerged from the cluster analysis (for instance FIRMNESS, SMOOTHNESS, or SURFACE APPEARANCE) are anchored in the data and agree with speakers’ own explanations of their groupings. Therefore they have a different ontological status than coarse-grained labels like Alexandre’s (1966) five-sense classification of ideophones. Moreover, the cluster analysis brings to light structures that do not easily fit into such broad classifications: categories that may combine content from multiple modalities (e.g. WET CONSISTENCY, which may combine vision and touch), or categories at a finer grain (as in the subcategories of HAPTIC TOUCH, which include SURFACE TEXTURE, MALLEABILITY and GRAININESS).

### Sorting task reproduces psychophysical dimensions

The clusters related to haptic touch provide a useful illustration of the nature of ideophones as sensory vocabulary. Ideophones encoding haptic touch sensations are common in Siwu (Dingemanse, 2011a), and are accordingly well-represented in the frequency-based selection of ideophones used in the sorting task. Independently, we know that Siwu speakers describe tactile stimuli predominantly with ideophones (Dingemanse, 2011b).

Psychophysical research in the domain of haptics has identified a number of salient dimensions of touch perception: rough-smooth, hard-soft, springiness, sticky-slipperiness, and firmness (Yoshida, 1968; Guest et al., 2010; Klatzky, Lederman, & Reed, 1987). The clusters identified through the cluster analysis correspond to these dimensions quite closely: we find ROUGHNESS, SMOOTHNESS, SOFTNESS, MALLEABILITY (the equivalent of springiness), and FIRMNESS. So the distinctions encoded by texture ideophones appear to map well onto the psychophysical properties of the domain.

What is it that makes ideophones good at encoding fine semantic distinctions in ways that reproduce psychophysical dimensions? One reason may be the nature of ideophones as a form class in natural languages. Guest et al. (2010) studied English texture words in order to develop a touch lexicon. They considered a mix of adjectives (rough, soft), verbs (burning, vibrating), terms derived from verbs (sticky, prickly), and source-based adverbs that use simile (sandy, woolly, furry). They found that when the set of words was systematically narrowed to improve the coverage of the touch lexicon, many of the source-based terms were removed, suggesting that abstract (i.e. non-source-based) terms and uniformity in linguistic resources may lead to a better coverage of the semantic-perceptual space. These two features, abstractness of meaning and uniformity of linguistic form, are precisely characteristic of ideophones.

Another reason may be that ideophones are special in their mode of signification. Across languages, ideophones tend to be produced with prosodic foregrounding and expressive features like reduplication and lengthening: signs of the fact that they are depictions, as opposed to descriptions, of sensory imagery (Kunene, 1965; Nuckolls, 1996; Dingemanse, 2011a). Being depictions, ideophones often employ several forms of sound-symbolism or iconicity (Westermann, 1927; Diffloth, 1972; Awoyale, 1983). The iconic use of verbal material, more gradient and less arbitrary than ordinary words, may make ideophones especially fit for representing sensory imagery. Three broad types of iconic mappings have been identified in Siwu ideophones (Dingemanse, 2011c), and similar mappings are found in other ideophone inventories (Tufvesson, 2011). Such iconic mappings allow ideophones to move beyond the imitation of singular events towards perceptual analogies and generalizations of event structure.

The close link between the structural properties of ideophones and the deeply sensory nature of their meanings suggests that ideophones constitute a promising area for research in embodied cognition and sensory science (Barsalou, 1999; Kita, 1997; Akita, 2010).

### Organizing principles and level of granularity

Earlier, we mentioned three hypotheses about the organization of ideophones in the mental lexicon: they may be organized in terms of aspects of sensory perception, in terms of generic connotative dimensions, or in terms of a combination of both. Analysis of the similarity judgment data revealed an array of fine-grained sensory categories, suggesting that for this set of ideophones, sensory perception is the most salient organizing principle. Connotative dimensions like activity, potency and evaluation, on the other hand, appear to play no role in the organization of the domain at this level of granularity.

Level of granularity may be a key concept here. The present study took a selection of high frequency ideophones across subdomains. Earlier studies, in contrast, have tended to focus on small subsets of ideophones from circumscribed semantic domains. Osaka (1990) for instance collected similarity data for Japanese ideophones in the semantic domains of talking, crying, and laughing, and found that in each of these domains it was possible to place the ideophones on sensory scales of intensity. This is not surprising: within any sufficiently semantically homogenous cluster of words, the broad connotative dimensions identified by Osgood et al. (1957) will likely play some role (Boster, 2005). This suggests that the third hypothesis, which holds that ideophones are organized by a combination of sensory aspects and generic connotative dimensions, is the most plausible one.

Combining the results from earlier studies and the findings of the present study, we suggest that the word class of ideophones as a whole is organized in terms of aspects of sensory perception, broadly construed; that the semantic distinctions made by ideophones in specific sensory domains may closely follow psychophysical properties; and that connotative dimensions like activity, potency and evaluation may play a role in the internal organization of subsets of sensory words that are sufficiently semantically homogenous.

### Conclusions

We have shown that the lexical space of ideophones is organized around aspects of sensory perception. The sensory categories identified through hierarchical cluster analysis are more fine-grained than previous classifications, demonstrating the utility of sorting tasks to capture native speaker intuitions and to map out semantic structures in the mental lexicon. In addition, several of the clusters that emerge from the analysis appear to map neatly onto psychophysical dimensions identified in other research, suggesting that ideophones constitute a sophisticated sensory vocabulary.

Our findings set the scene for cross-linguistic studies of ideophones in the future. Are the same aspects of sensory perception reproduced across languages, suggesting a shared semantic-perceptual space? Do languages impose their own organization on the domain? Does the finer organization of ideophones in specific sensory modalities match relevant psychophysical dimensions, as we see in Siwu ideophones for haptic touch? What are the cognitive consequences of having such dedicated sensory words in terms of mental representation, production and comprehension? And how do the design principles of ideophones relate to their fitness to evoke sensory imagery? The domain of ideophones is ripe for cross-linguistic investigation of these questions.

Ideophones are an example of the kind of linguistic structure that is in danger of being overlooked if the cognitive sciences keep focusing on the very thin slice of human behavior exhibited by Western populations (Henrich, Heine, & Norenzayan, 2010; Majid & Levinson, 2010). Here we hope to have shown that they provide a fruitful avenue to explore how languages can encode sensory perception, and that they are a powerful reminder of the fact that cross-linguistic diversity is an asset rather than an obstacle in the study of language and mind.

### Acknowledgments

We thank the Mawu people of Akpafu and Lolobi for supporting research on the Siwu language, and we are especially grateful to all participants in Mempeasem, Todzi and Adakɔ for their involvement. *Mi ndo karabra lo!* We also thank two anonymous reviewers for helpful comments. This work was funded by the Max Planck Institute for Psycholinguistics.

## Abstract

People often talk about musical pitch in terms of spatial metaphors. In English, for instance, pitches can be *high* or *low*, whereas in other languages pitches are described as *thick* or *thin*. According to psychophysical studies, metaphors in language can also shape people's nonlinguistic space-pitch representations. But does language establish mappings between space and pitch in the first place or does it modify preexisting associations? Here we tested 4-month-old Dutch infants' sensitivity to height-pitch and thickness-pitch mappings in two preferential looking tasks. Dutch infants looked significantly longer at cross-modally congruent stimuli in both experiments, indicating that infants are sensitive to space-pitch associations prior to language. This early presence of space-pitch mappings suggests that these associations do not originate from language. Rather, language may build upon pre-existing mappings and change them gradually via some form of competitive associative learning.

**Keywords:** cross-modal; multisensory; metaphors; synaesthesia; infant perception; language acquisition; language of perception; preferential looking

## Introduction

Does a cake taste yellow? Or a tone played by a trumpet sound scarlet? For some people they do. Yet synaesthesia, a condition in which stimulation of one sensory modality induces systematic perceptual experiences in another modality, is relatively rare. Other types of cross-modal associations, however, can be found in non-synaesthetes too. Psychophysical studies have shown that adults and children without synaesthesia associate higher pitches with sharper edges (Marks, 1987; Parise & Spence, 2009), positions higher in space (e.g., Ben-Artzi & Marks, 1995; Melara & O'Brien, 1987), lighter color (Hubbard 1996; Marks 1989; Melara 1989), and increasing brightness (Marks, 1987).

Even infants seem to be sensitive to some of these associations. Cross-modal correspondences between loudness and brightness have been demonstrated in 20- to 30-day-old infants (Lewkowicz & Turkewitz, 1980). In a preferential looking task, 3- to 4-month-old infants preferred congruent trials – in which visuospatial height and pitch height corresponded – over incongruent trials. (Walker et al., 2010); that is, infants looked longer at a ball moving upwards if it was accompanied by a rising pitch than if it was accompanied by a falling pitch. Also, prelinguistic infants under 1-year-old 'matched' visual arrows pointing

up or down with tones sweeping up or down in frequency (Wagner et al., 1981).

These findings have led to the assumption that cross-modal mappings are innately hardwired in the brain (Mondloch & Maurer, 2004) and represent an unlearned aspect of perception (Walker et al., 2010). Accordingly, some of these associations are posited to be universal (Marks, Hammeal, & Bornstein, 1987; see also Spence, 2011).

However, there are other findings that seem to be at odds with these conclusions. A number of cross-modal correspondences are only acquired later in the course of development. For instance, even 9-year-old children are not able to systematically match size and pitch, a task that is consistently solved by adults (Marks et al., 1987; but see Mondloch & Maurer, 2004). Cross-modal correspondences are also affected by developmental changes. Unlike adults and older children, 2-year-olds consistently map light grey to smaller objects and dark grey to bigger objects (Smith & Sera, 1992). In the course of language acquisition, however, children's associations gradually shift. As a result, it has been suggested that language may have an impact on the trajectory of cross-modal relations (Smith & Sera, 1992).

On one hand, language appears to mirror cross-modal experience. The auditory domain, for instance, is often linguistically encoded in terms of other sensory modalities (Williams, 1976). People use metaphors like "soft" voice, "dark" timbre or "high" pitch, suggesting that language echoes cross-modal perceptual impressions. On the other hand, language also seems to affect cross-modal associations. For example, Martino & Marks (1999) suggest that cross-modal effects, like the association between space and pitch, may be mediated by language. Various tasks show correspondences between spatial height and pitch consistent with high-low metaphors in language (Rusconi, et al, 2006, Evans & Treisman, 2010). However, since linguistic labels and height-pitch associations merely coincide, the direction of influence is hard to establish and the contribution of language remains unclear.

Cross-linguistic comparison provides one way to overcome this limitation. Not every language uses the same metaphors for pitch (Ashley, 2004; Levinson & Majid, 2007). For example, while languages like English and Dutch talk about pitch in terms of "height", other languages like, Farsi, Turkish and Zapotec (spoken in Mexico) describe

high-frequency pitch as “thin” and low-frequency pitches as “thick” (Shayan, Ozturk, & Sicoli, 2011). To find out whether these differences in spoken metaphors correspond to different mental representations of pitch, Dolscheid and colleagues, conducted a series of nonlinguistic psychophysical experiments in adult speakers of Dutch (a “height” language) and Farsi (a “thickness” language). Participants were asked to reproduce musical pitches that they heard in the presence of irrelevant spatial information, i.e. lines varying either in height or in thickness (Dolscheid et al., submitted). Dutch speakers’ pitch estimates were significantly modulated by spatial height but not by thickness. Conversely, Farsi speakers’ pitch estimates were modulated by spatial thickness but not by height. Overall, the results indicated that nonlinguistic pitch-space associations follow language-specific vocabulary, suggesting that cross-modal pitch representations are language-specific.

At this point, however, it is unclear whether language establishes cross-modal mappings between space and pitch in the first place, or whether it merely modifies preexisting associations. While some researchers stress the relevance of language in concept formation (e.g. Gopnik & Meltzoff, 1997), others argue that conceptual representations must precede the acquisition of language (e.g. Bloom, 2000; Bloom & Keil, 2001). The former position allows for a stronger role of language in space-pitch associations; while the latter position suggests that children are likely to have some notion of space-pitch correspondences prior to learning language. Consistent with this latter view, infants seem to be sensitive to height-pitch mappings even prelinguistically (Walker et al., 2010). Critically, however, nothing is known about the origins of thickness-pitch relationships. Do children also have this mapping available to them prior to language, or is it only learned on the basis of language-input?

One possibility is that children could start out with both a height-pitch and a thickness-pitch mapping even before they learn language. The strength of these mappings might then subsequently be adjusted, according to the relative frequencies of space-pitch metaphors in the languages children acquire (Casasanto 2008, 2010; Dolscheid et al., submitted; Smith & Sera, 1992). Alternatively, height-pitch and thickness-pitch associations might follow different trajectories. Whereas height-pitch associations are available to prelinguistic infants, the thickness-pitch mapping might only be learned later. Metaphors in language could provide one possible way to learn this association. Using thickness terminology to refer to pitch may invite speakers to align correspondent representations and extract similarities between space and pitch in a process called structural alignment (see e.g. Boroditsky, 2001; Gentner, 2003). In line with this proposal, Shayan et al. (submitted) found that Turkish and Farsi 2- to 5-year-olds were able to successfully map thickness to pitch but same-aged German children (who like English and Dutch speakers do not have a thickness metaphor) were not able to make this association

successfully. This is consistent with the proposal that language input promotes cross-modal associations between thickness and pitch. Note, however, that these results do not rule out the possibility that the thickness-pitch mappings were available to all infants prelinguistically, but are no longer equally available to German children.

In order to determine the prelinguistic availability of space-pitch mappings, we tested 4-month-old Dutch babies using a preferential looking paradigm. To investigate height-pitch correspondences, we followed Walker et al.’s (2010) procedure. Infants watched a ball moving up and down the screen accompanied by the sound of a sliding whistle. The whistle’s fundamental frequency changed at a constant rate. In the congruent condition, the pitch of the sound “rose” and “fell” in accordance with the movement of the ball. In the incongruent condition, the pitch of the sound “rose” and “fell” in opposition to the movement of the ball (see Fig. 1a). Walker et al. (2010) reported that infants looked longer at the congruent compared to the incongruent condition, suggesting an early preference for pitch-height congruencies.

In a second step, we tested prelinguistic infants in a thickness-pitch task analogous to the height-pitch task. Instead of balls moving up and down the screen, a vertical tube varied in thickness, changing continuously from thin to thick (see Fig. 1b).

We reasoned that if both, height-pitch and thickness-pitch mappings are available to infants prelinguistically, infants should prefer both congruent height-pitch and congruent thickness-pitch stimuli over incongruent ones. If however, height-pitch and thickness-pitch relationships follow different developmental trajectories, with thickness mappings only becoming acquired later, then infants should show preferences for congruent height-pitch stimuli but not for congruent thickness-pitch stimuli.

Figure 1: Examples of animations presented as stimuli in Experiment 1 (Panel a) and Experiment 2 (Panel b). In (a) the extremes of the ball’s vertical trajectory are shown. In (b) the extremes of thickness are depicted. The images are reproduced to scale.

## Experiment 1: Auditory pitch and visuospatial height

### Methods

**Participants** Ten male and ten female infants completed the first (pitch-height) experiment (mean age = 129 days, range: 113 to 138 days). Another seven infants were tested, but not included in the analyses: one infant was excluded due to experimenter error; a further six infants were excluded due to excessive fussiness.

**Materials and Procedure** QuickTime animations were presented on a 102 x 76 cm Sony LCD screen using HABIT software. Animations appeared within a 67 x 67 cm screen area ( $25.6^\circ \times 25.6^\circ$ ), and lasted a maximum of 60 s. Before each animation, a flashing light appeared to ensure that infants attended to the screen. Infants sat in a Maxi-Cosi infant seat which was placed on their parent's lap, viewing the animations from a distance of 1.50 m. Infants' visual fixations were monitored and recorded on video. Animations were stopped if the infant looked elsewhere for a single period of 1 s or more. The total duration an infant looked directly at the animation was logged online during the experiment using HABIT software and written to an output-file. Additionally, looking times were determined by a subsequent frame-by-frame coding of the digitized video using SuperCoder. Coding was performed by a coder blind to the experimental condition. 25 percent of the data was double-coded by a second person, also blind to the condition.

Infants watched a 10-cm ( $4^\circ$ ) diameter orange ball moving up and down a 50-cm vertical trajectory in front of a 20 x 20 grid of small, white dots on a black field. The ball moved at a constant speed of 20 cm/s and paused for 42 ms at each endpoint. Animations were accompanied by the sound of a sliding whistle (a sinusoidal tone). The fundamental frequency of the sound changed at a constant rate, between 300 and 1700 Hz over 2.5 s, coinciding with a single phase of the animation (e.g. the ball moving up). The amplitude of the sound increased and then decreased between 47 and 84 dB within each phase of the animation, peaking at 1000 Hz. Amplitude thus changed about twice as fast as pitch to ensure that variation in perceived pitch and loudness were not confounded.

Every infant viewed three congruent animations interleaved with three incongruent animations. Half of the children watched a congruent animation first and the other half watched an incongruent animation first. During the whole experiment, parents were listening to music via headphones. Since parents could not hear the sliding sounds, they were unable to distinguish between experimental conditions (the spatial trajectories of the stimuli did not differ between conditions). We therefore ensured parents could not bias their infant's looking behavior.

### Results

A high level of agreement was confirmed between the two observers in their coding of each infant's individual looking times (mean Pearson's  $r(28) = .99$ ,  $p < .001$ ).

14 of the 20 infants looked longer at the congruent animation than at the incongruent animation. On average, infants looked at the congruent animations for 31.7 s ( $SD = 11.4$ ) and at the incongruent animations for 26.1 s ( $SD = 13.3$ ). A paired-samples t-test confirmed that infants looked significantly longer at the congruent animations,  $t(19) = 1.99$ ,  $p = .03$ ,  $d = 0.45$  (one-tailed).

## Experiment 2: Auditory pitch and visuospatial thickness

### Methods

**Participants** Ten male and ten female infants completed the second (pitch-thickness) experiment (mean age = 127 days, range: 113 to 138 days). An additional eight infants were tested, but their data was not analyzed: one infant was excluded due to technical problems; a further 7 infants were excluded due to fussiness.

**Materials and Procedure** The same procedure as in Experiment 1 was used. This time, infants watched a vertical orange tube that varied in thickness, changing continuously from thin to thick (see Figure 1).

The animation was presented on a 20 x 20 grid of small, white dots on a black field, as in Experiment 1. The tube was 60 cm long ranging from 6 to 26 cm in width. It expanded at a constant speed of 8 cm/s and paused for 42 ms at each endpoint. Animations were accompanied by the sound of the exact same sliding whistle as in Experiment 1. The fundamental frequency of the sound changed at a constant rate, between 300 and 1700 Hz over 2.5 s, coinciding with a single phase of the animation (i.e. during tube expansion). Each infant viewed three congruent animations interleaved with three incongruent animations, with half of the children watching a congruent animation first and the other half watching an incongruent animation first. During the whole experiment, parents were listening to music via headphones.

### Results

A high level of agreement was confirmed between the two judges in their estimates of each infant's individual looking times (mean Pearson's  $r(28) = .99$ ,  $p < .001$ ).

13 of the 20 infants looked longer at the congruent animations than the incongruent animations. On average, infants looked longer at the congruent 24.4 s ( $SD = 11.8$ ) than the incongruent animations 19.4 s ( $SD = 11.5$ ). A paired-samples t-test confirmed that infants looked significantly longer at the congruent animations,  $t(19) = 2.19$ ,  $p = .02$ ,  $d = 0.43$  (one-tailed).

## Between experiment comparison

Dutch infants looked significantly longer at cross-modally congruent stimuli in both experiments. While this suggests a comparable starting point for both thickness-pitch and height-pitch mappings, it is nevertheless possible that infants display differential preference with respect to the two mappings. We therefore compared the results of the two previous experiments directly.

## Results

Submitting looking times to a 2 (Space: height vs. thickness) by 2 (Congruency: congruent vs. incongruent) mixed ANOVA yielded a significant main effect of Space ( $F(2,38) = 4.40, p = .04, \eta_p^2 = 0.10$ ), showing that looking times differed between height and thickness stimuli. Infants looked longer at height stimuli as compared to thickness stimuli, indicating that perhaps height was more salient for them. However, no interaction between Space and Congruency ( $F(2,38) = 0.03, ns, \eta_p^2 = 0.00$ ) was observed. There were thus no indications that looking time reductions induced by incongruency differed between the two experiments. In line with this, percentage reduction in looking time across experiments was of comparable size, i.e., 18% for the height-pitch experiment and 20% for the thickness-pitch experiment.

## General Discussion

Our results demonstrate that prelinguistic infants are sensitive to correspondences between auditory pitch and spatial information of two different types, visuospatial thickness as well as height. Dutch infants looked significantly longer at cross-modally congruent stimuli in both experiments, suggesting a comparable starting point for height-pitch mappings and thickness-pitch mappings.

It is possible that these mappings are only present in very young infants but get lost in the course of development due to neuronal pruning. Whereas 2-to 3-month-old infants were found to be sensitive to arbitrary associations between colors and shapes, 8-month-old infants no longer show this early synaesthetic association (Wagner & Dobkins, 2011). Does the same developmental trajectory hold true for space-pitch mappings? Unlike synaesthetic color-shape associations that seem highly individualized and thus unspecific (e.g., one infant might associate triangles with green, and another with red), space-pitch associations follow a specific pattern, showing the same congruity preferences found in languages. It is therefore possible that space-pitch mappings persist during infancy and childhood. In line with this suggestion, sensitivity to height-pitch associations has been reported in 6-month-olds (Braaten, 1993) as well as in children aged 4 to 5 years (Roffler & Butler, 1967). On the other hand, 2- to 5-year-old German speaking children have been found to be insensitive to the thickness mapping (Shayan et al., submitted). There is also contradictory evidence regarding children's sensitivity to size-pitch associations. Whereas Marks et al. (1987) report that

children are unable to systematically map size (big vs. small) to pitch until they are 13 years old, Mondloch and Maurer (2004) find evidence for size-pitch congruency effects in children as young as 3 years of age.<sup>1</sup> Details about the developmental trajectory of space-pitch mappings thus remain unclear and are subject to future research.

One aspect that seems to facilitate detecting cross-modal associations is motion (see also Jeschonek, Pauen & Babocsai, in preparation). Mondloch and Maurer presented children with moving balls that differed in size; while Marks et al. and Shayan et al. used static stimuli. In the present study, too, the dynamic display of spatial information (up- and downward movement or horizontal expansion) and pitch (presented as glides) may have facilitated the detection of corresponding information. Displaying stimuli dynamically and in synchronicity could direct infants' attention to the relational correspondences across modalities. However, movement by itself cannot explain the pattern of results: infants must still align stimuli attributes that are congruent to each other.

## Language acquisition and cross-modal associations

Our findings demonstrate that both height-pitch and thickness-pitch correspondences are perceived before the infant has mastery of language. While this finding is consistent with the view that representations precede language (e.g. Bloom, 2000), it does not entail that these associations are fixed. Language could still influence the structure and content of preexisting mental representations via simple learning mechanisms. In the course of language acquisition, the relative strengths of different space-pitch mappings could be adjusted according to the language-specific frequencies of metaphors that children acquire (Casasanto 2008, 2010). Over time, speakers of a "height" language like Dutch would strengthen the height-pitch mapping at the expense of the thickness-pitch mapping – and vice versa for speakers of a "thickness" language like Farsi (Dolscheid et al., submitted). Evidence in support of this associative learning account is provided by linguistic training experiments. Dutch speakers, after being trained to use Farsi-like metaphors describing pitch relationships in terms of thickness, demonstrated nonlinguistic thickness-pitch mappings just like Farsi speakers. By contrast, when participants received the same amount of linguistic training with an alternative space-pitch mapping that is not present in any known language, they showed no effect of training (Dolscheid et al., submitted). These training studies demonstrate a causal role for language in strengthening the use of some nonlinguistic mappings more than others.

---

<sup>1</sup> The thickness-stimuli used in Experiment 2 could also be interpreted as a size manipulation. Indeed, even though movement was restricted to the horizontal plane which is characteristic for thickness, there is a concomitant difference in overall size. For the present purposes, nothing rests on being able to make the distinction between thickness and size, per se, since the reported inconsistency in the ability to make the cross-modal mapping to pitch applies equally to both spatial parameters.

While language may enforce particular pitch-space mappings, this proposal has to take into account that metaphors pose additional demands in language acquisition. Pitch metaphors are inherently polysemous; the acquisition of both spatial and sound meanings is likely more complex than when a single meaning has to be acquired (see e.g. Johnson, 1992). Consistent with this proposal French speaking children trained to describe sounds using either the single-meaning terms *aigu* and *grave* (a pair of antonyms used only to label high and low pitches) versus the polysemous words *haut* and *bas* (which are used to refer to pitch and space) were better able to label sound stimuli (Costa-Giomi & Descombes, 1996).

Aside from polysemy, another important attribute of metaphorical language lies in its directionality. Taking spatial metaphors of time as an example, people talk about time in terms of space far more often (“a long vacation”; “a short meeting”) than they talk about space in terms of time (though it occasionally occurs: “I live two minutes from here”) (Casasanto, 2008, 2010; Lakoff & Johnson, 1980). For pitch metaphors the same asymmetry seems to hold, which has also been found to be reflected in adults’ nonlinguistic pitch representations (Casasanto, 2010). Note, however, that our results are agnostic of a space-pitch asymmetry in prelinguistic infants. While we have demonstrated that infants are able to detect space-pitch associations, our tasks do not speak to possible directionality. Future studies are necessary to determine whether language plays a role in introducing this asymmetry (e.g. see Meritt, Casasanto, & Brannon, 2010), or whether it is present independent of language (e.g. see Marks et al., 1987).

### Effects of cross-modal associations on language

Since cross-modal associations are present before children acquire language, it is possible that the associations themselves shape metaphors in language. We find the height-pitch metaphor in languages such as Spanish, German and Polish (Rusconi et al., 2006), as well as non-Indo-European languages, like Japanese and Chinese. In all of these languages, “high” refers to high frequency sounds and “low” to low frequency sounds, but not the reverse. Likewise, psychophysical studies demonstrated that participants associate higher pitches with smaller objects, not with larger objects (e.g. Gallace & Spence, 2006). For the Kpelle and Jabo people in Liberia, this association is also encoded in language: “small” refers to high pitch and “big” refers to low pitch (see e.g., Eitan & Timmers, 2010). Prelinguistic associations, alongside correlations of properties in the real world, may thus serve as guiding principles that constrain the way pitch gets lexicalized, across languages.

Consequently, it might be harder to learn linguistic metaphors that are inconsistent with cross-modal mappings for which there is evidence in the natural world. The results of a training study support this suggestion. Dutch speakers trained to use reversed thickness-pitch mappings

(thick=high, thin=low) were not able to master this association, even though they could learn the comparable congruent mapping (Dolscheid et al., submitted). It thus appears that language cannot easily retrain mappings that are supported by correlations present prelinguistically and/or supported by real world experience. Early sensitivity to certain mappings might therefore constrain the set of cross-modal associations that are likely to be observed in language and the mind.

### Origins of cross-modal mappings?

Are cross-modal mappings innate? Based on the current evidence, we can only conclude that cross-modal associations between space and pitch are present from very early. By the age of 4 months, however, infants may well have encountered enough relevant co-occurrences in their interaction with the world to have learned these mappings. Thickness-pitch mappings seem especially prevalent: thicker strings produce lower notes, bigger bells have lower chimes, and people with bigger (‘thicker’) bodies tend to have lower voices. While infants may have internalized these regularities, the case for innate height-pitch mappings is not conclusive (see also Walker et al., 2010).

### Conclusions

No matter whether cross-modal associations are inborn or learned, the finding that both height-pitch and thickness-pitch mappings can be observed in infants as young as 4 months of age constrains theorizing about the role that language plays in shaping nonlinguistic mental representations of pitch.

Our data show that space-pitch associations are present prior to language, suggesting that language is unlikely to create cross-modal mappings between space and pitch, even if language seems to play this role in other domains (Gentner, 2002).

It appears that both the height-pitch mapping found in languages like Dutch and the thickness-pitch mapping found in languages like Farsi are already present in prelinguistic infants’ minds. This suggests that people who use different spatial metaphors for pitch in their native languages come to think about pitch differently not because language instills in them one cross-modal mapping instead of the other, but rather because language strengthens one pre-existing mapping at the expense the other, via some form of competitive associative learning (Casasanto, 2008, 2010; Dolscheid, et al., submitted). The precise learning mechanisms that give rise to cross-linguistic differences in pitch representation, and the underlying neural mechanisms, remain topics for future research.

## Abstract

Theory of mind ('ToM') tasks elicit highly reliable neural activity across individuals and experimental paradigms. We compared activity in a very large sample of neurotypical ('NT', N=477) individuals, and a group of high functioning individuals with autism spectrum disorders ('ASD', n=27), using both region of interest ('ROI') and whole-brain analyses. Although ToM activity showed significant and reliable individual differences, these differences were not explained by participant gender or age, or most experimental parameters. Furthermore, there were no differences between ASD and NT individuals. These results imply that the social cognitive impairments typical of ASD can occur without gross changes in the size or response magnitude of ToM brain regions.

**Keywords:** Theory of mind; ASD; fMRI; TPJ; PC; precuneus; MPFC; DMPFC; MMPFC

## Introduction

Theory of Mind ('ToM') is the capacity to represent the mental states of others (Premack & Woodruff, 1978). Individuals with autism spectrum disorders (ASD) appear to have particular difficulty with aspects of ToM. In particular, children with ASD are disproportionately delayed on tasks that tap inferences about other people's beliefs (Baron-Cohen, 1989). The neural mechanism of this deficit remains unknown. However, in neurotypical (NT) adults and children, fMRI studies reveal a remarkable reliable group of brain regions recruited during ToM tasks. These regions include the left and right temporo-parietal junction (RTPJ and LTPJ), right anterior superior temporal sulcus (rSTS), the medial precuneus (PC), and the medial prefrontal cortex (MPFC) (U. Frith & Frith, 2003). Thus, a tempting hypothesis is that dysfunction of the brain regions typically implicated in ToM is responsible for the social cognitive impairments observed in ASD.

Previous attempts to characterize the function of ToM brain regions in adults with ASD have yielded conflicting results. Some studies suggest that ToM regions are hypoactive (i.e., produce a smaller or less selective response, (Kennedy & Courchesne, 2008; Lombardo, Chakrabarti, Bullmore), while other studies find no difference between ASD and NT individuals (Gilbert, Bird, Brindley, Frith, & Burgess, 2008), and still others find the

opposite pattern, hyperactivation, in ASD (Dichter, Felder, & Bodfish, 2009).

One explanation of these conflicting results may be that sample sizes are small, and individual variability is large. Small samples of individuals with ASD are problematic because individuals with ASD may be highly heterogeneous in their neural responses (e.g., Hasson et al., 2009). Small samples of NT participants are equally problematic, because they allow for calculation of only the mean response, not the distribution. Understanding the distribution is critical if neural measures are to be useful in a clinical setting. For most clinical applications, it is more important to be able to describe the neural activity pattern of each specific individual, relative to typical and atypical distributions. For example, using fMRI to help diagnose ASD would require comparing each individual to the typical distribution.

In order to measure the distribution of responses in ToM brain regions of NT participants, we aggregated data collected over 5 years from 477 NT participants. This large sample allowed us to investigate variability in ToM region responses, and measure any difference between NT participants and adults with ASD, with unusually high sensitivity. The main goal of the current paper is therefore to compare the response in these regions in a large sample of NT participants and a moderate sample of high-functioning adults with ASD. In order to do so, we also (i) identify and remove variance in the measured response, associated with basic experimental parameters such as the stimulus modality, number of stimuli, or experimental task, and (ii) test whether the response of ToM regions is related to basic demographic factors that may be relevant for ASD, including gender, age, and IQ.

## Methods

**Typical Participants:** Data were analyzed from 477 NT participants (M=25.2 years, range: 18-69 years; 179 male). IQ was measured in 60 of these participants (IQ 84-141, M=117.5, SD=12.4). Participants provided informed consent, in accordance with the guidelines of the MIT Committee on the Use of Human Experimental Subjects (COUHES), and were compensated approximately \$30 per hour for their time.

**ASD Participants:** 27 individuals with a clinical diagnosis of ASD (M=33.9yrs, range 18-66yrs; 20 male) were

included, having volunteered to participate in one of two (Moran et al., 2011; Redcay et al., 2012) previous studies. The Autism Diagnostic Observation Schedule (ADOS) was administered to 23 of the 27 ASD participants (ADOS communication score  $M=3.2$ ,  $SD=1.3$ ; ADOS social score  $M=5.8$ ,  $SD=1.8$ ). For 24 of the ASD participants, IQ measures were obtained by the Kaufman Brief Intelligence Test (IQ 69-141,  $M=116.3$ ,  $SD=16.8$ ). For direct NT vs. ASD comparison, a set of 24 NT participants (collectively termed ‘matched’) were chosen based on pairwise similarity with the ASD participants on IQ, age, and gender (age 20-54,  $M=29.9$  years,  $SD=8.8$  years; IQ 84-141,  $M=116.3$ ,  $SD=14.5$ ; 19 male).

**fMRI Tasks** All participants were presented with verbal narratives in English that described a character and his/her mental states (Mental condition) or described physical objects and events (Control condition). The stimuli were presented either visually as text on a screen, or aurally through headphones. After reading or hearing the narrative, participants performed one of 4 tasks. These tasks correspond to the functional localizers used in (Dodell-Feder, Koster-Hale, Bedny, & Saxe, 2010; Kliemann, Young, Scholz, & Saxe, 2008; L. Young & Saxe, 2008; L. Young & Saxe, 2009; L. Young, Camprodon, Hauser, Pascual-Leone, & Saxe, 2010; L. Young, Nichols, & Saxe, 2010; L. Young, Scholz, & Saxe, 2011) and unpublished data.

**fMRI Methods:** Participants were scanned on a 3T Siemens scanner at the Martinos Imaging Center at the McGovern Institute for Brain Research at the Massachusetts Institute of Technology ( $n=468$ ) or at the Massachusetts General Hospital ( $n=36$ ). NT participants were scanned between 2006 and 2011. ASD participants were scanned between 2007 and 2010. Matched NTs were scanned between 2007 and 2010. Functional data were acquired using single echo gradient echo echo-planar-imaging with voxel size  $3.125 \times 3.125 \times 4.000$  mm ( $TE=30$  ms, flip angle= $90^\circ$ , TR either 2.5 ( $n=36$ ) or 2 secs ( $n=468$ )). Participants were scanned on either a 12-channel or a 32-channel receive coil, both Siemens products. Data were analyzed using SPM2 or SPM8 (<http://www.fil.ion.ucl.ac.uk>) and in-house software. The data were realigned to account for motion, smoothed with a 5 mm Gaussian kernel and normalized to a standard template in Montreal Neurological Institute space.

**ROI Analyses:** Six functional ROIs (ROIs) from the ToM network were defined in individual participants, using the contrast Mental>Control, consistent with previous literature (e.g. (U. Frith & Frith, 2003; Saxe & Kanwisher, 2003)): RTPJ, LTPJ, PC, dorsal and middle MPFC (DMPFC and MMPFC) and rSTS.

To identify individually-defined functional ROIs, initial “hypothesis spaces” were defined as the 9mm radius sphere centered about local maxima for each region, in the group random effects analysis performed on all 477 NT participants (see figure 1). Each participant’s contrast image

(Mental>Control) was masked with the six hypothesis spaces; all voxels contiguous with the peak voxel and significant at  $p < 0.001$ , within a 9mm radius, were defined as the ROI. From each ROI three parameters were extracted: the peak voxel t-value, the size of the ROI (number of voxels included), and the mean T. The presence or absence of an ROI was used as a fourth parameter. The reliability of ROI parameters was assessed by split-half analysis. Contrast images were derived from even versus odd runs in each participant. ROIs were picked using a minimum cluster size of 10 and a significance level of  $p < 0.05$ . The correlation of the ROI even and odd parameter values was measured across participants.

Every subject for whom we had complete demographic and experimental data was then included in a multivariate general linear model (GLM). The resulting model was a seven-column (age, gender, group, modality, coil, number of stimuli, and the mean term) predictor matrix and included data from 383 participants. For the binary statistic that indicated whether or not the ROI of interest was identified in a given subject, the GLM presumed a binomial distribution and a logit linker function. The GLM used a normal distribution otherwise. Continuous regressors were mean-centered prior to regression. Correction for multiple comparisons was performed with Bonferroni correction, across all predictors and all dependent measures, within each ROI. In total there were six predictors for the four ROI parameters, a total of 24 comparisons per ROI; thus effects were taken to be significant if  $p < 0.0021$ . Any relationship significant at  $p < 0.01$  is discussed as a ‘trend.’

An identical procedure was conducted for the matched group, except that coil and modality did not vary within and thus were omitted. IQ was added to the predictor matrix, resulting in a total of 20 comparisons per ROI, and a significance threshold of  $p < 0.0025$ . Any relationship found to have a significance  $0.01 < p < 0.0025$  is discussed as a trend.

**Whole-brain analyses:** Whole-brain analyses were conducted for the contrast of interest (Mental>Control), in order to identify effects on the ToM brain regions. To correct for comparisons, nonparametric whole-brain analysis was performed using SnPM (<http://www.sph.umich.edu/ni-stat/SnPM/>). Each test used 3mm variance smoothing and 5,000 permutations, with no global normalization, grand mean scaling, or threshold masking. The corrected  $p$ -value for filtering was 0.05, with a threshold of 3, and a voxel-cluster combining theta value of 0.5. Permutations were repeated for each predictor of interest; all demographic and experimental predictor variables were included as nuisance regressors using modified SnPM plugins. Because (to foreshadow our results) we find a *lack* of significant differences between ASD and NT participants, we also examined the results using a substantially more lenient threshold: regions were considered significant if composed of a contiguous cluster of at least ten voxels at a t-value of 3 or greater, as this

corresponds to  $p < 0.001$  (uncorrected). This more lenient threshold is consequently a more stringent test of the hypothesis that there are no differences between the groups.

## Results

### ROI results

Six functional ROIs (ROIs) from the ToM network were defined in individual participants, using the contrast Mental>Control, consistent with previous literature (U. Frith & Frith, 2003; Saxe & Kanwisher, 2003): RTPJ (in 414/504, or 82.1%), LTPJ (77.2%), PC (84.7%), DMPFC (60.1%), MMPFC (64.7%) and rSTS (65.5%).

The goal of this project is to explain individual differences in the size and magnitude of brain regions involved in ToM. Before testing individual differences, however, it was critical to determine that (i) there was variability in these measures, and (ii) the differences between individuals on these measures are reliable (i.e. that inter-individual differences do not simply reflect noise in the measurement). All ROI parameters showed reasonable variability. The standard deviation of the peak T-value ranged between 1 and 2, and the standard deviation of ROI size (in voxels) ranged from 60 to 90 voxels. In order to test whether this variability reflects stable individual differences, we compared the ROI measurements within individuals. ROIs were picked independently from even and odd runs in the 235 participants from whom we had more than three runs of data. RTPJ was identified in 72% of participants, LTPJ in 66%, PC in 75%, DMPFC in 55%, MMPFC in 53%, and rSTS in 56%. Correlations between the even and odd parameter values (mass, x coordinate, etc.) and across subjects had an average Pearson's  $r$ -value of 0.51. These correlations were all significant at  $p < 0.001$ , and all but two at  $p < 0.0001$ . Thus, the ROI parameters are reliable within subject, making it worthwhile to explain inter-subject variability.

Next we used multivariate general linear regression analyses to estimate whether any variance in the size or

response magnitude of ToM brain regions is explained by ASD status. The first set of analyses compared all of the individuals with ASD ( $n=27$ , 23 male) to all of the NT individuals ( $n=439$ , 179 male). In these analyses, no parameter of any ROI was significantly predicted by the group membership (ASD vs. NT) of the individual ( $p > .09$  for all ROIs). The ASD participants were similar to NT participants on the ROI measures considered; no ASD participant fell outside of 3 standard deviations on any measure or any ROI, and only one ASD participant fell outside 2 SDs. In a second set of analyses, we compared individuals with ASD ( $N=24$ , 19 male) to a group of matched NT individuals ( $N=24$ , 19 male). Again, we found no significant difference between groups on any ROI parameter (all  $p > 0.01$ ). The new parameter of IQ was found to predict larger sized PC ROIs ( $p = 0.0064$ ,  $\beta=2.591\pm2.699$ , +1.7 voxels/IQ point) at the level of a trend. Finally, the effect of ADOS score was considered. For this analysis, participants were restricted to those from the ASD group. None of the parameters significantly predicted any measured ROI parameter, even at the level of the trend.

The choice of coil had the largest effect. The 32-channel coil produced significantly greater peak (means:  $p = 0.0004$ ,  $\beta = 0.610\pm0.470$ , 1.21 units higher in 32-channel ROIs) and mean T values (means:  $p = 0.0006$ ,  $\beta=0.309\pm0.212$ , 0.62 units) in all ROIs except DMPFC and PC compared with the 12-channel coil. PC mean ( $p = 0.0030$ ,  $\beta = 0.253\pm0.260$ , 0.541 units) and peak T ( $p = 0.0039$ ,  $\beta = 0.480\pm0.509$ , 1.01 units) was increased in the 32-channel as well, but at the level of a trend. The 32-channel coil additionally significantly increased the size of the RTPJ ( $p = 0.0001$ ,  $\beta = 40.35\pm30.38$ ), and increased the probability of finding the RSTS ( $p = 0.0087$ ,  $\beta = 1.354\pm1.589$ , 152% more likely) and its size ( $p = 0.0030$ ,  $\beta = 24.495\pm25.203$ , 58.7 voxels larger) at the level of a trend. We also found an unexpected effect of number of stimuli: as the number of stimuli used in the experiment increased, the probability of identifying regions in the medial prefrontal cortex (MMPFC and DMPFC) decreased (means:  $p=0.0073$ ,  $\beta=-0.067\pm0.079$ ,  $\sim -2\%$

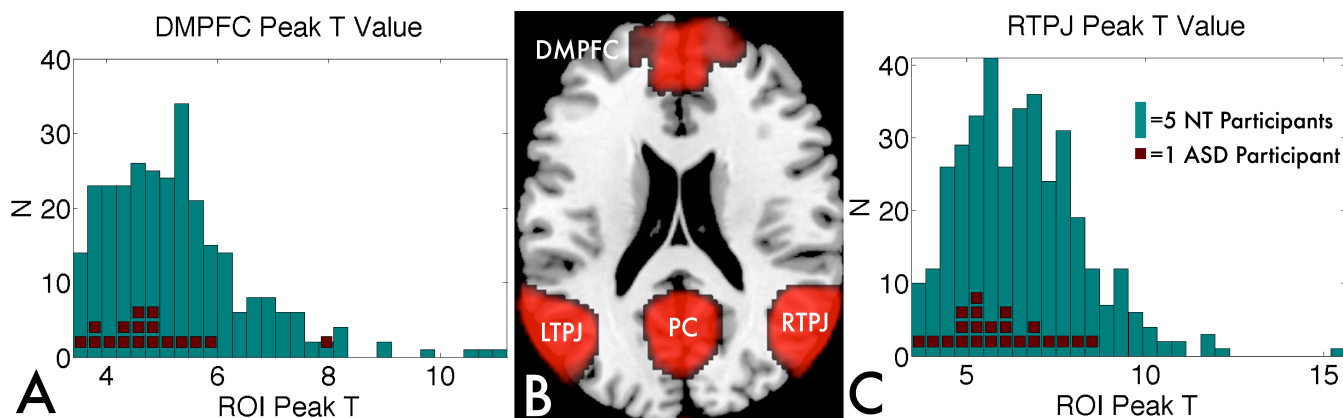

Figure 1: (A) Histogram of the DMPFC ROI peak T value for NT participants (teal) overlaid with the ASD participants (red). (B) Whole brain random effects analysis of the main effect, Mental > Control, in the full sample, corrected for multiple comparisons with permutations; axial slice shown at  $z = 22\text{mm}$ . Visible are RTPJ, LTPJ, DMPFC, and PC. (C) Histogram of the RTPJ ROI peak T value for NT participants (teal) overlaid with the ASD participants (red).

stimulus) at the level of a trend. There were no significant effects of age or gender on any parameter of any region.

In sum, ROI analyses suggest that while individuals differ reliably in the size and response magnitude of brain regions associated with ToM, these neural parameters are not affected by whether an ASD diagnosis. Experimental parameters, such as the MRI coil used, and demographic variables, such as IQ, explain some of the variance across individuals. Within the range of ADOS scores in the current sample, autism severity does not explain variance in ROI parameters, either. However, ROI analyses (and especially the three ROI parameters) provide a limited window on the brain, so to look further for differences between groups in ToM brain regions, we next conducted whole brain analyses.

### Whole brain analysis results

In the whole-brain analyses, the main effect identifies brain regions significantly recruited during Mental compared to Control conditions, controlling for variance explained by any of the nuisance regressors. This analysis identified robust activation in all of the regions previously associated with ToM, including RTPJ, LTPJ, medial PC and posterior cingulate, MPFC, and anterior STS. It also identified activation in other regions, including the left superior frontal gyrus (BA8 and BA6), the left medial frontal gyrus (BA8), regions of right middle frontal gyrus (BA6, BA8, BA9), the right superior temporal gyrus (BA38) and the right inferior frontal gyrus (BA47). Also present was activity in the cingulate (BA24) and anterior cingulate (BA32), as well as the thalamus (BA24) and the right amygdala.

Next, we compared activation in the full sample of individuals with ASD vs. NT. Regions were significant if the difference between activation during mental versus control tasks was greater in one group than in the other. When these analyses were corrected for multiple comparisons using permutations, we observed no regions of significant group differences. A more lenient threshold revealed a small region in the right cingulate gyrus ([2, 14, 22], peak  $T = 3.5$ ,  $128\text{mm}^3$ ) with a greater condition difference in ASD than NT groups. In this region, ASD participants showed greater deactivation in the control condition, but no difference during the Mental condition. There were no regions with greater difference between conditions in the NT participants.

We also compared the ASD group to a smaller matched group. When correcting for multiple comparisons with permutations, we again failed to find any regions significant for the ASD > NT contrast. More lenient traditional thresholds also failed to reveal any significant regions. In the reverse contrast (NT > ASD), a single region was found in the right middle occipital gyrus ([36, -62, -8], peak  $T = 5.09$ ,  $1032\text{mm}^3$ ) when corrected with permutations. This region was again identified using the more lenient threshold ([36, -62, -8], peak  $T = 5.8$ ,  $784\text{mm}^3$ ), along with regions in the left middle temporal gyrus ([-48, 10, -44, peak  $T = 4.44$ ,  $304\text{mm}^3$ ), the right middle posterior cingulate ([26, -68, 12],

peak  $T = 4.32$ ,  $736\text{mm}^3$ ), the left posterior lobe ([-44, -60, 38], peak  $T = 4.31$ ,  $488\text{mm}^3$ ), the left cingulate gyrus ([-16, -56, 26], peak  $T = 4.24$ ,  $424\text{mm}^3$ ), left inferior temporal gyrus ([-58, -28, -20], peak  $T = 4.24$ ,  $208\text{mm}^3$ ), the right posterior insula ([40, -24, 12], peak  $T = 4.12$ ,  $304\text{mm}^3$ ), right precentral gyrus ([32, -26, 68], peak  $T = 3.81$ ,  $168\text{mm}^3$ ), right superior temporal gyrus ([44, -60, 34], peak  $T = 3.77$ ,  $232\text{mm}^3$ ), and the left posterior cingulate ([-14, -54, 14], peak  $T = 3.76$ ,  $104\text{mm}^3$ ).

## Discussion

The main question we sought to address in this paper was whether individuals diagnosed with ASD show differences in the magnitude or extent of activity in ToM brain regions, compared to a large sample of NT participants. To this end, we aggregated data across multiple experiments to produce a large sample of NT individuals ( $N=477$ ) and a moderate sample of high functioning ASD individuals ( $N=27$ ). Before directly comparing them, we tested whether neural responses to Mental stimuli were reliable within participants and variable across participants, in the NT population. They were. Next, we tested whether the magnitude of neural responses to Mental vs Control stimuli differed between groups, either in targeted regions of interest or in whole brain analyses. For the most part, these analyses identified no reliable differences between groups, especially in the previously hypothesized ToM brain regions. These results suggest that differences between these groups of participants in ToM brain regions, if they exist, are small and could not be used to diagnose ASD.

We used two complementary analysis strategies: ROI analyses focused on previous identified ToM brain regions are more sensitive, whereas whole brain analyses find group differences anywhere in the brain, and are less restricted. For both kinds of analyses, we conducted two comparisons by regression with simultaneous nuisance regressors to control for demographic and experimental variance: the ASD group vs. the whole group of NT individuals, and the ASD group vs. NT individuals matched to the ASD group on age, gender, IQ and experimental parameters. For both comparisons, we found no reliable differences between groups in the size, response magnitude, or probability of identifying above-threshold voxels, in any ToM ROI. Indeed, the ROI parameters of individuals with ASD fell squarely within the distribution of typical values, almost never straying more than 2SD from the typical means. Also, ADOS scores of the ASD participants did not predict any ROI parameter, even at the level of a trend.

In the whole brain analyses, the results of group comparisons depended on the thresholds used for correcting for multiple comparisons. Permutation-based correction, which estimates the false positive rate empirically, revealed no significant differences between the two complete groups. When we reduced the sample to just the matched NT group, we found one region, in the right middle occipital gyrus, which showed increased response to Mental than Control stimuli in the NT group, but not the ASD group. However,

since this region did not show a higher response to Mental than Control stimuli in the overall main effect analysis of all participants, and is not typically associated with any kind of social cognition, we are cautious about making strong claims based on this effect.

Because these results suggest a null result - namely, no difference between groups - we also examined the same analyses at a more lenient threshold that could reveal true differences between groups that are just below the threshold for significance. Again we found no regions more active in the full NT sample, compared to the ASD group. A small ( $128 \text{ mm}^3$ ) region in right cingulate gyrus appeared more active in participants with ASD at this threshold; in this region, ASD participants showed greater deactivation to the control condition than NT participants. Reducing the sample to just the matched NT participants, and using the lower threshold, produced a number of small regions showing greater activation in NT than ASD participants. However, none were in any region in the main effect analysis of Mental > Control stimuli. Thus, we could not identify any region that both (a) was reliably recruited for Mental more than Control stimuli in 477 NT individuals, and (b) showed less activity in the same contrast, in individuals with ASD.

Using a similar analysis strategy, we also found that age and gender do not affect activity in ToM brain regions; nor do the modality of the stimuli (visual vs aural) or the experimental task. Thus, although individual differences in ToM brain regions are reliable and robust, they are not explained by simple demographic or experimental variables. The absence of an effect of gender is particularly noteworthy, because the full sample contained a large number of male and female participants. Behavioral measures of ToM often reveal an advantage for female participants (Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001; Baron-Cohen, Jolliffe, Mortimore, & Robertson, 1997); apparently this advantage is not due to grossly different ToM brain regions.

One significant factor was the coil used. The 32-channel coil has documented higher SNR (Triantafyllou, Polimeni, & Wald, 2011); we found that this difference translated into larger ROIs that were more likely to be detected in individual participants. Thus, our results suggest that for individually-defined ROI analyses, the increased SNR of the 32-channel coil provides a clear benefit. On the other hand, increasing the number of stimuli per condition did not have the same benefit: medial prefrontal regions were less likely to be identified, in experiments using more stimuli. This unexpected effect could reflect habituation, after more than 20 stories about characters' false beliefs.

With regard to our key null results, the current study has advantages and disadvantages. On the one hand, the large sample size provides more power and sensitivity to detect effects where they exist. In particular, although our sample of ASD individuals was only moderately large, the very large sample of NT individuals included gives us very high confidence on the true mean of the ROI parameters in NT individuals. Finding that the ASD population mean does

not differ from the NT mean is thus strong evidence that these groups' data cannot be attributed to different population distributions.

However, these results cannot be interpreted as ruling out any differences in the neural mechanisms for ToM in individuals with ASD. One qualification of the current results is that the parameters measured here provide only a limited measure of a region's function. Other measures include the functional connectivity of each region and within-region spatial pattern of responses (Biswal, Zerrin Yetkin, Haughton, & Hyde, 1995; Haxby et al., 2001). Participants with ASD may differ in these other measures of ToM region function (Kleinhans et al., 2008). Indeed work in our lab using multi-voxel pattern analysis (MVPA) demonstrated the existence of reliable differences between ASD and NT individuals (Koster-Hale, Saxe, and Young, submitted).

Another qualification is that the ASD participants in the current sample are very high functioning. Although they meet diagnostic criteria for ASD (and have been shown to have behavioral deficits in ToM tasks in a previous study, Moran et al., 2011), these individuals are highly verbal and pass first-order false belief tasks. Thus, our results do not rule out gross differences in the ToM regions of lower-functioning individuals with ASD. On the other hand, the individuals in our sample are diagnosed with ASD because of disproportionate difficulties with social interaction and communication, and are similar to populations used in previous fMRI studies. Also, we found no evidence that within our participants, increasing ASD severity had any effect on the measured ROI parameters. So the current results imply that social cognitive impairments can occur without gross changes in the size or position of ToM brain regions. Collectively, the current results provide strong evidence that the neural differences between high functioning adults with ASD and NT participants are not due to gross changes in the magnitude of ToM brain region activity.

These results leave open a number of key questions. First, it will be key to identify the neural differences between adults with ASD and NT individuals that account for behavioral differences in ToM. One key possibility is that individuals with ASD are highly heterogeneous, so that different neural sources explain the behavioral delays in different individuals. If so, the group-average analyses used here may have limited sensitivity to detect those differences. Second, the current study focused on adults. It will be important in future research to test whether the developmental trajectory of ToM brain regions differs in children with ASD compared to NT children, even if the mature states of the system are reasonably similar. Finally, it would be useful to extend these analyses to lower-functioning individuals with ASD. Nevertheless, the implication of this study is that social-cognitive impairments can occur without large changes in the activation of ToM brain regions.

## Abstract

When engaging in counterfactual thought, people must imagine changes to the actual state of the world. In this study, we investigated how people reason about counterfactual scenarios by asking participants to make counterfactual inferences about a series of causal devices (i.e., answer questions such as *If component X had not operated [had failed], would components Y, Z, and W have operated?*) and to explain their reasoning. Participants avoided breaking deterministic causal links (i.e., *W always causes X*), but were willing to break probabilistic causal links (i.e., *W sometimes causes X*) to keep prior causal events in the same states as in the actual world. Participants' explanations supported this pattern of inferences. When the causal links were deterministic, participants reasoned diagnostically to infer that the states of prior causal events would have been different in the counterfactual world. In contrast, when the links were probabilistic, participants cited the links' unreliability as an explanation for why the states of prior causal events would have been the same as in the actual world. Additionally, participants who were told that a component "had failed" (vs. "had not operated") were more likely to attribute the state of that component to it being "internally broken" and infer that causally upstream components would have operated. Our results suggest that people use their explanation of the antecedent event (the "if" clause) to guide their counterfactual inferences. We discuss the implications of these findings for two rival Bayes-net theories of counterfactual reasoning: Pearl's (2000) and Hiddleston's (2005).

**Keywords:** Counterfactuals, causation, explanation

## Introduction

People often engage in counterfactual reasoning (e.g., *If I hadn't partied the night before the exam, then I would have passed the exam*) to second-guess decisions, attribute credit or blame, and diagnose causal relations (see Byrne, 2005, for a review). Reasoning about counterfactual scenarios such as the preceding example requires imagining changes to the actual state of the world—for instance, imagining a counterfactual world in which I hadn't partied the night before the exam. One of the central issues in the study of counterfactual reasoning is how people re-imagine the world to satisfy the antecedent of a counterfactual scenario. (The *antecedent* is the "if" clause, and we will refer to the "then" clause as the *consequent*.) In particular, what types of events do people keep the same in the actual and counterfactual worlds and what types of events do people change?

One way people might reason about counterfactual scenarios, which we will call *pruning theory*, is by using an intervention to change the state of the antecedent event from

the actual state to the counterfactual state and then tracing the consequences of that intervention (Pearl, 2000; see also Woodward, 2003). The intervention severs the causal link between the antecedent and its immediate causes, and as a result of this "graph surgery," the counterfactual states of upstream events would be the same as in the actual world. However, downstream events that are a consequence of the antecedent would change states according to the causal laws governing the system. To illustrate this approach, consider a causal chain  $A \rightarrow B \rightarrow C$  and a counterfactual antecedent *If B had not occurred...* (in the actual world, *A*, *B*, and *C* all occurred). A person using pruning theory would intervene on *B* to change the state of *B* from present to absent. Since upstream events (*A*) are unaffected by this intervention, *A* would still have been present in the counterfactual world. But since *C* is an effect of *B*, *B*'s absence would in turn cause *C* to be absent.

Pruning theory might appeal to reasoners in two ways. First, by keeping all the events that are causally prior to the antecedent in the same states as in the actual world, pruning theory creates a counterfactual world that is maximally similar to the actual world with respect to these prior events. Second, the pruning approach makes counterfactual thinking computationally easy. The strategy of always keeping prior events in their original states allows reasoners to avoid the cognitively challenging process of reasoning backwards to determine the counterfactual states of upstream causes.

However, other researchers have questioned whether the type of change pruning theory proposes is necessarily the most reasonable way to modify the causal system in the counterfactual situation (e.g., Hiddleston, 2005). One criticism of pruning theory is that it is very disruptive to the structure of a causal system and can require reasoners to violate causal laws. Consider a deterministic causal system in which *A*, without exception, always causes *B*. In this setting, one might be reluctant to imagine a counterfactual world in which *A* occurred, but *B* did not occur (e.g., in answering the question *If B had not occurred, would A have occurred?*). Thus, when reasoning about this counterfactual scenario, one might be more likely to infer that the reason *B* did not occur was that *A* did not occur, and the absence of *A* caused *B* to be absent too (Hiddleston, 2005). We will call this alternative *minimal-network theory*. When the causal links are probabilistic (i.e., *A sometimes causes B*), however, minimal-network theory proposes that *A* might or might not have occurred, since either possibility is "legal" in accordance with the system's causal laws.

Table 1 compares the predictions of pruning theory and minimal-network theory for a device in which component A's operating usually causes component B to operate and component B's operating always causes component C to operate (at present, all three components are operating). The device's structure is illustrated as follows:

Table 1: Comparison of Pruning Theory and Minimal-network Theory

	If component B had not operated, would component A have operated?	If component C had not operated, would component B have operated?
Pruning Theory	Yes	Yes
Minimal-network Theory	Maybe	No

Previous empirical work has explored whether people's counterfactual inferences are consistent with either of these two theories of counterfactual reasoning. In one experiment, Sloman and Lagnado (2005) presented people with causal information about a simple rocket-ship device with the causal structure  $A \rightarrow B$  and asked them a variety of counterfactual questions. Sloman and Lagnado found evidence that people engaged in pruning when they were told that a component was *prevented* from operating, but not when told that the component was *observed* not to have operated. However, subtle differences in wording across their experiments led to significantly different patterns of counterfactual inferences, making it difficult to generalize from the data. In another study, Rips (2010) asked people counterfactual questions about three- and four-component mechanical devices. Although participants' counterfactual inferences did not provide strong support for either pruning theory or minimal-network theory, their inferences were more closely aligned with minimal-network theory (see also Dehghani, Iliev, & Kaufmann, 2012).

In the two experiments in this study, we presented participants with counterfactual questions for which pruning theory and minimal-network theory make different predictions. The wording of these questions was manipulated across two between-subjects conditions. One group of participants was told that a component of a mechanical device "had not operated," and another group was told that the component "had failed" (e.g., *If Component B had not operated/had failed...*). The neutral "had not operated" wording does not suggest a particular explanation for the state of the component; however, the "had failed" wording suggests an explanation that is local to the component (e.g., the component is internally broken). Thus, we predict that participants in the *not operated* and *failed* conditions will make different counterfactual

inferences about the operating states of the other components. Specifically, we predict that participants in the *not operated* condition will reason diagnostically about the states of the other components based on the device's causal structure, consistent with minimal-network theory. In contrast, we predict that participants in the *failed* condition will reason that since the antecedent component is broken, its operating state is not diagnostic of the states of the other components. Thus, participants will break the causal links between the antecedent and its causes and infer that causally prior components would have operated in the counterfactual situation, consistent with pruning theory. In addition to examining participants' inferences about which components would and would not have operated in the counterfactual situation, we analyzed participants' explanations of their reasoning. In Experiment 1, we analyzed people's explanations of why they thought the non-antecedent components would or would not have operated. In Experiment 2, we analyzed people's explanations of why the antecedent event would have occurred.

### Experiment 1

Participants in this experiment received a series of problems about a set of eight hypothetical devices, each with four components. For each device, they answered counterfactual questions of the form *If component X had not operated [had failed], would components Y, Z, and W have operated?* and provided explanations justifying their reasoning.

### Method

**Materials.** The questionnaire booklets contained three pages of instructions followed by 24 pages of questions. The instructions explained the experimental task and told participants how to interpret the diagrams of the causal devices on the following pages. Each question page contained a written description of how a device operated (e.g., Component A's operating always causes component B to operate, etc.), which was accompanied by the corresponding diagram in Figure 1.

As shown in Figure 1, there were eight different causal devices, all of which had "diamond" structures. The devices varied in whether the causal links between components were deterministic (solid lines in Figure 1) or probabilistic (dashed lines), and whether components B and C had to operate together to cause D to operate (arc connecting links in Figure 1) or could independently cause component D to operate (no arc). The order of the devices was counterbalanced across participants. We used devices with diamond structures for two reasons. First, previous causal reasoning studies have used diamond structures and have found that people make accurate causal inferences about these systems (Meder, Hagmayer, & Waldmann, 2008, 2009). Second, pruning theory and minimal-network theory make different predictions for many of the counterfactual questions about these devices.

After learning how each device works, participants were told the device's current operating state, which was always that "at present, components A, B, C, and D are all operating." Next, participants were asked a counterfactual question about the device, such as *If component B had not operated, would components A, C, and D have operated?* For each of the eight devices, participants answered three counterfactual questions, one question each with A, B, and D as the antecedent component. Since the devices were symmetric with respect to components B and C, we did not ask a separate question in which C was the antecedent. The order of the antecedent components for these questions (ABD vs. DBA) was balanced across participants.

Figure 1: Causal Devices Used in Experiments 1 and 2

In this figure, solid arrows indicate deterministic links (e.g., A always causes B) and dashed arrows indicate probabilistic links (e.g., A usually causes B). All causal relationships are in the direction shown by the arrows. The arcs indicate that component B and component C operating together cause component D to operate, but component B or component C operating alone never causes component D to operate (jointly caused devices). The absence of an arc indicates that component B or component C operating alone causes component D to operate (separately caused devices).

Participants were randomly assigned to one of two experimental conditions. In the *not operated* condition, participants learned that the antecedent component (component B in the preceding example) "had not operated." In the *failed* condition, participants learned that the antecedent component "had failed."

For each counterfactual question, participants indicated which of the three non-antecedent components would have operated in the counterfactual state. For each component, participants could say that the component (1) would have operated, (2) would not have operated, or (3) might or might not have operated. To gain insight into how participants were reasoning about the counterfactual questions, participants also indicated the order in which they reasoned about the non-antecedent components. After making these inferences, participants justified their answers by responding to the prompt "Please explain why you answered in the way you did."

**Procedure.** Participants received the questionnaire booklet from the experimenter and answered the questions at their own pace. The experiment took approximately 30 minutes to complete.

**Participants.** Participants were 32 undergraduate students at Northwestern University. Participants received course credit for their participation.

## Results and Discussion

We analyzed participants' answers to the counterfactual questions (e.g., *If component B had not operated, would component A have operated?*) to see if their inferences were consistent with minimal-network theory or pruning theory. Responses of "would have operated" were scored as +1, responses of "would not have operated" were scored as -1, and responses of "might or might not have operated" were scored as 0. The mean score for participants was higher in the *failed* condition ( $M = -0.14$ ) than in the *not operated* condition ( $M = -0.43$ ),  $F(1, 32) = 7.07$ ,  $MSe = 7.29$ ,  $p = .01$ .

In two cases, pruning theory and minimal-network theory make the same predictions: (1) when component A was the antecedent, and (2) for the devices in which components B and C must both operate in order for component D to operate (jointly caused devices), when component B was the antecedent and component D was the consequent. In case (1), both theories say that components B, C, and D would all not have operated, and in case (2), both theories say that component D would not have operated. For all the other counterfactual questions, pruning theory predicts that the consequent component definitely would have operated (producing positive scores), whereas minimal-network theory predicts that the consequent component either (a) definitely would not have operated or (b) might or might not have operated (producing negative or 0 scores respectively).

When we restricted our analysis to the cases in which pruning theory and minimal-network theory make different predictions, the mean score for participants in the *failed* condition was 0.17 and the mean score for participants in the *not operated* condition was -0.27. As was the case with the entire data set, the difference between conditions was significant,  $F(1, 32) = 11.96$ ,  $MSe = 6.27$ ,  $p = .002$ . The mean score for the *not operated* condition was significantly less than 0,  $t(17) = -4.50$ ,  $p < .001$ ; however, the mean score

for the *failed* condition was not significantly different from 0,  $t(17) = 1.68$ , n.s.

Next, we examined the serial order (1, 2, or 3) in which participants reasoned about the three non-antecedent components. The most interesting case is the one in which component B was the antecedent since participants could work their way downstream (i.e., reason about component D first) or upstream (i.e., reason about component A first). Most participants (69%) started upstream, reasoning about component A before component D (Binomial test,  $p < .001$ ). The mean serial position for component A was 1.44, whereas the mean position for component D was 2.32. The order in which participants reasoned about the components did not differ across the *failed* and *not operated* conditions.

We also examined participants' explanations of their counterfactual reasoning to see if the explanations were consistent with pruning theory or minimal-network theory. We classified explanations in two ways.

(1) Explanations were coded as *causal backtracking* if participants used the state of the antecedent component to reason diagnostically about the states of upstream components. A sample causal-backtracking explanation was "If B wasn't operating that would mean A wasn't working since A always causes B." Causal-backtracking explanations are consistent with minimal-network theory.

(2) Explanations were coded as *causes are independent of effects* if they suggested that the states of upstream "cause" components are not affected by the states of downstream "effect" components. A sample explanation was "Neither A, B, nor C are dependent on D so they all will have operated." Such an explanation is consistent with pruning theory.

Notice that these three types of explanations are only applicable when there are components that are causally upstream of the antecedent component. Thus, we restricted the following analyses to the counterfactual questions in which B or D was the antecedent. The data were coded by a person who was unfamiliar with the experimental hypotheses, and 25% of the data were coded independently by a second coder. Inter-coder reliability was 90%.

Participants in the *not operated* condition were significantly more likely to provide "causal-backtracking" explanations than participants in the *failed* condition (65% vs. 32% respectively,  $F(1,24) = 12.9$ ,  $MSe = 16.4$ ,  $p = .001$ ). In contrast, participants in the *failed* condition were significantly more likely to provide "causes are independent of effects" explanations than participants in the *not operated* condition (25% vs. 9% respectively,  $F(1, 21) = 5.57$ ,  $MSe = 3.90$ ,  $p = .03$ ). Participants in the *not operated* condition were significantly more likely to provide "causal-backtracking" explanations than "causes are independent of effects" explanations ( $t(14) = 6.33$ ,  $p < .001$ ); however, participants in the *failed* condition did not significantly prefer either type of explanation.

In sum, participants in the *not operated* and *failed* conditions differed in their counterfactual inferences. Participants in the *not operated* condition had a stronger tendency to say that non-antecedent components would not

have operated than participants in the *failed* condition, and they made inferences that were better predicted by minimal-network theory. The analysis of participants' explanations also showed that most participants in the *not operated* condition used causal backtracking to diagnose the counterfactual operating states of upstream components. In contrast, participants in the *failed* condition were more likely than participants in the *not operated* condition to say that the operating states of upstream components were independent of, and could not be diagnosed from the state of the antecedent.

## Experiment 2

The pattern of inferences and reasoning strategies in Experiment 1 suggests that participants in the *not operated* and *failed* conditions may have generated different explanations for why the antecedent component had not operated. We therefore performed a second experiment to investigate the possible relationship between participants' explanations of why the antecedent component had not operated and their counterfactual inferences.

### Method

The experiment contained two parts, an inference task and an explanation task. The same eight causal devices from Experiment 1 were used in Experiment 2 (see Figure 1). As in Experiment 1, participants were randomly assigned to either the *not operated* condition or the *failed* condition.

### Materials.

*Inference task:* The inference task was identical to Experiment 1 except that participants did not provide explanations of their counterfactual inferences during this part of the experiment.

*Explanation task:* In the explanation task, participants described why the *antecedent* component had not operated. Note that this is a different type of explanation than the ones participants provided in Experiment 1; in Experiment 1, participants explained why the *non-antecedent* components would or would not have operated. The explanation-task booklet included three pages of instructions followed by 24 pages of questions. As in the inference task and Experiment 1, participants received information about how the causal devices work and told that "at present, components A, B, C, and D are all operating." Participants in the *not operated* condition were asked questions of the form *If component X had not operated, which of the following would best explain why?* Participants in the *failed* condition were asked a question that was identical except that "not operated" was replaced by "failed." For each device, participants answered this question for each of components A, B, and D as the antecedent. For each participant, the order of the devices, and within each device, the order of the antecedent components, was the same in the inference and explanation tasks.

When component B was the antecedent, participants selected an explanation from the following list:

- (1) Component B was internally broken.
- (2) Factors external to the device prevented component B from operating.
- (3) Component B operates unreliably, and component B just didn't operate this time.
- (4) Component A did not operate, which in turn caused component B not to operate.
- (5) Component A operated, but component B just didn't operate this time because the connection between component A and component B is unreliable.
- (6) Component A operated, but the connection between component A and component B was broken.

The list of explanations was similar when component D was the antecedent, except that "component D" was substituted for "component B" and "component B and/or<sup>1</sup> component C" was substituted for "component A." When component A was the antecedent, only the first three answer choices were included since component A's operation is not caused by other components. The order of the answer choices (above order vs. reverse order) was balanced across participants.

After choosing an explanation, participants rated their confidence on a 0-9 scale with one-point increments, where 0 = "not at all confident" and 9 = "extremely confident."

**Procedure.** Half of the participants completed the inference task followed by the explanation task and the remaining participants completed the explanation task followed by the inference task. Each task took approximately 20 minutes with the entire experiment taking approximately 40 minutes.

**Participants.** Participants were 32 undergraduate students at Northwestern University who had not participated in Experiment 1. Participants received course credit for their cooperation.

## Results and Discussion

**Inference Task.** The inference task replicated the findings of Experiment 1. The mean score for participants in the *failed* condition was significantly higher than for participants in the *not operated* condition. This was true for all counterfactual questions ( $M = -0.16$  vs.  $M = -0.48$  respectively,  $F(1,30) = 14.47$ ,  $MSe = 4.14$ ,  $p < .001$ ) and for the subset of counterfactual questions for which pruning theory and minimal-network theory make different predictions ( $M = 0.27$  vs.  $M = -0.25$  respectively,  $F(1, 30) = 19.27$ ,  $MSe = 4.94$ ,  $p < .001$ ).

**Explanation Task.** Participants' explanations were coded as consistent with pruning theory, consistent with minimal-network theory, or consistent with neither theory. Explanations 1, 2, and 6 (see Method section) were

<sup>1</sup> If either component B or component C operating alone could cause component D to operate, the "and" wording was used. Otherwise, the "or" wording was used.

classified as pruning explanations. When the links between the antecedent and its causes were deterministic, explanation 4 was classified as a minimal-network explanation. When the links between the antecedent and its causes were probabilistic, explanation 5 was classified as a minimal-network explanation. All other responses were classified as "other." Since neither explanation 4 nor explanation 5 (the two possible minimal-network explanations) is applicable when component A was the antecedent, the following analyses were conducted only for the counterfactual questions in which component B or D was the antecedent.

Participants were significantly more likely to choose minimal-network explanations than pruning explanations (61% vs. 21% respectively,  $t(31) = 5.31$ ,  $p < .001$ ). This pattern was observed in both the *not operated* (60% vs. 14% respectively,  $t(15) = 4.92$ ,  $p < .001$ ) and *failed* conditions (61% vs. 27% respectively,  $t(15) = 2.85$ ,  $p = .01$ ). Notice that participants in the *failed* condition were significantly more likely to choose pruning explanations than participants in the *not operated* condition ( $F(1,29) = 4.56$ ,  $MSe = 3.04$ ,  $p = .04$ ). The results are shown in Figure 2.

Figure 2: Percent of Minimal-Network and Pruning Explanations by Condition

Interestingly, when the causal links between the antecedent and its causes were probabilistic, participants in both conditions were significantly more likely to choose a minimal-network explanation (e.g., Component A operated, but component B just didn't operate this time because the connection between component A and component B is unreliable) than a pruning explanation (e.g., Component B was internally broken; Factors external to the device prevented component B from operating; Component A operated, but the connection between component A and component B was broken), (*Not operated* condition:  $t(15) = 5.81$ ,  $p < .001$ , *Failed* condition:  $t(15) = 5.00$ ,  $p < .001$ ). All these explanations (both the pruning and minimal-network explanations) imply, and in some cases state explicitly, that causally upstream components would have operated. Even

though this counterfactual state is consistent with both pruning theory and minimal-network theory, participants in both conditions preferred minimal-network explanations.

As in Experiment 1, minimal-network theory better explained the inferences of participants in the *not operated* condition compared to pruning theory. While participants in the *failed* condition were more likely than participants in the *not operated* condition to say that non-antecedent components would have operated, participants in both conditions preferred minimal-network explanations over pruning explanations. Thus, Experiment 2 suggests that minimal-network theory might provide a starting point for a good psychological theory of counterfactual reasoning.

## General Discussion

In the two experiments in this paper, we examined (1) participants' counterfactual inferences about the states of variables in a causal system and (2) participants' explanations of their reasoning. Alternative theories of counterfactual reasoning such as pruning theory and minimal-network theory make different predictions about how people should modify (or preserve) the system's causal structure when reasoning about a counterfactual scenario.

A defining characteristic of pruning theory is the proposal that people treat counterfactuals as interventions. Under this account, people should simulate the counterfactual state by intervening on the causal system, and we would expect them to break both probabilistic and deterministic causal links and say that upstream components would have operated. Furthermore, they should endorse an interventionist explanation for the counterfactual state of the antecedent component, such as "factors external to the device prevented the antecedent component from operating."

Our data provide evidence against this hypothesis. Participants in the neutrally worded *not operated* condition made counterfactual inferences that preserved deterministic causal relationships between components' operating states. When the causal links between the antecedent component and its causes were deterministic, participants inferred that the antecedent component's causes would not have operated, which in turn caused the antecedent component not to operate. However, when the causal links were probabilistic, participants inferred that the antecedent component's causes would have operated, but the antecedent component would not have operated because the links were unreliable. These inferences and explanations are consistent with minimal-network theory, which proposes that people should prefer "legal" counterfactual states that preserve the system's (deterministic) causal laws, but they are inconsistent with pruning theory.

We also found that participants in the *not operated* and *failed* conditions reasoned differently about the counterfactual scenarios. The *failed* wording suggested to participants that the antecedent component was internally broken. Accordingly, these participants modified the devices' causal structure by breaking the causal links between the antecedent and its causes, and they inferred that

upstream components would have operated. Other studies that have varied the wording of counterfactual questions have found similar effects (Sloman & Lagnado, 2005).

Each type of wording supports a particular (and different) explanation for the counterfactual antecedent. The differences in participants' explanations across conditions suggest that these explanations may in turn shape participants' counterfactual inferences. Hempel (1965) famously proposed that causal explanations support predictive inferences, and our data suggest such a connection between explanation and inference in counterfactual reasoning (Goodman, 1955). Specifically, we propose that when engaging in counterfactual reasoning, people integrate their explanation of the counterfactual antecedent with their knowledge of the system's causal structure to infer the system's counterfactual state.

## Acknowledgements

We thank Ben Rottman, Steven Sloman, and members of the Northwestern University Higher Level Cognition Laboratory for their valuable feedback on these experiments. We thank Samantha Thompson and Joanna Westerfield for their research assistance. The research was supported by an NSF graduate research fellowship (BJE) and IES Grant R305A080341 (LJR).

## Abstract

Learning new concepts is critical to making sense of the world. Research on analogical reasoning suggests structure mapping and schema induction can enable discovery of new relational concepts. However, existing theories of schema induction and refinement are insufficient to explain acquisition of rich, compositional hierarchies of relational concepts. This paper offers a proposal for this sort of representation construction, founded on reinforcement learning to evaluate the predictive usefulness of higher-order relations, together with a mechanism of relational consolidation by which systems of relations (schemas) can be chunked into unitary entities. A computational model of these ideas is outlined and partially tested in simulations and human experiments. Implications and moderating factors for relational consolidation are considered.

**Keywords:** Relational Consolidation; Analogy; Schema Induction; Predication; Refinement; Concept Learning

## Introduction

Consider a second-order same-different task, in which the subject is presented with two pairs of objects and must recognize whether the pairs match in terms of whether their objects are the same or different. The pairs match if both are instances of *sameness* (e.g., A-A, B-B) or if both are instances of *difference* (e.g., A-B, C-D), and they mismatch if one is an instance of sameness and the other an instance of difference (e.g., A-A, B-C). Thompson, Oden, and Boyson (1997) tested naive chimpanzees on this task and found them unable to learn it, unless they were first trained on a first-order same-different task. In the first-order task, a single pair of objects was presented, and subjects learned to associate sameness and difference to two plastic tokens (e.g., a yellow triangle and a red circle, respectively). Thompson et al. argued this training enabled subjects to reduce the second-order same-different task to a first-order task, by mentally replacing each pair of objects with its associated token, and then determining whether those tokens matched (see also Clark, 2006).

Learning higher-order relations, such as in the second-order same-different task, is arguably critical to abstract conceptual development. In this paper, we argue that many concepts reside in relational hierarchies (relations among relations, and so on), and we investigate how such concepts might be learned. Our basic premises are that much structure in the world (or at least its mental representation) is hierarchically compositional, and that discovering (or creating) this structure is a powerful cognitive mechanism for both learning and designing complex systems.

For example, computer architecture, mathematical functions, and natural languages all exemplify multiple

levels of abstraction by chunking systems of relations at one level into building blocks at the next level. In computer architecture, digital logic gates are composed to form adders, which are composed with other digital circuits to form an arithmetic logic unit (ALU), which is a building block in a computer's CPU. Software design manages complexity by continuing this hierarchy, composing primitive functions into more complex functions, and from there to objects and design patterns. The conceptual progression in mathematics proceeds similarly, composing the counting operation to define adding, which is further composed to form multiplying, and then exponentiation. In traditional views of linguistics, phonemes, morphemes, words, and sentences form another example of a relational hierarchy.<sup>1</sup>

These examples motivate our basic research questions. How are relational hierarchies mentally represented? How are these representations learned or constructed through experience? Once a relational concept is learned, how can one discover the higher-order relations in which it can participate?

Here we consider the proposal that much of concept learning is driven by recognizing relational structure through analogy. Research on analogical reasoning has converged on a view that episodes or scenarios are represented as patterns of role binding, in which objects are bound to roles of relations (Gentner, 1983; Hummel & Holyoak, 2003). For example, the fact that the earth revolves around the sun is represented by binding *earth* and *sun* to the first and second roles of a *revolves\_around* relation. An analogy between two scenarios constitutes a determination that they share a common pattern of role binding. For example, in the analogy between the solar system and the atom (Gentner, 1983), each system has the property that the object playing role 1 of *revolves\_around* is the same as the object playing role 2 of *more\_massive\_than*.

Analogy formation can thus be viewed as a search for a pattern of linkage among relations (i.e., in terms of how they are bound to shared objects) that holds in two different scenarios. This linkage pattern is a type of higher-order relation among the linked relations. Theories of schema induction (e.g., Doumas, Hummel, & Sandhofer, 2008) offer one way for such higher-order relations to be learned. When an analogy is formed, an abstract schema is created that captures the common structure discovered by the

---

<sup>1</sup> Relational hierarchies are not taxonomic hierarchies. In a taxonomic hierarchy, each concept or category is a union of lower-level categories. In a relational hierarchy, each *instance* of a concept is a configuration of instances of lower-order concepts.

analogy. The schema can act as a new relational concept, in that it can be analogically aligned with future instances of the higher-order relation it embodies.

Although we agree with theories of schema induction, we argue it is insufficient to explain human relational learning. Schemas are explicit relational structures, and thus they cannot be bound to roles of yet-higher-order relations in the way unitary objects and relations can. The Thompson et al. (1997) study suggests that newly learned relations can only fill roles of other relations if they can be represented as atomic entities. Therefore, to explain acquisition of relational hierarchies, we put forward the hypothesis that useful schemas are eventually replaced (or supplemented) with unitary representations. Thus, a concept that was represented as a system of relations (via the schema) can now be represented as an atomic entity, capable of entering into relations itself. We label this process *relational consolidation*, in a deliberate parallel to theories of episodic memory consolidation (e.g., Squire & Alvarez, 1995).

We further propose that analogy, schema induction, and relational consolidation form a cycle that, when iterated, can produce relational hierarchies of arbitrary depth (height). This form of learning leads to a dualist view of objects and relations, in which (nearly) every concept is both a relational structure among its components and an object capable of participating in relations. The conceptual systems built from this hierarchical relational chunking are potentially quite powerful and flexible.

The remainder of this paper sketches a computational model under development that formalizes these ideas. We report experimental tests and discuss implications of human learning of higher-order relational structures.

## Model

We propose a computational model for learning hierarchies of relational concepts, named APEC for Analogy, Predication, Evaluation, and Consolidation. The first two stages (A, P) of the model draw on prior work on analogy and schema induction (Doumas et al., 2008; Forbus, Gentner, & Law, 1995; Larkey & Love, 2003). The last two stages make new proposals for how schemas are selected (E) and consolidated (C) into new concepts. Altogether, the model progresses through parallel processes of analogy formation, predication of relational structure by schema induction, evaluation and refinement of schemas in a reinforcement-learning setting, and consolidation of useful schemas into new atomic relations. Consolidated relations enter into new analogies, allowing the entire learning process to iterate.

The goal of the model is to identify new higher-order relations that are useful for making predictions and guiding behavior. There are an infinite number of higher-order relations that could be learned from any episode, and thus the challenge is selecting those that carry useful information (analogous to the problem of selecting configural cues in feature-based learning; e.g., Gluck & Bower, 1988). The present model addresses this problem in two ways. First,

analogical mapping identifies higher-order relations that recur across multiple episodes, to determine which schemas to induce (a form of unsupervised learning). Second, schema evaluation determines how useful each higher-order relation is for predicting outcomes or reward, to determine which schemas to consolidate (a form of reinforcement learning).

The model is currently being implemented within Conway's Game of Life (Gardner, 1970), a cellular automaton exhibiting hierarchical emergent structure, to test its ability to discover that structure. The model produces interesting patterns of schema formation and evolution, which will be reported elsewhere. Here we lay out the model's basic architecture and formulation.

## Analogy

APEC represents episodes as systems of role binding among entities, each of which is an instance of a known concept. Every entity is eligible to be bound to a role of one or more other entities, and all entities except primitive objects (used to seed the model) have roles that other entities can bind to. The goal of the analogy component of the model is to find correspondences between episodes that maximally preserve these role-filler relationships (i.e., parallel connectivity).

Formation of an analogy is achieved by a dynamic process of structure mapping. APEC's mapping dynamics are based on a simplified version of the Connectionist Analogy Builder (CAB; Larkey & Love, 2003). For every pair of entities (say,  $a_i$  in episode 1 and  $b_j$  in episode 2), a mapping weight ( $m_{ij}$ ) is defined. Mapping weights evolve according to excitatory and inhibitory dynamics. The raw evidence,  $R_{ij}$ , for mapping weight  $m_{ij}$  is derived by summing the excitation received from all other weights:

$$R_{ij} = \sum_{kl} w_{ijkl} m_{kl}$$

The excitation weight  $w_{ijkl}$  equals 1 if  $m_{ij}$  and  $m_{kl}$  correspond to immediately adjacent and compatible mapping connections (e.g.,  $a_k$  plays role  $r$  in  $a_i$ , and  $b_l$  plays role  $r$  in  $b_j$ ), and it equals 0 otherwise. The raw evidence is filtered through additional inhibitory mechanisms that encourage one-to-one mappings, and the result determines the incremental change to the mapping weights. These dynamics continue until all mapping weights converge to 0 or 1.

Following the MAC/FAC model of analogical retrieval (Forbus et al, 1995), APEC uses a measure of structural match to determine the quality of an analogy. An initial score is assigned to every matched pair of nodes to enforce a size preference. A preference for deep analogies (systematicity) is implemented via a trickle-down method, whereby initial match scores are passed down to increment the scores of matching components. The match scores are summed to get a global measure of structural match quality.

## Predication

If the analogy achieves a minimum match quality, a schema is induced that represents the structural commonalities of

the analogues and encodes the shared pattern of role binding embodied by the analogy. Specifically, an abstract entity is created for every mapping weight in the analogy, and these entities are role-bound to each other if the corresponding entities in the analogues are so bound. Once created, schemas are treated identically to episodes (they are just more abstract). This simple mechanism is drawn from prior work on schema induction (Gick & Holyoak, 1983; Doumas et al., 2008; Kuehne et al., 2000). A schema can be thought of as codifying the higher-order relation embodied by the analogy, hence turning it into an explicit predicate. Aligning the schema with any new episode enables a test of whether that episode instantiates the higher-order relation.

## Evaluation

When a schema is retrieved and compared to a new episode, it is refined, by abstracting the common structure between schema and episode (Doumas et al., 2008). This process is a form of intersection discovery, where the intersection of the set of relations in a schema and episode are encoded as a new schema. In this way, schemas shrink in size because the variability between episodes is abstracted over, leaving only the structure that is consistent across episodes. However, there may also be a need for schema elaboration, where schemas can grow in size (Corral & Jones, in press). We are currently exploring implementing schema elaboration in the model.

In parallel with schema refinement, schemas are evaluated as candidates for consolidation as new relational concepts. New concepts are useful because they can facilitate generalization. Learning about one instance of a concept can be applied to other instances. Jones & Cañas (2010) show how representations can be learned by improving generalization in a reinforcement-learning framework. The basic idea is that reward prediction error (TD error) can be used to determine when generalization from some past stimulus to the current stimulus was or was not helpful. In the present context, if a learner encounters an episode that is alignable with some stored schema, then analogical inference from that schema enables generalization from past instances of that schema. If this inference leads to improved prediction or behavior, then the schema is strengthened, and if not it is weakened. This process tunes generalization to depend more on higher-order relations that are predictive and less on those that are not.

## Consolidation

Relational consolidation is the process of a schema becoming chunked into a unitary concept that can be recognized automatically, retrieved from memory in parallel, and represented as an element of yet-higher-order relations. As summarized in Table 1, consolidation is hypothesized to confer properties to a concept that are not true of (unconsolidated) schemas, because consolidated concepts are recognizable perceptually, without explicit (working-memory dependent) structure mapping.

Table 1. Predicted consequences of consolidation

Not Consolidated	Consolidated
More affected by WM demands	Less affected by WM demands
Quicker at analogical inference, because structure mapping is active	Easier to learn higher-order structure, because instances can be represented by tokens
Serial retrieval	Parallel retrieval

It is important to note that consolidation is not a change in the declarative knowledge embodied by a concept. Rather, it is a proceduralization of the concept that enables future changes in knowledge – similar to the interaction between declarative and procedural knowledge in production systems (Anderson & Lebiere, 1998).

The DORA model of relational predication (Doumas et al., 2008) has an operation similar to relational consolidation, in which it recruits a new proposition node to bind lower-order relations. This new node can be bound to roles of yet-higher-order relations, but the relation is still explicitly structured. In contrast, consolidation might be viewed within the DORA framework as enabling the new proposition node at the top of the relational structure to evolve into a new semantic node at the bottom. We conjecture this difference has important implications for recognition and retrieval of instances of the concept.

Relational consolidation is best explained from the perspective of the MAC/FAC model of analogical retrieval (Forbus et al, 1995). MAC/FAC embodies the assumption that verifying the lower-level elements of an episode (i.e., objects and relations) is fast and automatic, whereas verifying relational structure is slower and requires working-memory resources. In the first stage of analogical retrieval (Many Are Called), the target episode is converted to a flat feature vector that is used to probe all episodic memories in parallel. Importantly, the dimensions in the MAC feature vector are predefined, based on the concepts the learner currently knows. Stored episodes that share content (objects and relations) with the target are retrieved, without regard for how those objects and relations are connected by role binding. In the second stage (Few Are Chosen), the episodes retrieved by the MAC stage are filtered by structural alignment to the target. Only those episodes that are alignable with the target survive this stage.

From the perspective of the MAC/FAC framework, relational consolidation enables a higher-order relation to be chunked and treated as a dimension of the feature vector used for memory probing. Prior to consolidation, retrieval of instances of a higher-order relation require something like the FAC stage, in which subjects explicitly map between those instances and the schema. Following consolidation, retrieval can rely solely on the MAC stage, thus operating much more rapidly and without requiring working memory. We also propose a similar difference for perceptual recognition of instances of the concept in the

Figure 1: The two ways a predicated relation can be represented or recognized. (A) Before consolidation, episodes must be structurally aligned to a schema. (B) After consolidation, an instance of the concept is explicitly represented and bound to the lower-order relations. The labels on the nodes refer to Experiments 1 & 2.

environment, through the creation of a perceptual detector for each consolidated concept. Figure 1 illustrates the difference between recognizing an instance of a higher-order relation that has versus has not been consolidated.

## Experiments 1 & 2

The goal of the present experiments was to test learning of categories defined purely by higher-order relations. That is, the set of objects and relations present in instances of each category were identical; only the way the relations were linked into a higher-order structure differed. If people can learn this type of category distinction, it would support our basic proposal for how higher-order relations are defined in constructing relational hierarchies.

Each trial showed animations of three spaceships racing each other in pairs. The categories were defined by the two logically possible structures these races could form: a *cycle* (e.g., A beats B, B beats C, C beats A) and an *ordering* (e.g., B beats A, B beats C, C beats A). The races are thus first-order relations between spaceships, and cycle and ordering are the possible higher-order relations (see Figure 1 for an example of the cycle structure).

According to APEC, three types of learning potentially contribute to this task. First, analogical alignment between episodes (trials) leads to induction of schemas capturing their common structure or properties. Some of these schemas will capture the true category structure, whereas others will be based on irrelevant information (e.g., ship color or spatial position). Second, feedback following each trial is used to strengthen or weaken schemas that contributed to each response, so that eventually the correct higher-order relations should come to dominate performance. Third, with sufficient learning, the correct higher-order relations may become consolidated. The results reported below primarily bear on the first of these mechanisms.

## Methods

110 and 62 undergraduates participated in Experiments 1 and 2, respectively. Subjects were told they would observe alien spaceship races, in sessions of three races each. The aliens were said to have two names for possible outcomes of a session, and the subject's task was to learn their meaning.

On each trial, three spaceships (differing only in color) raced in pairs in a sequence of three races. The subject classified the session as "Dekal" or "Koplu" by typing D or K. The correct answer was then displayed. The experiment lasted until the subject met a learning criterion of 8 out of 10 trials correct, or until 25 minutes elapsed (50-70 trials).

Each experiment included two orthogonal manipulations designed to bias attention between objects (spaceships), relations (races), and higher-order relations. In Experiment 1, the trials were described as either "tournaments" or "sessions". In addition, the main task was preceded by a series of footraces among 5 cartoon characters, after which subjects were asked either which character had done best overall or which of two characters had won a specific race. The tournament label and overall-winner question were predicted to make rankings salient, thus shifting attention to higher-order relations.

In Experiment 2, half the subjects were given a first-person perspective by adding a gold star to mark "your ship" on each trial. In addition, the three colors used for the spaceships were either constant or variable from trial to trial. The marked ship and constant colors were predicted to make individual objects more salient, thus shifting attention away from higher-order relations.

## Results

There were no differences across conditions in either experiment in meeting the learning criterion or number of trials to criterion. All subsequent analyses are based on collapsing the groups of both experiments.

The results demonstrate that subjects could learn the difference in categories. 113 subjects (65.7%) met the learning criterion. Figure 2A shows the distribution of trials to criterion for these subjects ( $M = 30.9$ ). Ten subjects learned without making a single error; they were excluded from the remaining analyses, which are based on errors.

Figure 2B shows a backward learning curve, aligned on each subject's last error (for subjects who solved the task but made at least one error). Performance prior to the last error is only slightly above chance, indicating learning was nearly all-or-none. This is consistent with our hypothesis that learning is triggered by inducing the correct schema.

Figure 2. A: Distribution of trials to criterion, for subjects solving the task. B: Backward learning curve.

If learning depends on analogical mapping, then it should be most evident following consecutive stimuli in the same category (assuming subjects most often compare stimuli from consecutive trials). Assuming the schema was induced following the trial of the last error ( $t_{\text{last}}$ ), this predicts the stimuli on trials  $t_{\text{last}} - 1$  and  $t_{\text{last}}$  should tend to be of the same category (see Figure 3). This prediction holds for 59 of the 103 subjects ( $p = .084$ , one-tailed binomial test). If we relax the all-or-none assumption and examine performance of all subjects on all trials  $t$ , we find a highly reliable advantage when trials  $t - 2$  and  $t - 1$  are of the same category (mean difference 4.3%, paired  $t_{169} = 3.42$ ,  $p < .001$ ).<sup>2</sup> This suggests comparison of recent stimuli from the same category had a significant effect on performance.

Figure 3. Example sequence of trial types and the most likely moment of schema induction. Triangles indicate ordering trials and circles indicate cycle trials.

## Discussion

Analogy and metaphor are pervasive in cognition (Hofstadter, 2001; Lakoff, 1980) and play a critical role in abstract reasoning. The past three decades of research have led to a strong consensus that analogy hinges on recognition of common relational structure between two or more situations (e.g., Gentner, 1983; Hummel & Holyoak, 2003). This suggests that acquisition of new higher-order relations plays a critical role in human conceptual development.

We propose that many (if not most) abstract concepts exist in relational hierarchies, in which entities are at once relational structures among their components and elements of higher-order relations. The structure-mapping process of analogy (Gentner, 1983) can be viewed as a search for relations among relations, in the sense of how relations are connected to one another by operating on the same objects. Successful analogies—those that lead to useful inferences or predictions—might thus be treated as candidates for new relational concepts.

Our approach builds on models of analogical retrieval (Forbus et al., 1995), structure mapping (Falkenhainer, et al., 1989; Hummel & Holyoak, 1996; Larkey & Love, 2003), predication, and refinement (Doumas et al., 2008). Importantly, our model goes beyond previous models of schema induction (Doumas et al., 2008) by positing relational consolidation as a means for learning new relational concepts. A further contribution of our approach is embedding predication within a reinforcement-learning framework in order to modify analogical similarity, and thus

generalization, by representation change (Jones & Cañas, 2010; see also Tomlinson & Love, 2006).

Taken together, these ideas lead to a model, APEC, which iterates the Analogy, Predication, Evaluation, and Consolidation stages to build relational hierarchies in a long-term conceptual learning system. Our eventual aim for the model is a system that can autonomously discover useful structure in its environment by construction of these relational hierarchies.

Although the present experimental results indicate a role for analogical comparison and schema induction, we do not have strong evidence here for consolidation. Indeed, we believe it more likely that the categories were learned only as schemas. The experiments do provide a test of one fundamental assumption of the model: that people can learn higher-order relations defined solely by the configuration of shared role binding among lower-order relations.

Future experiments could build the tournaments into third-order structures that require consolidation of the tournament type in order to solve the task. Another future experiment is to test transfer of learned relational structure to an alternate domain with different lower-order relations. The lack of effect of our manipulations suggest it is an open question what factors influence the kind of learning tested in these experiments.

Evidence for relational consolidation could also come from process dissociation between the two modes of representation outlined in Table 1. Other evidence may come from neurological studies. We speculate that relational consolidation is implemented neurally by a process of hippocampal-to-cortical feedforward training, in line with models of episodic memory consolidation (Gluck & Myers, 1993; McClelland, McNoughton, & O'Reilly, 1995). The hippocampus is well suited for storing schemas, which are inherently structured, given the conjunctive and localist nature of hippocampal representations.

Relational consolidation is similar to the career-of-metaphor hypothesis, by which a metaphor is originally an analogical mapping between the base and target domain, but it can become conventionalized so that the target is recognized immediately as an instance of the base category (Gentner et al., 2001). This transition from novel to conventional metaphor resembles the transition from non-consolidated to consolidated relations, in that both involve a transition from recognition via structure mapping to more automatic, perceptual recognition. The major difference is that in the career of metaphor, the base concept was already consolidated, and the conceptual change is a form of sense extension of that base concept. The conventionalization process does not create new concepts; it just extends their meaning. Therefore it does not function to build up relational hierarchies. Nevertheless, the two ideas seem intimately linked, in that the career-of-metaphor mechanism might play an important role in extending and refining the meaning of concepts after they have been consolidated.

Language is almost certainly an important factor in relational consolidation. Thompson et al.'s (1997) finding

<sup>2</sup> Two additional subjects were excluded because they experienced no alternation trials before meeting the learning criterion.

of chimps learning higher-order relations depended on initial training with material tokens. In humans, words can act as linguistic tokens (Clark, 2006) and have been shown to aid category learning (Lupyan, Rakison, & McClelland 2007). Son, Dumas, and Goldstone (2010) offer two possible roles of language in relational learning: “(1) words invite learners to compare, highlight, and represent relations (the Generic Tokens [GT] hypothesis), and/or (2) words carry semantic cues to common structure (the Cues to Specific Meaning [CSM] hypothesis)” (p. 55). The lack of significant effect of the CSM manipulation in our Experiment 1 could be explained by the cue word appearing only at the start of the experiment, or by the relatively subtle difference in semantics evoked by the cues “tournament” vs. “session”. A stronger test of CSM would be to cue subjects with category labels whose meanings structurally match or mismatch the category schema.

Finally, we do not claim that relational consolidation is the only mechanism for acquiring new relational concepts. Research on basic-level objects (Rosch et al., 1976) suggests there are truly primitive object concepts that are not originally constructed as relational systems. Clearly a lot of discovery comes from analyzing the substructure of objects, and that process should be included in any complete model. For example, categories can be induced for objects that fill the same roles (Jones & Love 2007). Although we have been working on concept learning through mechanisms of synthesis, a future goal is to explore how combinations of analytic and synthetic mechanisms of relational learning might be more powerful than both alone.

# “Eyes Closed” and “Eyes Open” Expectations Guide Fixations in Real-World Search

Tom Foulsham (foulsham@essex.ac.uk)

Department of Psychology, University of Essex  
Wivenhoe Park, Colchester, CO4 3SQ, UK

## Abstract

Investigations of search within realistic scenes have identified both bottom-up and top-down influences on performance. Here, I describe two types of top-down expectations that might guide observers looking for objects. Initially, likely locations can be predicted based only on the target identity but without any visual information from the scene (“Eyes closed”). When a visual preview becomes available, a more refined prediction can be made based on scene layout (“Eyes open”). In two experiments participants guessed the location of a target with or without a brief preview of the scene. Responses were consistent between observers and were used to predict the eye movements of new observers in a third experiment. The results confirm that participants use both types of top-down cues during search, and provide a simple method for estimating these expectations in predictive models.

**Keywords:** scene perception; visual search; attention; eye movements

## Introduction

Imagine walking into a friend’s kitchen to look for a coffee mug when you have never been there before. Even before you open the door you would already have a significant amount of knowledge about where this object might be. For example, you would not expect it to be on the floor or near the ceiling, so you would be unlikely to look in these locations. When entering the room, the first glance tells you that, in this particular kitchen, there is a large window on one side of the room and shelving with cupboards on the opposite side. You refine your expectations about where the object will be and subsequently recognize the mug on a shelf.

As this scenario reveals, searching for something in the real world involves not just the matching of visual information to a stored template but also the use of detailed semantic knowledge about scenes and objects. Although visual search has been very well studied in cognitive psychology, this has mostly been in the context of simple search displays and models that predict performance based on target features (e.g., Wolfe, 1998). More recently, there has been significant interest in exploring the mechanisms involved in directing attention during search within natural scenes, and in testing these mechanisms by measuring eye fixations.

In one approach, computational models of bottom-up visual salience have been proposed that select targets based on the degree to which they stand out from their background (Itti & Koch, 2000). By this account, participants will attend

to regions of high salience until they find what they are looking for. However, it is clear from several experiments that, when searchers know what they are looking for, this knowledge, and not simple visual salience, dominates the locations inspected during search (Chen & Zelinsky, 2006; Foulsham & Underwood, 2007).

This has led to more realistic models that combine top-down knowledge of the searcher to prioritize those locations in a scene in which an object is likely to appear. One way to do this is to compare scene locations with a representation of target *appearance*. If one knows that the target is red, locations with this colour should be more likely to be fixated. This principle underlies several models of search guidance (Wolfe, 1994; Navalpakkam & Itti, 2005), and can be successful at predicting fixations in real scenes (Zelinsky, 2008; Kanan et al., 2009).

However, it is clear from the scenario at the beginning of this paper that searchers also have access to detailed expectations about target *location*. There is evidence from several different experiments that these expectations are used to direct attention during search. For example, scrambling an image—so that local visual features remain the same but their configuration is altered—impedes search and alters eye movements (Biederman et al., 1973; Foulsham, Alan & Kingstone, 2011). Objects that are incongruent with their context or out of place may be found more slowly (Henderson, Weeks & Hollingworth, 1999). The contextual guidance model proposed by Torralba et al. (2006) accounts for these effects by combining bottom-up salience with a Bayesian prior for where an object is likely to be, conditioned on the global features of an image. In essence, the model recognizes the gist and layout of a scene (e.g., finding street level in an urban environment), learns the target’s likely location within this representation, and searches accordingly (e.g., by looking for people at street level).

The top-down guidance by context discussed so far emerges early, with the first glance of a scene, but requires visual input in the form of low spatial-frequency features and “gist”. On the other hand, it is likely that the semantic information associated with different objects might include general expectations about position within a scene-centered or person-centered frame-of-reference which could be activated *before* exposure to the to-be-searched scene. The present paper investigates whether these expectations are reliable and whether they effect the distribution of attention in real-world search. If so, they could be incorporated into probabilistic models (e.g., Kanan et al., 2009; Torralba et al., 2006).

I will distinguish between “Eyes closed” expectations, which can be made prior to any perception of the scene, and “Eyes open” expectations, which are affected by a rapid perception of scene gist, as might be available during the first fixation on a scene. I describe two simple experiments to quantify “Eyes closed” and “Eyes open” predictions, and these predictions are then compared to the eye fixations made by independent searchers. If contextual guidance of attention occurs only in response to scene features then “Eyes closed” expectations will not be a good description of where people look during search.

## Experiments 1 and 2

In Experiments 1 and 2, participants guessed where a target object would be located based on very little information.

### Method

**Participants** Eighteen student volunteers (12 females) took part in return for course credit. All participants took part in Experiment 1 first, followed by Experiment 2. The mean age was 19.4 years.

**Stimuli and Apparatus** The stimuli for all experiments were derived from 72 colour photographs of indoor and outdoor scenes collected from the Internet. Scenes were chosen which contained a single example of an easily nameable target object that was not located directly in the centre of the image. The name of this object was the matching target label for the scene.

Each target label was also matched to another scene from the set in which it could plausibly be found. This led to 144 label-scene pairs, half of which were “target-present” trials, where the scene contained the target, and half of which were “target-absent”. The same target labels were used in both experiments.

Target labels were presented in large black font centred above a grey rectangle representing the scene. In Experiment 2, scene images were presented at a resolution of 1024 x 768 pixels. Stimuli were presented on a 19-inch CRT monitor with a refresh rate of 60Hz. Presentation was controlled by PsychoPy (Pierce, 2007), and responses were entered with the mouse.

**Procedure** Figure 1 depicts the procedure. In Experiment 1, participants were instructed to “make their best guess” where a target was located in an image. The experiment began with a practice example of a target and scene. In the experimental trials, a target label was presented alongside a grey rectangle representing the image frame, and participants were instructed to click with a mouse cursor where in the frame they thought the target was located. In order to motivate participants, feedback was given after every 12 trials in the form of a percentage score representing how close their mouse clicks had been to the actual target locations.

Figure 1: The procedure for one trial in Experiment 1 (top) and Experiment 2 (bottom). The target is highlighted in the scene preview, for display purposes only.

Scores were calculated from the average Euclidian distance between the chosen location and the centre of the target object, in target present trials only, and normalized by the scene diagonal. All 72 target labels were presented in a random order, but the actual scenes were not shown to participants.

In Experiment 2, participants were given a brief preview of the scene in which the target was located before they made their response. In each trial, a text prompt told participants to get ready, and a fixation cross was then presented in the centre of the screen for 1s. The scene was then presented briefly for 67ms, followed by a target label presented alongside a grey rectangle representing the image frame. The brief preview was chosen because it is known that scene gist can be perceived very quickly (Biederman et al., 1973), and also to limit the possibility that targets would be attended during the preview. A pattern mask was not included, and so after-images may have persisted, although the guess prompt had the effect of partly masking the display and drawing attention away from the scene. As in Experiment 1, participants were instructed to guess the location of the target with a mouse click, and feedback was given regarding average performance over the previous 12 trials. In Experiment 2, all 144 label-scene pairs were presented in a random order.

### Analysis and Results

The results were analysed in order to estimate the inter-observer agreement, i.e., the degree to which different participants “guessed” in similar locations for each target label. The approach used closely followed that in previous studies of fixations in real-world search (Torralba et al., 2006; Ehinger et al., 2009). Participant-selected locations were first combined to produce a spatial model of target predictions—an “expectation map”—which was then used to predict search behaviour in Experiment 3.

Expectation maps were formed by representing each participant’s guessed location as a 2-dimensional Gaussian and summing across all participants. The highest points on this map indicate locations that, according to the

participants, are most likely to contain the target. The dispersion of the map will reflect between-participant agreement: maps that cluster into a few small areas signify that participants agreed on where a target was likely to appear. Maps were computed separately for each target label in Experiment 1, and for target-present and target-absent trials in Experiment 2.

The receiver operating characteristic (ROC) curve was used to evaluate expectation maps. The ROC curve is a non-parametric measure of sensitivity originating from signal detection theory. This measure has become common in machine learning, and also in studies of spatial attention and eye movements, as it allows spatial distributions (e.g., salience maps) to be compared to specific locations (e.g., eye fixations). Full coverage of this method can be found elsewhere (e.g., Ehinger et al., 2009). The area under the curve (AUC) was computed as a summary statistic. AUC values indicate the probability that the map will rank a selected location more highly than a non-selected location and range from 0 to 1, with a score of 0.5 indicating chance performance.

**Inter-Observer Agreement** An all-except-one method was used to compute the between-participant agreement for each expectation map. In this analysis, a map was computed based on the responses of all participants except one, and the ROC curve was used to evaluate how well this model predicted the location chosen by the remaining participant. This process was repeated for all participants, and the mean AUC value obtained is an indicator of the inter-observer agreement in guessed locations.

Figure 2 shows a target expectation map for two example target labels from Experiment 1. The first is from a target on which participants showed considerable agreement, while the mouse clicks in the second are more distributed. Table 1 summarizes the between-participant AUC scores across all targets in Experiments 1 and 2. Critically, all the scores are much greater than 0.5, confirming that participants were indeed consistent in the points that they chose. This was true for Experiment 2, where participants saw a brief preview of the search scene, and also for Experiment 1, when participants guessed (“eyes closed”) with only the target identity to go on.

Figure 2: Expectation maps for two targets in Experiment 1. AUC scores represent the inter-observer agreement, which is high for one target (left) and much lower for the other (right).

The targets used were distributed throughout the scene, and could appear anywhere. However, some of the agreement may have originated because, across all trials, objects and mouse clicks were more likely to be in some locations (such as the centre of the image) than others. To control for this, an additional “between-target” analysis was performed using the method described above but with the responses associated with each object used to predict those from a *different* target (e.g., how well do guesses for the location of a flower pot predict those for a ceiling fan or a TV?). This control analysis will therefore quantify convergence that is independent of the particular target. This between-target control was higher than 0.5, probably because some objects were in a similar position. Importantly, inter-observer agreement was significantly higher than the between-target control AUC, in both Experiments (all  $t(71) > 3.8$ ,  $p < .001$ ).

Table 1: Inter-observer agreement in target guesses in Experiments 1 and 2. AUC values give the mean and standard deviation across all targets.

Trial type	AUC	
	Mean	SD
Experiment 1: “Eyes closed”		
All trials	0.79	0.07
Experiment 2: “Eyes open”		
Target-present	0.88	0.08
Target-absent	0.83	0.08
Between-target control	0.71	0.1

Inter-observer agreement was significantly higher in the preview Experiment 2 than in Experiment 1. Moreover, this was the case in both target-present scenes (where participants could have, in theory, perceived the target object during the preview;  $t(71)=5.6$ ,  $p<.0001$ ) and in target-absent scenes (where there was no target to find;  $t(71)=3.5$ ,  $p<.001$ ). In other words, exposure to a brief glimpse of a scene made participants more likely to predict the same location for an object, even when that object was not present. Figure 3 shows the expectation map for the target label “TV”, from responses in Experiment 1 (where participants made a blind guess) and for a target absent trial in Experiment 2 (where participants saw the depicted preview scene which did not contain a TV). Participants responding in Experiment 2 changed their guesses considerably and focused on a spot where a TV might appear.

Figure 3: Expectation maps for the target label “TV” when guessing in Experiment 1 (left) and in Experiment 2 (right, superimposed over the preview scene that was shown).

### Experiment 3

Experiments 1 and 2 confirmed that people were consistent in their expectations about where a named target would be likely to appear in a real world scene. The target maps provide a simple way of representing these expectations. Experiment 3 tested whether the eye movements of a new group of observers could be predicted from the target guesses.

#### Method

**Participants** Eighteen new participants (12 females), who had not taken part in Experiments 1 and 2, were recruited for payment. All participants had normal or corrected-to-normal vision, and their mean age was 22.5 years.

**Stimuli and Apparatus** The same set of target labels and scenes was used as in the previous experiments. To avoid trial-to-trial learning, each scene was presented once only, with half of the scenes containing the target and half without (i.e. matched with a different target label not present in the scene as in Experiment 2). Across participants, each scene appeared in both target-present and target-absent conditions.

Stimuli were presented on a 19-inch monitor positioned 60cm from the observers. Participants rested on a chin-rest, which ensured a constant viewing distance and restricted head movements. Scene images filled the screen, subtending 33 x 26 degrees of visual angle at this viewing distance.

Eye movements were recorded during search using the EyeLink 1000 system (SR Research), which used a desk-mounted camera to record monocular eye position from a video image of the pupil and the corneal reflection. This eye-tracker has a high spatial resolution (error of less than 0.5 degrees on average) and captured eye position at 1000Hz. Samples were parsed into oculomotor events using the EyeLink system’s default algorithm, which identifies saccades and fixations based on velocity and acceleration thresholds. Search responses were entered via a button box.

**Procedure** The experiment began with an eye-tracker calibration (using a nine-dot grid), followed by instructions and 8 practice trials. The experimental trials followed a standard visual search procedure. First, a target label was presented, written in black font in the centre of the screen

for 1s. This was replaced by a fixation point presented in the centre of the screen and participants pressed a button to proceed with the search. At this time the eyetracker checked that fixation was on the centre. The search scene then appeared, and participants were told to press one of two buttons as quickly and accurately as possible to identify whether or not the target was present in the scene. The search response terminated the trial, which ended with a blank screen for 500ms. All 72 trials were presented in the same way, in a random order, and the eye-tracker was recalibrated at the halfway point.

#### Results

**Search Performance** Participants responded accurately on a mean of 89% of all trials. In correct, target-present trials, the mean reaction time was 1350ms (standard error of the mean, SEM = 134) and participants made 5.5 fixations on average, per trial (SEM = 0.4). As with most visual search tasks, target absent trials were responded to more slowly ( $M = 2063\text{ms}$ ,  $\text{SEM} = 237$ ) and with more fixations per trial ( $M = 7.9$ ,  $\text{SEM} = 0.7$ ). Figure 4 gives an example of the locations fixated during a trial.

### TV - Search

Figure 4: The locations of fixations made by all participants searching for the target “TV” in a target-absent trial. White markers indicate the first fixation in the trial.

#### Predicting Fixation Locations From Expectation Maps

The remaining analyses aimed to assess whether fixation locations in the visual search task could be predicted based on the expectation maps derived from each target in Experiments 1 and 2. As previously, an ROC approach was followed. For each target-scene pair, the analysis asked how well the expectation maps formed from guesses could discriminate between fixated and non-fixated locations. Because it was anticipated from theory and previous experiments that attentional priorities might change over time, separate ROC curves were computed from each participant’s first saccade target (i.e., the location of the first fixation away from the central starting point) and from all fixations in the trial. It is also essential to take into account the general tendencies for fixations (and probably mouse clicks) to be located near to the centre of the image and away from the scene edges.

Table 2: Predicting fixation locations from the guessed locations in Experiments 1 and 2.

Prediction	Trial type	AUC (all saccades)		AUC (first saccade)	
		M	SD	M	SD
Experiment 1: “Eyes closed”	Target-present	0.67	0.12	0.71	0.16
	Target-absent	0.68	0.13	0.73	0.17
	Between-trial control	0.62	0.05	0.67	0.05
Experiment 2: “Eyes open”	Target-present	0.82	0.12	0.83	0.13
	Target-absent	0.76	0.11	0.79	0.10
	Between-trial control	0.64	0.07	0.72	0.11

Therefore, following Ehinger et al. (2009), I computed a between-trial control comparison where the expectation map for one target/scene was used to predict the fixations made while searching for a different object.

Table 2 displays AUC summary statistics for the comparison between expectation maps and fixated locations. There were several noteworthy results. First, all the AUC values are greater than 0.5, showing that fixation locations could be predicted on the basis of the mouse responses made in Experiments 1 and 2. Moreover, in all trial types, the observed AUC values are greater than the between-trial control estimate. This was statistically reliable across the different target/scene pairs (all  $t(71) > 2.6$ ,  $ps < .01$ ) and confirms that the results cannot be attributed to general spatial biases.

In addition, both expectation models were better predictors of the first saccade in a trial than they were of all saccades. This may be because the initial saccade was most likely to move toward the expected location, whereas later saccades might be exploring different areas of the picture. However, the between-trial control also led to higher AUC values when only the first saccade was evaluated, so it seems the first saccade is more predictable *in general*. This might be because of a strong central bias in scene viewing which tends to decrease over time, particularly when viewing starts in the centre (as it did here).

Most importantly, the guesses made by participants who saw a brief preview of the scene (“Eyes open”) were a significantly better predictor of fixation locations than those who guessed blindly without seeing the scene. The best performance came in target-present trials, which indicates that participants in Experiment 2 had seen the target at least some of the time when guessing. Searchers in Experiment 3 were obviously highly likely to look at this correct target location, whereas there was more variability in target-absent images. However, it is important to note that, even when there was no target, the “Eyes closed” guesses of an independent group of participants were a significant predictor of fixation.

**Predicting Between-target Variation** An additional question concerns the relationship between expectations and search performance. If target objects are strongly associated with a particular location then we would expect a

considerable amount of inter-observer agreement in the expectation maps (e.g., compare the two maps in Figure 2). If these expectations are an important factor in real world search, then the inter-observer agreement should correlate with reaction time in Experiment 3.

The mean reaction time was calculated across all participants for each correct, target-present trial, and then correlated with the AUC values representing inter-observer agreement from Experiments 1 and 2. In both cases there was a negative correlation (see Figure 5). When participants were more consistent in their guesses about where an object would appear, this object was found more quickly. The correlation with “Eyes closed” guesses approached significance ( $r = -.21$ ,  $p = .08$ ), while the correlation with “Eyes open” guesses was larger and statistically reliable ( $r = .50$ ,  $p < .001$ ).

Figure 5: The correlation between inter-observer agreement and search RT. Each data point represents a target/scene pair from Experiments 1 or 2, with least-squares regression lines.

## Discussion

In this paper I have proposed a distinction between the different types of top-down information available in guiding search in real-world scenes. Unlike previous descriptions of contextual effects (Biederman et al., 1973; Torralba et al., 2006), I specifically emphasized the fact that some predictions based on semantic knowledge can be made prior to the onset of the search scene. There were several interesting findings, which point to promising future directions for this approach.

First, participants showed a reliable amount of agreement when asked to blindly guess the target location. Although participants initially found this task unusual they were able to do so quickly and often chose the same locations for an object. There was some variation between different objects, with objects showing the largest amount of agreement those which are strongly constrained to spatial locations (such as light fittings). The method described here could be used in further research to characterise different search objects and their effects on performance. It should be noted that, because the present studies were limited to a fixed image frame on a monitor it mainly measured knowledge about picture composition (e.g., where the horizon is likely to be in a scene). How participants use such information in real life, where frames of reference change with head and body position, remains an open question and could be explored by looking at attention in active, real-world environments (see Foulsham, Walker & Kingstone, 2011).

Second, “Eyes closed” predictions were at least partly separable from those made in response to a preview of the scene. A brief preview of the scene gist, prior to seeing the target label, was enough to increase agreement between observers, even when there was no target to find. In other words, additional information about the scene was used by participants in a consistent way. It would be interesting to determine some of the cues that participants are responding to in this situation, as they could potentially be both appearance-based (selecting something which looked like the target) and location-based (selecting a region where the target might reasonably occur).

Third, the guesses of the participants in Experiments 1 and 2 were reliable predictors of fixation locations in independent searchers in Experiment 3. This was true when participants guessed based on a brief preview of the scene, which confirms that searchers look towards the parts of the scene which are contextually relevant given the gist. This finding, in both target-present and target-absent scenes, is similar to that reported by Ehinger et al. (2009), who used a “context oracle” defined by the responses of independent observers predicting the y-coordinate where pedestrians should occur in street scenes. However, what is surprising in the current experiments is that, even without the scene, participants are able to predict target locations, and these predictions are reflected in fixation behavior. In future work this could be modeled by positing a “blind” statistical prior which could then be refined according to global features

such as those in the contextual guidance model of Torralba et al., (2006).

# Maximum utility unitary coherent perception vs. the Bayesian brain

Charles Fox (charles.fox@sheffield.ac.uk)

Department of Computer Science, University of Sheffield, UK

Tom Stafford (t.stafford@sheffield.ac.uk)

Department of Psychology, University of Sheffield, UK

## Abstract

Our subjective experience of the world is ‘unitary coherent’ (UC). ‘Unitary’ means we only perceive one interpretation at a time rather than a blur of multiple possible worlds. ‘Coherent’ means that we almost always perceive scenes that do not contain contradictory parts. While this form of first-person perceptual experience may seem obvious, it is in opposition to the requirements of optimal decision making, and to some forms of the ‘Bayesian brain’ hypothesis. We hypothesise that there are at least three types of ‘Bayesian’ action selection occurring in cognition, including a ‘maximum utility (MU) percept’ strategy that makes use of UC percepts. We give evidence from a video game experiment that is compatible with MU/UC perception and action selection, and is incompatible with optimal actions. Furthermore, it is compatible with the presence of utility bias in MU/UC perception: by changing the available actions we may be able to manipulate the subject’s percept of a fixed ambiguous stimulus.

**Keywords:** Bayesian; psychophysics; utility; bias; perception

## A paradox about perception

Our subjective experience of the world is ‘unitary coherent’. *Unitary* means we only perceive one interpretation at a time (e.g. either a face *or* a vase in the Rubin Vase illusion) rather than a blur of multiple possible interpretations (never the face *and* vase together). *Coherent* means that we almost always perceive scenes that do not contain contradictory parts. (e.g. we do not see part face and part vase). While the UC nature of perception may seem obvious from subjective experience, it is in opposition to the requirements of optimal decision making, which require consideration of *all* possible interpretations of sensory data (Bernardo & Smith, 2000). In particular, the ‘Bayesian brain’ hypothesis (Doya, Ishii, Pouget, & Rao, 2007) views perception as computing probabilities of many interpretations, and optimal actions would be found by integrating out the utility of all actions under all percepts. If both Bayesian brain research and optimal action theory (Körding & Wolpert, 2004) suggest that perception should operate using a distribution, or ‘Bayesian blur’ of possible percepts, why then is our subjective experience limited to a unitary coherent percept instead? And which unitary coherent percept do we perceive: the most probable one or the most useful one? This study argues that as full Bayesian perception and action selection is computationally hard, an approximation which we call ‘maximum utility (MU)’ perception is a useful surrogate. It then presents evidence in support of the maximum utility perception hypothesis using a video game style experiment.

## Types of perception and action selection

When a unitary coherent percept is required in machine perception, such as the output of a machine vision (Felzenszwalb & Huttenlocher, 2005) or speech recognition system (Young et al., 2006), the maximum a posteriori (MAP) state is often used by system engineers,

$$s_{MAP} = \arg_s \max P(s|d), \quad (1)$$

where  $s$  are world states and  $d$  is the available data. However real-world agents are often required to make actions as well as – or instead of – reporting percepts. In these cases, perceiving the MAP state does not necessarily lead to the best action if the following naive action-selection rule is used as a separate stage following MAP perception,

$$a_{naive} = \arg_a \max U(a, s_{MAP}), \quad (2)$$

where  $U$  is utility,  $a$  are actions. Instead, optimal actions are obtained (Bernardo & Smith, 2000) by maximising *expected* utility (MEU), which requires integrating over the ‘Bayesian blur’ of possible worlds,

$$a_{MEU} = \arg_a \max \int_s U(a, s) P(s|d) ds. \quad (3)$$

MEU action selection has no role for unitary coherent percepts. Instead it must consider *every* interpretation  $s$ . Computational approximations to this integral might ignore some improbable interpretations (Spiegelhalter, Thomas, Best, & Gilks, 2008), but still sum over a *set* of possible world states  $s$  rather than privileging any particular unitary state.

In many cases humans have been claimed to make optimal actions (Griffiths & Tenenbaum, 2006). This may occur for low-level, rapid stimulus-response type actions, and for high-level cognitive decisions such as business and financial decisions. Much recent work in ‘Bayesian Cognitive Science’ proceeds by *assuming* an MEU framework, then reasoning backwards from observed actions to report human priors on various stimuli (Stone, Kerrigan, & Porrill, 2009).

So why then do we bother to perceive UC percepts? Do they have some functional significance as well as being correlates of subjective experience? If they do have a function, this would suggest that Bayesian Cognitive Science’s assumption of optimal action is flawed, and could potentially invalidate some of its reported human priors.

Bayesian inference and hence MEU decision making is generally an NP-hard problem (Cooper, 1990) so is impractical for all but the most constrained percepts and actions.

Figure 1: 3D environment used in the training phase of the game. A joystick moves the missile launcher around a 2D ( $x, z$ ) plane on the ground. Pressing and holding the joystick button fires a missile (not shown) vertically upwards ( $y$  axis). Releasing the button detonates the missile. Points are scored for detonation close to the target(s) shown by white crosses. The training phase shown here includes colour, overlap, perspective and support cues to make the cube's configuration unambiguous. These cues are removed in the test phase to leave an ambiguous Necker cube, with ambiguous 3D target positions. Figure is best viewed in colour.

It has been suggested (Gigerenzer & Todd, 1999; Goldstein & Gigerenzer, 2002) that making actions based on a single 'best' percept (such as the 'take the best' heuristic and 'less if more; effect) could be a useful heuristic to speed up the decision making process at the expense of optimality. However the 'percepts' in these cases are high level logical states of the word rather than actual perceptual objects in three dimensional space.

We propose an alternative form of perception and action selection to MAP perception and MEU action selection, which we call *maximum utility perception (MU)*. In MU we choose a UC state and action together,

$$(s_{MU}, a_{MU}) = \arg_{s,a} \max U(a, s) P(s|d) \quad (4)$$

which yields the best possible action assuming that only a single world state can be considered.

### The MU Hypothesis

We hypothesise that humans have at least *three* kinds of decision making behaviour, moving from fast and simple to slow and accurate:

1. *Immediate stimulus-response (S-R)*. A fast association from input data directly to an action. Such mappings do not need to build a UC percept. The could be implemented neurally at the sub-cortical level, such as direct links from supe-

rior colliculus to basal ganglia (Redgrave, Prescott, & Gurney, 1999). For simple mappings, it is possible that simple computational structures such as small neural networks could learn to perform near-optimal action selection, as has been demonstrated by computational experiments (Ramamoorthy & Verguts, 2012). Near-optimal performance in fast, low-level tasks such as reaching and pointing *quickly* at spheres having different locations and utilities (Kording & Wolpert, 2007); and 'simple heuristics' (Kahneman, Slovic, & Tversky, 1982; Gigerenzer & Todd, 1999) would be candidates for this mechanism. For simple tasks this method would give MEU-like results but without explicitly performing the MEU integration.

2. *Fast MU/UC percept-response (P-R)* which achieves suboptimal MU action in reasonable computation time. UC perception could be implemented cortically, with high-level perceptual areas computing a single most *useful* percept of the world, jointly with action selection under utility bias. Evidence for UC perception is found in binocular rivalry experiments (Srinivasan & Nunez, 2006), and in computational models (Riesenhuber & Poggio, 1999) as well as in everyday subjective experience. This paper gives evidence for MU/UC perception.

3. *Full MEU* action selection, via conscious sequential consideration of many possible percepts and responses. This slow type of decision making would occur for example when making a business decision, where several minutes (or even hours or days) are set aside to consciously perceive one possible world at a time, and the effects of many possible actions in them are simulated, and the resulting utilities averaged over. Humans are well-known to be poor at this kind of computation (Kahneman, 2003), and real-life action selection of this type is often performed in the business world by specialised operations researchers making use of computers to calculate the expected utilities (Pourret, Naïm, & Marcot, 2008), rather than relying on their own cognitive faculties.

If multiple decision making systems exist, it seems likely that the basal ganglia system is used to switch between them, for example taking account of time pressures for the type of decision to be made (Lengyel & Dayan, 2008; Redgrave et al., 1999; Daw, Niv, & Dayan, 2005). Strong support for the existence of at least two systems comes from the Ebbinghouse illusion, which produces different perceptual reports in verbal and stimulus-response type actions. It has been shown (Goodale & Milner, 1992) that the motor actions are consistent with optimal MEU-like decisions in the *same* subjects that make incorrect verbal reports.

While research on near-Bayesian optimal decisions of the S-R and Full MEU types abounds, there has been comparatively little work on the role of unitary-coherent perception in decision making. While our subjective experience tells us very clearly that *something* in the brain is computing a UC percept (which is incidentally presented to our conscious experience), and researchers have modelled how MAP percepts could be computed in this way (Riesenhuber & Poggio, 1999)

there has been little study of how this type of perception could be used in action selection as a replacement for S-R and MEU behaviour. Our hypothesis is that MU perception and action is in fact the dominant mode of everyday, aware, perception and action – the type of cognition that occurs consciously but not deliberately.

It is difficult to design experiments to isolate this middle, MU, level of perception, because as soon as subjects know their performance is being monitored they tend to start deliberating as in Full MEU, rather than performing ‘everyday’ perception and action selection. Conversely, if tasks are too low-level and fast-paced, they will use rapid S-R behaviour. Perhaps that is why few experiments have noticed MU effects before. To this end, we have carefully designed a simple 3D perception task, and examine two hypotheses:

*Hypothesis H1* is that there are examples of human behaviour that are consistent with UC perception and inconsistent with both Full MEU (deliberative) and approximate MEU (S-R). A positive result here would stimulate further research into delimiting the circumstances in which the different behaviour types are employed.

*Hypothesis H2* is that the particular kind of UC used in human perception is the MU percept. To find evidence for this stronger hypothesis, we will examine if it is possible to bias the percept from equally a priori probably percepts by altering the available action set, as predicted by MU.

## Methods

A video game – loosely based on “space invaders” – was designed and implemented<sup>1</sup>, having optimal MEU actions that require consideration of multiple scene interpretations, and having MU actions giving suboptimal rewards. If human behaviour in this (or any other) game could be shown to deviate from MEU behaviour and be consistent with MU, then evidence is provided for H1. Further, if the human behaviour is consistent with predictions made by MU selection, then evidence is provided for H2. An overview of the phases of the game is given here, followed by details of each phase.

In phase one of the game, shown in fig. 1, subjects were trained in several rounds to fire missiles from a launcher in a 2D plane, in an unambiguous simulated 3D environment. They received rewards according to how close to aerial targets (shown as white crosses in the figure) they get. After demonstrating that they understand the utility function and controls by passing a second, ‘examination’ phase, they are then tested (phase three) in an ambiguous bi-stable environment. A true MEU strategy would consider both interpretations of this environment, whereas a UC based strategy would use only one and lead to a different action. Phase one consists of several rounds which teach the subject about the game. The choice of tasks here is fairly arbitrary, as the logic of the experiment is that *if* subjects can pass the phase two exam *then* they have demonstrated an understanding of the rules sufficient to play the real test game in phase three. Phases one and two may

be repeated in any order as many times as the subject desires, until the exam is passed successfully.

### Phase 1: exploratory training round

The game environment consists of a visible 2D horizontal plane on which a missile base can move around, a wire-frame cube in the 3D space above the plane, and one or two targets located at vertices of the cube. The environment is drawn using very strong perspective<sup>2</sup>, and the vertices of the cube are connected vertically to the plane by lines to make their 3D locations unambiguous. In addition, edges of the cube are drawn with thick lines of different colours, producing additional disambiguation cues where one lines is seen to cross in front of another.

Subjects control the  $(x, z)$  position of a missile base using an analogue joystick (Logitech Extreme 3D Pro) and fire a missile by pressing and holding the joystick trigger. Once fired, the missile moves upwards (the  $y$  direction) until the trigger is released. The missile then explodes at position  $\mathbf{m} = (m_x, m_y, m_z)$ .  $N \in 1, 2$  targets are present in the environment at positions  $\mathbf{t}^i = (t_x^i, t_y^i, t_z^i)$ ,  $i = 1 : N$ , and a Gaussian reward  $R$  is received and displayed centre-screen after the explosion,

$$R = \sum_{i=1}^N r_i, \quad (5)$$

$$r_i = 100 \times \exp - \frac{(\mathbf{m} - \mathbf{t})(\mathbf{m} - \mathbf{t})^T}{2\sigma^2}. \quad (6)$$

The spread,  $\sigma$  was fixed at a large enough value ( $\sigma = 2\sqrt{3}/\sqrt{2\ln 2}$ ) so that if two targets are present, the score is always highest when firing at the point between them than when firing directly at one of the targets.

In the exploratory round, single targets are presented at different vertices of a fixed cube. Subjects have unlimited time to position the missile base and fire. They are then represented with a visual display of the reward, then the next target is presented. They are given 50 such targets to practice with, no cumulative score display, and are encouraged to experiment to learn about the rewards available at different distances from the target by an introductory message.

### Phase 1: utility training round

In the exploratory round, subjects obtained high scores by firing as close to the target as possible. To help them learn about the shape of the Gaussian utility function, a series of rounds takes place in which fixed cubes are shown and the subject is asked to deliberately score *only* 50, 70 or 90 points. Thus they are encouraged to try aiming at locations at different distances from the target.

### Phase 1: double target training

This round is similar to the first exploratory round, but uses two targets presented together at each trial. By construction

<sup>1</sup>in Python, source code available on request.

<sup>2</sup>OpenGL: gluPerspective(45, 1.0\*width/height, 0.1, 100.0); gluLookAt(7,0.05,7, 0,-1.25,0, 0,1,0). Cube faces are 2\*2 units.

(choice of  $\sigma$ ), the optimal action is now always to aim at the point midway between the targets.

### Phase 1: blackout training rounds

Two further training rounds take place. In the first, the lower half ( $x + z > 0$ ) of the missile-launching area is ‘blacked out’. It is coloured red, and the joystick is unable to move into the red area. In the second round, the situation is reversed at the top half of the grid ( $x + z < 0$ ) is blacked out. Subjects learn that that optimal strategy when faced with a target in the blacked out region is to fire from a position as close to it as possible that is on the centre line.

### Phase 2: examination round

The purpose of the examination round is to demonstrate that the subject has learned the optimal actions for single and double targets, as well as possessing sufficient motor skills to control the game using the joystick. 20 trails are presented in rapid succession (one every 5s) and a cumulative score is maintained. If subjects fail to score 2170 points or more, they are sent back to the exploratory phases then made to repeat the examination (or allowed to leave the experiment). The qualifying score was chosen such that it can only be obtained by using the optimal strategy of aiming closer to the centre of each pair of double targets than to either individual target. Thus by passing the examination phase, subjects demonstrate knowledge of this strategy.

### Phase 3: Ambiguous test round

In trials within this round, a bi-stable ambiguous (Necker) cube is presented to the subject very quickly, at random orientations. In some (80% of) trials there is one target at a random vertex. In others there are two targets, which may be at opposite (10% of trails) or non-opposite (10% of trials) vertices. The percept is made ambiguous by switching the projection from perspective to orthographic, dropping the vertex-to-plane cues, and drawing all edges in white to remove overlap cues. To motivate subjects, they are told that their cumulative score from all rounds of phase three will be their reported result, and that the subject with the highest reported result will receive twenty UK pounds in cash. (Subjects were undergraduate psychology students and were not paid otherwise; but received credit towards their degree for participating.)

### Phase 3: Blackout test rounds

The ambiguous test round is repeated twice more, with blacked out near and far regions as in the learning phase.

### Debriefing

It is crucially important that subjects do not become aware of the ambiguity, because this could allow high-level (Full MEU) reasoning to aim in the centre, and destroy any UC-revealing behavioural effects. For this reason, after phase 3, subjects were told about Necker cubes and asked if they were aware of the Necker ambiguity.

Figure 2: Example of a single-target trail,  $(x, z)$  plane. The viewer’s position is in top right corner. Blue crosses show the two ambiguous target positions resulting from a single target vertex on a Necker cube. The red cross shows the firing position. Black lines show the centre line and the two classification boundaries, dividing the launching area into near (top-right), centre and far (bottom-left) firing regions.

### Processing

25 subjects were tested. Of these, 20 completed the exam and proceeded to generate data in the test phases. In debriefing, no subjects reported awareness of the ambiguity in the Necker cubes. For each trial, the 3D positions of both ambiguous locations of the target or targets were computed. This was achieved by transforming the  $x, z$  joystick co-ordinates into a horizontal and depth pairs,  $(h, d)$ , then flipping the depth coordinate,

$$\begin{bmatrix} h \\ d \end{bmatrix} = H \begin{bmatrix} x \\ z \end{bmatrix}, \quad (7)$$

where  $H$  is the Hadamard matrix,

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}. \quad (8)$$

The complementary ambiguous location is thus

$$\begin{bmatrix} x' \\ z' \end{bmatrix} = H^{-1} \begin{bmatrix} h \\ -d \end{bmatrix}. \quad (9)$$

Furthermore, the height coordinate was transformed by  $y' = y - cd$ , where  $c$  is a constant ( $c = 0.9$ ) which compensates for the choice of viewing angle in the projection images.

All shots were classified into three regions (fig 2), according to whether their  $(x, z)$  firing locations were closest to the near ambiguous target location, the far ambiguous target location, or the centre line.

## Results

### Non-blackout trials with single targets

In these trials, the MEU action by construction (i.e. choice of  $\sigma$  as described in phase 1) is to fire at the point on the centre line between the two possible ambiguous locations. (fig. 2). In contrast, the MU action is to fire directly at a

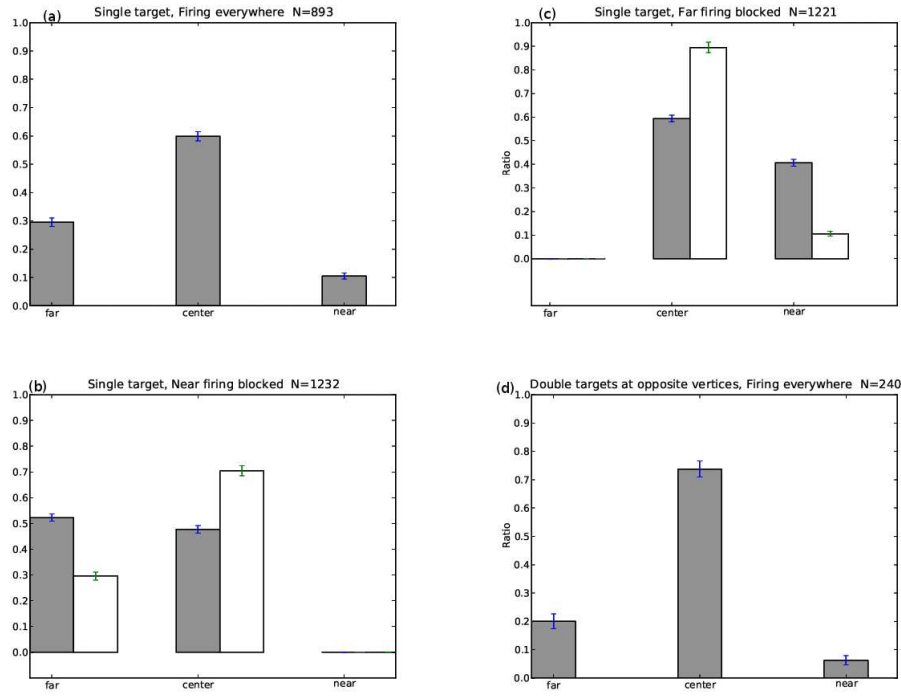

Figure 3: Results. Grey bars: observed frequency ratios, with Beta posterior, one-standard-deviation confidence intervals. White: predictions for blocked firings under the null hypothesis. The null hypothesis is that the unblocked area is unchanged from the 'single target, firing everywhere' case, while the centre is the sum of the centre and blocked firings from that case. All error bars assume IID observations and ignore which observation came from which subject.

randomly-chosen single one of those locations. This is because the MEU action averages over the two possible states of the world, which gives the same calculation as choosing where to fire in an unambiguous double target case; whereas the MU action picks just one interpretation of the target location, then fires directly at it.

Fig. 3a shows the distribution into region classes, over all subjects and trials of this type. Treating each action by each subject as an independent observation (i.e. ignoring subject-specific effects), and beginning with a flat Beta prior over the ratio of shots in each region, we infer posterior ratios, along with uncertainties. The figure shows the mean and one standard deviation error bars inferred about the population ratio of shots fired of each type. Signal detection theory can be used to obtain the  $p$  values, but broadly two ratios are significantly different if pairs of error bars do not overlap.

The results of these trials are surprising but inconclusive. Although target locations are perfectly ambiguous between near and far positions, subjects show a preference for the far target over the near one. That is, they are already interpreting the Necker cubes percept in a biased way, to favour interpretations with the target at the back of the scene.

If the MEU strategy was followed perfectly, we would see all shots fired in the centre and none in the near or far regions. If the MU strategy was followed perfectly, we would see all shots in the near and far regions and none in the centre. Unfortunately, we see shots in all three regions. Whilst this

is incompatible with a pure MEU strategy, it can weakly be explained from a MU perspective: A large number of shots are fired from the centre line, which may be due to subjects losing all depth perception (i.e. not perceiving the cube as 3D at all) and hedging by firing in the centre; they may also be due to limited depth perception resulting in a stable cube percept but an inaccurate joystick placement. (Some subjects commented on the lack of training in the absence of the vertical supports, and consequent loss of skill at pointing to the depth of the targets.) The near and far shots would be correct MU actions, and the centre shots due to a problem with the experiment, requiring a better communication of the depth to the subjects in future versions whilst retaining the ambiguity.

### Blackout trials with single targets

In these trials, the pure MEU action is *still* to fire at the point on the centre line between the two possible ambiguous locations. Points on the centre line are still available during a blackout, so the optimal strategy is unchanged.

Fig. 3b shows the results when the near-side is blacked out. The majority of shots are now fired in the far region. This is consistent with the MU strategy: actually *perceiving* and acting on the Necker cube in the configuration which enables the target to be reached; an optimism bias. If we assume UC perception and action, these new results then show MU-like bias occurring within in. For comparison, we show in white the prediction of a null hypothesis. This is obtained taking

the Single target histogram of fig. 3a and moving its near mass to its centre mass, as would occur if UC percepts were unchanged by the utility bias, and near shots were substituted by firing on the centre line as close to blacked-out near targets as possible. MEU theory is unable to explain why the observed frequencies are so different from this null hypothesis. MU theory explains it easily: there is no utility in *perceiving* near targets; but if they are re-perceived as far targets, then an increased utility can be obtained by firing at them.

Similarly, fig. 3c shows the results when the far-side is blacked out. Again compared to a null hypothesis (white bars) which moves the mass from the far region to the centre region from fig. 3a, we see a significant difference, again suggesting the MU-like change in both percept and action towards the obtainable (non-black-out) target position.

Fig. 3d is shown as a control. It is the distribution from the non-black-out trials having two targets at opposite cube vertices. In these cases, the MEU and MU strategies are the same – fire in the dead centre of the grid, and the results show a significantly increased rate of firing in the centre region over that of fig. 3a. This again supports the presence of MU over MEU, because MEU would give identical results in 3a and 3d but MU would give an increase in the centre region in 3d over 3a, which we do see here.

## Discussion

In informal discussions, we often argue that “perception is obviously UC from subjective experience”. Operationalists challenge this statement and would prefer us to cite an experiment to demonstrate the claim in the third person. While MEU actions are known to occur at both low-level psychophysical tasks and at high-level cognitive reasoning tasks, we have here presented evidence for the existence of a largely unexplored middle ground in which action selection is consistent with MU, and inconsistent with both Full deliberative and S-R approximate MEU, as in Hypothesis H1.

MU, but not MEU, can explain the deviations from the null hypotheses seen in figs. 3b and 3c, and also the difference between figs. 3a and 3d. The match of the data to MU behaviour in these cases gives some support for Hypothesis H2.

It was disappointing for the MU theory that fig. 3a did not present conclusive evidence by itself of MU over MEU, as pure MU would predict all shots to be fired in near and far regions, not in the centre. One way to explain the data away here is that the stimuli used were insufficiently informative to give subjects a sense of space, so they fire in the centre by default in the absence of any meaningful percept. Future work should try to refine the experiment to see if such hypothetical null percepts can be replaced by true percepts, for example by using different input and display systems while retaining the ambiguity in the Necker cube itself. Finally, the assumption that all shots by all subjects are mutually independent is strong, and future work should employ more subjects so that the assumption of independence of shots belonging to each subject can be dropped in the analysis.

# Measuring children's visual access to social information using face detection

Michael C. Frank

mcf Frank@stanford.edu

Department of Psychology

Stanford University

## Abstract

Other people are the most important source of information in a child's life, and one important channel for social information is faces. Faces can convey affective, linguistic, and referential information through expressions, speech, and eye-gaze. But in order for children to apprehend this information, it must be accessible. How much of the time can children actually see the faces of the people around them? We use data from a head-mounted camera, in combination with face-detection methods from computer vision, to address this question in a scalable, automatic fashion. We develop a detection system using off-the-shelf methods and show that it produces robust results. Data from a single child's visual experience suggest the possibility of systematic changes in the visibility of faces across the first year, possibly due to postural shifts.

Keywords: Social development; face processing; head-camera.

## Introduction

Faces are perhaps the most important source of social information for young children. Infants show a preference for faces and face-like configurations from birth (Johnson, Dziurawiec, Ellis, & Morton, 1991; Farroni et al., 2005), and they will fixate faces to the exclusion of nearly everything else when attending to complex naturalistic stimuli (Frank, Vul, & Johnson, 2009; Frank, Vul, & Saxe, 2011). By their first birthday, they are sensitive to facial information about emotion (Cohn & Tronick, 1983) and social group (Kelly et al., 2005), and they will readily follow gaze to an attended target (Scaife & Bruner, 1975). As they begin to speak and understand language, joint attention becomes a powerful cue for learning the meanings of words (Baldwin, 1991).

To extract all of this important information in the natural environment, infants and children must attend to people's faces. Nearly all of what we know about children's attention to—and understanding of—faces comes from tightly-controlled lab experiments. In such experiments, the stimuli are typically presented in a very accessible format: at eye-level, large enough so that all details can be appreciated. How often do children actually see the faces of the people around them, though? And how often are the faces large enough to discern details from?

Head-mounted cameras provide a new technique for measuring access to faces during development. While the method of placing a miniature camera on the head of an infant or young child is still relatively new, a number of investigators have begun using it to record children's first-person perspective (Yoshida & Smith, 2008; Aslin, 2009; Smith, Yu, & Pereira, in press). Some studies have even used head-mounted eye-trackers to measure what part of the visual scene the child is fixating, a good proxy for what parts of the world

the child is attending to (Franchak, Kretch, Soska, Babcock, & Adolph, 2010).

Of particular interest is the result, reported by Franchak et al. (2010), that 14-month-olds rarely fixated their mother's face, even when she spoke to them directly. They looked instead at her hands or other parts of her body. The authors speculated that this result might have been due to the mother's location, usually high above the child. When mothers were sitting down, their faces were much more visible to their children. In our current investigation we follow up on this suggestion, investigating the possibility that the posture of caregivers and the infant's own posture work together to cause developmental changes in the accessibility of social information.

The introduction of these new methods mean that for the first time, we can see what babies are looking at as they interact with—and learn from—the people around them. This development opens up many new questions for investigation. Yet work of this type is hindered by the tremendously slow and resource-intensive task of manually annotating videos, frame by frame. Up until now, only a few research groups have grappled with the task of how to analyze the massive datasets captured using these methods.

The current study thus serves two purposes. First, it is designed to measure the accessibility of social information—in the form of faces—to infants. To investigate this question across development, we make use of a previously-described dataset (Aslin, 2009), in which a head-mounted camera recorded 2–3 hours of the visual experience of a single child at ages 3, 8, and 12 months (sample frames shown in Figure 1). Second, we investigate the possibility of using automated face detection to measure social information. It might in principle be possible to hand-annotate the presence of faces in each of the million-odd frames in our dataset (such annotation can be done around 4–8 times slower than real-time, yielding around 25–50 hours of total annotation time). For any larger study with more participants, annotation costs would quickly become prohibitive. Our study thus was designed to serve as proof-of-concept for the automated strategy.

Detection of upright faces in static images is widely considered to be a solved problem in computer vision, with the work of Viola and Jones (2004) providing a computationally-efficient solution that is now used in a wide variety of systems and consumer electronics. Nevertheless, the dataset we used presents a distinct set of challenges for such methods. In what follows, we describe our method for handling these challenges using a collection of out-of-the-box techniques from computer vision and machine learning. We end by describing

Figure 1: Sample frames showing head-camera data plotted along with face detector data. A separate rectangle is plotted for each active detector. Frames were selected in which annotations and model predictions matched.

developmental changes in the prevalence and size of faces in the field of view of the infant we studied. These changes suggest that there may be a number of important factors influencing the accessibility of social information during early development.

## Methods

Although in principle a single joint detection and tracking system could be constructed to detect faces in head-camera video, in practice such a system would be complex and computationally-intensive. Thus, we pursued a two-step approach to face-detection (Figure 2). We first preprocessed each frame of our data separately using simple but noisy detectors, which find faces in static images. We then tested a number of supervised post-processing models on their performance in picking frames with successful rather than spurious detections.

Because of this two-step scheme, conventional annotations of a gold standard training sample (e.g. face/no face) were not maximally effective. If the detectors did not find a face in a

frame, training the post-processing model that the frame contained a face would be counterproductive. Instead, our strategy was to create two annotated sets. The first was a training set that indicated whether, for each frame, the detectors had correctly identified a face. The second was a generalization dataset that indicated whether a face was in fact present in the frame, allowing us to test what proportion of faces our models identified on a completely independent dataset (different clips from the same corpus). In addition, we annotated the child's posture in each video of the corpus. These annotations (along with the details of the dataset) are described below.

## Data and annotation

**Aslin (2009) head-camera dataset** Data for the study consisted of videos collected on three days during the infancy of a single child, at ages 3, 8, and 12 months. This dataset was originally collected by Aslin (2009); the data are described in detail in Cicchino, Aslin, and Rakison (2010). The method of collection was a small wireless camera mounted

Figure 2: Schematic of our face-processing approach. Step 1: process frames with noisy Haar-style detectors. Step 2: filter detections with conditional random field (CRF) model.

on the infant’s head, allowing recording of a large portion of the infant’s visual field. The camera was a Sony 480TVL CCD “bullet” camera, embedded in a headband and wirelessly transmitted to a digital video recorder. Videos were approximately 126, 190, and 140 minutes long for the segments collected at 3, 8, and 12 months, respectively. Recordings were made while the infant was in a number of different locations, including in the home, on a shopping trip, on a walk, and at a playgroup. Due to the variation in activities across ages, the natural statistics of these three samples were unmatched (likely due to both sampling issues and true differences in the distribution of activities across ages); thus we will not attempt to compare across activity types.

**Annotation of detectors (training set)** We annotated a sample of videos to provide training data for our models. For this annotation effort our goal was to select frames in which the raw face detectors had correctly selected a face (and reject those for which the detections were incorrect). We classed a frame as containing a correct detection if there was at least one detector around the face of a person (thus a frame could still contain some spurious detections, though in practice this was relatively rare). We annotated nine clips of one minute each (16k frames). Three minute-long clips were selected for each age group randomly, with the caveat that they included some correct face detections in each.

**Annotation of face presence (generalization set)** We additionally performed frame-by-frame annotations of whether a face was present in the video frame. We selected 3–4 one-minute clips at each of the three ages for a total of 11 minutes of video at 30 frames per second (20k frames). One-minute clips were selected randomly, again with the caveat that they needed to contain at least some instances of faces. We counted a frame as containing a face when a face was fully visible with no occlusions at three-quarter view or greater (both eyes visible). This stringent annotation criterion was used because occluded or profile-view faces are much less

Figure 3: Time spent in each coded posture at each age.

likely to be useful for inferring eye-gaze direction, emotional state, or other social information.

**Posture annotation** We additionally annotated the posture of the child during the videos, in order to use this factor in our analysis of position and size of detected faces. We attempted to estimate the child’s posture wherever possible, categorizing it as lying, sitting, standing, crawling, or being held. Figure 3 shows descriptive data for this measure. Annotation of this measure was somewhat subjective, but inter-rater agreement was relatively high with  $\kappa = .72$  for five categories.

## Models

Although face detection is generally considered to be a solved problem (Viola & Jones, 2004), face detection in developmental, first-person data presents a number of challenges that do not usually occur in static photographs or standard videos. First, faces are often occluded and at odd orientations for children. Second, in our case, the video was transmitted wirelessly and contained some artifacts due to the transmission method. Third, the head-mounted camera was subject to quick movements as the child moved his head, meaning that many methods applicable for scene segmentation or motion tracking in static-camera applications could not be used here. Our modeling goal in this project was to combine computationally-inexpensive techniques to address these challenges.

Our preprocessing step made use of off-the-shelf Haar-style detectors from the OpenCV package (Bradski & Kaehler, 2008). Each frame was processed with four separate detectors: three full-face and one profile detector. These detectors were noisy, capturing many faces but also spuriously identifying many background elements as faces as well (e.g. doorknobs, high contrast windowpanes, see Figure 4). This processing step ran at approx. 10% of real time on a quad-core machine, taking around 4 days to process all detectors.

Next, we trained post-processing models to discriminate valid detections from invalid detections, using our detector-annotated training set. Our primary model of interest was a

Figure 4: Frames in which CRF model incorrectly predicted that the detectors had correctly identified a face.

conditional random field (CRF) model (Lafferty, McCallum, & Pereira, 2001). CRFs are discriminative sequence models: they take input data of sequences of observations (with some feature set describing each observation) and return a classification of each observation in the sequence. Their key difference from feature-based classifiers (e.g. Naive Bayes or MaxEnt) is their ability to use sequential information; likewise, their key difference from sequence models (e.g. hidden Markov models) is their ability to incorporate rich featural information about each observation. They have been applied successfully to a number of tasks including natural language processing and computer vision. For this application, we used the Matlab CRF toolbox (Schmidt & Swersky, 2008).

We included two other simpler models for comparison: a Naive Bayes (NB) classifier and a hidden Markov model (HMM). The classifier made use of exactly the same feature set but considered each frame in isolation (neglecting sequential dependencies). The HMM considered only the sequence of decisions and the number of detectors that were active. Thus, the difference in performance between the CRF and the classifier provides a rough measure of the contribution of sequential information (provided by the video), while the difference between CRF and HMM provides an estimate of the gain due to adding featural information.

We created a set of binary features to describe the detections in each frame. These included a separate feature for whether each detector was active, a feature for each detector pair to indicate whether the detector centers fell within a certain threshold (5 pixels) of one another, and features for each detector indicating whether it changed in size or disappeared in either the preceding or following frame. We used this feature set to train the models to classify the training data as containing correct or incorrect detections.

Table 1: Model performance on detector-annotated training dataset (“Tr,” 9 minutes, only frames with successful detections) and generalization dataset (“Gen,” 11 minutes, all frames with human-visible faces). P = precision, R = recall, F = F-score (harmonic mean of precision and recall).

	Tr P	Tr R	Tr F	Gen P	Gen R	Gen F
NB	.64	.82	.72	.76	.55	.64
HMM	.72	<b>.85</b>	.78	.81	<b>.57</b>	<b>.67</b>
CRF	<b>.85</b>	.77	<b>.81</b>	<b>.85</b>	.53	.65

Table 2: CRF model performance on generalization training set by age. Prop. faces refers to the proportion of total faces in the gold-standard dataset for that age.

	3 months	8 months	12 months
Precision	.92	.89	.33
Recall	.60	.48	.35
F-score	.73	.62	.34
Prop. faces	.46	.45	.07

## Results

Table 1 shows evaluation results for each of the models on the two datasets we annotated, the detector-annotated training dataset and the gold-standard generalization dataset. (Rather than using a technique like cross-validation to test generalization performance, we report results on both the training data and an independent generalization set that was never used for training). The CRF model performed best on the training data, capturing a slightly better tradeoff between precision and recall. The gain in performance was relatively slight from the HMM to the CRF, indicating that the majority of the value of the CRF was due to the sequential dependencies enforced by the model. Knowing that a previous frame contained a successful detection was helpful in deciding whether the current one did as well.

When we applied the three models to the generalization dataset, F-scores were within a small range of one another, with the HMM outperforming the CRF, perhaps indicating some overfitting of feature weights to the training data. Nevertheless, the CRF produced the highest precision on the generalization dataset. Because our aim was to measure the quantity and spatial distribution of faces at each age, we judged precision more valuable than recall and chose the CRF model for our analysis (though we note that results do not change meaningfully if the other models are chosen).

Performance on the generalization set was highly asymmetric across the three ages, with high precision and recall for the 3-month data, mid-level performance on the 8-month data, and very low performance on the 12-month data (Table 2). A number of experiments attempting age-specific training failed to find major gains in performance by training only on e.g. 12-month data. There were few faces in the 12-month

Figure 5: Heat maps showing probability of finding a face in each location of the camera field for 3, 8, and 12-month-old data. Dotted lines show the vertical locations of maxima.

Figure 6: Proportion of faces detected by CRF model at each age. Error bars show standard error across video clips.

data (7% of frames, compared with 46% of frames in the 3-month data), and those that were present were very hard to detect correctly, perhaps because of their small size. Figure 4 shows frames in which the CRF model incorrectly reported a face; these typically showed consistent spurious detections for some superficially face-like configuration of objects.

We evaluated the CRF model on the entire dataset, using the settings established in training. Congruent with the generalization data, we found very few faces in the 12-month data relative to the other two ages. Figure 6 shows the estimated proportion of face-containing frames across clips at each age. Nevertheless, we should be cautious in interpreting these results, due to the relatively small amount of data available in this dataset. It may be the case that these results are skewed due to, e.g., participating in a play-group at 8 months with many children present.

Figure 5 shows a heat map of the probability of finding a face at each location in the camera's field for each of the three samples.<sup>1</sup> Faces were higher in the image plane at 8 and 12

months than at 3 months. This shift could potentially be due to postural differences: the child was more likely to be held or lying down at 3 months and more likely to be sitting or standing at 8 and 12 months. In a sitting or standing position, faces tend to be higher in the visual field than when lying down and looking up over the edge of the crib.

Faces were also different sizes in the older videos. The 3-month videos had a qualitatively different distribution of detected face sizes (Figure 7). We cannot completely rule out the possibility that some of the smaller faces in the 8- and 12-month videos were spurious detections. Nevertheless, the relatively similar distribution for each of these (compared with the drop in precision from 8 to 12 months) suggests that decreasing precision of detections was not the only factor here. Though speculative, a postural explanation for the shift in size might also be proposed: at older ages, the child was less likely to be lying or being held close to the face of a caregiver. Instead, in a seated or standing position, the faces of others would be further away.

Our final analysis directly measured size and vertical position of faces by posture (due to the limited overlap in postures between ages, regression analysis was not possible). The lying posture, seen only at 3 months, had a much larger face size than the other postures (almost 9% of camera field, as opposed to 2.5% for holding, 3% for sitting, and 4% for standing). Both lying and being held also had lower average vertical positions (.50 and .52 respectively, where 1 was the top of the screen) than sitting and standing (.60 and .57, respectively).

## General Discussion

We investigated the possibility of using automated face detection techniques to measure the accessibility of social information to infants. With head-mounted videos from a single infant at 3, 8, and 12 months, we constructed a discriminative model of face-detection that made use of inexpensive but noisy detectors and a secondary filtering step using a conditional random field model. This approach was relatively suc-

<sup>1</sup>For this and the remaining analyses, we averaged across all detections for each frame, potentially including some noise due to spurious detectors in correct frames. Future work should look estimate

the location of correct detections as well as frames in which they occur.

Figure 7: Smoothed histogram of detected face sizes at 3, 8, and 12 months. Height shows proportion of detections at each size; horizontal axis is scaled in log proportion of camera field. Dashed lines give means.

successful in picking out correct detections for the dataset as a whole.

The face-detector data revealed a surprising pattern. Faces were far less frequent in the 12-month data (and harder to detect, providing a potential caveat to our descriptive results). In addition, those faces that were detected in the older part of the dataset were both smaller and higher in the visual field of the infant. These differences seemed related to the distribution of postures across different ages, and indeed size and horizontal position did vary with posture. Nevertheless, further research (and considerably more data) will be necessary to check these conclusions.

The speculative picture that emerges is nevertheless congruent with previous work (Franchak et al., 2010). As children grow and become more adept at locomotion, they create a situation where the faces of others in their environment are further away from them and less visible. While the young infant is constantly having the faces of others pressed into his, the toddler lives in a world populated by knees.

More broadly, the methodological upshot of this work is that head-camera footage may be an extremely valuable tool for studying social attention and access to social information “in the wild.” Nevertheless, this work cannot proceed if hand-annotation is the only solution. Computer vision methods that are appropriate for data of this type must be developed, and this study took a first step in that direction, revealing suggestive developmental differences.

## Acknowledgments

Special thanks to Richard Aslin for generously sharing the primary dataset used in this project. Additional thanks to Ally Kraus for help with data organization and annotation, as well as to Adam Vogel and Evan Rosen for work on an earlier

version of this project. This work was supported by a John Merck Scholars Fellowship.

# The Effects of Feedback During Exploration Depend on Prior Knowledge

Emily R. Fyfe (Emily.R.Fyfe@Vanderbilt.Edu)

Bethany Rittle-Johnson (Bethany.Rittle-Johnson@Vanderbilt.Edu)

## Abstract

Providing exploratory activities prior to instruction has been shown to facilitate learning. However, questions remain regarding the provision of guidance during the exploration phase. In this study, we replicated and extended a previous experiment by examining the effects of feedback during exploratory problem solving for children with varying levels of prior knowledge. Ninety-five children (M age = 8 yrs) solved 12 novel math problems and then received brief conceptual instruction. After solving each problem, they received (a) no-feedback, (b) outcome-feedback, or (c) strategy-feedback. Consistent with the previous experiment, the results resembled an aptitude by treatment interaction. Feedback during exploration prior to instruction improved children's procedural knowledge, but only for those with low prior knowledge. For children with higher prior knowledge, no feedback resulted in better procedural knowledge. Results suggest that providing feedback may not always be optimal.

**Keywords:** Guided Discovery Learning; Feedback; Aptitude by Treatment Interaction; Math Equivalence.

## Guided Discovery Learning

An emerging consensus suggests that people learn best through some form of *guided discovery*, which is defined as exploratory learning with supplemental instructional guidance. Learning tasks are exploratory if learners have not received instruction on how to complete them and instructional guidance encompasses a variety of tools, from in-depth instruction manuals to minimal feedback or hints. For example, Mayer's review (2004) suggests a "mixture of guidance and exploration is needed" (p. 17). Additionally, Alfieri et al.'s (2011) recent meta-analysis revealed the superiority of guided discovery over both pure discovery learning and pure direct instruction.

Providing exploratory activities prior to instruction is one form of guided discovery that has been recommended by researchers in education and cognitive psychology alike (e.g., Hiebert & Grouws, 2007; Schwartz & Bransford, 1998), and it is the form we focus on in this study. For example, several mathematics education researchers suggest, "each person must struggle with a situation or problem first in order to make sense of the information he or she hears later" (Stigler & Hiebert, 1998, p. 3). Similarly, Schwartz and Bransford (1998) suggest that exploratory activities facilitate the development of differentiated knowledge of the target problem space, which prepares learners for subsequent instruction.

There is a growing body of evidence to support the claim that exploration prior to instruction is beneficial (e.g., DeCaro & Rittle-Johnson, 2011; Schwartz & Bransford,

1998; Schwartz & Martin, 2004; Schwartz, Chase, Oppezzo, & Chin, 2011). For example, college students who explored novel examples learned more from a subsequent lecture than students who merely summarized a relevant text prior to the lecture (Schwartz & Bransford, 1998). Further, the timing of exploration and instruction matters. For example, children in elementary school benefited more from solving unfamiliar math problems before receiving instruction rather than vice versa (DeCaro & Rittle-Johnson, 2011).

However, questions remain regarding how and for whom this form of guided discovery is effective. First, should any guidance be provided during the exploratory activity? Mayer's review (2004) indicates that it is the guidance provided *during exploratory problem solving* that is crucial. Second, for whom is this guidance during exploration most advantageous? As noted by Cronbach and Snow (1977), often "the instructional approach that is best on the average is not best for all persons" (p. 1).

## Feedback and Prior Knowledge

Feedback is touted as one form of guidance that may be particularly beneficial during exploration. *Feedback* is any information about performance or understanding that the learner can use to confirm, reject, or modify prior knowledge. For example, Alfieri et al. (2011) specifically recommend "providing timely feedback" as an optimal approach to learning (p. 13). Similarly, Mayer (2004) cites feedback as an effective tool (among others) for keeping learners on track. Further, past research indicates that feedback's primary function is to identify errors and encourage the adoption of correct alternatives (e.g., Kulhavy, 1977), which may be particularly helpful when exploring a novel problem space. Given these positive effects, it seems likely that providing feedback during exploration would be universally beneficial.

However, a growing body of research indicates that the effects of feedback depend on learners' prior domain knowledge (e.g., Fyfe, Rittle-Johnson, & DeCaro, 2011; Kraise, Stark, & Mandl, 2009; Luwel et al., 2011). For example, college students with low prior knowledge learned more about statistics if they received feedback during problem solving than if they did not. However, students with higher prior knowledge did not benefit from such feedback (Kraise et al., 2009). Similarly, Luwel et al. (2011) examined children's performance on a numerosity judgment task that could be solved using one of two correct strategies. Children who knew neither strategy at pretest benefited greatly from feedback in terms of correct strategy selection,

but feedback had a much weaker effect for children who already knew the strategies at pretest. Together, these studies suggest that learners with low prior knowledge should benefit from feedback during exploration, but learners with higher prior knowledge may not.

This idea is consistent with past work on aptitude by treatment interactions (Cronbach & Snow, 1977), which occur when instructional treatments have positive effects for one kind of person, but neutral or even negative effects for another. Importantly, these interactions often occur in the context of differing levels of external guidance. For example, Snow and Swanson (1992) suggest tutors “should provide more scaffolding for less able learners and less scaffolding for more able learners” (p. 610). A large number of aptitude by treatment interactions involve interactions between instructional guidance and learners’ prior knowledge in the target domain (Kalyuga, 2007). For example, learners with low prior knowledge learn more from studying structured worked examples than from solving problems on their own. However, as knowledge increases, independent problem solving becomes the superior learning activity (e.g., Kalyuga & Sweller, 2004). In general, this work supports the notion that providing guidance (i.e., feedback) during exploration prior to instruction may help learners with low prior knowledge, but learners with higher prior knowledge may not need it.

### Previous Experiment

Thus, we compared the effects of feedback (i.e., guidance during exploration) to no feedback (i.e., no guidance during exploration) prior to instruction. We hypothesized that feedback during exploration would result in higher learning than no feedback. However, we expected the effect to be stronger for children with low prior knowledge.

We also explored whether the type of feedback mattered. *Outcome feedback* provides a judgment about the accuracy of the learner’s response, whereas *strategy feedback* provides a judgment about how the learner obtained that response. Outcome feedback has been studied extensively and is generally related to positive outcomes (e.g., Kluger & DeNisi, 1996). In contrast, few empirical studies have examined the effects of strategy feedback (e.g., Luwel et al., 2011). The limited evidence suggests strategy feedback can benefit strategy selection, but more research is needed to examine its effects across tasks and outcome measures.

We examined the effects of feedback in the context of children exploring math equivalence problems (problems with operations on both sides of the equal sign, such as  $3 + 4 + 5 = 3 + \underline{\quad}$ ). These problems are not typically included in elementary mathematics curricula (Rittle-Johnson et al., 2011), and research shows that U.S. children exhibit poor performance on math equivalence problems (e.g., Alibali, 1999; McNeil, 2008). Thus, these problems are novel and difficult for elementary school children, providing an apt domain to investigate exploratory problem solving.

In an initial experiment, children received a tutoring session that included exploratory problem solving followed

by brief conceptual instruction (Fyfe et al., 2011). The session was identical for all children with the exception that the feedback provided after each problem differed by condition. In the strategy-feedback condition, children received feedback on how they solved each problem. In the outcome-feedback condition, children received feedback on their answer to each problem. In the no-feedback condition, children did not receive feedback and were simply told to go on to the next problem. After the tutoring session, children completed a posttest (immediately and after a 2-week delay) that assessed conceptual and procedural knowledge of math equivalence. *Conceptual knowledge* is an understanding of the principles governing a domain and *procedural knowledge* is the ability to execute action sequences to correctly solve problems (e.g., Rittle-Johnson et al. 2011).

In line with our hypothesis, the effects of feedback on procedural knowledge depended upon prior knowledge. For low-knowledge children, feedback during exploration improved their procedural knowledge relative to no feedback. In contrast, for children with higher prior knowledge, no feedback resulted in superior performance than feedback, though this effect was slightly stronger for strategy-feedback than outcome-feedback. There were few effects on children’s conceptual knowledge. Thus, the results resembled an aptitude by treatment interaction. Children with low knowledge benefitted from receiving feedback, but children with higher knowledge benefitted more from exploring independently without feedback.

Although we predicted that prior knowledge would moderate the impact of feedback, we did not have a prior reason to expect a reversal such that feedback would actually harm learning for children with higher prior knowledge. Also, several limitations in the design constrained the strength of the conclusions. First, the manipulation was not as clean or as strong as it could have been. For example, all children were asked to report how they solved each problem, which inevitably guided all children’s attention to their strategies. The strategy-feedback manipulation would be stronger if only children in the strategy-feedback condition were encouraged to attend to their strategy use. Also, the feedback provided in both feedback conditions was relatively vague and not specific to the child’s response. For example, in the strategy-feedback condition, incorrect strategies were referred to as “not a correct way,” which may have been unclear. Further, children in both the strategy-feedback and outcome-feedback conditions were told if their target response (strategy or answer, respectively) was correct, but only children in the outcome-feedback were given additional information (i.e., the correct answer). The contrast between the two feedback conditions could be improved.

Second, we sought to clarify the influences of feedback type during exploration prior to instruction. Given the paucity of research comparing outcome-feedback to strategy-feedback, we wanted to confirm that feedback type is not central to children’s learning during exploration. To address these concerns, we conducted a second experiment

similar to Experiment 1, but with several modifications intended to strengthen the design.

## The Current Experiment

The current experiment was designed to strengthen the condition manipulation in Fyfe et al. (2011) and verify the results with an independent sample. Specifically, we attempted to replicate the finding that low-knowledge children benefit from feedback during exploration prior to instruction, whereas children with higher prior knowledge benefit from no feedback. Additionally, we sought to clarify the influences of outcome-feedback and strategy-feedback to confirm that feedback type did not impact children's learning during exploratory problem solving.

We strengthened the condition manipulation in three ways. First, to differentiate the conditions, we only had children in the strategy-feedback condition report how they solved each problem. Children in the other conditions were asked to report other information to mimic the interaction with the experimenter (i.e., their answer in the outcome-feedback condition and their completion of the problem in the no-feedback condition). Second, we made the feedback more specific by re-voicing the child's response. In the strategy-feedback condition we restated the child's strategy and in the outcome-feedback condition we restated the child's answer. Finally, we did not provide the correct answer in the outcome-feedback condition. In Fyfe et al. (2011), only children in the outcome-feedback condition received additional information (i.e., the correct answer). An alternative solution was to provide children in the strategy-feedback condition with additional information (i.e., a correct strategy). But, telling people how to solve a problem is a form of direct instruction, and we were interested in the guidance provided *prior* to direct instruction. So we eliminated the correct answer in the outcome-feedback condition to enhance parallelism across conditions.

Consistent with Fyfe et al. (2011), we predicted that children who received feedback during exploratory problem solving prior to instruction would exhibit better procedural knowledge of math equivalence than children who did not. However, we expected this effect to be larger for children with lower prior knowledge and to reverse for children with higher prior knowledge. Further, we did not expect any differences in children's conceptual knowledge.

## Method

Elementary school children received a tutoring session that included exploratory problem solving followed by brief conceptual instruction about math equivalence. The presence and type of feedback was manipulated during the exploratory problem solving.

### Participants

Participants were 111 second- and third-grade children. Ten were excluded from participation because they scored above 80% on pretest measures designed to assess children's prior

knowledge of math equivalence. Six additional children were excluded from analysis for not completing all activities. The final sample contained 95 children ( $M$  age = 7 yrs, 11 mo; 60 girls, 35 boys; 97% Black, 3% White).

### Design and Procedure

We used a pretest – intervention – posttest design with a two-week retention test. For the intervention, children were randomly assigned to one of three conditions: strategy-feedback ( $n = 31$ ), outcome-feedback ( $n = 33$ ), or no-feedback ( $n = 31$ ). Children completed the pretest in their classrooms in a 20-minute session. Within 1 week they completed a one-on-one tutoring intervention and posttest in a single session lasting approximately 45 minutes. Approximately two weeks after the intervention session, children completed the retention test in their classrooms.

The intervention began with exploratory problem solving. Children solved 12 novel math equivalence problems (e.g.,  $9 + 7 + 6 = \_\_ + 6$ ). In Fyfe et al. (2011), the problem were presented one at a time on a computer screen. In this study, we presented the problems in paper/pencil format to simulate a more typical classroom activity.

In the *strategy-feedback condition*, children reported how they solved each problem and received feedback on the strategy, which included a re-voicing of their report (“Good job! That is one correct way to solve that problem. [Child's strategy] was a correct way to solve it. / “Good try, but that is not a correct way to solve the problem. [Child's strategy] is not a correct way to solve it.”). The experimenter re-voiced the strategy just as the child reported it to ensure no added information was provided. In the *outcome-feedback condition*, children reported their numerical answer and received feedback on it, which included a re-voicing of their report, but not the correct answer (“Good job! You got the right answer, [child's answer] is the correct answer.” / “Good try, but you did not get the right answer, [child's answer] is not the correct answer.”). In the *no-feedback condition*, children reported when they completed each problem and were then told to move on.

After exploratory problem solving all children received brief conceptual instruction on the relational function of the equal sign. The experimenter provided a definition of the equal sign and explained how the left and right side of a problem were equal, using number sentences as examples (e.g.,  $3 + 4 = 3 + 4$ ). Between the exploratory problem solving and instruction, children completed a brief form of the assessment (midtest) to gauge the immediate effects of exploration prior to instruction.

### Math Equivalence Assessment

The math equivalence assessment, adapted from past work (Rittle-Johnson et al., 2011) was administered at pretest, posttest, and retention test. It included both conceptual (10 items) and procedural (8 items) knowledge subscales. Conceptual items assessed knowledge of the meaning of the equal sign and the structure of equations. Procedural items consisted of math equivalence problems,

and scores were based on children's use of a correct strategy to solve the problem. Example items and scoring are presented in Table 1. A brief version of the assessment (5 more difficult items) was used as the midtest.

Table 1: Example items on the assessment.

Task	Scoring
<i>Procedural Knowledge</i>	
Solve $8 = 6 + \square$ (operation on right side)	Use correct strategy (if unclear, response must be $\pm 1$ of correct answer)
Solve $3 + 4 = \square + 5$ (operations on both sides)	Same as above
Solve $\square + 6 = 8 + 6 + 5$ (blank on left)	Same as above
<i>Conceptual Knowledge</i>	
Define equal sign	Provide relational definition (same amount)
Judge equations such as $3 = 3$ as true or false	Correctly judge equations
Select choice that shows 10¢ is same as 1 dime	Select equal sign

## Analysis and Results

We used a planned contrast analysis of variance model. Because our condition variable had three groups (no-feedback, outcome-feedback, strategy-feedback), we created two coded variables. The first variable (feedback) compared no-feedback to the two feedback conditions combined. This allowed us to address our primary hypothesis regarding the presence or absence of guidance during exploration. The second variable (feedback type) compared outcome-feedback to strategy-feedback and allowed us to explore differences in the type of guidance provided. To evaluate whether condition effects depended on prior knowledge, we included two interaction terms: feedback by prior knowledge and feedback type by prior knowledge. We used procedural knowledge pretest scores as the prior knowledge measure as it is the most relevant domain knowledge for learning during exploratory problem solving. Finally, we included three covariates (children's age as well as procedural and conceptual knowledge pretest scores).

To evaluate children's performance on the assessment we conducted repeated measures ANCOVAs with feedback (feedback vs. none) and feedback type (outcome vs. strategy) as between-subject variables and time (midtest, posttest, retention test) as the within-subject variable. The two interactions and three covariates were also included. We examined procedural and conceptual knowledge separately.

### Pretest

On the pretest, children answered few procedural ( $M = 20\%$ ,  $SD = 18\%$ ) and conceptual ( $M = 19\%$ ,  $SD = 18\%$ ) items correctly. Importantly, there were no differences between conditions on either scale at pretest,  $F$ 's  $< 1$ .

## Procedural Knowledge

Children's procedural knowledge increased from midtest ( $M = 26\%$ ,  $SE = 3\%$ ) to posttest ( $M = 37\%$ ,  $SE = 3\%$ ), and stayed similar two weeks later ( $M = 32\%$ ,  $SE = 3\%$ ).

There were no main effects of feedback or feedback type, nor did feedback type interact with prior knowledge,  $F$ 's  $< 1$ . However, consistent with Fyfe et al. (2011), there was a feedback by prior knowledge interaction,  $F(1, 87) = 4.67$ ,  $p = .03$ ,  $\eta_p^2 = .05$ . As prior knowledge increased, the benefits of feedback decreased ( $B = -1.06$ ,  $SE = 0.49$ ). To help interpret the interaction, we categorized children as having higher prior knowledge (scored above the median on the procedural knowledge pretest measure) or low prior knowledge and examined the main effects of feedback for each group (see Figure 1). For the low-knowledge group, children who received feedback exhibited higher procedural knowledge ( $M = 33\%$ ,  $SE = 4\%$ ) than children who did not receive feedback ( $M = 20\%$ ,  $SE = 5\%$ ),  $F(1, 87) = 4.00$ ,  $p = .05$ ,  $\eta_p^2 = .04$ . For the higher-knowledge group, children who received feedback exhibited lower procedural knowledge ( $M = 28\%$ ,  $SE = 5\%$ ) than children who did not receive feedback ( $M = 50\%$ ,  $SE = 6\%$ ),  $F(1, 87) = 7.54$ ,  $p = .007$ ,  $\eta_p^2 = .08$ . Feedback during exploration was more beneficial than no feedback for children with low prior knowledge, but for children with higher prior knowledge, the reverse was true. Feedback type did not matter, suggesting that both types of feedback were beneficial for low-knowledge children, and both types of feedback were detrimental for higher-knowledge children.

Figure 1: Percent correct on procedural knowledge assessment by condition and prior knowledge. Scores are estimated marginal means based on midtest, posttest, and retention test scores.

## Conceptual Knowledge

Children's conceptual knowledge increased from midtest ( $M = 21\%$ ,  $SE = 2\%$ ) to posttest ( $M = 50\%$ ,  $SE = 2\%$ ) and stayed similar at retention test ( $M = 43\%$ ,  $SE = 2\%$ ).

There were no main effects of feedback or feedback type, nor did feedback type interact with prior knowledge,  $F$ 's  $< 1$ . However, there was a marginal feedback by prior knowledge interaction,  $F(1, 87) = 3.63$ ,  $p = .06$ ,  $\eta_p^2 = .05$ .

As prior knowledge increased, the benefits of feedback tended to decrease ( $B = -0.70$ ,  $SE = 0.37$ ). To help interpret the marginal interaction, we examined the effect of feedback for low- and higher-knowledge children separately (based on a median split of procedural knowledge pretest scores; see Figure 2). For the low-knowledge group, children who received feedback exhibited somewhat higher conceptual knowledge ( $M = 44\%$ ,  $SE = 3\%$ ) than children who did not receive feedback ( $M = 37\%$ ,  $SE = 4\%$ ),  $F(1, 87) = 2.56$ ,  $p = .11$ ,  $\eta_p^2 = .03$ . For the higher-knowledge group, children who received feedback exhibited somewhat lower conceptual knowledge ( $M = 29\%$ ,  $SE = 3\%$ ) than children who did not receive feedback ( $M = 39\%$ ,  $SE = 5\%$ ),  $F(1, 87) = 2.60$ ,  $p = .11$ ,  $\eta_p^2 = .03$ . Although not reliable, particularly when dichotomizing prior knowledge, these results resemble the pattern of findings found for procedural knowledge.

## Discussion

Guided discovery generally facilitates deeper learning than discovery or instruction alone (e.g., Alfieri et al., 2011; Mayer, 2004). For example, providing exploratory activities with subsequent instruction can be beneficial (e.g., DeCaro & Rittle-Johnson, 2011; Schwartz & Bransford, 1998). However, the amount of guidance provided during the exploratory activities has largely gone unstudied, leaving questions as to how and for whom the guidance can work. In a previous experiment, we attempted to address these questions by examining the effects of feedback during exploratory problem solving prior to instruction. Some children received feedback (on their answer or on their strategy) after solving each problem, while others did not. In this study, we strengthened the condition manipulation and verified the results with an independent sample of children. Our results were consistent with those in Fyfe et al.'s original report. For children with low prior knowledge, feedback led to higher procedural knowledge than no-feedback. But for children with higher prior knowledge, feedback hindered performance relative to no-feedback.

There was a similar, but weaker effect for conceptual knowledge. Feedback type had little effect in general. Overall, we replicated the previous findings and provided evidence for the reliability of the results.

The results are consistent with prior work demonstrating aptitude by treatment interactions, which demonstrate that a single instructional method is often not best for learners with varying levels of prior knowledge (Cronbach & Snow, 1977; Kalyuga, 2007). In particular, a common conclusion is that low-knowledge learners benefit from more guidance, while high-knowledge learners benefit from less guidance (Snow & Swanson, 1992). Aptitude by treatment interactions have been found in a variety of domains including math, science, and problem solving (see Kalyuga et al., 2003). The current study (coupled with Fyfe et al., 2011) extends the aptitude by treatment interaction work to the presentation of feedback during exploratory problem solving. Children who enter the situation with low knowledge of the domain need feedback to improve their knowledge of correct procedures. Children with higher domain knowledge, on the other hand, do not need this feedback and actually perform better without it. This occurred even though higher knowledge children in our study were far from experts and still had a lot to learn.

Despite the growing evidence that prior knowledge moderates the impact of feedback during problem solving (e.g., Fyfe et al., 2011; Kraise et al., 2009; Luwel et al., 2011), the reasons underlying this effect remain unclear. One potential explanation relies on the learner's experience of cognitive load (Paas, Renkl, & Sweller, 2003). For low-knowledge learners, novel tasks can easily overload their working memory; thus, they often need some form of external guidance to reduce cognitive load. In contrast, higher-knowledge learners can use their existing, relevant schemas to help them complete the task without cognitive overload; thus, they often do not need external guidance. This may explain why low-knowledge learners benefited from feedback, but high-knowledge learners did not. It is also possible that differences in motivation would help explain the findings. Children who are more knowledgeable may also be more motivated to learn. In turn, those who are more motivated may thrive in less structured, challenging environments whereas children who are less motivated may not (Schnotz, 2010). Finally, changes in children's strategy knowledge may also play a role. For low-knowledge children, the constraining effects of feedback may have sped up the process of strategy acquisition, which in turn could jumpstart subsequent strategy changes including the strengthening of correct strategies (Siegler, 1996). However, for higher-knowledge children, the constraining effects of feedback may not have been necessary since these children already knew a correct strategy. More work is needed to tease apart these alternative explanations.

Our results also have important implications for research on guided discovery learning. They suggest that prior knowledge (and other learner characteristics) should be considered when evaluating the efficacy of guided discovery

methods (Cronbach & Snow, 1977). They also highlight the need to evaluate and optimize different aspects of guided discovery techniques. We examined the amount of guidance provided during exploration prior to instruction and found that more was not always better. Unfortunately, even when researchers recognize the benefits of combining exploration and instruction, the recommendation is usually to include more guidance (e.g., Alfieri et al. 2011).

Despite the positive contributions of the current study, future research is needed. For example, researchers should continue investigating the effects of feedback type. We did not detect many differences between outcome feedback and strategy feedback, but past research suggests strategy-feedback can be more beneficial, at least in terms of strategy selection (Luwel et al. 2011). Further, research should more carefully address what counts as sufficient prior knowledge. As more research finds that the effectiveness of instruction depends on prior knowledge, instructors will need guidance on how to choose instructional techniques for particular children with particular levels of prior knowledge.

This study extends research on guided discovery learning in which exploration is provided prior to direct instruction. Providing feedback during the initial exploration facilitates learning for low- but *not* higher-knowledge children. Thus, providing feedback may not always be optimal.

## Abstract

By the time children begin to rapidly acquire new word meanings they are already able to determine the grammatical category of novel words based on syntactic and morphological cues. Here we test whether children can leverage this knowledge when inferring the meaning of a novel word. Through a novel word learning experiment we determine that children can use this information, drawing different conclusions for the most likely meanings of novel words in distinct grammatical categories. We use a Bayesian model to formalize the higher level knowledge that children might have about noun and adjective meanings. Simulations show that children's behavior reflects the type of shift we would predict on the basis of noun and adjective meanings in the English lexicon.

**Keywords:** language acquisition; word learning; Bayesian inference

One of the most striking phenomena in language acquisition is children's ability to rapidly learn the meanings of novel words with only limited exposure. How exactly children do this has been researched extensively, with three lines of inquiry dominating the attempts to formalize this process: *hypothesis elimination* (Berwick, 1963; Pinker, 1989; Siskind, 1996), *associative learning* (Colunga & Smith, 2005; Regier, 2005) and *Bayesian inference* (Xu & Tenenbaum, 2007). Xu and Tenenbaum argue that Bayesian inference is superior to hypothesis elimination and associative learning because it uniquely allows the learner to take advantage of 'suspicious coincidences' when learning words for overlapping concepts. For example, in a word learning experiment they found that when children were shown three Dalmatians labeled with a novel object label, there was a strong bias for children to think that the novel word meant Dalmatian, rather than dog, or animal. This bias was not as strong when children only saw one Dalmatian labeled with the novel label. Neither hypothesis elimination nor associative learning predict the effect of the suspicious coincidence that results from the narrow distribution of exemplars on the kind hierarchy (which is in turn contingent on the number of exemplars). Xu and Tenenbaum's model does predict this effect, via the likelihood term, which takes into account both the number of exemplars and the size of the hypothesis.

One key assumption that Xu and Tenenbaum relied on was that the candidate concepts fell on a hierarchy of kinds. That is, in their model the learner does not have to determine what domain to generalize across, as this domain was given by the kind hierarchy. This assumption has two implications for their model: (1) most of the work in hypothesis selection is being done by the likelihood, as the prior probability of each hypothesis is comparatively much less variable and

(2) it largely limits the model to the discussion of object label learning, as this is the domain that primarily uses the kind hierarchy.

In this paper we probe the predictions of the Bayesian model on different grammatical categories, nouns and adjectives, which tend to draw from different concept hierarchies. This allows us to better test the role of the prior probability of a concept given a grammatical category by letting us examine the link between grammatical category and concept hierarchy. Toward these goals we conducted a word learning experiment that replicates Xu and Tenenbaum's finding with learning novel nouns, and extends the paradigm to novel adjective learning. We find that children use the grammatical category of the novel word to constrain their hypotheses about the meaning of the novel word. This is demonstrated through their sensitivity to the suspicious coincidence in the distribution of exemplars on the kind hierarchy when learning nouns but not adjectives. A Bayesian model that takes into account not only conceptual similarity but also the link between grammatical category and concept matches the qualitative shift between nouns and adjectives seen in the children's data. The model's ability to capture this shift highlights the crucial role that children's prior beliefs contribute to their generalizations in word learning. Through this work we extend the Bayesian model of word learning in ways that make it more realistic with respect to both the structure of natural language and the task faced by a child acquiring novel words.

Our paper is organized as follows. We first present our word learning experiment. We then use a Bayesian model to formalize children's prior distribution over concepts. The next section presents simulations comparing the model to children's behavior. We conclude by discussing the implications that this work has for language acquisition, in particular the importance of considering how a learner's prior knowledge affects the way in which the data from the environment are used in language acquisition.

## Word Learning Experiment

In a novel word learning experiment children were presented with an array of animals and vehicles and taught a novel label (noun or adjective) for a concept. Children were then asked to generalize their inferred concept to novel items. The stimuli allowed generalization along both kind and property dimensions. If children are able to use syntactic information to constrain their inference of words' meanings, then we should expect them to generalize differently when learning nouns versus adjectives.

Figure 1: The stimuli for our experiment included 36 objects in subordinate, basic, and superordinate vehicle and animal categories. Half the items were striped and half spotted.

## Methods

Our experiment tested two groups of children using a between subjects design. The noun group learned two novel nouns, and the adjective group learned two novel adjectives.

**Participants** Participants were 24 children (mean age = 4;0, range = 3;6-5;0) recruited from the greater College Park area as well as an on campus preschool. Children either visited the lab with their parents or were visited by researchers at their preschool. Four children were excluded from the final analysis for the following reasons. One was too shy to interact with the snail and three said they didn't know when they were asked to perform the generalization task outlined below.

**Stimuli** All children were presented with an array of pictures (Figure 1) that included 36 items from two superordinate categories on the kind hierarchy (18 vehicles and 18 animals). Each category had items from several basic levels (animals: 12 dogs, 2 cats, 2 squirrels, 2 owls; vehicles: 12 roofed cars, 2 convertibles, 2 vans, 2 trucks). One basic level from each superordinate category had items from two subordinate level categories (dogs: 6 Dachshunds and 6 Yorkshire terriers, roofed cars: 6 taxis and 6 police cars). There were both striped and spotted items of each item type.

**Procedure** A snail puppet was introduced to the child, and the child was told that the snail spoke a funny snail language that was mostly like English but included some new words. The experimenter explained that they would try to figure out the snail's words by listening to him talk about some of the pictures. Before proceeding further, the experimenter checked that both the snail and the child could see all of the pictures in the array. This ensured that participants were aware of the range of items in the experimental world.

During the **word learning phase** the snail looked at the pictures and pointed out an item from one of the subordinate

Speaker	Utterance	Action
Snail	'This is a <i>blicky one</i> '	points to striped Dachshund 1
Snail	'Look, another <i>blicky one</i> '	points to striped Dachshund 2
Snail	'Here's another <i>blicky one</i> '	points to striped Dachshund 3
Snail	'I'm going to go have a rest'	retreats to shell
Experimenter	'Here are some more pictures. Can you put circles on all the <i>blicky ones</i> to surprise the snail?'	lays out new array of pictures and gives the child a set of rings
Child	—	puts rings on items that match child's hypothesis for the meaning of <i>blicky</i>

Table 1: Sample adjective trial. Noun trials were identical with *blick* substituted for *blicky one*.

level categories (e.g., a striped dachshund). In the noun condition he described it as *a blick*, and in the adjective condition he described it as *a blicky one*. This happened 3 times, with the snail pointing to a different striped dachshund each time. Then the snail would get tired and retire to his shell for a nap.

While the snail slept, the experimenter initiated the **test phase**, during which the child was presented with another array of pictures and asked to place circles on the other *blicks* (noun condition) or *blicky ones* (adjective condition). A single trial is schematized in Table 1. The entire procedure was repeated for a second novel word used to describe another item from a different subordinate level (e.g., a spotted taxi). Order of item (dog before vehicle or vice versa), described subordinate level item (dachshund vs yorkie and taxi vs police car), and described pattern order (striped before spotted and vice versa) were counterbalanced across subjects.

## Results

Each item presented during the word learning phase was consistent with seven candidate concepts (illustrated in Table 2), picking from the kind hierarchy, property hierarchy or combining concepts from both. For data analysis, children's hypotheses were collapsed depending where the generalization fell on the kind hierarchy. Children's choices were coded as follows, with one response recorded per trial. Subordinate responses were recorded if children chose only items from the same subordinate level as the example (e.g., only dachshunds after being presented with dachshunds). Basic responses were recorded if children chose from only the basic level (e.g. either dog type after being presented with

Hypothesis	Dimension	Level
Dachshund	Kind	subordinate
Dog	Kind	basic
Animal	Kind	superordinate
Striped	Property	neutral
Striped $\wedge$ Dachshund	Property $\wedge$ Kind	subordinate
Striped $\wedge$ Dog	Property $\wedge$ Kind	basic
Striped $\wedge$ Animal	Property $\wedge$ Kind	superordinate

Table 2: Candidate concepts, given three exemplars of striped Dachshunds.

dachshunds) or from the basic and subordinate levels. A superordinate response was recorded if children chose only from the superordinate level (e.g., any animal after being presented with dachshunds) or from the superordinate level with any combination of the lower levels. Finally, neutral responses were recorded if children chose from anywhere on the kind hierarchy (e.g., anything from the vehicle hierarchy after being shown a dachshund). All items chosen by children with neutral responses were consistent with the property (either striped or spotted) that they had been taught.

Results are shown in Figure 2(a). In the noun condition, we replicated Xu & Tenenbaum’s finding, uncovering a bias for the subordinate level meaning when all observations fall into the same subordinate level. In the adjective condition, however, we see a different pattern. The placement of the item on the kind hierarchy had no bearing on children’s choices, with the overwhelming majority choosing the neutral interpretation, indicating their belief that the novel adjective’s meaning referred just to the most salient property (striped versus spotted) rather than the kind. Planned comparisons revealed that the proportion of trials that children chose the subordinate and neutral meanings differed significantly by condition (subordinate:  $t(33) = 3.49, p < 0.002$ , neutral:  $t(26) = 3.39, p < 0.003$ ).

## Discussion

These results demonstrate that children use their knowledge of grammatical categories, and the associated kinds of meanings that correlate with these categories, when inferring the meanings of novel words. In particular, they favor concepts from a kind hierarchy for novel nouns, and from a property hierarchy for novel adjectives. In one respect this result is not new, as infants as young as 14 months have been shown to know the mapping between grammatical and conceptual categories (Waxman & Markow, 1998; Booth & Waxman, 2003, 2009). Instead, the novelty is in showing that this mapping constrains children’s inferences. A very low prior probability for a hypothesis on the kind hierarchy blocks it from being determined the most likely for a novel adjective meaning, despite it being the narrowest possible hypothesis.

This finding emphasizes the role of the hypothesis space, since the most likely hypothesis differs depending on the grammatical category of the word being learned. In order

to determine whether children are behaving optimally with respect to a specific hypothesis space (conditioned by grammatical category and the information available to them in the English lexicon), we used a Bayesian model to predict generalization behavior from the nouns and adjectives that are likely to be present in the children’s early lexicons.

## Model

We assume the generative model shown in Figure 3(a). Our model assumes that the snail in our experiment, having chosen a grammatical category for the word he will teach the children, chooses a concept to teach (such as *dog*, *striped*, or *dachshund*), and then independently chooses three objects as examples of that concept.

The children in our experiment inferred what concept a new word referred to based on the grammatical category of the novel word (noun or adjective) and the objects the snail identified as examples of that word. Our model therefore computes the probability of each concept  $C$  for a given grammatical category  $P$  and set of objects  $X$ ,

$$\mathbb{P}(C|X, P) \quad (1)$$

We can use Bayes’ rule to compute the posterior probability over concepts given a set of examples and a word’s grammatical category,

$$\mathbb{P}(C_i|X, P) = \frac{\mathbb{P}(X|C_i) \cdot \mathbb{P}(C_i|P)}{\sum_{C_j \in \{\text{all concepts}\}} \mathbb{P}(X|C_j) \cdot \mathbb{P}(C_j|P)} \quad (2)$$

We assume that the probability of the data  $X$  depends only on the concept  $C$  and is independent of the grammatical category, given the concept. Since the normalizing constant in the denominator will be the same for all candidate concepts, we only need to find the values of  $\mathbb{P}(X|C_i)$  and  $\mathbb{P}(C_i|P)$  for the concepts we are considering.

### Concept Prior: $\mathbb{P}(C|P)$

Following Goodman, Tenenbaum, Feldman and Griffiths (2008) (cf. Austerweil & Griffiths, 2010), we represent concepts according to the concept grammar in Figure 3(b), with nonterminal nodes *Kind* and *Property* representing the dimensions a concept is defined along. Words like *dog* and *striped* are defined along only one of these dimensions (*Kind* and *Property*, respectively). Words like *kitten*, which describes a young cat, are defined along both dimensions (*Kind  $\wedge$  Property*). The derivation of each concept involves first applying a rule determining the dimension of the concept and then applying the dimension-specific rules until all terminal nodes have been identified. For example, in our concept language, the concept *dog* is formed by first applying the rule *Concept*  $\rightarrow$  *Kind* and then applying the rule *Kind*  $\rightarrow$  *dog*.

If we assign probabilities to each of the rules in this concept grammar and assume that the rules are applied independently of one another, then the resulting PCFG will determine the

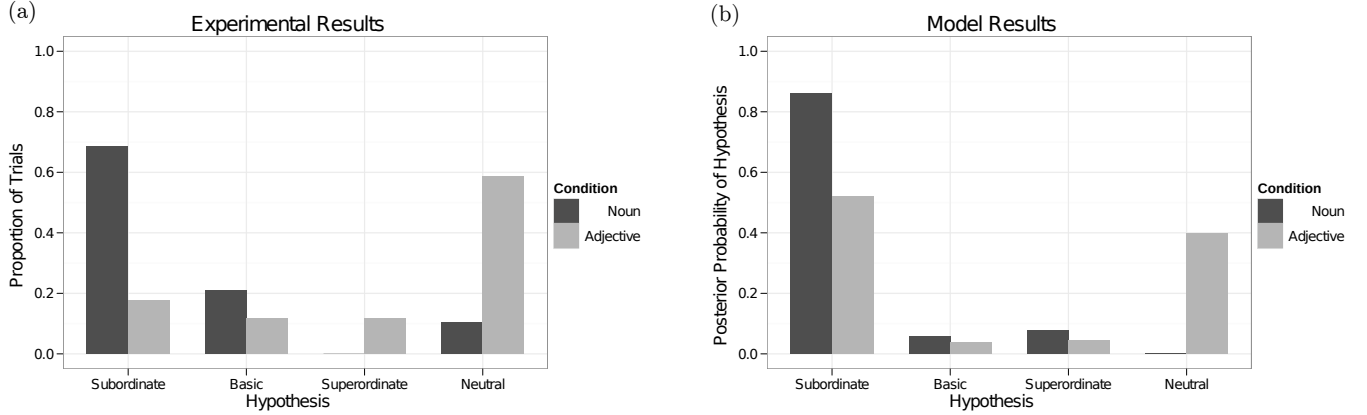

Figure 2: (a) Results of word learning experiment and (b) results of modeling.

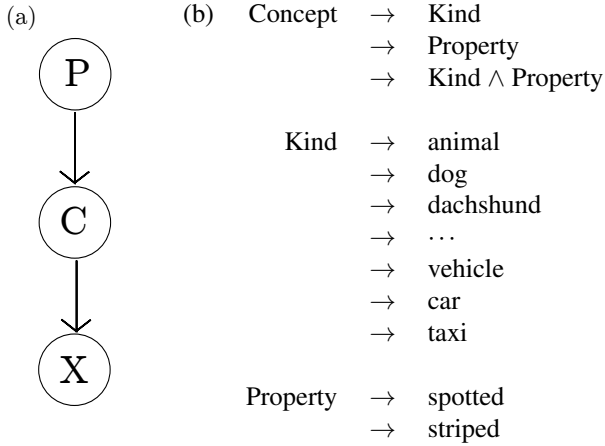

Figure 3: (a) Grammatical categories  $P$  determine the parameters for our prior over concepts  $C$ . Specific objects  $X$  are sampled from the set of items that exemplify a concept. (b) A probabilistic context-free grammar for concepts. Probabilities for each expansion rule are discussed in the Concept Prior section.

probabilities of all the concepts in our experiment. The probability of each concept would be the product of the probabilities of the rules applied to form it,

$$\mathbb{P}(C) = \prod_{R \in \{\text{rules to form } C\}} \mathbb{P}(R) \quad (3)$$

The differences in the types of concepts denoted by nouns and adjectives are represented in our model through differences in the probability distributions over the set of rules that expand *Concept* to particular dimensions. We assume children are computing this prior distribution separately for each part of speech, keeping track of the number of nouns or adjectives whose meanings denote a kind, a property, or both a kind and a property. They can estimate the rule probabilities from these counts using a Dirichlet-multinomial model. Under this model, the prior over dimension expansions based on

	Kind	Property	Both
Noun	335	4	24
Adjective	3	61	2

Table 3: Average counts (rounded) from 22 participants’ ratings of nouns and adjectives as descriptions of kinds, properties, or both.

the counts  $p_{d_i,P}$  of the productions seen by the learner of a particular dimension  $d_i$  for that grammatical category  $P$  is

$$\mathbb{P}(d_i|P) = \frac{p_{d_i,P} + 1}{\sum_{d_j \in \{\text{all dims}\}} p_{d_j,P} + 3} \quad (4)$$

We approximated these production counts from a Mechanical Turk survey where for each word in a vocabulary list of 429 words (363 nouns and 66 adjectives) that 30-month-old children likely know (Dale & Fenson, 1996), we asked adult English speaking participants to judge whether the word was best described as a kind, a property, or both. Different but often overlapping sets of 10 people were asked to respond to each word, and so we had a total of 22 participants in our study. Two participants’ judgments were excluded due to an extraordinarily high proportion of *Both* responses (proportion *Both* > 0.36, over two standard deviations outside the mean proportion of *Both* responses). While the children in our experiment (3-5 year-olds) were much older than 30 months, we believe that this vocabulary list is appropriate for our purposes, since the children in our experiments are almost certainly familiar with these words and differ only in additional words they might know. We assume that the distribution of noun and adjective dimensions in this set of words is representative of that of the larger and more varied set of words that our participants are familiar with. Table 3 shows the average counts of each description for each grammatical category.

For kinds, we assume a structure like Xu and Tenenbaum (2007) where the probability of a concept depends on its distinctiveness. For these measures we use a hierarchical cluster

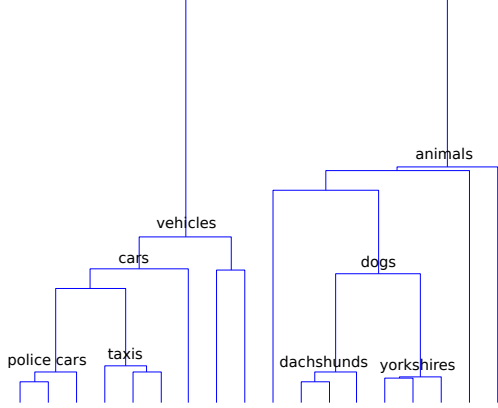

Figure 4: Hierarchical clustering of experimental item similarity.

tree, shown in Figure 4. To make this tree, we conducted a similarity judgment study, similar to Xu and Tenenbaum’s using the items that the snail had labeled in our experiment. Our participants, 26 students from the University of Maryland who received course credit for their participation, rated the similarity of all possible pairs of the 36 pictures on a scale from 1 (not similar at all) to 9 (very similar).

To incorporate cluster distinctiveness, Xu and Tenenbaum measure the branch length (which represents the Euclidean distance) between the concept node and its parent node. By this measure, the further a particular node is from its parent, the more distinct it is considered to be. Where  $\mathcal{K}$  is the set of all *Kind* concepts, the probability of a concept  $C_i$  given that it is defined over the *Kind* dimension is the branch length normed over all *Kind* concepts,

$$\mathbb{P}(C_i|\text{Kind}) = \frac{\text{height}(\text{parent}(C_i)) - \text{height}(C_i)}{\sum_{C_j \in \mathcal{K}} \text{height}(\text{parent}(C_j)) - \text{height}(C_j)} \quad (5)$$

For properties, we assume that in our experiment they are chosen from a multinomial distribution with each property equally likely to be selected. Since there were only two very salient properties in our experiment, we give each property the probability of  $\frac{1}{2}$ ,

$$\mathbb{P}(C|\text{Property}) = \frac{1}{2} \quad (6)$$

**Example Derivation of a Concept Prior** Under this model of the concept prior, the prior probability that the noun *bllick* refers to the concept *Dachshund* will have the following derivation. First, we have production counts for nouns that describe kinds  $p_{\text{Kind}, \text{Noun}}$  that were found in our Mechanical Turk study (we found that on average 335 out of 363 nouns were categorized as kinds). From this production count and the total production counts for nouns, we derive the probability of expanding *Concept* to *Kind*.

$$\begin{aligned} \mathbb{P}(\text{Kind}|\text{Noun}) &= \frac{p_{\text{Kind}, \text{Noun}} + 1}{\sum_{d \in \{\text{Kind}, \text{Property}, \text{Both}\}} p_{d, \text{Noun}} + 3} \\ &= \frac{335 + 1}{363 + 3} = 0.92 \end{aligned} \quad (7)$$

Then we find the probability of the concept being *Dachshund* given that it is defined only along the *Kind* dimension, using the height of the branch *Dachshund* and its immediate parent *dog*. These heights were 0.1259 and 0.3115, respectively.

$$\begin{aligned} \mathbb{P}(\text{dachshund}|\text{Kind}) &= \frac{\text{height}(\text{parent}(\text{dog})) - \text{height}(\text{dog})}{\sum_{C \in \mathcal{K}} \text{height}(\text{parent}(C)) - \text{height}(C)} \\ &= \frac{0.1856}{1.7576} = 0.1056 \end{aligned} \quad (8)$$

Finally, to compute the prior probability of the concept *Dachshund* given that it is a noun, we multiply the probability of expanding *Concept* to *Kind* by the probability of the concept being *Dachshund*.

$$\begin{aligned} \mathbb{P}(\text{Dachshund}|\text{Noun}) &= \mathbb{P}(\text{Kind}|\text{Noun}) \cdot \mathbb{P}(\text{Dachshund}|\text{Kind}) \\ &= 0.92 \cdot 0.1056 = 0.09715 \end{aligned} \quad (9)$$

### Concept Likelihood: $\mathbb{P}(X|C)$

We assume that, given a set of objects that are examples of a concept  $C$ , each object is equally likely to be chosen by the snail.<sup>1</sup> Therefore, the probability of the data given a concept is proportional to the size of the set of things matching that concept. For example, for the concept *dog*, the probability of picking a particular dog, Fido, is inversely proportional to the number of dogs there are in the scene. So if  $n$  objects are chosen by the snail as examples of a concept  $C$ , and these objects are plausible examples of the concept,

$$\mathbb{P}(X|C) = \left( \frac{1}{|C|} \right)^n \quad (10)$$

### Simulations

For each experimental trial we computed the posterior probability over concepts using both the noun and adjective priors. We assumed that on each trial children were sampling a concept from the posterior distribution over concepts given the

<sup>1</sup>Xu and Tenenbaum use a different estimate of category sizes for kinds, which is based on the same heirarchy as their concept prior. We found little difference when we compared the our own likelihood distributions with those computed by Xu and Tenenbaum’s methods on our experimental items. A very similar ordering applied over concepts, and each item was on the same order of magnitude for both measures of the likelihood.

grammatical category of the novel word. Thus the posterior probability over concepts as generated by the model should give us the frequency with which a child should show any given behavior. In order to be able to compare the model to the experimental data, we sorted the concepts into the same categories that we used for analyzing the experimental data: subordinate, basic, superordinate and neutral. The candidate concepts for *striped Dachshund*, along with the levels they mapped on to, are found in Table 2 (in the Results section of the Word Learning Experiment, above).

The results of our model are shown in Figure 2(b). Overall the model captures the qualitative shift seen between noun and adjective generalization in the experimental results, with a much higher posterior probability for the subordinate level given a noun, and a shift of a large part of the probability to the neutral level given an adjective.

## Discussion

In this paper we have shown that while children tend to map novel nouns onto a kind hierarchy, they prefer to map novel adjectives onto a property hierarchy. This behavior is predicted if children use their knowledge of grammatical categories and the distributions of different concept types within these categories to constrain the space of hypothesized meanings when learning novel words. A Bayesian model trained on the distribution of concepts across grammatical categories in the English lexicon predicts a qualitatively similar generalization pattern. Together these results suggest that not only are children able to use what they know about grammatical categories when inferring the meanings of novel words, the way they do this is predicted by the distributions of concept types across grammatical categories in English. Moreover, the constraints imposed on inference by grammatical category are powerful enough to overcome much of the effect of the size principle on the likelihood.

These findings have several implications for language acquisition and models of language acquisition. First, while the ‘size principle’ has received considerable attention as a solution to the word learning problem, this work demonstrates that the beliefs children bring to the word learning task also play a key role in word learning. Second, while a model based on priors derived from the lexicon captured the shift we see between noun adjective generalizations, it does not perfectly predict children’s behavior. Future research will probe whether this can be explained by making a closer approximation of the child’s lexicon (as our Mechanical Turk task may have overestimated the number of *both* concepts), or whether it stems from the learner’s tendency to amplify biases that exist in the input (e.g. Hudson-Kam & Newport, 2009). Third, we can ask how children behave with respect to concept hierarchies in languages that collapse the distinction between nouns and adjectives (e.g., Georgian). Does the size principle play a role only to the extent that nouns are likely to draw from the kind hierarchy? Next, as these beliefs are attributable to the distribution of concept types across grammat-

ical categories in the children’s own lexicons, there are obvious extensions of this work to modeling the infant word learning by weakening (or making nonexistent or unavailable) the link between grammatical category and concept hierarchy. There are several findings that would be interesting to model this way, including (1) that 11-month-olds make the same generalizations for words presented as nouns and adjectives and these generalizations are neutral with respect to kind vs. property meanings (Waxman & Booth, 2003), or (2) that the noun-kind link is established earlier than the adj-property link (Booth & Waxman, 2003, 2009). Finally, we can ask to what degree a group of exemplars’ distribution on a given concept hierarchy is used in acquiring linguistic phenomena that extend beyond word meanings (e.g., word classes).

## Abstract

Children acquiring languages with noun classes (grammatical gender) have ample statistical information available that characterizes the distribution of nouns into these classes, but their use of this information to classify novel nouns differs from the predictions made by an optimal Bayesian classifier. We propose three models that introduce uncertainty into the optimal Bayesian classifier and find that all three provide ways to account for the difference between children's behavior and the optimal classifier. These results suggest that children may be classifying optimally with respect to a distribution that doesn't match the surface distribution of these statistical features.

**Keywords:** language acquisition; noun classes; Bayesian classification; statistical learning.

Learners are surrounded by statistical information. Considerable evidence suggests that they can make use of statistics to learn about their environment. For example, when acquiring artificial languages, children track distributional cues that allow them to discover phonetic categories (Maye, Werker & Gerken, 2002), word boundaries (Saffran, Newport & Aslin, 1996), grammatical categories (Mintz, 2003; Reeder, Newport & Aslin 2009, 2010), grammatical dependencies (Gomez & Maye, 2005; Saffran, 2001) and phrase structure (Takahashi, 2009). This leads to a commonly held belief in the language acquisition literature that children are perfect statistical learners (e.g. Elman, Bates, Johnson Karmiloff-Smith, Parisi & Plunkett 1996).

The hypothesis that children are perfect statistical learners predicts that when tested on their ability to generalize aspects of their native language in an experimental setting, children's linguistic knowledge should always reflect the distribution of statistical information in the input. However, this is not always the case. Work by Hudson-Kam and Newport (2009), for example, suggests that children are not perfectly veridical learners, in that they sometimes override statistical patterns in the service of amplifying some other facet of the language they are acquiring. As this work has largely focused on artificial language learning, here we examine another type of non-veridical statistical learning involving the acquisition of noun class (grammatical gender) in a natural language, Tsez. We present evidence showing that children exhibit behavior that is inconsistent with the statistical information available in the input when assigning novel nouns to noun classes. This inconsistent

behavior suggests that there is more to language acquisition than a simple mapping of external statistical information to an internal representation of this distribution. In particular it suggests that properties of the learner shape the statistical information in the input into the subset of information that is used to guide inferences in language acquisition: the intake. We use a Bayesian model of noun classification to probe what underlies the difference in the measureable *input* and the *intake* that children use to acquire noun classes.

As a general framework, we assume that optimal performance in an experimental task involves the following four components:

- (1) Accumulation of knowledge of the statistical distribution of features relating to some phenomenon
  - (2) Observation of features in a novel experimental item
  - (3) Knowledge of which features are relevant for the statistical computation
  - (4) Bayesian computation to determine how to generalize the phenomenon in question to the novel instance
- (1) depends on the learner's ability to observe and encode a statistical distribution of features pertaining to some phenomenon. (2) is similar to (1), but refers to encoding these features given a situation where the learner will be performing a computation to classify or otherwise deal with a novel instance. (3) requires the learner to know which features are relevant for a computation and is by no means trivial, as not every feature related to every phenomenon is relevant to the associated computation. (4) is an assumption that we are making about the kind of computations that learners use distributional information for. While step (4) is often assumed to be the culprit when learners show suboptimal performance in experimental tasks, in principle steps (1) through (3) can also contribute to suboptimal performance.

Our case study on Tsez noun classification examines how each of these pieces could result in a reshaping of the statistical information in the input. We begin with an outline of the distributional information that characterizes Tsez noun classes. We then compare children's use of this information in classification with that of a naïve Bayesian classifier. Finally, we explore three models that introduce uncertainty in levels (1)-(3) from above, in an effort to determine what underlies the difference between children's performance and predictions made by the Bayesian model.

## Tsez Noun Classes

Many languages make use of subclasses of nouns, called noun classes or grammatical gender. The presence and number of noun classes, as well as the distribution of individual nouns into classes varies greatly across languages, but several features remain constant. All noun class systems exhibit some degree of distributional information both internal and external to the noun. Noun internal distributional information consists of commonalities among the nouns in a class, such as semantic or phonological features. Noun external distributional information is made up of class defining information that is separate from the noun, such as agreement morphology that is contingent on noun class. We will look at noun class acquisition in Tsez as a case study.

Tsez, a Nakh-Dagestanian language spoken by about 6000 people in the Northeast Caucasus, has four noun classes. These classes can be characterized based on noun external distributional information (e.g. prefixal agreement on vowel initial verbs and adjectives) (Table 1), and noun internal distributional information (semantic and morphophonological features on the nouns themselves) (Table 2).

Table 1: Noun External Distributional Information.

Class 1	Class 2	Class 3	Class 4
Ø-igu uži	j-igu kid	b-igu k'et'u	r-igu čorpa
I-good boy	II-good girl	III-good cat	IV-good soup
<i>good boy</i>	<i>good girl</i>	<i>good cat</i>	<i>good soup</i>

Table 2: Noun Internal Distributional Information (a selection)

Feature	Value	Class predicted	% class with this feature value	% nouns with this value in predicted class
Semantic	female	2	13	100
Semantic	animate	3	22	100
First Segment	r-	4	9	61

Gagliardi and Lidz (under review) measured noun internal distributional information by taking all nouns from a corpus of Tsez child directed speech, tagging them for potentially relevant semantic and morphophonological cues and using decision tree modeling to determine which features were most predictive of class (cf. Plaster, Harizanov & Polinsky, in press). The features shown in Table 2 are only a selection of the most predictive features of class, with only the most predictive values of these features shown.<sup>1</sup> The full structure of each feature that we assume in our model is given below in Table 3. Each feature has specified values that were

<sup>1</sup> Here we talk about ‘noun classes’ to refer what is often called grammatical gender. One of the cues to noun class is often natural gender, but this is only one of several cues, and many other nouns are in each class that don’t have this (or potentially any) cue predicting their class.

highly predictive of some class and an unspecified value that ranges over all other possible values that were not predictive.

Table 3: Structure of Features

Feature	Specified Values	Unspecified Value
Semantic	male, female, animate	other
First segment	r-, b-	other
Last Segment	i	other

In this paper we will focus on how children use noun internal distributional information. In particular we will look at whether a child can make use of the predictive phonological and semantic information when classifying novel nouns, and how they perform when a noun has two features that make conflicting predictions. Returning to the four components of statistical learning outlined above, we will be looking at

- (1) Whether Tsez children have knowledge of the noun internal distributional information
- (2) Whether they can observe these features on novel nouns
- (3) Whether they assume all features are relevant for classification
- (4) We assume for the purposes of our analysis that the computation they make based on this information is Bayesian.

## Classifying Novel Nouns in Tsez

To assess whether children can use the statistics of noun internal information available in their input, we compare classification of novel nouns by Tsez acquiring children to the classification behavior that is predicted by a Bayesian model trained on the input data from our corpus. We describe the experimental data and the model in turn.

## Classification by Tsez Children

To determine whether or not children classified novel nouns consistently with the predictions made by the probabilities associated with their noun internal features, 10 native Tsez speaking children (mean: 6yrs, range: 4-7yrs) participated in a classification task. Here we give an overview of the experiment; for further details, including adult data, see Gagliardi and Lidz (under review).

**Method** Children were presented with unfamiliar items labeled with novel nouns by a native Tsez speaker. They were instructed to first tell a character to begin eating and then tell the character whether or not to eat the other labeled items. As the both the intransitive (eat) and transitive (eat it) forms for *eat* are vowel initial in Tsez (*-iš* and *-ac'o* respectively), classification of the novel word could be seen on the agreement prefix. Furthermore, intransitive verbs in Tsez agree with the agent (the eater) and transitive verbs agree with the patient (the thing eaten). An example trial is schematized in Table 4.

The test items had either a single noun internal distributional feature from Table 2, or a combination of these features that made conflicting predictions (e.g. semantic = [animate] and initial = [r]). The exact feature combinations used in this experiment, along with the classes each feature predicts, are shown in Table 5. While these only represent a selection of the most predictive features, we focus on them here as they are a representative set of predictive semantic and phonological features.

Table 4: Example Experimental Trial

Speaker	Utterance	Action/Conclusion
Experimenter	kid girl(class2) girl	Points to girl on page
Child	sis, q'ano, ɬono, j-iš one two three CL2-eat One two three, Eat!	Tells <i>kid</i> to start eating using Class 2 prefix <b>j</b> / <b>kid is in Class 2</b>
Experimenter	zamil novel[animate]	Points to unfamiliar animal and labels it with the novel noun <i>zamil</i>
Child	zamil b-ac'xosi aanu zamilCL3-eat-pres.part neg pro isn't eating the <i>zamil</i>	Says whether or not the girl is eating the <i>zamil</i> using Class 3 prefix <b>b</b> / <b>zamil is in Class 3</b>

Table 5: Features Used in Experiment and Simulations

Feature	Value	Class Predicted
Semantic	female	2
Semantic	animate	3
First Segment	r	4
Semantic & First Segment	female & r	2 and 4
Semantic & First Segment	animate & r	3 and 4

Figure 1: Proportion of novel nouns assigned to each class (by cue type) in the experimental task

**Results** The proportion of nouns that children assigned to each class are shown in Figure 2. When nouns had no conflicting features, children assigned more nouns to the class most strongly predicted by the feature than to any other class. However, when nouns had more than one

feature that made conflicting predictions, children relied more heavily on the phonological feature [r-] than on the semantic feature. This is not likely to be predicted by the distribution of these features in the input, where nouns with the [animate] and [female] values of the semantic feature never occur in Class 4.<sup>2</sup>

### Classification by an Optimal Bayesian Classifier

Given these experimental data, we can evaluate whether children are optimally using the statistics in their input by examining how a Bayesian model would classify each novel noun. That is, what would an ideal learner, exposed to input with these features, do when asked to classify novel words?

Our model is shown in Equation 1. The prior probability of a class  $p(c)$  corresponds to its frequency of occurrence, and the likelihood terms  $p(f|c)$  for each of  $n$  independent features  $f$  can be computed from feature counts in the lexicon.

$$p(c | f_1, f_2 \dots f_n) = \frac{p(f_1 | c)p(f_2 | c) \dots p(f_n | c)p(c)}{\sum_i p(f_1 | c_i)p(f_2 | c_i) \dots p(f_n | c_i)p(c_i)} \quad (1)$$

The results of classification with this model are shown in Figure 2. Just as we did with children, we tested the model on classification with each semantic and phonological feature from Table 2 individually, as well as cases where these features were in conflict with one another. As would be expected based on the relative strength of these features (Table 2), when semantic and phonological features make conflicting predictions the model classifies in line with the predictions made by the semantic feature.

Figure 2: Predicted classification of novel nouns by an optimal naïve Bayesian classifier

The model's classification differs from that of the children in that when features made conflicting predictions the model relied on the statistically strongest cue (the semantic feature), while the children did not rely so heavily on this.

### Predicting Suboptimal Performance

While children roughly align with the model when classifying based on one highly predictive feature, they diverge when features make conflicting predictions. Children appear to use phonological features out of proportion with their statistical reliability. That is, children

<sup>2</sup> For a more detailed description of the results of the experiment, see Gagliardi & Lidz (under review).

appear to prefer the weaker predictions made by the phonological feature to the stronger ones made by the semantic feature. In order to determine the source of this asymmetry it is useful to first consider the fundamental differences between semantic and phonological features that could lead to this kind of behavior, and then to determine where and how these factors could affect our model.

There are several differences between semantic and phonological features that could affect their use in noun classification, but here we will focus on a fundamental difference in how reliably perceived and encoded each feature type may be during early acquisition. Every time a word is uttered (or most of the time, allowing for noisy conditions and fast speech) phonological features are present. However, especially during the early stages of lexical acquisition, the meaning of a word, and thus the associated semantic features, is much less likely to be available or apparent. Below we will consider how this sort of asymmetry could lead to a disparity in the way children end up using them in novel noun classification.

### Three Models of Uncertainty

The difference between semantic and phonological features could affect each of the three components from the schema of noun classification in different ways. In this section we will model each of these to see how building the asymmetry into each level changes the classification by the model.

#### Knowledge of Noun Internal Distributional Information

An asymmetry in the reliability with which semantic and phonological features of nouns are perceived and encoded during word learning could lead to a disparity in the way phonological and semantic features are represented as compared with how they are distributed in the input.

In our first manipulation (the Semantic Incompetence Hypothesis) we examined how classification by the model would be affected if the learner was misrepresenting some proportion of the semantic features that they should have encoded on nouns in their lexicon. We assume that learners represented the remaining proportion of nouns as predicted (accurately observing features during the experiment and assuming that both semantic and phonological features were relevant in classification). In doing this, we assume that learners' beliefs about which features are predictive of which class is built up as they observe different feature values on words belonging to different classes. One way of quantifying this is by modeling the learner's belief about the likelihood terms  $p(f|c)$  from Equation 1 under the assumption that these beliefs are derived from the counts that a learner accumulates of nouns in each class that contain a given feature. We assume learners use a multinomial model with a uniform Dirichlet prior distribution to estimate the proportion of items each class  $c$  that contain a particular value  $k$  for feature  $f$ . Under this assumption, each likelihood term is equal to:

$$p(f = k | c) = \frac{N_{c,f=k} + 1}{N_c + K} \quad (2)$$

where  $N_c$  denotes the number of nouns in the class,  $N_{c,f=k}$  denotes the number of nouns in the class for which the feature has value  $k$ , and  $K$  is the number of possible values for the feature.

We introduce misrepresentation of semantic features into this model by manipulating the number of observations of a noun with a certain feature value in each class. Since the semantic incompetence hypothesis posits that children misrepresent semantic feature values some proportion of the time, we reduce the count of nouns in each class that contain the relevant semantic features, changing them instead to the unspecified feature value [other]. We then compute the posterior probability of noun class membership using these adjusted feature counts. We can use this model to ask how low the counts would have to be in order for children's behavior to be optimal with respect to their beliefs.

We evaluated the model by comparing its behavior to children's behavior from the classification task. The model produced a close fit to the data in each condition (Figure 3). Furthermore, the estimated degree of misrepresentation was highly consistent across all semantic features and conflicting feature combinations. The best fitting level of uncertainty ranged from 0.96-0.91, meaning that children would be only using 4-9% of the semantic cues available to them. A generalized likelihood ratio test in which the level of misrepresentation was held constant across simulations (0.95) demonstrates that our semantic incompetence model significantly outperforms the optimal naïve Bayesian classifier ( $p < 0.0001$ ).

Figure 3: Classification of novel nouns as predicted by a Naïve Bayes Classifier with 95% of predictive semantic features misrepresented as [other].

Although this model produces a close fit to the empirical data, it predicts an extremely high degree of misperception. To understand why this is the case, consider that using likelihood terms for each class that are proportional to the

true empirical counts  $\frac{N_{c,f=k}}{N_c}$  would yield optimal noun

classification performance, regardless of the exact proportion of time children are misrepresenting features. That is, substituting  $\beta * p(f_i|c)$  for each term  $p(f_i|c)$  in Equation 1, where  $\beta$  is a constant denoting the degree of misperception, does not result in any change in the posterior probability distribution. This analysis suggests that changes in model predictions under this account of feature
