our proposal, causal knowledge is important in categorization because it provides people with explanatory links such that they can make sense of presented exemplars. Thus, categorization is seen as inference to the best explanation (Murphy & Medin, 1985; Rips, 1989). And because the explanatory value of causal knowledge is engrained in people's beliefs about underlying mechanisms (and not statistical regularities), we derived at least two possible explanatory roles of causal models: First, a causal model can serve as explanation why a prototypical exemplar is as it is (e.g., why most birds can fly). Second, a causal model can also serve as explanation why a category member might deviate from the prototypical exemplar (e.g., why some birds cannot fly). Depending on which kind of causal model people have in mind for a given category we expect people to judge different exemplars as best and worst category members.

We presented an experiment in which we manipulated the explanatory role of the instructed causal knowledge directly, and we found huge differences in membership ratings. Interestingly, in the *typical* condition (i.e., typical feature values were linked by causal mechanisms) judgments exhibited a causal status effect. In contrast, in the *atypical* condition (i.e., atypical feature values were link by causal mechanisms) we found a strong coherence effect. Therefore, we believe that causal-status as well as coherence effects are both faces of the same coin.

# Sparse category labels obstruct generalization of category membership

## Abstract

Studies of human category learning typically focus on situations where explicit category labels accompany each example (supervised learning) or on situations where people must infer category structure entirely from the distribution of unlabeled examples (unsupervised learning). However, real-world category learning likely involves a mixture of both types of learning (semi-supervised learning). Surprisingly, a number of recent findings suggest that people have difficulty learning in semi-supervised tasks. To further explore this issue, we devised a category learning task in which the distribution of labeled and unlabeled items suggested alternative organizations of a category. This design allowed us to determine whether learners combined information from both types of episodes via their patterns of generalization at test. In contrast with the prediction of many models, we find little evidence that unlabeled items influenced categorization behavior when labeled items were also present. **Keywords:** Semi-supervised category learning; rule induction; unsupervised learning

## Introduction

Category learning is a critical cognitive ability which is central to many aspects of cognition. As a result, considerable research over the last 50–60 years has explored the psychology of category learning using laboratory tasks. The majority of this work can be divided into two groups. Most research has focused on *supervised learning* tasks where corrective feedback or category labels are presented following or alongside each observation of a stimulus (e.g., Medin & Schaffer, 1978; Nosofsky, 1986). More recently, there has been an interest in *unsupervised learning*, wherein participants must organize examples in the absence of explicit instruction using the distributional properties of the stimuli (e.g., Clapper & Bower, 1994; Love, 2002; Pothos et al., 2011). However, neither of these situations adequately reflect the problem of real world category learning, in which feedback is not altogether absent nor always present, but is typically sparse and intermittent. Such tasks require learners to combine information from both labeled and unlabeled episodes. In machine learning, this problem is frequently studied under the name *semi-supervised learning* (for review, see Zhu, 2005).

Aside from offering a more ecologically relevant approach to the study of category learning, the study of semi-supervised learning has important implications for theories of human concept learning. Consider the problem of learning a concrete noun such as *horse*. One proposal is that word learning essentially links sound tokens (words) to already-acquired hypotheses or representations (Bloom, 2000; Gentner, 1982). Under this view, the label information from a teacher or parent about a single example horse must be integrated with the

child's pre-linguistic grouping of objects in their environment into classes.

A similar position is advocated by a number of influential theories of category learning which hold that supervised and unsupervised learning are subserved by a single underlying learning process (e.g., the rational model of categorization, Anderson, 1991; or the Supervised and Unsupervised STRatified Adaptive Incremental Network, abbreviated *SUSTAIN*, Love, Medin, & Gureckis, 2004). Such models naturally predict that semi-supervised learning should not only be possible, but may be the primary way in which people learn categories and their respective names.

## Can people acquire categories via semi-supervised learning?

Despite these arguments, recent empirical attempts to demonstrate semi-supervised category learning in the lab have met with mixed success. For example, Vandist, De Schryver, and Rosseel (2009) found that adding unlabeled training examples to a mostly supervised task offered no additional benefit beyond learning from only the supervised trials. However, the category structures they tested (known as *Information-Integration* categories) are typically difficult for people to learn even in fully unsupervised settings (Ashby, Queller, & Berretty, 1999), which may explain the limited impact that the unlabeled examples had.

On the other hand, Kalish, Rogers, Lang, and Zhu (2011) showed that after learning a simple category distinction on a single dimension from a small set of labeled examples, participants' estimate of the category boundary could be shifted by the presentation of a large number of unlabeled examples whose distribution was shifted compared to the labeled set (see also Lake & McClelland, 2011). While this study provides some evidence of semi-supervised learning, there remain alternative explanations of the effect. For example, since the central tendency of both categories are shifted in these studies it is unclear whether people are separately updating each category representation or responding to the global shift in the stimulus space.

Finally, Rogers, Kalish, Gibson, Harrison, and Zhu (2010) compared learning in a semi-supervised learning condition with a fully supervised condition. In this study, adding unlabeled items to a supervised category learning task caused faster learning only when trials were speeded. However, the question of whether people can integrate labeled and unlabeled training examples is logically separate from claims about

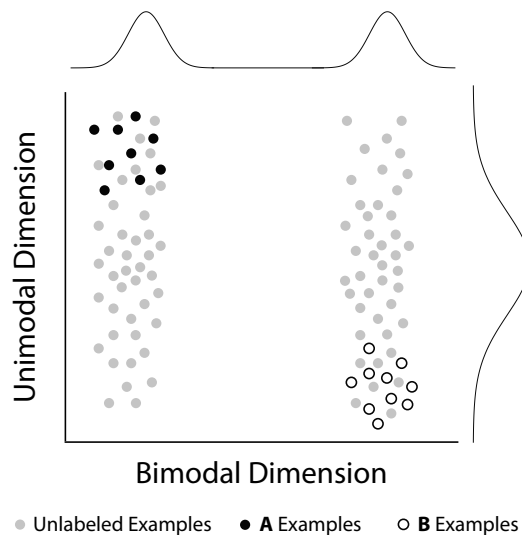

Figure 1: A schematic depiction of the design used in the experiment. Category stimuli varied along two continuous dimensions. The plot edges represent the marginal distribution of examples. Unlabeled examples fall in two columnar clusters, while two clusters of examples with labels A and B appear in the corners of the space. Taken alone, the distribution of labeled examples is ambiguous concerning how to generalize, since a rule on either dimension alone could explain the labels.

learning rates between tasks. For example, a participant's learning rate might vary based on features of the overall task context rather than the information conveyed by any subset of examples.

Collectively, these results tell a surprisingly unclear story. Despite decades of research on supervised and unsupervised learning with artificial stimuli, studies which have attempted to combine these two forms of learning fail to show robust and consistent effects. Some find limited evidence of semi-supervised learning while others fail to find any evidence at all. The goal of the present study is to attempt to revisit this issue with a novel design which may be more diagnostic of semi-supervised learning. As will be revealed shortly, our results add modest light to an already murky picture.

### Evaluating semi-supervised learning through patterns of generalization at test.

Our study (summarized abstractly in Figure 1) departs from the studies described above in a number of ways. In some previous work, the distributional properties of both labeled and unlabeled examples were identical (e.g., Vandist et al., 2009). In contrast, we manipulated the distribution of examples so that the distribution of unlabeled examples and the distribution of labeled examples suggested alternative organizations of the category. In particular, the labeled items alone were ambiguous about the basis for the category difference. However, the distribution of unlabeled examples suggested a clear organization of the categories along a single dimension. Our

Figure 2: A range of possible category strategies consistent with the category in Figure 1. In the Bimodal strategy, the learner classifies all the items that fall in each clustered column with the label given to the labeled items within the column. In the Unimodal strategy, the learner divides the example along the unimodal dimension. This strategy is acceptable if the unlabeled examples are ignored. The 2D strategy is more complex (in the sense that it depends on attention to both stimulus features) but is also consistent with the labeled examples and inconsistent with the unlabeled distribution.

prediction was that if people combine information from both the labeled and unlabeled examples, they will generalize the label information according to the distribution implied by the unlabeled examples. This should be clearly captured in their patterns of generalization in a test phase (see Figure 2).

In addition to comparing semi-supervised learning to fully supervised learning we also include a second control condition assessing fully unsupervised learning. In fact, this condition of our study represents a conceptual replication of a previous study on unsupervised category learning by Zeithamova and Maddox (2009, henceforth referred to as Z&M). This served two purposes. First, it allows us to establish a baseline measure of behavior for both extremes of supervision. Second, this ensures that participants *can* learn the category from the distribution of unlabeled examples alone.

Finally, rather than test a single semi-supervised learning condition, we systematically explore the effect of the *number* of labeled examples on semi-supervised learning. Our design thus interpolates between fully unsupervised learning to fully supervised learning by changing the relative amount of labeled versus unlabeled information.

## The Experiment

In our experiment, we developed a cover story which provided a plausible explanation for why some category examples were unlabeled (but still came from the same category). The cover story asked participants to imagine that they were working in a tv repair shop in a town where people tuned special loop antennas to pick up one of only two possible channels (similar to Markant & Gureckis, 2010). Similar antennas tended to pick up similar channels. Although all the tvs were tuned to one of the two channels, many had broken tubes making it impossible to turn on and verify the channel. The participants' job over the course of the experiment was to determine how different settings of the antennas determine which channel the tv is tuned to pick up. They were reminded that learning about the antennas was possible even if the tv tube was broken.

The experiment was organized into two phases. The first was a training phase in which participants were shown various category members with and without labels (depending on condition). The second was a test phase in which participants were asked to classify novel examples. Decision bound models (Ashby, 1992) were fit to subjects' responses during the test phase in an attempt to infer the strategy they applied. We then analyzed the frequency by which different strategies were adopted as a function of condition.

## Methods

**Participants** 124 New York University undergraduates participated for course credit. Participants were randomly assigned to one of four possible conditions: Unlabeled ( $N = 33$ ), 10-Labeled ( $N = 31$ ), 40-Labeled ( $N = 30$ ), or 40-All-Labeled ( $N = 30$ ). Four participants, three in the Unlabeled Condition and one in the 10-Labeled Condition, were classified as responding randomly (see the results section) and were dropped from the analysis, leaving 30 participants in each condition.

**Materials** The objects to be categorized were line stimuli varying in their length and orientation. The stimulus properties (lengths and angles) of the antennas were chosen to be similar to those used by Z&M (2009). The range of possible angles was different for each subject, but it covered  $60^\circ$  and was constrained not to cross the vertical or horizontal axes. The range of lengths was always between 100 and 560 pixels. The line stimuli were attached to pictures of TV via a stem. Category label information was given by changing what was showing on the TV screen. For unlabeled examples, the screen took on the appearance of broken glass. Participants were told that these TVs were broken, but still tuned correctly to one of the two channels. When category label information was given, the letters CH1 or CH2 appeared on the screen, indicating that the TV was set to pick up one of the channels (see the top row of Table 1 for examples).

**Design** During the training phase, the TVs were drawn from two elongated distributions which were naturally separable along one of the stimulus dimensions (the *bimodal* dimension). For reasons of control, stimuli were sampled using a discrete binning method described in Figure 3. This differs slightly from Z&M (2009) who used bivariate normal distributions but was necessary to ensure tight control over the distributional properties of the stimuli, and in particular to ensure that the distributions of labeled items were unbiased with respect to the particular categorization strategies.

Our primary experimental manipulation was to alter the training that participants received in the task. Four training conditions ranging from completely unsupervised to completely supervised (with no unlabeled training items) were included (see Table 1 for a summary).

**Unlabeled Condition.** In this condition, all TVs were broken (i.e., unlabeled). This condition is a traditional unsupervised category learning task and a conceptual replication of the *intermixed* condition from Z&M (2009), Exp. 1A.

**10-Labeled Condition.** This condition was identical to the Unlabeled Condition except that ten of the items in the corners were presented along with category labels (i.e., the appropriate channel).

**40-Labeled Condition.** This condition was similar to the Unlabeled Condition and the 10-Labeled Condition except that all of the items in the corners (40 in total) were presented along with category labels.

**40-All-Labeled Condition.** In this condition, all antennas were labeled in the training phase, meaning that this condition was fully supervised. However, to hold other aspects of the task consistent with the other conditions, 240 broken TVs without antennas (sham trials) took the place of the unlabeled examples, giving participants in this condition the same number of training trials as those in other conditions, and similar temporal spacing between labeled items to participants in the 40-Labeled Condition.

	 Labeled	 Unlabeled	 Sham	Total
Unlabeled	0	280	0	280
10-Labeled	10	270	0	280
40-Labeled	40	240	0	280
40-All-Labeled	40	0	240	280

Table 1: Summary of the four training conditions. All participants viewed 280 items in the training condition. *Labeled* and *Unlabeled* here denotes a TV with an antenna, which were either working (labeled) or broken (unlabeled). A *sham* TV consisted of a broken TV set without an antenna (examples are provided along the top).

Regardless of condition, labeled items in the training phase always came from the corners of the space as depicted in Figure 3, which meant they were always non-diagnostic with respect to the best category rule.

The test phase was identical for all four groups and, following Z&M (2009), involved the presentation of 50 broken TVs sampled from the same distribution as used during training. Participants were asked to predict the channel based on the antenna setting.

All remaining arbitrary aspects of the design (e.g., which dimension served as the bimodal dimension) were counterbalanced across conditions.

**Procedure** The experiment was administered on standard Macintosh computers using an in-house data collection system written in Python<sup>1</sup>. Participants were tested over a single one-hour session.

The instructions emphasized that all of the antennas were in good working order and purposefully tuned either to CH1 or CH2. Participants were also told that, as a result, the antennas as a whole constituted two categories of items. Although many of the TVs were broken, being broken had nothing to do with the setting of the antenna or the potential to pick up one of the two channels. Broken TVs were missing some information, but were otherwise not different from the others. To confirm that they had understood the instructions, participants were given a brief quiz and misconceptions were addressed.

Next, participants observed 80 randomly generated antennas in quick succession (100ms each), giving information about the range of values for each of the two stimulus dimensions (angle and length).

On each trial of the training phase, participants viewed a new TV (which was broken, working, or a sham), and after 500ms were prompted to press the space bar to continue. After the button press, the stimulus remained on the screen for 500ms. Between trials the screen was blank for an inter-stimulus interval of 500ms.

The test phase consisted of 50 trials in which participants saw a broken TV drawn from the same distribution as the training trials. On each test trial, participants viewed a new broken TV and were asked to press a button on their keyboard to indicate whether they believed the antenna was tuned to CH1 or CH2. After each trial, a thank you message (along with the original stimulus) remained on the screen for 1000ms. No feedback was given. The next trial followed after 500ms.

## Results

**Accuracy Analysis** In our first analysis, we considered whether participants correctly applied the category labels in the unambiguous regions of the space (i.e., the corners) in the 10-Labeled, 40-Labeled, and 40-All-Labeled conditions. Responding was significantly above chance in all conditions: 10-

<sup>1</sup> Available at <http://www.pypsyexp.org>

Figure 5: Histogram showing the trend in the number of subjects adopting each strategy across conditions. There is a general trend of an increase in the use of 2D rules in the presence of labeled items, as well as a drop in the use of a 1D rule on the bimodal dimension, but trends among the labeled conditions were weak.

the same bias can be evaluated in other conditions. Overall, the difference between the Unlabeled and 40-All-Labeled conditions was driven largely by the increase in the use of 2D rules in the 40-All-Labeled Condition. Note that while the distribution of labeled examples in the 40-All-Labeled Condition is logically consistent with all three strategies (Unimodal, Bimodal, 2D), a bias toward 2D rules is in line with the predictions of the optimal linear discriminant for the labeled examples.

Turning to the semi-supervised conditions, the distribution of strategies did not differ significantly between these two conditions (Fisher’s exact test,  $p = .79$ ). In addition, the proportion of participants using 2D rules did not vary between the conditions (Fisher’s exact test,  $p = .78$ ).

Combining the two semi-supervised conditions, we find an overall interaction between condition and the use of 2D rules (3 conditions  $\times$  2 strategies, Fisher’s exact test,  $p < .05$ ). However, the primary source of this effect seems to be the difference between the Unlabeled Condition and the other conditions. When we aggregate all the labeled conditions together, we see a greater use of 2D rules by the labeled conditions than the unlabeled condition (2 conditions  $\times$  2 strategies, Fisher’s exact test,  $p < .05$ ), while evidence for a parallel effect when aggregating the conditions had access to unlabeled training items together fell short of significance (2 conditions  $\times$  2 strategies, Fisher’s exact test,  $p = .07$ ). In summary, we found minimal evidence that the semi-supervised conditions were different from the all-labeled condition.

## Discussion

Semi-supervised learning is a bit like the Higgs boson in particle physics. It is believed to occur (e.g., to allow word learning) and is strongly suggested by theories of human category

learning (Anderson, 1991; Love et al., 2004), but has proven surprisingly difficult to observe. Our study represents yet another attempt to find laboratory support for this form of category learning. However, the patterns of generalization behavior exhibited at test during the two semi-supervised conditions most closely resembled the strategies of participants who learned in the fully supervised condition.

This result is striking for two reasons. First, unlike some of the previous work on semi-supervised learning, our experiment closely following existing protocols for studying unsupervised category learning in the literature in successfully replicating the results of Z&M (2009). In addition, given no other information participants in our study were willing to generalize according to the distribution of unlabeled examples. In the Unlabeled Condition, the most common strategy was to use a rule on the bimodal dimension. However, when labeled examples were included, participants responded similarly to the 40-All-Labeled Condition. This is the response pattern we would expect to see if subjects mostly failed to incorporate the unlabeled items into their representation of the category in the semi-supervised learning conditions. In this sense, our results join a growing chorus of studies which have failed to find semi-supervised learning except under very specific and limited circumstances (Gibson, Zhu, Rogers, Kalish, & Harrison, 2010; Rogers et al., 2010; Vandist et al., 2009).

In the following sections, we outline a number of possibilities about why semi-supervised learning has been so elusive in the lab.

**Noticing “gaps” in the input?** In our design, the distribution of labeled examples was systematically biased. One possibility is that learners eventually noticed the “gaps” in their input (i.e., that the labels only appeared with particular items) and thus inferred that these examples were somehow special or different. Such a hypothesis may be consistent with a rational learner who tries to determine which items should be clustered together (Griffiths, Sanborn, Canini, & Navarro, 2008). Under this view, an even smaller number of labeled examples (perhaps even one) may actually facilitate generalization (since the amount of data is enough to learn, but not enough to infer some systematic bias). We attempted to get at this issue by modulating the number of labeled training examples, and found no evidence of a trend. However, recent studies of one-shot learning suggest that often even a single labeled example can support robust generalization (Lake, Salakhutdinov, Gross, & Tenenbaum, 2011).

**Overweighting of labeled examples** Another interpretation, suggested by Zhu et al. (2010) and Lake and McClelland (2011), is that labeled items may simply be given more weight. Although this seems plausible, it would appear that the 10 labeled items in the 10-Labeled Condition outweighed the other 270 trials in the training phase, suggesting a weight for unlabeled items much lower than the previously reported estimate of around 40% (Lake & McClelland, 2011). Interestingly, subjects in our 10-Labeled Condition spent consider-

ably more time studying the labeled items, presumably raising their relative influence. One possibility is that the weight given to labeled items is actively adjusted by learners based on the task context.

**Pedagogical sampling** While assuming that labeled examples are given more weight might *describe* the lack of semi-supervised learning, it offers no specific proposal for why this should be the case. One possibility is that participants believed that the experimenter was providing information to teach them the category via the labeled examples (i.e., the labeled examples were pedagogically sampled). In this case, it may be reasonable to trust that the labeled items are particularly informative about the category distinction. For example, Shafto, Goodman, Gerstle, and Ladusaw (2010) have shown that adults adjust their inferences based on the intention of a speaker (either pedagogical or overheard). It is possible that participants in a lab-like setting often assume that training examples are presented pedagogically, causing them to downplay the relevance of unlabeled trials.

**Is an explicit prediction required?** A final hypothesis, there were minor differences between our task and previous work that may have influenced performance. For example, participants made observations and then simply pressed the space bar to acknowledge each item. By contrast, both Kalish et al. (2011) and Lake and McClelland (2011) asked participants to make a response on each trial. It is possible that making a response or prediction on each trial facilitates the integration of information across learning episodes. Consistent with this view is the fact that subjects 40-All-Labeled Condition showed evidence of learning from the items presented at test (where predictions were required)—recall that participants were slightly biased to respond according to the bimodal dimension, even though the only information about its bimodality was provided by the distribution of test examples. A similar effect may have carried over to the semi-supervised conditions as well.

Current work is exploring each of these possibilities. The hunt for semi-supervised learning continues.

## Abstract

Both automated priming (Pickering & Garrod, 2004) and partner-specific adaptation (Brennan & Hanna, 2009) have been proposed to underlie lexical entrainment (the repetition of words across interlocutors). Since activation levels of infrequently used words are relatively low, the effect of automated priming is predicted to be weaker in L2- than in L1-conversations, leaving more room for deliberate partner-specificity (Costa, Pickering, & Sorace, 2008). We tested this prediction by means of a production experiment, in which we varied whether participants interacted in their L1 or L2, and whether they addressed the confederate who had introduced a certain reference or another addressee. We found that in their L2, participants repeated references more frequently when addressing the person who had introduced the reference. Yet we did not find this effect of partner-specificity in the L1 conditions. Therefore, our results support the proposed combination of the two accounts.

**Keywords:** Speech production; alignment; lexical entrainment; interactive-alignment account; conceptual pact

## Introduction

When people interact in dialogue, the referring expressions they use tend to converge (e.g. see Branigan, Pickering, Pearson, & McLean, 2010). For example, if one person refers to a landmark as 'the cathedral', it is likely that a conversation partner would refer to it as such as well, rather than saying 'the church'. This process is known as *lexical entrainment* (Garrod & Anderson, 1987). Different explanations have been proposed for this observation, either relying on automated processes (Pickering & Garrod, 2004) or on the more deliberate process of grounding (Brennan & Clark, 1996; Clark, 1996). In the current study, we test predictions made by each of these two accounts.

## Accounts of Lexical Entrainment

Lexical entrainment can be measured by comparing the ways in which people refer to objects, locations, times, actions, people, etc. If two interlocutors use the same expressions, they are said to be lexically entrained (Garrod & Anderson, 1987). Brennan and Clark (1996) describe three factors that influence reference production that are independent of a conversation's history: informativeness, lexical availability, and perceptual salience. If all speakers

choose their referring expressions based on these factors, they may end up choosing the same references as a result. However, most referents can be referred to in very many ways (Brennan & Clark, 1996). Therefore, these three factors alone are insufficient to explain the (frequent) occurrence of lexical entrainment. Rather, the course of a conversation needs to be taken into account too.

Brennan and Clark also propose four factors influencing reference production that are related to the conversation history: recency, frequency of use, provisionality and partner-specificity. The first two factors imply that speakers choose the reference that was used successfully for a certain referent most recently, taking into account the frequency of occurrence as well. That is, if a certain referring expression has repeatedly been used successfully (e.g. 'couch') and then an alternative reference is used successfully only once (e.g. 'sofa'), speakers may still revert to the more frequently used reference afterward. The factors recency and frequency of use together provide an explanation of lexical entrainment.

These two factors are compatible with a view that lexical entrainment is based on automated priming (Pickering & Garrod, 2004). In a (partly) connectionist model of cognition (Anderson & Lebiere, 1998; McClelland & Rumelhart, 1986; Rumelhart & McClelland, 1986), both frequency of use and recency affect the availability of chunks of information, such as lexical items. In line with such models, Pickering and Garrod (2004) propose that through the process of automated priming, interlocutors align their linguistic representations, which causes them to produce similar utterances. For example, when hearing a certain reference, linguistic representations are associated with it in the process of interpretation. As a result, the activations of these representations increase, which makes it more likely that they will be used in the process of language production. Therefore, a referent that has been heard frequently or recently is more likely to be produced. This automated account of lexical entrainment, known as the *interactive-alignment* account, predicts that lexical entrainment will occur whenever speakers are exposed to, and thus primed with, linguistic input.

Effects of provisionality and partner-specificity are not necessarily predicted by such an automated account. These

factors have to do with a more active view of dialogue, in which interlocutors are actively trying to establish common ground (Clark & Brennan, 1991). According to Brennan and Clark, "[w]hen speakers present a reference, they do so only provisionally, and they then work with their addressee to establish that it has been understood" (Brennan & Clark, 1996, p. 1484). Once this is established, interlocutors are said to have formed a *conceptual pact*, which they are likely to maintain. Since a conceptual pact results from an active process, conceptual pacts are established between specific interlocutors only (partner-specificity). Therefore, they cannot simply be transferred to new interaction partners. Rather, the process of grounding a referring expression will have to start anew with any new interlocutor. Therefore, in Brennan and Clark's account of lexical entrainment, entrainment is more likely to occur when interlocutors share a conversation history.

### Adaptation in L2 and L1

Consistent with the interactive-alignment account of lexical entrainment, Costa, Pickering and Sorace (2008) propose that lexical entrainment will be less pronounced when at least one of the interlocutors needs to speak a second language (L2) instead of the native language (L1). Since some lexical items may have been used very rarely by an L2 speaker, their basic level activation may be very low. Therefore, even though recency enhances this activation, it may still be too low for the lexical item to be repeated. This could lead to partially failed entrainment, as in the following example, taken from Costa et al. (2008, p. 538):

- (1) L2 speaker: I need a piece of paper with nothing on it  
 L1 speaker: A blank sheet of paper?  
 L2 speaker: Yeah, a blank piece of paper.

The more frequent word 'blank' is successfully entrained on, which can be explained as it reaching a level of activation that is sufficient for production. However, the infrequent word 'sheet' is not repeated, which may evidence a too low activation level, even after the recent occurrence. Thus, interlocutors are less likely to entrain on words they have encountered only infrequently, such as less familiar words in their L2.

Apart from the automated process of priming underlying lexical entrainment, which Costa et al. (2008) propose to be the default, they also recognize that speakers can make conscious decisions to either suppress the outcomes of this automated process, or to entrain in situations where automated priming does not facilitate entrainment. This leaves room for the factors proposed by Brennan and Clark (1996), such as partner-specificity. Bortfeld and Brennan (1997) for example, found that native speakers were more likely to entrain on the reference 'wheel' to refer to a tire when interacting with an L2-speaker, than when interacting with another L1-speaker. This seems to illustrate a conscious decision by the L1-speaker, based on their knowledge of their interlocutor's proficiency in the L2.

Thus, deliberate motivations for entrainment can also play a role in L1-L2 conversations. Costa et al. (2008) predict that there will always be some extent of lexical entrainment due to automated priming, but this extent will be larger when interlocutors have similar activation profiles for lexical items, such as in L1-L1 conversations, than when they have dissimilar activation profiles, such as in L1-L2 or L2-L2 conversations. Therefore, more deliberate ways of reaching alignment of representations may be more likely to come into play in L1-L2 and L2-L2 conversations.

### Present Study

We are not aware of any empirical study that tested the predictions made by Costa et al. (2008). Therefore, in this study we aim to test the predictions previously laid out, as well as the predictions made by Brennan and Clark's theory on conceptual pacts (Brennan & Clark, 1996). To do so, we measure the degree of lexical entrainment when speakers are talking to an interlocutor who just addressed them (No Switch condition) and when they need to switch to a different addressee (Switch condition). In addition, we assess whether there is a difference in the extent to which this factor affects lexical entrainment when interlocutors communicate in their native language (Dutch, L1-L1), as compared to when they communicate in their second language (English, L2-L2).

In order to keep track of who adapts to whom, we use a controlled experiment, in which participants interact with a confederate. The confederate introduces certain references in one speech turn. We measure the degree to which these references are repeated by the participant in the subsequent speech turn.

The prediction following from grounding theory is that participants are more likely to (partially) repeat a reference when interacting with the partner who introduced the reference than when switching partners. Even though interactivity is limited in our study, participants can decide to accept the reference (provisionally) introduced by the confederate, introduce an adaptation of it, or introduce a completely new reference. It is expected that participants are less likely to produce a completely new reference for a given referent, when interacting with a partner who already introduced a reference for that referent.

The interactive-alignment account does not necessarily predict such a difference between the Switch and No Switch conditions, since whether a referent is reproduced solely depends on automated priming and the linguistic input does not differ across these settings. However, the characteristics of the person who introduced the reference may serve as a prime as well, such that an automated account may also predict a (slight) difference, with more lexical entrainment in the No Switch condition (e.g. Horton & Gerrig, 2005).

In both the L1 (Dutch) and L2 (English) conditions, the confederate uses scripted route directions, with references that were designed in advance. In the L2 conditions, these

references include lexical items that participants may have come across only infrequently. Therefore, the account by Costa et al. (2008) predicts that the automated process of priming plays a more important role in our L1 conditions than in our L2 conditions. Since the effect of automated priming is predicted to be weaker in the L2 conditions, the effect of deliberate partner-specificity is predicted to be stronger there.

## Method

### Participants

Forty-eight (14 male) native Dutch first-year students from Tilburg University participated in our study as part of their curriculum. They were aged between 18 and 35 years old ( $M = 21.94$ ,  $SD = 3.59$ ). In the Netherlands, formal teaching in (British) English starts around the age of twelve. Hence, all participants knew English as a second language, but they were not raised with it.

### Design

We used a 2 x 2 between participants design with two factors: Partner (levels: No Switch, Switch) and Language (levels: L1/Dutch, L2/English). As dependent variable, we used the mean number of (partial) repetitions of the confederate's descriptions of certain landmarks. Two confederates were counterbalanced across the different conditions. Both confederates were male, native speakers of Dutch, from the same (linguistic) region, similar in age (22, 24) and overall appearance (e.g. length, body type, dress, haircut, complexion and hair color).

### Task and Material

A confederate and a participant took turns describing two routes to each other, which were depicted on bird's-eye view maps of a city (see Figure 1). While one interlocutor described a route as depicted on their map, the other interlocutor tried to draw this route on a map that was identical, except that the route was not depicted on it yet. Interlocutors were instructed not to interrupt one another during the route descriptions.

Figure 1: Example of a map used in the experiment.

### Procedure

Participants were randomly assigned to the No Switch or Switch conditions, as well as to the L1 (Dutch, L1-L1) or L2 (English, L2-L2) conditions. In the L1 conditions, the entire experiment was carried out in Dutch. In the L2 conditions, the routes had to be described in English, but instructions were given in Dutch.

In the Switch conditions, two participants came to the lab, where two confederates showed up as participants as well. The experimenter took the four 'participants' to a room and handed out written instructions to the participants and confederates, who were allowed to ask clarification questions. Once all was clear, one confederate and one participant were selected by the experimenter to start the experiment in another room. In each room, the participant and confederate were seated across from each other, with a table in between that had a low visual barrier on it, such as to keep the listening interlocutor from already seeing the route. A camera was positioned on one end of the room, which was used to make recordings of the interaction.

In each of the two rooms, a confederate started the task by sequentially describing two routes to a participant, who was to draw these routes on corresponding maps. Once two routes were described, the two participants were asked to switch rooms, while the two confederates stayed in the same room (this procedure was explained in the written instructions). Each participant then described two routes to the confederate whom they had not yet interacted with. After these two descriptions, the participants switched rooms again and the cycle repeated once. That is, the participants heard two more routes from the confederate they first interacted with and described two more routes to the other confederate. Thus, in the Switch conditions, participants never described routes to the confederate who had given them route descriptions as well, but always to the other confederate.

In the No Switch conditions, there was only one confederate and one participant at a time. Both the participant and the confederate switched rooms after the confederate had described two routes and then the participants described two routes in the other room, to the same confederate. The interlocutors then switched rooms again and the cycle was repeated once. The switching of rooms was the same as in the Switch condition, to ensure equal intervals between hearing and describing routes. In the No Switch conditions, participants described routes to the confederate who had also given them route descriptions.

After all routes had been described, the participants and confederates filled out a questionnaire, including questions on their native and second language. In the English conditions, the questionnaire included the participant's high school grade in English and a short 'fill in the gaps' test on English. Finally, participants were asked consent for the use of their data for research and educational purposes. All participants consented to their data being used in this study.

Table 1: Examples of landmark descriptions given by the confederates.

Landmark Descriptions	
Dutch:	English:
historisch stadspaleis	historical city palace
hoge symmetrische fontein	tall symmetrical fountain
kleurrijke tramstation	colorful tram station
arenavormige voetbalstadion	arena-shaped soccer stadium
kleine intieme terras	small intimate terrace

Since all our participants were students in the same year, we did not inform them on the use of confederates before the study was completed, to ensure they would not know of this in advance. Participants could freely withdraw from the study at any point during and after the experiment.

### Stimuli and Coding

Each route description given by a confederate included three unique critical references to landmarks; see Table 1 for some examples. Since word boundaries sometimes differ between English and Dutch, these references each consisted of three content units, for example 'historical city palace' or the Dutch equivalent: 'historisch stadspaleis'. The confederate started by describing two routes on two different maps. The participant was then to describe two different routes that were depicted on the same maps that the confederate's routes had been on. This allowed for the three landmarks that the confederate had described to be along the participant's route as well, such that partial or full repetitions of the confederate's references could occur. To reduce the possibility of participants accidentally using the same references as the confederate, that is, due to factors independent of the conversation history, the confederate used rather specific wordings (Table 1).

We first transcribed participants' descriptions from the videos. We then coded any literal repetition of content units originally contained in the confederate's critical references. Because full repetitions (3 content units) of references were rare, we report the total number of partial (1 or 2 content units) and full repetitions of the confederate's references. Since true dialogue was not possible between interlocutors, a conceptual pact may not have been fully established yet after the confederate had described the landmarks once. Therefore, participants may still shorten, elaborate on or adapt the reference (provisionally) introduced by the confederate. By counting each reference that contained a literal repetition of at least one content unit, these adaptations were mostly included in our measure of entrainment, while avoiding subjective coding. Note that although the confederate described twelve landmarks, it is possible for a participant to repeat a single landmark more

Table 2: Mean (SD) number of (partial) repetitions of the confederate's landmark descriptions by participants.

Language condition	Partner condition	N	Number of Repetitions:
L1: Dutch	No Switch	11	9.72 (2.24)
	Switch	14	10.00 (2.94)
	Total	25	9.88 (2.60)
L2: English	No Switch	11	11.27 (3.26)
	Switch	12	8.42 (2.39)
	Total	23	9.78 (3.13)
Total	No Switch	22	10.50 (2.84)
	Switch	26	9.27 (2.76)

than once. Hence, a participant could produce more than twelve repetitions.

### Results

We performed an ANOVA with Partner (levels: No Switch, Switch) and Language (levels: L1, L2) as independent factors. In line with the predictions, analysis of participants' (partial) repetitions of the confederate's descriptions, as listed in Table 2, showed a marginally significant interaction between the two factors, such that the difference between the No Switch and Switch conditions was larger in the L2 conditions than in the L1 conditions,  $F(1, 44) = 3.86$ ,  $p = .06$ ,  $\eta_p^2 = .08$ . We did not find a main effect of Partner,  $F(1, 44) = 2.63$ ,  $p = .11$ ,  $\eta_p^2 = .06$ , or Language,  $F(1, 44) < 1$ ,  $p = .98$  on the number of (partial) repetitions.

Posthoc analyses by means of independent-samples T-tests did not reveal an effect of Partner in the L1 conditions,  $t(23) = .26$ ,  $p = .80$ . In the L2 conditions however, there was an effect of Partner,  $t(21) = 2.41$ ,  $p < .05$ ,  $\omega^2 = .17$ , such that participants repeated more of the confederate's references if they were interacting with the same partner ( $M = 11.27$ ,  $SD = 3.26$ ) than when they had to switch ( $M = 8.42$ ,  $SD = 2.39$ ).

Given our design, it is important that participants in the L2 (English) conditions were equally proficient in English in the No Switch and Switch condition. Analysis of the score participants obtained on the short English post-test did not reveal a difference between the English No Switch ( $M = 7.00$ ,  $SD = .89$ ) and the English Switch condition ( $M = 6.83$ ,  $SD = 1.19$ ),  $t(21) = .38$ ,  $p = .71$ . Similarly, we did not find a difference in the reported high school grade in English between the English No Switch ( $M = 7.55$ ,  $SD = .96$ ) and the English Switch condition ( $M = 7.08$ ,  $SD = 1.12$ ),  $t(21) = 1.05$ ,  $p = .30$ . (These high school grades are on a 1 to 10 scale, with 6 being sufficient and 10 being exceptional.) Since there seems to be a numerical difference in the high school grades between the English Switch and the English No Switch condition, we also performed an ANOVA on the data from the English conditions with high-school grade as a covariate. Similar as before, analysis of participants' repetitions of the confederate's descriptions revealed an effect of Partner,  $F(1, 23) = 5.05$ ,  $p < .05$ ,  $\eta_p^2 = .20$ , such

that in the English conditions, participants repeated the confederate's reference more often when they interacted with the same partner, than when they had to switch. We did not find an effect of high school grade in this analysis,  $F(1, 23) < 1, p = .84$ .

Similar results were obtained when analyzing at most one repetition per landmark, and also when separate variables were computed for each half of the experiment (the order of the routes was counterbalanced across the first and second half of the experiment).

## Discussion

Our results confirm the prediction that the effect of partner-specificity is stronger for non-native speakers than for native speakers (Costa, et al., 2008). When participants were asked to communicate in a foreign language (English), they more often repeated parts of a confederate's referring expressions when they were talking to the confederate who introduced the reference, compared to when they were addressing a third person. When speaking in their native language (Dutch), the difference between addressing the same or a different partner was not as large. This finding seems to support both grounding theory (Brennan & Clark, 1996; Clark & Brennan, 1991) and the interactive-alignment account (Pickering & Garrod, 2004).

In the English conditions, we found that when participants did not need to switch conversation partners in between hearing and giving route descriptions, they repeated the confederate's references to a greater extent than when they had to switch partners. This goes well with the prediction that conceptual pacts are partner-specific (Brennan & Clark, 1996). Even though our paradigm did not allow for interlocutors to freely interact in arriving at conceptual pacts, repeating part of a previously (provisionally) introduced reference can be seen as a first step in forming a conceptual pact. We found that in the L2 conditions, participants produced such a repetition more often to the person who had introduced the reference than to a person who had no knowledge of this conversation history. Therefore, these results support the account of lexical entrainment based on grounding theory (Clark, 1996; Clark & Brennan, 1991).

The prediction by Costa et al. (2008) that automated priming will be more prominent when interlocutors interact in their native language than when they interact in a foreign language also seems to be supported by our data. Our results show that the effect of partner-specificity, which can be thought of as a more deliberate factor, was stronger when participants were asked to interact in a foreign language as compared to when they interacted in their native language, exactly as predicted. The explanation offered by Costa et al., that the weaker effect of automated priming in L1-L2 and L2-L2 conversations would allow more room to such deliberate factors seems very plausible. Because the lexical items from the native language are very familiar, they are

easily primed by recent uses. This process does not depend on whom is being addressed. Therefore, no effect of partner-specificity is predicted in the L1 conditions, which is in line with our findings. Yet when using the L2, the activation levels of less frequently used lexical items may be too low for these items to be primed by a single recent use. Therefore, the effect of automated priming is weaker in L2 conversations. Speakers may therefore make a more deliberate decision on whether to entrain on a given reference or not in the L2 conditions, which could very well depend on whom they are interacting with. The stronger effect of partner-specificity that we found in the L2 conditions thus indirectly supports the interactive-alignment account.

Can our findings be accounted for without the interactive-alignment account? One can think of many reasons why we did not find an effect of partner-specificity in the Dutch (L1) conditions. For example, there were only few turns and participants were not free to engage in dialogue. However, these factors equally apply to the English (L2) conditions, in which we did find an effect of partner-specificity. This also holds for the argument that in the second half of the experiment, there may be some conversation history in the Switch conditions. (Critical landmarks from the first half of the experiment did not occur in the second half.) Thus, from grounding theory alone, it is hard to explain why we did not find an effect of partner-specificity in the L1 conditions, whereas we did find this effect in the L2 conditions.

A possible explanation of our results in terms of a deliberate process is that in the L2 conditions, participants did not repeat the confederate's references as frequently when they had to switch partners, because they were less certain of their new interaction partner's proficiency in English. Therefore, they may have used more common references instead. At the same time, when interacting with the same partner, the already introduced reference was most likely to be understood. This explanation fits the numerical pattern in our data, as the larger effect of partner-specificity in the L2 conditions seems to result both from there being more repetitions in the No Switch condition and from there being fewer repetitions in the Switch condition (see Table 2). However, although to a lesser extent, similar deliberate considerations apply to the L1 conditions. Moreover, in the L1 condition in which participants had to switch partners, there seems little reason for participants to repeat the reference introduced by the confederate at all (which they did to the same extent as in the No Switch condition), other than because of automated factors. Therefore, deliberate partner-specificity alone does not convincingly explain all of our results.

Can our findings be accounted for without deliberate partner-specificity? The interactive-alignment account predicts that interlocutors will show less lexical entrainment in their L2, but it does not predict an effect of either addressing the person who introduced the reference or

another person. That is, a main effect of the factor Language would be predicted, rather than an interaction between the factors Language and Partner. Horton and Gerrig's *association account* states that conversation partners automatically form an association between a given expression and a conversation partner (e.g. Horton & Gerrig, 2005). Hence, the conversation partner may serve as a prime as well, leading to more entrainment when interacting with the same partner as compared to when switching partners. This could provide an automated account of partner-specificity. Yet importantly, if partner-specificity were fully automated, there is no reason to expect its effect to be stronger in the L2 than in the L1 conditions. That is, a main effect of the factor Partner would be predicted, rather than an interaction between Partner and Language. Yet although we did not find an effect of partner-specificity when interlocutors interacted in their L1 (Dutch), we did find that in their L2 (English), participants showed more lexical entrainment when they kept interacting with the same partner than when they had to switch. This interaction effect cannot be accounted for by an automated account alone. Therefore, a combination of both the interactive alignment account (Pickering & Garrod, 2004) and more deliberate partner-specificity (Brennan & Clark, 1996), as proposed by Costa et al. (2008), explains our results best. Moreover, this account *predicted* the results that we found.

Our study illustrates that automated and deliberate accounts of adaptation in dialogue are compatible (also see Brennan & Hanna, 2009; Costa, et al., 2008; Pickering & Garrod, 2004). In future work, it would be interesting to further explore what factors influence the extent to which automated and deliberate factors come into play, as well as to assess which factors are more automated and which are more deliberate, given a certain setting. Next to the theoretical merit, this could provide insight into how and when to facilitate effective communication.

## Conclusion

Our results on lexical entrainment support both the interactive-alignment account (Pickering & Garrod, 2004) and the account of partner-specific conceptual pacts (Brennan & Clark, 1996). However, neither of these two theories alone predicted the pattern of results that we found. When interacting in their second language, speakers were shown to entrain more on previously heard references when interacting with the person who introduced these references, than when interacting with another partner. When speakers interacted in their native language, this effect did not reach significance, evidencing an interaction between the factors of whether or not speakers used their native language and whether or not speakers switched conversation partners. This interaction was previously predicted, yet not tested, by Costa et al. (2008), who combined the two theories and predicted that the effect of automated priming on lexical

entrainment would be stronger when interlocutors interact in their native language, compared to when at least one of them uses a non-native language. Therefore, when interlocutors interact in their non-native language, the effect of more deliberate factors, such as partner-specificity, will be (relatively) stronger. This is exactly what we found. Our findings thus support the view that both automated priming and deliberate partner-specific adaptation influence the degree of lexical entrainment between interlocutors.

## Acknowledgements

We gratefully acknowledge all speakers for allowing us to analyze their data, we thank the anonymous reviewers for their insightful suggestions and we thank Nathalie Bastiaansen for drawing the maps used in this experiment.

## Abstract

Different functions have been proposed for the hand gestures speakers spontaneously produce while speaking. The Information Packaging Hypothesis (Kita, 2000) states that gestures can structure rich spatio-motoric information into packages suitable for speaking. It therefore predicts that how information is divided over different gestures affects how it is divided over different processing units in speech: clauses. We indeed found that if participants were asked to express the manner and path of a motion in one gesture, they were also more likely to conflate this information into one clause in speech, whereas if they were asked to produce separate gestures, they were more likely to express manner and path in separate clauses too. These results support the view that there are speaker-internal motivations for gesture production. They confirm predictions made by the Information Packaging Hypothesis, which the Lexical Retrieval Hypothesis and the Image Activation Hypothesis do not make.

**Keywords:** Gesture; Speech; Production; Motion Event

## Introduction

When speaking, most people tend to produce hand gestures that are closely synchronized with their speech semantically (e.g. McNeill, 2005), temporally (e.g. Chui, 2005), and structurally (e.g. Kita & Özyürek, 2003). Because of this careful coordination, it is generally assumed that the processes of speech and gesture production are somehow related. Yet what is the exact role of gesture production in relation to speech production?

## Gesture and Speech Production

In this paper, we focus on representational hand gestures (McNeill, 1992). Representational gestures either depict action, motion or shape ("iconic gestures") or indicate a location or direction ("deictic gesture"). Much evidence has been gathered in support of a theory that (representational) gestures, like speech, are part of a speaker's communicative effort (Kendon, 2004). In line with this view, Growth Point Theory (McNeill, 2005; McNeill & Duncan, 2010) starts from the observation that gesture and speech co-express idea units, each using a different form of semiosis. While gesture employs a global/synthetic form of representation, speech is expressed in an analytic/ combinatoric form. It is assumed that gesture and speech production share a common origin: the growth point. From this origin, a bimodal utterance develops from the interplay of imagistic

and linguistic processing. Thus, in this view, gesture and speech are two outcomes of a single process.

In addition to the line of thought that gestures are intended communicatively, it has also been proposed that there are speaker-internal motivations for gesture production. Some propose that gesture production facilitates cognitive processes in general, by lightening cognitive load (Goldin-Meadow, Nusbaum, Kelly & Wagner, 2001). Others propose that gesture production facilitates a specific process in speech production. In this article, we focus on the latter class of proposals. There are three prominent proposals in the literature: The Lexical Retrieval Hypothesis, the Image Activation Hypothesis, and the Information Packaging Hypothesis.

The Lexical Retrieval Hypothesis (LRH) states that gestures facilitate the retrieval of lexical items from the mental lexicon (Krauss, Chen, & Gottesman, 2000). In this view, gesture production is based on spatial imagery in working memory. Rather than there being an interplay between the processes of gesture and speech production, the execution of a gesture is thought to activate spatio-dynamic features, which in turn activate conceptual information. Through cross-modal priming, this aids the retrieval of lexical items. Thus, gesture production precedes speech formulation entirely.

The Image Activation Hypothesis (IAH) states that gesturing serves to keep an image (Freedman, 1977) or certain spatial features (De Ruiter, 1998) activated while they are encoded by the process of speech formulation.

The Information Packaging Hypothesis (Kita, 2000) critically differs from the Lexical Retrieval Hypothesis and the Image Activation Hypothesis in its assumptions on the for-speaker motivations of gesture production, and on the interplay between gesture and speech production. Rather than simply activating information or maintaining the activation of spatial information, gesture production is thought to structure information, and to package it into units that are suitable for the speech formulation process.

Like Growth Point Theory, the Information Packaging Hypothesis (IPH) assumes that different forms of processing underlie gesture and speech. It is proposed that gesture is based on spatio-motoric processing and speech on analytic processing. The IPH assumes that "[s]patio-motoric thinking, which underlies representational gestures, helps speaking by providing an alternative informational

organization that is not readily accessible to analytic thinking, the default way of organizing information in speaking" (Kita, 2000, p. 163). Furthermore, it assumes that "[s]patio-motoric thinking and analytic thinking have ready access to different sets of informational organizations" (Kita, 2000, p. 163). The representations in these two modes of thinking are thought to be coordinated online during language production, such that they tend to converge.

The Information Packaging Hypothesis is implemented in the Interface Model (Kita & Özyürek, 2003), which adds gesture production components to Levelt's (1989) model of speech production. In the Interface model, what needs to be expressed is determined in the communication planner. This module informs the action generator, where gestural contents are determined, as well as the message generator, where the preverbal message is determined. Importantly, the action and the message generator are bi-directionally linked to each other, allowing for gesture and speech to coordinate their contents during language production. Lastly, the message generator is also linked bi-directionally to the formulator, which converts a preverbal message into an utterance, through accessing the mental lexicon and retrieving and processing morphological, syntactic and phonological information. This way, the formulator can pass on information to the action generator, via the message generator. Thus, the *bidirectional* link between the action and message generator allows for gesture and speech production to be coordinated semantically and structurally. It is assumed that the processes of speech and gesture generation constantly exchange information, which is transformed from one format into another, such that the content of both modules tends to converge.

What is the evidence for this convergence of information packaging in speech and gesture? The evidence for the speech-to-gesture influence comes from studies of motion event descriptions (Kita, 2000; Kita & Özyürek, 2003; Özyürek, Kita, Allen, Furman, & Brown, 2005). It was found that whether speakers used a single or multiple clauses to verbally describe the manner and path of a motion tended to match whether they expressed manner and path in a single or in separate gestures. For example, "he rolled down the hill" would likely be accompanied by a gesture in which the hand describes circular motions as it is moved down diagonally, while "he rolled, as he went down the hill" would be more likely to be accompanied by one gesture illustrating the rolling and another gesture illustrating the downward path. In one study on English speakers (Kita, et al., 2007), different clausal structures in speech were elicited by varying whether a manner was incidentally or causally related to the path of a motion in the stimulus animations. Different clause structures lead to the predicted different patterns of packaging of manner and path in gestures.

The evidence for the gesture-to-speech influence comes from studies in which the availability of gestures was manipulated (Alibali & Kita, 2010; Alibali, Spencer, Knox,

& Kita, 2011). It was found that the availability of gestures changed the type of information encoded in speech. More specifically, when gestures are produced, speakers tended to encode spatial information that gestures readily had access to. To date, there is no study that manipulated gesture structure (as opposed to gesture availability) to examine its influence on speech production.

## Present Study

We will test the prediction made by the IPH (but not by the LRH and IAH), that the information structure underlying gesture production can influence the information structure underlying speech. In doing so, we will use the task of describing motion events, as in the study described above (Kita, et al., 2007). Yet how can we measure the analytic representations underlying speech production?

Bock and Cutting (1992) propose that syntactic processing units comprise of (finite) clauses. Using a procedure to elicit verb agreement errors, they found that these errors occurred more frequently when the head noun and its verb were separated by a phrase (e.g. "The claim about the stolen babies was rejected", p. 104) than when they were separated by a relative clause (e.g. "The claim that wolves were stealing babies was rejected", p. 104). Assuming a hierarchical processing structure, they explain this as that the more information is introduced within a single processing unit, the more sources of interference there are between similar, concurrently active elements. In this example, when the head noun and the local noun are part of a single clause, their numbers are more likely to interfere than when they are part of separate clauses. Thus, within a clause, elements are more likely to interfere than across clauses. This supports the notion that clauses are the units of syntactic processing. Following Bock and Cutting (1992), we will assume finite clauses to be indicative of the processing units underlying speech.

We instructed participants to either conflate the manner and path of a motion into a single gesture (Conflated condition), or to produce one gesture for the manner and a separate gesture for the path of the motion (Separate condition) and observed the syntactic packaging of manner and path in speech. Since the IPH assumes that the processing units underlying speech and gesture are coordinated, it predicts this manipulation will affect the clausal structure of speech, such that conflated gestures tend to go with single, conflated clauses, whereas separate gestures tend to go with separate clauses for manner and path.

The Image Activation Hypothesis may not make specific predictions as to the difference between the conflated vs. separate gesture condition. Both the conflated gesture and separate gesture condition should equally boost the activation of the imagery of manner and path. More crucially, the hypothesis does not propose any mechanism as to how linguistic expressions are influenced by gesture

production, aside from the assumption that more strongly activated imagery leads to better quality descriptions.

The Lexical Retrieval Hypothesis may predict an effect of gesture production on speech production. Yet this effect is different from the effect predicted by the IPH. Rather than the clausal structure of speech being affected by the way speakers gesture, it may predict that speakers who use different gestures would activate different lemmas and would thus use different words.

## Method

### Participants

Twenty-one native Dutch first-year students (4 male) from Tilburg University participated in our study as part of their curriculum. They were aged between 18 and 24 years old ( $M = 21.24$ ,  $SD = 1.61$ ). Four participants were left-handed. The number of male and left-handed participants was equal in the two conditions.

### Material

The ten stimulus clips that our participants described were from a set of animated cartoons known as 'the Tomato Man movies' (Özyürek, Kita, & Allen, 2001). Each clip consisted of an initial entry event, followed by a target event in which one of the two figures completes a motion along a certain path and in a certain manner, and finally a closing event (see Figure 1).

Figure 1: Example of a stimulus clip, taken from (Kita, et al., 2007).

### Procedure

Participants came to the lab and were randomly assigned to one of the two gesture conditions. They first received a written instruction, after which they were allowed to pose clarification questions. The instruction explained that the participant was to watch animated cartoons in which a cartoon figure sometimes conducted a motion involving both a certain manner and a certain path of movement. In the Conflated condition, participants were asked to produce a hand gesture with their description of such motions, such that 'the gesture illustrates both the path and manner of movement at the same time'. In the Separate condition, participants were requested to produce two different gestures with their description of the motion, with 'one

gesture illustrating the path, while the other gesture shows the manner of movement'. Note that participants were asked to *gesture* differently only. Otherwise, the instructions were exactly the same in both conditions.

Participants were seated next to a table with a laptop on it, which showed a Powerpoint presentation. Upon pressing a button, an animated cartoon played twice, after which the participant was to describe it to the experimenter, who was seated across from the participant. Behind the experimenter was a camera, capturing the participant. The first clip was a practice clip. If needed, the experimenter gave additional instructions on how to do the task, by asking specific questions (e.g. "And how exactly did the figure go around the tree?") or by describing how the gestures produced by the participants differed from the gestures requested. The participant then proceeded to watch and describe the ten stimulus clips. Afterward, the participant filled out a short questionnaire, which asked for participants' native language and whether they were left or right handed. Lastly, they filled out a consent form. All participants permitted their data to be used for research and educational purposes.

### Coding and Analysis

All recordings were analyzed using Elan (Max Planck Institute for Psycholinguistics; Wittenburg, Brugman, Russel, Klassmann, & Sloetjes, 2006). For each description of a target event, speech was transcribed into finite clauses and gestures were coded. We used finite verbs to decide on clause boundaries. Each clause contained one conjugated verb. Hence, the first two examples in Table 1 (next page) were both coded as a single clause. Few utterances contained a praedicativum, as in (1). *Al springend* is linked both to the verb and to the noun. Its status is therefore not entirely clear. It can be thought of as an adjective, a verb or an adverb (Jansen & Lentz, 2002). Because of this and since these cases were few, we excluded them from our analyses.

- (1) "Al springend gaat hij omhoog."  
while in a jumping manner goes he up.  
"(While) jumping he goes up."

For each clause and each gesture, it was determined whether it contained information on manner, on path, or on both. Verbal descriptions in which manner and path were solely expressed in a single clause were coded as *conflated*. Descriptions in which there were separate clauses for manner and path were coded as *separate*, even if the description also contained a clause in which the two were conflated. Descriptions in which either manner or path was described in a separate clause, yet not both, and in which there was a conflated clause as well were coded as *mixed*. Table 1 provides some of participants' utterances and our coding. Gestural descriptions were coded analogously, for whether manner and path were conflated into a single gesture, expressed in separate gestures or a mixture of both.

Table 1: Examples of utterances and our coding. Coded clause boundaries are indicated by forward slashes.

Utterance:	Label:
"het rode rondje draait dan zo omhoog" /the red circle (+diminutive) turns then like this upwards/ the red circle then <i>twists upwards</i> like this	conflated
"en hij gaat zo springend omhoog" /and he goes like this in a jumping manner upwards/ and he <i>goes jumping upwards</i> like this	conflated
"en die draait terwijl die naar boven gaat" /and that (pronoun feminine/masculine) turns/ while that to up goes/ and he <i>turns</i> as he <i>goes up</i>	separate: (manner, path)
"en de driehoek gaat omhoog en dat doet ie door uh te springen" /and the triangle goes up/ and that does he by uh to jump/ and the triangle <i>goes up</i> and that he does by uh <i>jumping</i>	separate: (path, manner)
"de appel die rolt en hij rolt van links naar rechts omhoog" /the apple that rolls/ and he rolls from left to right upwards/ the apple <i>rolls</i> and it <i>rolls upwards</i> from left to right	mixed: (manner, conflated)

Occasionally, participants failed to describe both the manner and the path of a motion in gesture and speech (8 cases). Also, participants sometimes failed to comply with the instructions, only producing separate gestures for manner and path in the Conflated condition (3 cases), or only producing a conflated gesture in the Separate condition (24 cases). These cases were discarded from our analyses. The more frequent problems in the Separate condition may indicate that conflated gestures (along with conflated speech) are more common among Dutch speakers, similarly to English speakers (Kita & Özyürek, 2003). The remaining dataset contained 175 descriptions (verbal and gestural) by 21 participants. To ensure fair comparison between participants and between conditions, despite an unequal number of descriptions, we computed the proportion of verbal expressions of a certain type (conflated, separate, mixed) for each participant, rather than using the raw counts. The means of both conditions were compared using independent-samples T-tests. When Levene's test for equality of variances was significant, we report the adjusted statistics.

## Results

Participants produced greater proportions of verbal descriptions in which manner and path were conflated into a single clause when they were asked to produce a single conflated gesture for manner and path ( $M = .88$ ,  $SD = .18$ ),

than when they were asked to express manner and path in two separate gestures ( $M = .19$ ,  $SD = .31$ ),  $t(19) = 6.26$ ,  $p < .001$ . The reverse pattern was found for descriptions in which manner and path were expressed in separate clauses (see Table 2). Similar results were obtained when descriptions on which participants failed to comply with the instruction were included. We did not find any effects of gender, or left or right-handedness.

## Discussion

Our results show that the way people gesture influences the way they speak. When asked to divide manner and path information over two gestures, participants were more likely to also use two clauses for manner and path. These results are in line with the Information Packaging Hypothesis (Kita, 2000). Being required to separate manner and path into two gestures forced speakers to think about the event in a certain way spatially. That is, it requires them to separately focus on the path of the motion and the manner of the motion sequentially, as each unit of information is the base of one unit in gesture. This differs critically from the conflated condition, in which participants were asked to conflate manner and path into a single gesture, which calls for spatially processing the motion as a whole, that is, a single unit of information. The Information Packaging Hypothesis predicts that the analytic processing units underlying speech tend to converge with the spatio-motoric processing units

Table 2: The effects of gesture condition (Conflated vs. Separate) on the mean proportions (SD) of verbal descriptions in which manner and path were expressed in a single clause (conflated), separate clauses (separate) or a combination (mixed).

Verbal descriptions	Conflated gesture (N=10)	Separate gestures (N=11)	Statistics
proportion conflated	.88 (.18)	.19 (.31)	$t(19) = 6.25$ , $p < .001$
proportion separate	.09 (.11)	.63 (.31)	$t(12.7) = 5.46$ , $p < .001$
proportion mixed	.03 (.07)	.18 (.24)	$t(19) = 1.85$ , $p = .08$

underlying gesture. We have taken clauses to be a measure of the analytic processing units (Bock & Cutting, 1992). When gesture production forced participants to spatially process the motion as a whole, manner and path were more frequently conflated into a single clause, reflecting one analytic processing unit. Yet when gesture forced participants to process the manner and the path of the motion separately, they more frequently expressed manner and path in two separate clauses, reflecting two units in analytic processing. This supports the prediction made by the Information Packaging Hypothesis, that the processing units underlying speech can be adapted to the processing units underlying gesture.

Our results also support the Interface Model of gesture and speech production (Kita & Özyürek, 2003). Specifically, they confirm that the link between the action generator and the message generator is bidirectional in nature. Earlier work had already shown that the constraints a language imposes on what information can be linguistically expressed within a clause affect gesture production (Kita & Özyürek, 2003) and that the structure of speech could affect the structure of gesture (Kita, et al., 2007; Özyürek, et al., 2005). Our current study shows that when gesture formulation is constrained, this affects speech formulation as well, exactly as the model would predict.

Since gesture is generally assumed to be less conventionalized than speech, it may not be as straightforward to see in what kind of naturalistic situations gesture would impose constraints on speech formulation. However, there is a growing body of evidence that speakers adapt their gestures to one another (Holler & Wilkin, 2011; Kimbara, 2008; Mol, Krahmer, Maes, & Swerts, 2012; Parrill & Kimbara, 2006). When a gesture shape or a structure in gesture is imitated from another speaker, this may in turn influence the speech formulation process, potentially causing speech to converge across interlocutors as a result. Also, there can be cultural and pragmatic constraints on gesture (Enfield, Kita, & De Ruiter, 2007; Kita & Essegbey, 2001). More importantly though than gesture imposing constraints on how information can be expressed, it can open up new possibilities of organizing information, by supporting spatio-motoric thinking (Chu & Kita, 2008; Kita, 2000). Our results confirm that speech production can benefit from gesture this way. This supports theories in which gesture results from speaker-internal motivations.

Can the current findings on clause structure be accounted for by the Lexical Retrieval Hypothesis? The Lexical Retrieval Hypothesis may be supported if the manipulation of gestures caused different choices of manner verbs in the two conditions, which in turn lead to different clause structures. Though, in principle, any Dutch manner verb can be used in both clausal structures, we examined the manner verbs in the two conditions. We included all inflections of manner verbs, such as in (2), as well as manner adverbs, as in (3).

(2) *hij rolt zo omhoog*  
he rolls like this upwards  
"he rolls up like this"

(3) *hij gaat rollend van de helling af*  
he goes in a rolling manner from the hill off  
"he goes rolling off the hill"

The numbers of manner (ad)verbs used in the two conditions were highly correlated,  $R(11) = .90, p < .001$ , see Table 3. This indicates that the compositions of (ad)verbs used in the two conditions were very similar. Thus, there is no support for the idea that gesture affected clause structures via different choices of manner (ad)verbs.

Can the current findings be accounted for by the Image Activation Hypothesis? According to this hypothesis, gestures boost the activation level of the imagery that is intended to be communicated. This hypothesis does not specify the relationship between clause structures and imagery; thus, gesture's effect on clause structure cannot be accounted for.

## Conclusion

Our results demonstrate that gesture production can influence speech production. Specifically, the way information was divided over individual gestures affected the way information was divided into clauses. This supports the Information Packaging Hypothesis (Kita, 2000), in which gesture production serves to organize rich spatio-motoric information into packages suitable for speaking, and the spatio-motoric processing units underlying gesture production are coordinated with the analytic processing units underlying speech production. Therefore, these results also support the view that there are speaker-internal motivations for gesture production.

Table 3: Manner (ad)verbs used in each condition.

Lemma:	Translation:	Number of occurrences:	
		Conflated	Separate
draaien	turn	34	34
springen	jump	13	23
rollen	roll	12	16
stuiteren	bounce	11	3
cirkelen	circle	8	0
huppen/hoppen	hop	5	6
twisten	twist	0	1
tuimelen	tumble	0	3
koprollen	rollover	0	1
kantelen	topple	0	1
buitelen	tumble	0	1
Total:		83	89

## Acknowledgements

We gratefully acknowledge all participants for allowing us to analyze their data, we thank Pieter Spronck for helping with the analysis of word frequencies and Maria Mos, Jorrig Vogels and Joost Schilperoord for sharing their knowledge on clause structures in Dutch. We thank the anonymous reviewers for their comments and suggestions.

# Modeling Millisecond Time Interval Estimation in Space Fortress Game

Jungaa Moon (jungaam@andrew.cmu.edu)

John R. Anderson (ja+@cmu.edu)

Department of Psychology, Carnegie Mellon University  
Pittsburgh, PA 15213 USA

## Abstract

We investigated sources of the asymmetric bias found in estimation of a time interval (250–400 ms) embedded in the Space Fortress task (Donchin, 1989). Two hypotheses to explain this bias were tested in a behavioral experiment: 1) contamination from a different time interval representation, and 2) pressure to complete the task in time. Participants alternated between producing the target interval and producing either a shorter or a longer interval while the total time allowed for the task was manipulated. The results showed that the target interval estimate was significantly influenced by both manipulations. The effects were captured by incorporating the timing model of Taatgen and Van Rijn (2011) into the ACT-R model for Space Fortress (Bothell, 2010). Time estimation performed in a dynamic task requires understanding the influence of external temporal tasks as well as the procedural demands of performing multiple tasks under time pressure.

**Keywords:** Time estimation; cognitive model; multitasking.

## Introduction

Time interval estimation underlies various skills such as motor control (Ivry, Spencer, Zelaznik, & Diedrichsen, 2002), musical performance (Jones, 1990), and speech processing (Schirmer, 2004). Millisecond-to-second interval timing is critical in real-time dynamic tasks that require adaptive responses to the changing environment. For instance, when driving it is necessary to estimate how long one can attend to a navigator before switching back to attending to the road and driving control (Salvucci, Taatgen, & Kushleyeva, 2006).

Time estimation can be studied under various paradigms (Zakay, 1990). Participants can be asked to retrospectively generate verbal estimation of an interval, to judge whether a presented interval is the same length as a target interval, or reproduce a target interval. Studies using the reproduction paradigm typically show response distributions that are 1) centered at the real-time criteria, 2) symmetrical, and 3) have a standard deviations that increase in proportion to the mean interval (e.g. Rakitin, Gibbon, Penney, Malapani, Hinton, & Meck, 1998).

In most studies under those paradigms, time estimation is often an isolated task performed in a static environment. It is the primary task on which participants focus, even when a secondary task is given for various purposes (Fortin, Rousseau, Bourque, Kirouac, 1993; Rakitin, et al., 1998). However, one may wonder to what extent the time estimation performed in those paradigms reflects the time estimation that people usually perform in various

multitasking situations. As in the driving example, time estimation is often an implicit secondary task that one performs to coordinate primary tasks. In addition, people sometimes need to estimate multiple time intervals concurrently (e.g., cooking breakfast). It seems plausible that time estimation in those circumstances will exhibit properties not seen when it is performed as an isolated task in a static environment. We investigated this question in the Space Fortress task (Donchin, 1989), a video game that simulates real-time complex tasks performed in dynamic environments (e.g., piloting an aircraft).

## Time Interval Estimation in Space Fortress Task

The goal of the Space Fortress task (Figure 1) is to maximize the total scores by navigating a ship in a frictionless space, destroying a fortress multiple times and handling mines while protecting the ship from the fortress and mines. The participant navigates the ship by rotating left or right (A/D keys) or thrusting (W key) to make it fly within an area enclosed by two hexagons. A fortress stationed in the center rotates like a turret, tracking the ship's trajectory and firing shells at it. The participant has to shoot the fortress with a missile (spacebar) at least ten times and then make a rapid double-shot to destroy it.

Figure 1: Schematic representation of the Space Fortress task (left) and performance in the IFF tapping task (right).

The mine task, which is the focus of the current study, consists of a series of activities in a specific order. At the beginning of the game, the participant is presented with a screen with three alphabetic letters ('foe letters') and asked to remember them. During the game, a mine appears at a random location on the screen 5 seconds after the destruction of the previous mine and starts pursuing the ship with the intent of crashing into the ship. When a mine appears, the participant has to check a letter that appears in

the IFF box in the bottom panel (see Figure 1). The mine is a foe if the letter matches one of the foe letters; otherwise, it is a friend. Mine identification is a version of the Sternberg memory-scanning task (Sternberg, 1966). If the mine is a foe, one has to perform an Identify Friend/Foe (IFF) tapping task, which involves tapping the J key twice with a 250-400 ms interval ('IFF interval') between the two key presses. Once a correct interval has been generated, the mine can be destroyed by aiming the ship at the mine and firing a missile. A missile can be fired even after a wrong IFF interval, but the missile can destroy the mine only after a correct IFF interval. If the mine is a friend, then the IFF tapping task should not be performed and the mine can be destroyed by a missile shot. If all steps are completed successfully before the mine reaches the ship, then the mine is destroyed and points are earned. Otherwise, the mine eventually collides with the ship and points are lost.

As a time interval estimation task, the IFF tapping task has three notable characteristics. First, it is a prospective time estimation task. Participants are initially told the target interval in written instructions, and then produce the interval whenever a foe mine appears during a game. Immediately after each attempt, the produced interval is displayed as feedback (e.g., "378") in the INTRVL box in the bottom panel. Second, both the initiation and the termination of the interval are under the control of participants. Finally, and most importantly, it is performed not as an isolated task but as part of a real-time complex task. The game requires time-sharing multiple tasks such as navigating the ship while dealing with the fortress and the mines. Even within the mine task, a series of activities precede (checking the letter and determining the mine's identity) and follow (aiming the ship and firing a missile) the IFF tapping task, all of which need to be completed within a brief period of time, usually 2-3 seconds.

A study previously conducted in our laboratory revealed an interesting pattern of performance in the IFF tapping task. Figure 1 (right) displays the percentage of responses within each of three categories: correct (the produced interval was between 250-400 ms), too-early (<250 ms), and too-late (>400 ms) responses. The figure shows the average percentages from 100 participants over 300 attempts (30 attempts per bin). Participants improved with practice, as indicated by the percentage of correct responses reaching almost 70% accuracy by the end. More notable is the error pattern, with participants making too-early responses more often than too-late responses.

This too-early bias deviates from the roughly symmetrical responses observed in time interval estimation studies (e.g. Rakitin, et al., 1998). We suspected two factors might be responsible for the too-early bias. The first possibility is that estimating a shorter time interval contaminated performance in the target interval. In the Space Fortress task, the fortress task involves shooting a fast double-shot (<250 ms interval). Studies (Grondin, 2005; Jones & Wearden, 2004; Taatgen & Van Rijn, 2011) suggest that representations of different time intervals are not independent of each other. Participants

in Taatgen & Van Rijn (2011) study alternated between producing a short interval and a long interval. When the feedback criterion for the long interval was shifted unbeknownst to the participants, not only did the estimate of the long interval change, but the estimate of the short interval also changed. Thus, estimating the shorter interval for the fortress task might have influenced estimating the target interval for the mine task.

A second possibility is that participants might be more likely to commit too-early errors as less time is allowed for the mine task. Note that the mine task consists of multiple demanding activities that are in competition with each other for the limited length of time available for the mine task. One might hypothesize that participants adjust the IFF interval based on their estimation of time remaining to fire a missile before the mine crashes into the ship.

## The IFF Tapping Experiment

We tested those two hypotheses in a within-subjects design by manipulating 1) the speed of tapping (fast/slow) alternated with the IFF (intermediate) tapping, and 2) the distance between ship and mine (short/long) at mine onset. We created three types of games: fast-tap, slow-tap, and intermediate-tap-only games. Those games were a simplified version of the original Pygame Space Fortress task (Destefano, 2010).

Figure 2: Sample sequence of trials in the fast-tap game.

Figure 2 shows a sample sequence of trials in the fast-tap game. The game had a static ship fixed at the bottom left of the screen always correctly aimed toward the mine that appeared from the other side. During the game, 8 red static and 8 green moving mines appeared in a strictly alternating order. For a red static mine, participants simply had to produce a fast (<250 ms) double-tap (spacebar). In the following trial, a green mine containing a letter appeared and approached the ship. For the green moving mine, participants had to 1) check the letter and determine its identity, 2) produce the IFF interval using an appropriate key (F key for friend and J key for foe), and 3) fire a missile (space bar). If all steps were successfully completed, the mine was destroyed. If any of the three steps were missed or performed incorrectly, the mine became invincible and eventually destroyed the ship. The slow-tap games were identical to the fast-tap games except that they had blue static mines (instead of red static mines) for which participants produced a slow (400-650 ms) double-tap. The distance manipulation was applied to the green moving

mines in the fast-tap and slow-tap games. The distance between ship and mine at the moment of mine onset was randomized to be either short (283 pixels, corresponding to 1.86 s until mine collision) or long (566 pixels, 3.73 s). The intermediate-tap-only games were intended to test whether the too-early bias would still be present when participants produced the target interval without the demands of the mine task and without estimating different time intervals. In each trial, when a letter (either F or J) appeared in the center of the screen, participants simply produced the IFF interval using the corresponding key. Each intermediate-tap-only game had eight trials.

Twenty participants (5 males, mean age: 19 yrs) from Carnegie Mellon University participated in the experiment. The experiment consisted of 12 blocks of games. Each block had one intermediate-tap-only game, one fast-tap game, and one slow-tap game in a randomized order.

### Behavioral Results

Figure 3 (left) presents the IFF tapping performance in intermediate-tap-only games over 12 blocks. Participants overall performed very well (mean accuracy: 86%). Importantly, the too-early bias was not present confirming our prediction. Participants committed too-early and too-late errors with roughly equal frequencies in the first block, but they quickly reduced their too-early errors. Thus, there was a small too-late bias on later trials, which may reflect a floor effect on the shortest intervals participants could produce. Figure 3 (right) shows that the mean produced IFF interval fell within the targeted 250-400 ms range and did not fluctuate much over blocks.

Figure 3: IFF tapping performance in intermediate-tap-only games: percentages of correct/too-early/too-late responses (left) and mean produced IFF intervals (right).

The results from the fast-tap and slow-tap games confirmed both the contamination and the distance hypotheses. Figure 4 displays the performance in the IFF tapping task in the four conditions defined by crossing the tap speed (fast/slow) and the distance (short/long) manipulations: fast-short, fast-long, slow-short, and slow-long. The percentage of correct responses increased over practice in all conditions. In all conditions the too-early responses dominated the first couple of blocks, but afterwards the bias stabilized at a lower level. The largest too-early bias was present in the fast-short condition,

whereas the smallest too-early bias (and the largest too-late bias) was found in the slow-long condition. Note that the fast-short condition best reflects the original Space Fortress game in which participants handle both mines (IFF taps) and the fortress (fast-taps), and have only a short time for the mine task (short-distance).

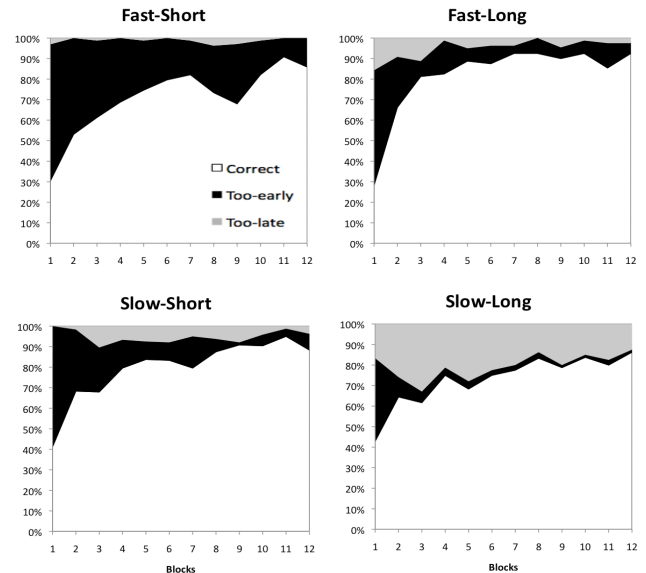

Figure 4: IFF tapping performance in fast/slow-tap games.

A repeated measures analysis of variance was performed with tap speed (fast/slow), distance (short/long), and practice (early: block 1-6 vs. late: block 7-12) as within-subjects factors and the mean produced IFF interval as the dependent measure. There were significant interactions between tap speed and distance ( $F(1,19) = 10.23, p < 0.01$ ), tap speed and practice ( $F(1,19) = 5.13, p < .05$ ), and distance and practice ( $F(1,19) = 11.62, p < 0.01$ ). The interaction between tap speed and distance reflects the larger distance effect in the slow-tap condition compared with the fast-tap condition. The interactions between tap speed and practice, and distance and practice reflect that those effects were larger in earlier blocks than in later blocks. The three-way interaction was not significant.

### The ACT-R Model

We developed a simulation model of our time estimation task, incorporating ideas from the Taatgen and Van Rijn (2011) timing model into a task model based on the ACT-R model for Space Fortress (Bothell, 2010). The model<sup>1</sup> was implemented in the ACT-R architecture (Anderson, Bothell, Byrne, Douglass, Lebiere, & Qin, 2004), which allows us to simulate all aspects of the task, not just the timing component. In ACT-R, time estimation is achieved through the processing in the temporal module (Taatgen, Van Rijn,

<sup>1</sup> Model parameters: :rt 1.0, :lf 1.1, :ans 0.385, :mp 2.25, :time-master-start-increment 0.011, :time-multi 1.1, :time-noise 0.0015.

& Anderson, 2007) and its interaction with the rest of the system. The temporal module, based on the internal clock model (Matell & Meck, 2000), assumes a pacemaker keeps accumulating pulses as time progresses. The production system can access the current pulse value through the temporal module's buffer and compare it with a criterion (e.g., a value retrieved from memory) to determine if the target interval has elapsed.

The model uses an instance-based approach to learn the required tapping times. When the model produces a time interval (e.g., 15 pulses) and observes its outcome (e.g., too-early), the specific instance of that experience is stored in declarative memory as a chunk. This chunk can be retrieved later to serve as a basis for deciding how long to wait the next time the model has to produce the interval. As such chunks are added to memory, the speed of retrieval increases and the accuracy of the retrieved result improves (similar to Logan's 1988 instance theory)

Figure 5 displays the series of steps in which the model performs the IFF tapping task. When a mine appears, the model attends the letter and determines its identity by retrieving the letter from memory. The model then starts retrieving a criterion value for the IFF interval. The retrieval of the criterion value is based on the blending mechanism discussed in the next section. If blending is successful, the model uses the blended result as the criterion. If blending fails, the model uses a default value. Once the criterion is determined, the model issues the first tap and starts incrementing the pulse value in the temporal buffer. When the current pulse value exceeds the criterion, the model issues the second tap that terminates the interval. The model then taps the spacebar to fire a missile. After completing both IFF tapping and the missile firing, the model attends the feedback<sup>2</sup>, evaluates the outcome (too-early, correct, or too-late), and assigns a feedbackshift value (positive for too-early, zero for correct, and negative for too-late) so that the criterion could be appropriately adjusted in the next trial.

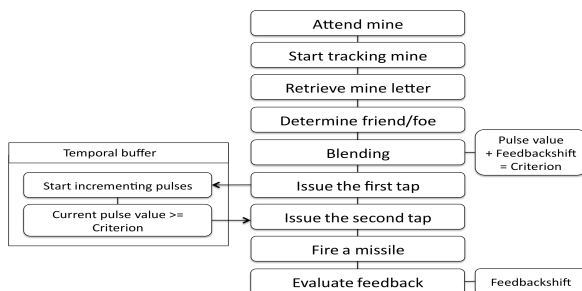

Figure 5: The ACT-R model of the IFF tapping task.

<sup>2</sup> According to our data, approximately 90% of the wrong IFF intervals were followed by a missile firing. We interpret this as indicating that participants tended to execute the entire sequence of key presses as a unit rather than interrupting the sequence after the IFF tapping to attend to feedback.

## Blending

The ACT-R blending mechanism (Lebiere, Gonzalez, & Martin, 2007) was adopted to model the contamination from representations of different time intervals. In the standard retrieval mechanism of ACT-R, a retrieval request results in retrieval of a single chunk with the highest activation that exceeds the retrieval threshold. Blending is an alternative mechanism that allows retrieval of a weighted aggregation of all candidate chunks available in memory. Each candidate chunk is given a different weight based on how recently the chunk has been created and how closely it matches the retrieval request.

Figure 6 illustrates how contamination occurs during the blending in the fast-tap game in which the model alternates between the intermediate-tap and the fast-tap. When the blending request is made for pulse value (the value that was previously used for the 'intermediate-tap' and its outcome was 'correct'), blending is performed for candidate chunks that perfectly match the request (e.g., interval44 with 'intermediate-tap' type and 'correct' outcome) and imperfectly matching chunks (e.g., interval45 with 'fast-tap' type and 'too-late' outcome), with the latter penalized according to their degree of mismatch with the blending request<sup>3</sup>. Due to the contribution of fast-tap chunks (e.g. interval45), the final pulse value (15.551) is smaller than it is supposed to be had only intermediate-tap chunks contribute to blending. The model performed blending separately for pulse value and feedbackshift value, then used the sum of those two ( $15.982=15.661+0.321$ ) as the criterion.

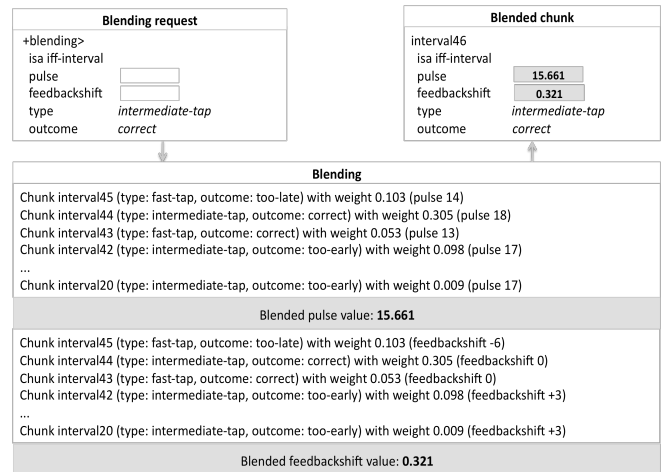

Figure 6: Blending for intermediate-tap.

## Modeling the Distance effect

The model has a production rule that issues the second IFF tap when the current pulse value is greater than or equal to the criterion. We modeled the distance effect by adding an additional 'emergency' production for the second IFF tap.

<sup>3</sup> Partial matching was enabled for the tap type (fast/intermediate/slow) and outcome (too-early/correct/too-late).

During the trial, the model tracks the mine's trajectory by updating the visual-location buffer with the mine's current location. The emergency production specifies a threshold value in pixels that forces the model to issue the second tap such that it will have enough time remaining to fire a missile before it hits the ship. The model ignores the pulse value in the temporal buffer when this production fires.

## Model Results

Contrary to human, we found that the model does not show the burst of too-early responses in early blocks. This is not surprising because the model starts out with a perfect representation of the task instructions, whereas participants have to work out any misunderstandings. Thus, participants show many more start up errors (e.g., no response). Since our goal is not to model this skill learning, we decided to focus on modeling the stable effects in the last 8 blocks, where participants and the model have both mastered the basic task requirements. Figure 7 offers comparisons of human and model performance in the last 8 blocks based on 100 model runs. The model successfully captures not only the lack of a too-early bias in the intermediate-tap-only condition, but also the distance and contamination effects in the other conditions. The overall correlation between model and participants equals .992.

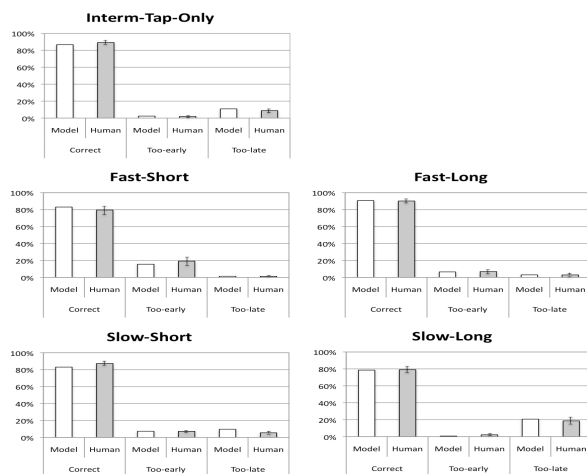

Figure 7: The model fit.

## Discussion

Two factors appear to be responsible for the too-early bias in time estimation that occurs in the context of a dynamic task. First, the representation of the shorter or longer interval shifted the representation of the intermediate interval, supporting the claim (Taatgen & Van Rijn, 2011) that more than a single experience determines the representation of the target interval. The blending mechanism of ACT-R offers quantitative descriptions of interference among time interval representations in declarative memory. Second, the time remaining until the end of the task influenced time interval production. It shows

that time estimation can be sensitive to one's knowledge of what is about to happen, consistent with animal literature (e.g., Church, Miller, Meek, and Gibbon, 1991). Our model captures this by having a procedural rule that overrides the outcome of the internal temporal estimate based on its perceptual processing of the environment.

Regardless of the conditions, participants showed a strong too-early bias in the early blocks (see Figure 4). There are a number of possible explanations for this result. First, participants were likely learning how to speed up other aspects of the task besides the blending process across blocks. In early blocks, these other processes might have been so slow as to increase use of the emergency rule. Second, participants might not even have been trying to time the target interval in the early blocks; instead they may have just practiced the sequence of responses in the task and focused on time estimation only when they had become proficient at responding. The third possible explanation is arousal. Studies (e.g., Penton-Voak, Edwards, Percival, & Wearden, 1996), suggest that arousal can affect the subjective duration of intervals by speeding up the rate at which a temporal pacemaker produces pulses.

The clear contrast between performance in the intermediate-tap-only condition and the other conditions demonstrates that time estimation performed in a dynamic task can exhibit properties different from when it is performed as an isolated task in static environments. External temporal or nontemporal tasks can influence production of the target time interval not only when those tasks are performed concurrently (Van Rijn & Taatgen, 2008) but also when performed in the same context in an alternating order (Taatgen & Van Rijn, 2011). Those results emphasize the virtue of modeling time estimation in the integrated cognitive architecture of ACT-R. The critical aspect of our model is not just the module's internal temporal processing, but also the contributions of the declarative and procedural components. This integrated approach of modeling time estimation in cognitive architecture can be especially useful in understanding time estimation in multitasking situations.

One possible application of our results concerns the training of time estimation tasks. In skill acquisition literature, two instructional strategies, part-task training (e.g., Frederiksen & White, 1989) and integrated training (e.g., Gopher, Weil, & Bareket, 1994), have been compared. The contrast between the intermediate-tap-only condition and the other conditions in our study suggests that a greater training emphasis can be directed to integrating timing with other subtasks (whole-task approach) rather than drilling on timing alone (part-task approach). Good performance in the intermediate-tap-only condition did not transfer to good intermediate timing in the more complex games.

Human factors researchers have studied timing performance and patterns of timing errors in dynamic multitasking situations (e.g., Rantanen & Xu, 2001). Similar to those studies, another potential application of our results regards to improving safety and reducing errors in time-

critical multitasking situations (e.g., traffic environments). Identifying patterns of timing errors and investigating the underlying causes may suggest changes in work procedures. For instance, a timing-critical task can be separated from other tasks that involve less critical timing, putting it under lower time pressure.

The time estimation mechanism in ACT-R has successfully captured time estimation performance in dual-task conditions (Taatgen et al., 2007) as well as in dynamic multitasking situations (Salvucci, et al., 2006). We explored millisecond-level time estimation embedded in a complex real-time task that imposes especially high perceptual-motor demands. The model provided an integrated account of why time estimation performed in this context exhibited different properties than when it was performed in an isolated context. This study further supports the need to model time estimation in the broader context of cognition as we attempt to expand our understanding of human temporal cognition in the domain of complex skills.

## Abstract

Previous research has provided evidence that second language (L2) learners use gesture to enhance spoken communication with interlocutors, and that gesture facilitates L2 word learning. The current study investigates how L2 learners use gesture to communicate in conversational settings, and whether their gesturing in these settings facilitates L2 acquisition beyond the immediate context. The results reveal that L2 learners produce more iconic gestures when their interlocutor is visible, and that gesture production predicts their recall for novel words introduced in conversation. As such, they indicate that conversational gesturing enhances acquisition of the target language more broadly, facilitating L2 communication, acquisition, and retention.

**Keywords:** Second language acquisition, word learning, gesture, mental imagery, embodied cognition

## Introduction

Language acquisition, like other aspects of human communication, is profoundly multimodal. Children learning how to speak often use their hands and bodies to express themselves, even before they can speak (Acredolo & Goodwyn, 1988). Once children begin speaking, they begin producing gestures concurrently with speech to help them express themselves (Iverson & Goldin-Meadow, 2005). However, it is less well-known how gesture facilitates second language (L2) learning by adults. Although previous research has provided evidence that isolated gestures can enhance L2 word learning in instructional settings (Allen, 1995; Kelly, McDevitt, & Esch, 2009; Tellier, 2008), it is unclear whether L2 learners' discourse comprehension benefits from conversational gestures. Furthermore, it is unclear whether L2 learners' gestures facilitate communication with interlocutors in the target language, or whether they benefit only the speaker by providing a method of "thinking out loud." The present research addresses these questions by examining how interlocutor visibility and gestural priming affect gesture use among L2 learners. Moreover, this research examines whether enhanced real-time comprehension transfers to other domains, benefiting L2 learning more broadly.

## How Gesture Affects L2 Communication

To date, little research has addressed how gesture affects communication between L2 learners and their interlocutors in real-time conversation. Work examining the question of whether speakers use gesture in a communicative sense in general has provided evidence that speakers modify their gesture qualitatively and quantitatively when interlocutors are visible. In particular, this work has revealed that speakers produce gestures that are more iconic, elaborate, and larger when they are speaking to an interlocutor who is present and visible, as opposed to an interlocutor who is present but occluded or an interlocutor who is on the phone (Alibali, Heath, & Myers, 2001; Bavelas, Gerwing, Sutton, & Prevost, 2008). These results suggest that speakers do indeed use gesture as a communicative device.

If speakers use gesture to facilitate communication, then it follows that they should also modify their gestures when conversing with L2 learners, who often encounter difficulty comprehending L2 speech. Indeed, related research has shown that native speakers hyperarticulate vowels when speaking to adult L2 learners, demonstrating that they are aware of L2 learners' comprehension-related needs (Uther, Knoll, & Burnham, 2007). In one of the few studies to examine native speakers' gesture in the presence of L2 learners, native speakers of English produced more deictic and iconic gestures when retelling a narrative to L2 English learners than to English-speaking interlocutors (Adams, 1998). This finding suggests that speakers rely on gesture as a communicative medium to a greater degree with L2 learners than with native interlocutors.

There is also evidence that the gestures that L2 learners produce when speaking the target language differ qualitatively from the gestures that they produce when speaking their native language, as well as from gestures produced by native speakers of the target language. One such difference is that gestures accompanying L2 learners' utterances in the target language tend to be over-explicit. For example, L2 learners are much more likely to produce iconic gestures when referring to entities that they have previously mentioned when speaking the target language

than their native language (Gullberg, 2003). This tendency mirrors their use of nouns rather than pronouns to refer to previously mentioned entities in the target language. Other work has provided evidence that the syntax and semantics of L2 learners' native language influences the gestures that they produce when speaking the target language. As a result, L2 learners' gestures differ in subtle ways from the gestures of native speakers of the target language, such as in the way that path and manner are expressed (Stam, 2006; Yoshioka & Kellerman, 2006). Nevertheless, it is unclear whether native speakers of the target language notice these differences in L2 learners' gesture, and to date, there is no conclusive evidence that they hinder communication between L2 learners and native interlocutors.

In fact, despite the nuanced ways in which L2 learners' gesture may differ from the gesture of native speakers, there is evidence that gesture *facilitates* communication between L2 learners and native interlocutors. To this end, one study revealed that L2 learners frequently gestured when they were unable to complete an utterance in Japanese, prompting Japanese interlocutors to suggest semantically appropriate completions (Mori & Hayashi, 2006). Along similar lines, a case study of gesture use between a L2 English learner and his tutor revealed that the learner often gestured when searching for words, cuing the tutor to complete the learner's utterances while simultaneously producing similar gestures (McCafferty, 2002). Taken together, these findings reveal that both L2 learners and native speakers use gesture to convey information that their interlocutors may not be able to comprehend via speech, serving as an alternative channel of symbolic communication. Furthermore, these findings suggest that both L2 learners and native interlocutors can understand and use information conveyed via gesture to rectify incomprehensible or incomplete utterances, thereby facilitating communication in the target language.

### How Gesture Affects L2 Acquisition and Retention

Given the evidence that L2 learners can use gesture to facilitate their production and comprehension of the target language in conversational settings, it follows that gesture may facilitate not only communication, but also *acquisition* and *retention* of the target language. Indeed, research has provided evidence that gesture can enhance the acquisition and recall of L2 lexical items. One study showed that first-semester L2 students learned French figurative expressions accompanied by representational gestures more effectively than expressions that were presented without gesture (Allen, 1995). Similarly, individuals unfamiliar with Japanese recalled the meanings of Japanese verbs over the course of a week more accurately when they were presented with representative iconic gestures than when they were presented as speech only, without gesture (Kelly et al., 2009). Finally, during instruction spanning 4 weeks, children learning English recalled more words from this language when they enacted representative iconic gestures than when they learned the word meanings via images.

Taken together, these results indicate that iconic gesture may help beginning L2 learners to associate L2 lexical items with their meanings, thereby facilitating L2 word learning.

Despite the preponderance of evidence that gesture facilitates L2 lexical acquisition, research examining the effect of gesture on other aspects of L2 acquisition has been rather sparse and has produced inconsistent findings. The results of several studies have failed to show evidence that beat (simple rhythmic), deictic (pointing), or iconic gestures can enhance the perception of novel L2 phonological contrasts (Hirata & Kelly, 2010; Jesse & Mitterer, 2011; Kelly & Lee, 2011). To date, no published research has investigated whether gesture can facilitate the acquisition of morphosyntax by L2 learners. On a broader level, some work (Lazaraton, 2004; Sueyoshi & Hardison, 2005) has provided evidence that gesture facilitates L2 learners' comprehension of instructional lectures given in the target language. However, it is unclear from this work what types of gestures enhance listening comprehension, as well as which aspects of comprehension they affect.

Although previous research has not directly investigated the cognitive processes responsible for gesture's impact on various aspects of L2 acquisition, it is possible to make some inferences about them by considering the foci and design of the studies discussed above. First, gesture's facilitation of the acquisition of lexical items but not phoneme perception suggests that the benefits of gesture in L2 learning may be localized to individual stimuli, rather than generalizable to related members of a category. This interpretation is particularly plausible in light of the fact that most of the research investigating the effect of gesture on L2 acquisition has been conducted with novice L2 learners, who lack an understanding of how various elements of the target language are related. Second, the observation that representative iconic gestures—but not non-representative iconic gestures or other types of gestures—enhance L2 lexical acquisition suggests that isomorphism between gestures and the visuospatial properties of referents is necessary for gesture to benefit L2 word learning. Third, the more pronounced effect of gesture enactment than gesture viewing on L2 lexical acquisition suggests that the engagement of embodied action may also play a key role in explaining gesture's facilitation of L2 word learning.

## Methods

### Participants

Sixty undergraduates were recruited in pairs from the participant pool at UCSC. All recruited individuals were fluent English speakers<sup>1</sup> and confirmed that they had no knowledge of Hungarian prior to the experiment. Additionally, all recruited individuals had normal hearing and normal or corrected-to-normal vision.

<sup>1</sup> Participants were not required to be native English speakers, given that the English glosses of the signs were common words that should be comprehensible to non-native undergraduates, who must be sufficiently proficient to understand academic English.

Table 1: Hungarian and English words used in study.

Hungarian	English	Hungarian	English
<i>Betegség</i>	Illness	<i>Unott</i>	Bored
<i>Kalapács</i>	Hammer	<i>Varrni</i>	To sew
<i>Kulcs</i>	Key	<i>Öltözet</i>	Clothing
<i>Löni</i>	To shoot	<i>Leforgatni</i>	To record
<i>Mászni</i>	To climb	<i>Csomó</i>	Knot
<i>Megütni</i>	To hit	<i>Hosszú</i>	Long
<i>Órá</i>	Watch	<i>Bajusz</i>	Moustache
<i>Öröm</i>	Joy	<i>Testgyakorlás</i>	Sports
<i>Seprű</i>	Broom	<i>Kezbasiteni</i>	To deliver
<i>Tréfa</i>	Joke	<i>Kefe</i>	Brush

### Stimuli

Twenty Hungarian words were selected for use in this study (see Table 1). Prior to this research, 15 English speakers who did not participate in this study were asked to rate the concreteness, imageability, and meaningfulness of the English glosses of 80 candidate words, and to gesture in a way that represented the meaning of each gloss. The 20 words with the most consistent responses from each of the three categories listed above were selected for inclusion in the study. Videos of iconic gestures were created by recording a fluent Hungarian-English bilingual saying these words in each language while enacting the gestures produced by the most participants. In order to control for possible vocal iconicity, audio of the pronunciation of Hungarian and English words was extracted from the iconic gesture videos and was played during presentation of text words in the non-gesture presentation condition.

### Procedure

In the learning phase of the experiment, participants were randomly assigned via coin flip to be either the teacher or the learner, and to be in either the visible or occluded condition. Participants were seated on either side of a table that was either unobstructed or was divided by a large, opaque cardboard screen. The teacher was seated in front of an iMac G4 with a 20 in. screen, on which the stimuli were presented. Prior to beginning the experiment, participants were told that the focus of the study was to examine teaching and learning strategies for L2 vocabulary. To this end, the teacher was told that he or she would learn the meanings of twenty Hungarian words one-by-one. The teacher was instructed to teach each word to their partner “however [they] think the learner will learn them best,” with the only restriction being that both the teacher and learner must remain seated at the table during the entire learning phase. The learner was told that he or she would be tested after the learning phase to determine how well he or she had learned the words. After ensuring that the participants understood the instructions, the experimenter left the room.

Although participants were informed that their speech would be audio recorded during the learning phase for later analysis, they were not told that they would also be video

recorded while learning the words. A video camera hidden behind a one-way mirror oriented perpendicular to the table was focused on participants during the learning phase of the experiment, providing a 180° view of them (see Figure 1). The screen of the computer on which stimuli were presented was oriented at a 180° angle from the camera, in order to ensure that the experimenters were blind to the presentation modality of the words. Participants’ interactions were never heard or seen by anyone other than the experimenters.

During trials of the learning phase, a Hungarian word was presented to the teacher for 2500 ms., and after a 1000 ms. interval, its gloss was presented for 2500 ms. Words in both languages were presented to the teacher as speech over headphones connected to the computer. Words were presented visually via either video of a Hungarian-English bilingual saying them while concurrently producing an iconic gesture representing their meaning, or via text displayed on screen; word presentation modality was varied within participants. Following a 2000 ms. interval, the words were repeated once in this sequence, and then a screen instructing the teacher to teach the word to the learner was displayed until the teacher pressed a button to indicate readiness to proceed to the next trial. After all 20 words had been presented, participants were told to summon the experimenter so that the learner could be tested.

In the test phase, the teacher was informed that he or she would also be tested to gauge how well he or she had learned the words. Both participants were placed in separate rooms for this part of the experiment. During test trials, each Hungarian word that participants had learned was presented as text and speech. Participants responded by saying the corresponding English word or by saying “skip” if they could not remember it. After having completed the test phase, participants were debriefed and informed of the actual purpose of the experiment, and were given the opportunity to have their recordings destroyed. All declined.

### Coding

Participants’ speech was transcribed verbatim, and all gestures were identified. Gestures were classified as one of three types: iconic (handshape and/or motion resembles referent attributes), beat (non-iconic emphasizing), or deictic (pointing). Individual gestures were distinguished from one another by a change in hand shape or motion. For

Figure 1: Screenshot of video captured during learning phase of participants assigned to occluded condition.

Table 2: Average amount of speech and target words produced during learning task, by participant and condition.

PP	Measure	Visible	Occluded
Teach	Total speech	633.30 (305.89)	856.83 (486.37)
	Target words	103.70 (14.10)	94.54 (22.04)
Learn	Total speech	352.00 (214.97)	584.67 (370.83)
	Target words	110.10 (18.89)	106.35 (33.43)

example, an extension of the hand forward with the palm up produced concurrently with the word “to deliver” was coded as one iconic gesture. If a similar movement occurred as the first motion of a sequence in which the fingers of the hand closed and the hand moved in a lateral turning motion (for key), this entire sequence was coded as one iconic gesture.

## Results

### Learning task

In order to investigate the relationship between speech and concurrent gestures produced during the learning task, we first examined the quantity and content of participants’ speech. A univariate ANOVA conducted on total amount of speech produced in the learning task revealed main effects of participant role,  $F(1, 59) = 6.22, p = .02, \eta_p^2 = .14$ , and visibility,  $F(1, 59) = 4.23, p = .05, \eta_p^2 = .10$ . However, the interaction between these factors failed to reach significance. Bonferroni-corrected post hoc tests showed that teachers spoke significantly more than learners, ( $p = .02$ ), and that occluded interlocutors spoke more than visible interlocutors ( $p = .05$ ; see Table 2). Nevertheless, all participants repeated the target words with comparable frequency across the visible and occluded conditions, suggesting that differences in speech were caused by verbal elaboration rather than repetition of target words.

Prior to analysis, the distribution of gesture data was examined to determine whether it was normal. Shapiro-Wilk tests revealed that none of the distributions of any of the gesture types for either participant were normal. As can be seen from Table 3, this was primarily due to the skewness and kurtosis of the data. Because analysis of variance is robust against violations of normality (Hays, 1973), it was used as the primary method of analysis. However, non-parametric tests were also conducted to ensure the validity of the results obtained using parametric statistics.

Before conducting the main analyses, it was necessary to determine whether the number of gestures produced by

teachers and learners differed reliably for pairs assigned to the visible and occluded conditions. Independent-samples  $t$  tests revealed that the difference between the number of iconic gestures produced by teachers and learners whose interlocutor was visible was marginally significant,  $t(29) = 1.92, p = .07, d = .86$  (this was confirmed by a Mann-Whitney  $U$  test,  $U(29) = 22.50, p = .04$ ). No other significant differences were found between teachers’ and learners’ production of iconic, beat, or deictic gestures. Based on the results of these preliminary analyses, teachers’ and learners’ iconic gestures were analyzed separately, but beat and deictic gestures were collapsed across participants.

To determine whether interlocutor visibility and word presentation mode affected iconic gesture production, iconic gesture data was submitted to two repeated measures ANOVAs (one for the teacher and one for the learner). The analysis of teachers’ iconic gesture showed a main effect of word presentation mode,  $F(1, 29) = 21.33, p < .001, \eta_p^2 = .50$ , and interlocutor visibility,  $F(1, 29) = 6.95, p = .02, \eta_p^2 = .25$ ; however, the interaction between these two factors failed to reach significance (see Figure 2). The effect of word presentation mode on teachers’ iconic gesture was confirmed by a Wilcoxon signed-rank test,  $Z(29) = 3.61, p < .001$ , and the effect of visibility was confirmed by a Mann-Whitney  $U$  test,  $U(29) = 23.50, p = .02$ . Bonferroni-corrected post hoc tests revealed that teachers produced a significantly greater number of iconic gestures when conveying the meanings of words that they had learned via iconic gesture than words that they had learned via text ( $p < .001$ ), and that they produced more iconic gestures when communicating with visible interlocutors than occluded interlocutors ( $p = .02$ ). The analysis of learners’ iconic gesture failed to show a main effect of either presentation mode or interlocutor visibility; similarly, the results of a Wilcoxon signed-rank test and a Mann-Whitney  $U$  test failed to reach significance. However, in this case, the interaction between word presentation mode and interlocutor visibility reached significance,  $F(1, 29) = 4.71, p < .04, \eta_p^2 = .18$ ; see Figure 2. Taken together, these results provide evidence that the acquisition of novel word meanings via iconic gestures and the presence of a visible interlocutor cause L2 learners to increase their production of iconic gestures, thereby facilitating communication.

To determine whether interlocutor visibility and word presentation mode affected participants’ production of beat and deictic gestures, data for each of these gesture types was examined using a repeated measures ANOVA.

Table 3: Descriptive statistics and normality test results for gesture types, by participant role.

Gesture	Teacher			Learner		
	Iconic	Beat	Deictic	Iconic	Beat	Deictic
Mean (SD)	11 (10.17)	20.17 (26.63)	3.96 (4.25)	5.13 (7.61)	18.09 (37.10)	1.96 (5.10)
Range	0-40	0-121	0-15	0-129	0-177	0-24
Skewness	1.24	2.87	0.86	2.01	3.88	4.00
Kurtosis	1.62	9.44	0.17	3.83	16.71	17.38
Shapiro-Wilk	.89, $p = .01$	.66, $p < .001$	.85, $p = .003$	.71, $p < .001$	.50, $p < .001$	.43, $p < .001$

Figure 2: Boxplots showing number of iconic gestures produced by teachers and learners, by word presentation mode and interlocutor visibility.

This analysis revealed no significant effects of either interlocutor visibility or presentation mode, indicating that participants produced beat and deictic gestures with similar frequency, regardless of these factors.

## L2 Word Recall

L2 word recall was quantified using a binary coding scheme for each word (1 = correct, 0 = incorrect/skipped), which was summed across words to yield a total number of words recalled out of twenty for each participant. Prior to investigating the gesture data, we first examined whether total amount of speech and target word repetitions predicted word recall accuracy.

Three separate linear regression analyses revealed that the amount of speech produced by teachers and learners significantly predicted their word recall, and that the amount of teachers' speech also predicted learners' recall.

However, additional analogous analyses failed to show that repetitions of target words by teachers and learners during the learning phase predicted their own word recall at test, or that teachers' target word repetitions during learning predicted learners' recall at test (see Table 4).

In order to examine whether the viewing of iconic gestures during the learning phase affected L2 word recall for the teacher, word recall data was submitted to a paired-samples *t* test using word presentation modality as a within-participants factor. This analysis showed that teachers recalled words with comparable accuracy regardless of whether the words had been presented with iconic gestures or text in the learning phase,  $t(29) = 1.08$ ,  $p = .29$ ,  $d = .20$ . In order to examine whether gesture viewing during the learning phase affected word recall for the learner, learners' word recall scores were regressed on number of iconic gestures produced by teachers during the learning phase. This analysis showed that teachers' iconic gestures failed to predict learners' word recall accuracy,  $b = -.28$ ,  $t(29) = 1.04$ ,  $p = .31$ . Together, these results indicate that simply viewing iconic gestures during L2 word learning is insufficient to promote word recall.

Finally, in order to determine whether gesture enactment affected L2 word learning, teachers' and learners' word recall scores were regressed on the number of gestures (iconic, beat, and deictic) that they produced during the learning phase. This analysis revealed that teachers' beat and deictic gestures positively predicted their recall of L2 words, but that their iconic gestures negatively predicted L2 word recall. Moreover, this analysis failed to reveal that learners' gestures predicted their word recall at test (see Table 4).

## Discussion

The current study examined the impact of gesture production on communication and acquisition of a novel second language. The results showed that participants produced more iconic gestures when the meanings of L2 words are conveyed to them via gesture, and when they are communicating with a visible interlocutor. This indicates that viewing iconic gestures primes the production of iconic gestures. More importantly, however, it demonstrates that interlocutors use iconic gesture to facilitate communication in a novel second language, corroborating the findings of other studies of

Table 4: Word recall, as predicted by teachers' and learners' speech and iconic, beat, and deictic gesture production.

Predictor	Dependent variable	Teacher			Learner		
		<i>b</i>	<i>SE b</i>	$\beta$	<i>b</i>	<i>SE b</i>	$\beta$
Speech	Constant	1.95	1.21		4.02	1.52	
	Total speech	.008	.001	-.77	.006	.003	.46
	Word repetitions	-.04	.03	-.29	.02	.02	.20
Gesture	Constant	5.84	.97		5.03	1.21	
	Iconic gestures	-.18	.08	-.45	.24	.17	.44
	Beat gestures	.08	.03	.49	.07	.08	.23
	Deictic gestures	.62	.21	.63	-.09	.27	-.11

L2 learners' conversational interactions (Adams, 1998; McCafferty, 2002; Mori & Hayashi, 2006). Furthermore, the results of the current study revealed that participants produced more gestures when their interlocutor was visible, but more speech when their interlocutor was occluded. This dissociation indicates that interlocutors are aware of the communicative properties of each modality, and use them appropriately when conveying L2 words.

More interestingly, however, the results of the current study provide evidence that participants' use of beat and deictic gesture during conversational interactions enhanced their L2 acquisition beyond the immediate communicative context, whereas their use of iconic gestures did not produce this effect. Considered as a whole, these results suggest that gesture effectively supplements information conveyed via speech, but cannot replace it. Moreover, the lack of facilitation of gesture viewing for both teachers and learners is inconsistent with work showing that mere exposure to gesture facilitates L2 word learning (Allen, 1995; Kelly et al., 2009), but is consistent with work showing that gesture enactment enhances L2 word learning more effectively than gesture viewing (Tellier, 2008). Future research should investigate the circumstances under which gesture enactment and viewing differentially benefit L2 acquisition, further clarifying its role in the communication, acquisition, and retention of a novel second language.

### Acknowledgements

This research was supported by a National Defense Science and Engineering Graduate Fellowship and the Perlino Award to Laura M. Morett. The authors thank Eve LeBarton and Jana Iverson for helpful discussion.

## Abstract

What types of learning or reasoning are involved in forming a new communication system? To answer this question, this paper presents a computational model for forming a new communication system. The model was developed with ACT-R (Adaptive Control of Thought-Rational). In the model, two agents autonomously assign their roles to themselves. Agents also possess general learning mechanisms implemented in ACT-R. By incorporating imitative learning into these general learning mechanisms, this paper studies the role of imitation in the process of forming a new communication system. Finally, we compared the proposed model against a human experiment. The results of the simulation indicate that through imitation, after a short period of interaction, an isomorphic system is created. The result of the simulation also suggests the existence of imitation in the process of forming a human communication system.

**Keywords:** Communication; Imitation; ACT-R

## Introduction

People try to communicate with others even when they do not have a common language. They also understand intentions of others through repeated interactions. Apparently, humans have the ability to develop a new communication system where only a few common ground rules are shared in advance. How can a new communication system be developed? What types of learning or reasoning are involved in this process? Addressing these questions will contribute not only to understand the origins of our communication but also to predict changes in our communication in this era of globalization.

Some researchers have examined these questions by designing communication environments in the laboratory (for a review Scott-Phillips & Kirby, 2010). For example, Galantucci (2005) conducted an experiment to observe the formation of communication systems in which a pair of participants communicated through a medium that restricted the use of standard communication means such as utterances and letters. He observed the process of forming a new communication system, and discussed that implicit information was conveyed through routine behavior, and reported that a temporal order of messages was built into communication systems. However, this study cannot answer the questions above because he did not identify the cognitive mechanism involved in this process.

The present study focuses on imitation as the type of reasoning in forming a new communication system. Imitation has been investigated in various fields of cognitive science (Barnes & Thagard, 1997; Gergely, Bekkering, & Király, 2002; Tomasello, 1999; Thagard, 2001). For example, Tomasello (1999) described the role of imitation in language acquisition by the infant/child. He especially argued

that a type of imitation called “role-reversal”, in which the child aligns herself with the adult speaker, is essential for producing a communicative symbols.

However, there is an important difference between language acquisition and forming a new communication system. In language acquisition, there is a clear distinction between a learner and an instructor (or a demonstrator). On the other hand, a new communication system usually emerges from a situation where no predefined roles exist. Although several studies concerning imitation exist, only few studies have dealt with this situation.

We argue that the model-based approach is the best method to explore the role of imitation in an interactive situation. From this perspective, we present a computational model, in which two agents autonomously assign roles to themselves. Agents also possess general learning mechanisms such as reinforcement learning and instance-based learning to form a new communication system. By incorporating imitative learning into these general learning mechanisms, we investigate the role of imitation in the process of forming a new communication system. Furthermore, we compare the constructed model against a human experiment. The results of this comparison reveal the cognitive mechanism involved in the formation of a human communication system. Before presenting our model, we will provide an overview of our previous experiment.

## Experiment

The present study simulates the experiment reported in Konno, Morita, and Hashimoto (in press), where we modified and used a coordination game taken from Galantucci (2005). As in Galantucci’s study, the game environment contained two characters, each controlled by a player, and four intercommunicating rooms. The game was composed of several repeated rounds. At the beginning of a round, characters were randomly placed in two different rooms. Players were unaware of the location of each other and aimed to bring their characters to the same room. The characters could not move to rooms that were located diagonally. Owing to this constraint, players need to communicate before moving their characters.

Figure 1 presents the flow of each round consisting of three steps: step 1 for exchanging messages; step 2 for moving characters; and step 3 for confirming the result of the movement. Among these steps, step 1 is the most crucial for the success of this task. In this step, the two players construct their own messages composed of two figures such as “”. Using six available figures: , , , , , and . The meanings and usage of the figures were not shared among

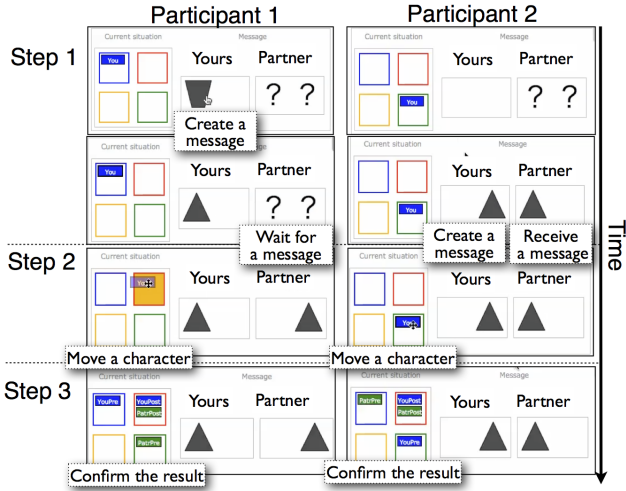

Figure 1: A round of the coordination game consists of three steps. In step 1, to create a message, participants select figures by clicking the segments indicated by “Yours”. Each time a participant clicks a segment, a figure appears in the order of , , , , and . In step 2, a character (blue boxes indicated by “You”) is moved by drag-and-drop. In step 3, the result of the movement are shown to the participants. Blue boxes (“You-Pre” and “You-Post”) and green boxes (“Pat-Pre” and “Pat-Post”) represent a movement made by the participant and the partner, respectively. In the case of this figure, they succeeded in moving to the same room (the upper-right room).

the participants in advance. Each player could send only one message per round, but they could take turns in exchanging messages. A message sent by the first sender instantly appeared on the screen of the other player. The second sender could compose her/his message after observing the message of her/his partner (see the participant 2 in Figure 1). By this turn-taking approach (role-settings), the first sender could transmit her/his current room location, and the second sender could transmit the destination while taking into account the current room location of her/his partner. Importantly, the participants were not assigned their roles by the experimenter. They were required to assign their roles by themselves.

The experimental procedure consisted of one trial session and three test sessions. In the trial session, the participants (21 pairs) attempted to develop a communication system within one hour time limit. When characters moved to the same room, players received two points, otherwise they lost one point, but the scores did not drop below zero. The trial session was terminated when the score reached 50 points.

Test sessions were conducted subsequently. The  $T_{NM}$  (Test with No Message exchanges) did not allow message exchanges. In the  $T_{SM}$  (Test with Simultaneous Message exchanges), messages were displayed on the screen of each player after both players had sent their messages. Thus, taking turns in sending messages was prevented in this test session. The  $T_{IM}$  (Test with Immediate Message exchanges) was conducted under the same conditions as in the trial session. Each test had 12 rounds that contained all possible room combinations for two characters. The order of appearances was set at random.

Figure 2: Schema of the model.

The results of the experiment confirmed the success of forming a shared symbol communication system, indicating the differences of the performance between the three tests. The detailed results are shown in a latter section.

## Model

### Architecture

The task presented in the previous section requires symbolic learning for constructing a new symbol system. In addition, according to Galantucci (2005)’s report, implicit learning, which is not present in symbolic systems, possibly plays a role in this task. In this study, we construct a model using ACT-R (Adaptive Control of Thought-Rational: Anderson, 2007), which integrates symbolic and subsymbolic learning mechanisms.

ACT-R is composed of several independent modules. The modules used in this study are presented in Figure 2. Except for the production module, each module has a buffer to temporarily store information called a chunk (a set of slot-value pairs). The production module integrates the other modules using production rules, which consist of a condition-action pair that is used in sequence with other productions to perform a task. The conditions and actions in production rules are specified along with buffer contents of each module.

In our model, two independent agents interact through a simulated task environment developed in the ACT-R graphical user interface (AGI). AGI provides screens that hold visual information as chunks. In this study, the locations of the characters and messages associated with each agent are displayed on the screen. An agent’s visual module searches for a character and stores its location (room) into a visual buffer. The visual buffer also stores the symbols that compose a message, attending to the screen locations where the figures appear. The simulated task environment also provides a virtual mouse to change the figures and move the characters on the screen.

Visual information stored in the visual buffer are transferred to the goal buffer through the production module. The goal buffer holds the goal of the current task and other task-related information. Specifically, our model has nine slots for

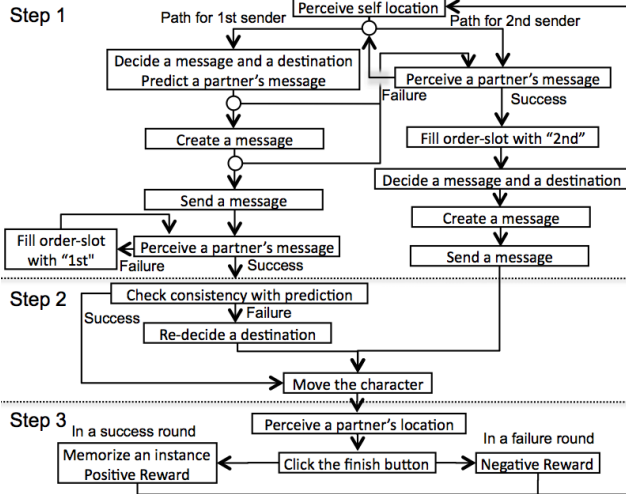

Figure 3: Process of the model. Circles indicate decisions based on conflict resolution.

the goal buffer: four slots for storing room locations (initial (from)-destination (to)  $\times$  self-partner), four slots for storing the symbols (left-right  $\times$  self-partner), and a slot for encoding the order for exchanging messages.

The declarative module stores past states of the goal buffer as instances. It also stores chunks representing task constraints such as path information indicating a room the characters can move to (e.g., *from* *to* *isa\_path*) or figures the agent can use to construct a message (e.g., *isa\_figure*). An agent uses these chunks (i.e., declarative knowledge) to choose its destination and construct a message.

## Process of the model

**Overview** We prepared 169 productions that construct the process presented in Figure 3. This process is divided into three steps just as in the original experiment (Figure 1).

In addition, the operation of taking turns to send a message is autonomously managed by this process. There are two paths in this process. The left path is for the first sender and the right path is for the second sender. The choice of path is made by conflict resolution, which is a comparison of two conflicting productions with noise added utilities. In each phase of the path of the first sender, there is a conflict (indicated by circles) between keeping the path of the first sender and changing to the path of the second sender. If in any of these the agent selects the path of the second sender, the agent tries to perceive the message of her/his partner from the screen. When the agent obtains the message of her/his partner, s/he realizes that s/he is the second sender (fills the order slot with "2nd"). Otherwise, s/he resolves a conflict by waiting for the message of her/his partner and changing to the path of the first sender. This conflict loop continues until one of the agents sends a message.

**Decision making** In step 1, regardless of the contents of the order slot, both agents make decisions about their destinations

Figure 4: Three types of decision strategies.

and their messages. Concurrently, the first sender predicts the message that s/he will receive from her/his partner. The predicted message is checked against the message received in step 2. When the received message is inconsistent with the predicted message, the agent makes a new decision about her/his destination.

Summarizing, there are three situations where agents make decisions. In these situations, agents apply one of the three decision strategies shown in Figure 4<sup>1</sup>. Every decision strategy begins by retrieving chunks from the declarative module by using the current goal buffer as a cue. In the trial-error strategy, chunks concerning task constraints (chunks representing a path and symbols) are retrieved, and are used to fill in the blank goal slots. In the instance-based strategy, the agent retrieves an instance that is consistent with the current goal buffer. The retrieved instance is used to fill slots concerning a destination and symbols. The imitation strategy also uses an instance, but the roles of an agent and her/his partner are reversed when retrieving and filling slots.

The implementation of the trial-error and instance-based strategies follow a past study on decision making using ACT-

<sup>1</sup>Figure 4 explains each strategy by using an example of the first sender in step 1. In the case of the second sender in step 1, a partner's message is added to the retrieval cue. The first sender in step 2 uses a message as a cue to retrieve an instance and make a new decision about the destination.

R (Lebiere, Gonzalez, & Martin, 2007; Reitter & Lebiere, 2011). The imitation strategy is constructed according to the role-reversal imitation described by Tomasello (1999).

**Learning** The decision making strategy implemented in this model changes through a learning process. This model uses the standard symbolic and subsymbolic learning mechanisms of ACT-R. Symbolic learning includes instance-based learning and production compilation. Subsymbolic learning includes utility learning and activation updating.

Instance-based learning and utility learning occur at the end of each round (see Figure 3). In a success round (two characters meet in the same room), the agent stores a state of the goal buffer into the declarative module. Conversely, in a failure round (two characters move to different rooms), the agents do not store an instance. Regardless of the results of the movement, the utilities, which are used in conflict resolution, are updated by the following formula.

$$U_i(n) = U_i(n-1) + \alpha[R_i(n) - U_i(n-1)] \quad (1)$$

where  $\alpha$  is the learning rate and  $R_i(n)$  is the reward value given to production  $i$  at time  $n$ . In a success round, productions used in the round receive positive rewards ( $R_i(n) = 10$ ). Otherwise, productions used in the round receive negative rewards ( $R_i(n) = 0$ ).

As instances are accumulated, the chance to retrieve an instance increases, but utility learning does not directly affect decision making. In each decision strategy, there are no conflicting productions. Instead, each decision strategy needs to select declarative chunks because a single state of the goal buffer usually matches several chunks. The selection of chunks is controlled by the activation values of the chunks<sup>2</sup>. In ACT-R, an activation value is updated by the following formula.

$$B_i = \ln\left(\sum_{j=1}^n t_j^{-d}\right) + \beta_i \quad (2)$$

where  $n$  is the number of presentations of chunk  $i$ ,  $t_j$  is the time since the  $j$ th presentation, and  $d$  is the decay parameter<sup>3</sup>. This value is determined by the frequency and recency of a particular chunk. Therefore, an agent usually retrieves a chunk that has been frequently observed or retrieved in the past round.

Even though utility learning does not directly affect decision strategies, there is a possible effect that occurs through production compilation. Production compilation is a mechanism that creates a new production integrating sequentially firing two productions. It typically occurs when the first production requests a retrieval and the second harvests it. The resulting production is specialized to include the retrieved information. In other words, the declarative knowledge is proceduralized into the production. Because compiled productions receive rewards, it is possible to change behavior through production compilation and utility learning.

<sup>2</sup>The simulation uses a summation of this base-level activation and the spreading activation values

<sup>3</sup>In this study, we use  $d = 0.50$  and  $\beta = 0.00$

Table 1: The performance in the trial session. The numbers in parentheses indicate standard deviation.

	Data	Trial-error	Instance	Imitation
Success rates	0.66	0.00	1.00	1.00
Round	48.42 (13.36)	NA (NA)	72.08 (16.95)	54.50 (15.93)

## Simulation

### Simulation conditions

To explore the cognitive process behind forming a communication system, we set up the following three models controlling the decision strategies presented in Figure 4.

- **Trial-Error model:** This model does not have a decision strategy other than the trial-error strategy. The agent tries to construct a communication system from subsymbolic learning and production compilation.
- **Instance model:** This model, in addition to the trial-error strategy, also has the instance-based strategy. The agent first tries the instance-based strategy. If the instance-based strategy fails, the agent chooses her/his destination and message based on the trial-error strategy.
- **Imitation model:** This model extends the instance model by adding the imitation strategy. The agent first tries to choose her/his destination and message using the instance-based strategy. If the agent fails to retrieve an instance, the imitation strategy is applied. When all other decision strategies fail, the agent uses the trial-error strategy.

By comparing the imitation model with the other two models, we can identify the role of imitation in forming a shared communication system. We also identify the required learning mechanism from the difference between the trial-error model and the other models. Furthermore, by comparing the experimental data, we reveal the features of human communication systems.

In this simulation, each model runs 100 times. In each run, the model continued the trial session for 3,600 sec<sup>4</sup> or until the scores reached 50 points. Following the trial session, the model was engaged in three test sessions similar to the experiment presented in the section 2.

## Results

**Performance of trial session** Table 1 shows the proportion of runs/pairs whose scores reached 50 points, which is a termination condition for the trial session. It also presents the numbers of rounds required to reach the termination condition. All runs with the trial-error models failed to form a communication system whereas all runs with the instance and imitation models succeeded in completing the session. Even though there were some pairs that did not reach the termination condition, the number of rounds required to complete the session in the experiment (data) was smaller than that in the instance and imitation models. Compared to the instance model, the imitation model finished the session in less number of rounds, and the difference in the number of rounds

<sup>4</sup>We used the simulation time estimated by ACT-R.

Figure 5: Performance of three test sessions. Solid lines in the graph indicate the results of the experiment. Error bars and dashed thin lines represent the standard error of means. The dashed thick line indicates chance-level performance (2/9).

Figure 6: Rate of using each symbol. Solid lines in the graph indicate the data obtained in the experiment. Error bars and dashed thin lines represent the standard error of means.

between the experimental data and the imitation model is quite small (i.e., 48.42 and 54.50 respectively, compared with 72.08 in the instance model).

**Performance of tests sessions** Figure 5 presents the results of the three tests. The experimental data reveals significant differences between the three tests. The imitation and the instance models reproduced these differences well. From the difference between  $T_{NM}$  and  $T_{IM}$ , we confirmed that the pairs/models formed effective symbol communication systems. In addition, from the difference between  $T_{SM}$  and  $T_{IM}$ , we confirmed that the pairs/models take turns in transmitting messages. In contrast to the other models/data, we did not observe the differences of the three tests in the trial-error model.

**Messages constructed in the trial session** To examine the messages created in each model/experiment, we first computed the frequency of using each symbol in the trial session. From Figure 6, we can observe the decrease in the frequencies with respect to the order of the figures (see the caption of Figure 1). Using the symbols listed in the earlier order is considered as an adaptive behavior that reduces the time to construct a message. The three models reproduced this behavior. We postulate that this behavior is derived from the activation updating mechanism. As shown in formula 2, activation values are influenced by the frequencies of observing/retrieving chunks. Hence, symbols listed in the earlier order usually receive higher activation values.

We examined this distribution for each participant/agent

Table 2: Indices of sharing when using symbols.

	Data	Trial-error	Instance	Imitation
Single	0.80 (0.25)	0.92 (0.04)	0.76 (0.14)	0.94 (0.07)
Combination	0.63 (0.31)	0.52 (0.19)	0.28 (0.19)	0.84 (0.11)

Table 3: Bias of using symbols.

	Data	Trial-error	Instance	Imitation
Single	0.48 (0.22)	0.07 (0.02)	0.31 (0.12)	0.33 (0.17)
Combination	1.81 (0.48)	0.43 (0.07)	1.43 (0.26)	1.57 (0.30)

and computed symbol sharing indices within pairs. The indices were computed as the dot-product of two unit-vectors that consisted of the frequencies of using each symbol. These indices were computed not only for single symbols (e.g.,  $\blacksquare$ ,  $\blacklozenge$ ) but also for combinations of symbols (e.g.,  $\blacksquare\blacklozenge$ ).

Table 2 shows the computed indices of symbol sharing. The imitation model has the highest indices for both the single symbol and combination of symbols. Conversely, the indices in the instance model are the lowest. This suggests that an agent in the imitation model created an isomorphic symbol system with a partner. The values obtained in the experiment are between those of the instance and imitation model, implying that imitation certainly occurred in the experiment.

The other explanation of the high indices of sharing symbols is that agents/participants chose symbols according to a uniform-distribution. To exclude this possibility, we computed a bias index using the geometric mean of two Kullback-Leibler divergences of the probability distributions  $P$  and  $E$ .

$$B = \sqrt{D_{KL}(P_1||E) \cdot D_{KL}(P_2||E)},$$

$$D_{KL}(P_i||E) = \sum_{n=1}^N P_i(n) \log \frac{P_i(n)}{E}, \quad (3)$$

where  $P_i$  is the probability distribution of the use of symbols of agent/participant  $i$ ,  $E$  is the uniform distribution, and  $N$  is the number of bins of the probability distributions<sup>5</sup>. If the distribution  $P$  deviated from the uniform distribution, the index would increase.

The results are presented in Table 3. The trial-error model, which had the high symbol sharing indices, has the lowest values for both the single symbol and combination of symbols, indicating that the choice made in the trial-error model was less biased. Contrary to the trial-error model, the other two models and the experiment were biased towards using specific symbols, indicating that they communicated with a small number of symbols.

## Discussion and Conclusions

This study constructed a model that forms a new communication system through interactive coordination. To date, many

<sup>5</sup>For the distribution of using a single symbol,  $E = 1/6$  and  $N = 6$ . For the distribution of using a combination of symbols,  $E = 1/36$  and  $N = 36$

models for language evolution have been developed (for a review Steels, 2011). In addition, there exists a research work that uses ACT-R to simulate experiments of forming a communication system (Reitter & Lebiere, 2011). However, these researchers did not deal with a situation with spontaneous turn-taking or role-setting operations. Most of the previous models assign roles to agents, such as director or matcher, using simulation parameters.

Unlike the previous studies, we dealt with a situation where roles are autonomously assigned. In such a situation, agents efficiently develop a shared communication system through a two-way imitation, which uses a single instance in two ways by reversing roles. It reduces trial-errors, and results in a faster forming process as presented in Table 1. In addition, differently from the instance model, the imitation model create an isomorphic symbol system as indicated by Table 2. Summarizing these results, we conclude that with few interactions, imitation can create an isomorphic symbol system.

Moreover, the comparison of the models with the experiment revealed the existence of imitation in the formation of a human communication system. Table 2 showed the apparent difference in the sharing index between the instance model and the experimental data. This result is consistent with previous laboratory experiments, in which participants used similar symbols in pairs through interactions (Fay, Garrod, Roberts, & Swoboda, 2010; Garrod, Fay, Lee, & Oberlander, 2007).

An additional finding was observed from the trial-error model. Unlike the imitation and the instance models, the trial-error model failed to construct a communication system. All models possess a common subsymbolic learning that updates activations of chunks and utilities of compiled productions. Therefore, this difference indicates an advantage of symbolic learning. Our results suggest that subsymbolic learning by itself have a limitation in constructing a communication system. Rather, subsymbolic learning are used to adapt to the structure of the environment as shown in Figure 6. We consider that this adaptivity provides a scaffold for forming a new symbolic communication system (Konno et al., in press).

There are several limitations in this study. We could examine neither the syntax (combination rules of symbols) nor the symbol-meanings mappings. These important features of human communication systems, namely language, are difficult to be captured by simple statistics. We need analysis methods to understand how a new language emerges in an experiment or computer simulation.

To extend our model to more complex situations, the goal buffer of the model should be hierarchically decomposed. The current design of the goal buffer cannot be applied to a complex situation where many symbols are combined. Imitation strategy also needs to include more detailed processes. We believe that the theory of analogical reasoning (Gentner, 1983) can be applied to a model of a complex imitation strategy. There is some previous research that point out that imitation is a type of analogical mapping (Barnes & Thagard,

1997; Thagard, 2001). It is a big challenge for the broad cognitive science community to examine how analogical mapping is changed through symbolic and subsymbolic learning when forming a new language.

# Force Dynamics as a Basis for Moral Intuitions

Jonas Nagel (jnagel1@uni-goettingen.de)

Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)

Department of Psychology, University of Göttingen, Gosslerstr. 14, 37073 Göttingen, Germany

## Abstract

People seamlessly generate moral intuitions about a wide range of events they observe, but to date the cognitive processes underlying this competency are poorly understood. We propose that our moral intuitions are grounded in force-dynamic intuitions. We show how the evaluation of entities engaged in schematized interactions can be predicted from specific force-dynamic properties of those interactions, and we point out how these evaluative tendencies relate to our moral norm of not interfering with others' interests.

**Keywords:** moral judgment; intuition; force dynamics

## A New Theory of Moral Intuitions

Recent moral psychology views intuitions as important determinants of our moral judgments. Haidt (2001) defined moral intuitions as “the sudden appearance in consciousness of a moral judgment, including an affective valence (good-bad, like-dislike), without any conscious awareness of having gone through steps of searching, weighing evidence, or inferring a conclusion” (p. 818). Intuitions are thus mainly defined in contrast to deliberative reasoning.

However, to date there is no worked-out theory of the automatic processes by which our moral intuitions are formed. How do we solve this computational task? Which observed events elicit which specific moral intuitions? In what format are these events represented, and how is this representation automatically integrated with pre-existing evaluative standards? We propose that the semantic category of *force dynamics* (Talmy, 1988) provides a cognitive structure that might serve as a representational basis in this task.

## The Semantic Category of Force Dynamics

Talmy (1988) described force dynamics as a semantic category of how entities interact with respect to force. When two entities interact in the world, our language assigns to them the two thematic roles of *patient* (*P*) and *agent* (*A*). (Talmy uses the terms *agonist* and *antagonist*.) *P*, the focal entity, is perceived to have an intrinsic force tendency either towards rest or towards motion. In force-dynamic interactions, *P* finds itself in opposition to *A*, another entity with the opposed force tendency. *A* is mainly thought of in terms of the effects it has on the resultant force manifested by *P* as outcome of the interaction.

*P*'s resultant force depends on the relative strength of the two opposing forces. If *P*'s force is stronger than *A*'s, then *P*'s resultant force equals its intrinsic tendency. This constellation is expressed in familiar words in our natural language, such as *despite* or *although*. In “The flame [*P*] kept burning despite the wind [*A*] blowing at it,” *P*

manifests its intrinsic tendency (to burn) in spite of the opposing force exerted by *A*.

If *A*'s force is stronger than *P*'s, then *P*'s resultant force is opposed to its intrinsic tendency. There are many words in natural language describing variants of this basic constellation (e.g., *make*, *cause*, or *prevent*). In the sentence “The wind [*A*] made the flame [*P*] go out,” *P* does not manifest its intrinsic tendency (to burn) but the opposite (to go out). Note that both example sentences “are about” *P*, while *A* is mainly relevant in terms of the effect it has on *P*.

Talmy (1988) argues that force dynamics is a fundamental semantic category, profoundly structuring our cognitions in a variety of domains. Whether we deal with the physical, the (intra-)psychic, or the social world, the same basic force-dynamic concepts pervade our language and thought. Thus, force dynamics is conceived as a domain-independent representation underlying intuitions in various domains, not only in the physical domain. Actually it is interesting to see that when force dynamics is applied to physical tasks, the resulting intuitions about forces and intrinsic tendencies seem to be more compatible with our understanding of actions than with Newtonian physics. For example, the intuition that causes have stronger forces than effects is inconsistent with Newtonian physics but seems to be grounded in sensory-motor representations of our actions (White, 2009). Analyzing social interactions in terms of force dynamics is thus not a reduction of the social to the physical domain. Force dynamics is better viewed as a domain-independent *abstract* conceptual framework.

## Force Dynamics as a Basis for Moral Intuitions

The category of force dynamics combines causal and teleological aspects and is abstract enough to be naturally applicable across physical and social domains. These properties make it a promising candidate to serve in the process of enriching representations of observed events with a basic evaluative aspect.

Imagine observing the following event: Jack shoves Jones. In a first step, the observer could abstract the force-dynamic pattern instantiated by this event. This would include assigning *A*- and *P*-roles to the entities involved in the interaction, determining *P*'s intrinsic tendency and resultant force, and comparing the latter two. In this example, this would yield a representation of *A* (Jack) forcing *P* (Jones) to deviate from his intrinsic tendency (toward rest) into a different resultant force (motion). This is an instance of *onset causing of motion* (Talmy, 1988).

In a second step, this abstract representation could be automatically subjected to default normative principles formulated on the same level of abstraction. We stipulate

the existence of a *noninterference principle (NIP)*: By default, *patients should be allowed to manifest their intrinsic tendencies*. This substantive assumption (which has itself a force-dynamic structure) can be motivated with reference to the negative prima facie duty not to interfere with others' interests, which seems to be a fundamental moral norm at least in Western cultures. In *onset causing of motion*, this abstract principle is violated. *P* changes its tendency because of *A*'s impingement.

Finally, the fact that *A* is identified as causing a violation of the principle leads people to evaluate *A* negatively relative to *P*. This negative evaluation is then applied to the concrete observed instance of *A* (in this case, to Jack).

In the current research we focus on basic scenarios with only two protagonists (*A*, *P*). Obviously, there are many more complex instances of *onset causing* patterns in which *A* might eventually be evaluated positively. Imagine you receive the additional information that Jack shoved Jones *out of harm's way*. Such more complex constellations will not be treated here, but it seems that our theory can in principle be extended to handle them as well (e.g., Jack could be evaluated positively for *preventing* another agent [the harm] to violate the NIP by means of intervening on *P*).

In what follows, we will provide initial evidence that such default evaluations are in fact assigned on the abstract level of decontextualized force-dynamic representations. To this end, we had experimental subjects evaluate the movements of two abstract shapes engaged in simple interactions.

### Force Dynamics in Abstract Animated Displays

Displays of moving objects allow for a non-verbal presentation of decontextualized force-dynamic interactions. In the absence of linguistic cues, we first need to explicate the criteria according to which we assume our subjects to abstract force-dynamic patterns from our visual displays (i.e., the first step in the process outlined above).

We instantiated the *onset causing of motion* pattern with a version of the well-known *launching event* (Michotte, 1963; see Fig. 1). A stationary Object Y is situated in the center of the stage. After a moment, another Object X enters the scene from the side and approaches Object Y on a straight line and at constant speed. At the moment of contact, Object X stops and Object Y immediately starts moving as if it was continuing on X's trajectory.

According to our theory, subjects first need to assign agent and patient roles to these interacting entities. We argue that the extremely impoverished nature of this display leaves but three cues to make this assignment: (a) pre-collision movement relative to the position of the other entity; (b) causing change of state in the other entity; and (c) appearing on the scene after the other entity. According to Dowty (1991), the first two cues increase the likelihood that a given entity is assigned the agent role in an interaction. Concerning the third cue, the entity appearing first will likely be seen as the focal entity the display "is about" (i.e., the patient); the second entity should therefore be regarded as agent affecting this focal entity. We assign the agent role

to an entity if it embodies more of these three cues than the alternative entity. In the launching event, Object X's behavior is consistent with all three cues (a+, b+, c+), while Object Y only causes Object X to stop (b+), but does not move initially (a-) and is first on the screen (c-). Object X is therefore assigned the agent role, while Object Y is the patient. There is ample evidence that this analysis is in line with people's qualitative experience of launching events. For example, X is seen as *exerting force on* Y, whereas Y is perceived to merely *exhibit resistance against* X (White, 2009).

Next, subjects need to infer *P*'s intrinsic tendency and resultant force. We assume that in the absence of further contextual cues indicating the presence of external forces, *P*'s pre-collision movement will be regarded as its intrinsic tendency. The identification of *P*'s resultant force with its post-collision movement seems unproblematic.

Finally, *P*'s intrinsic tendency and resultant force need to be compared in order to determine the force-dynamic pattern and to decide whether the NIP was violated, as would be indicated by a change of *P*'s movement as a result of the collision event.

### Hypothesis

With all force-dynamic concepts operationalized, we now turn to the specifics of the hypothesis we tested in the present experiment. We predict that in the *Launch* case described above, which instantiates *onset causing of motion*, subjects asked to evaluate the movements of both entities on a negative/positive dimension will evaluate Object X more negatively than Object Y. We contrast this case with a *Blocked* case which is identical to *Launch* except that Object Y does not start moving on X's trajectory after the collision, so that the interaction ends with both entities at rest in the center of the screen. In this case, X has two agentic cues (a+, b-, c+) while Y has only one (a-, b+, c-). Object Y is thus still the patient, and its intrinsic tendency (rest) is identical to its resultant force (rest). This corresponds to a *despite* pattern in Talmy's (1988) terminology. The NIP is not violated here, so we do *not* expect *A* (Object X) to be rated negatively relative to *P* (Object Y) in this case. Across the cases, we expect *A* to be rated more negatively in *Launch* than in *Blocked*.

Figure 1: Animation of the launching event. Dark sphere = *A*; light sphere = *P*. See text for details.

## Experiment

We divide the presentation of the experiment into two parts. In the first part, we test the hypothesis just explicated. The second part will deal with an additional aspect. However, the data for both parts were gathered within one and the same experiment and from the same subjects. Therefore, we begin by describing the general procedure for the whole experiment before we discuss the specific materials and the results for both parts separately.

### Participants and Procedure

31 undergraduates of the University of Göttingen (23 female, mean age 22 years) participated in a computer-based experiment containing 27 trials in random order.<sup>1</sup> Each trial consisted of three consecutive screens. The first screen displayed the trial number and a button with which the subjects could start the animation. The second screen contained a looped display of one of 27 animations. Each animation started with a fixation cross displayed for one second in the center of the stage. Then the initial state was presented for one second, before the force dynamic interaction began to unfold. The interaction always consisted of a blue sphere and a green sphere moving in specific ways on the same straight horizontal trajectory. After the interaction was finished, the stationary end state remained on the screen for one second. As an example, Figure 1 illustrates how we implemented the *Launch* case described above. Each condition was instantiated in two animations, counterbalanced for color assignment and direction of movement. Subjects watched each animation as often as they wished before they proceeded to the third screen, where two identical 7-point rating scales ranging from “-3 (negative)” to “+3 (positive)” were presented above one another. Each referred to one of the two entities from the animation. The question wording was “How do you evaluate the movement of the blue/green figure?”

### Part 1: Interference with Intrinsic Tendency

**Design and Material** In this part we tested whether people’s intuitive evaluations of the entities in *Launch* and *Blocked* can be predicted from the underlying force dynamics in combination with the noninterference principle (NIP). In the initial state of all animations, *P* was displayed at rest in the center of the stage. The force-dynamic interaction always began with *A* entering from one side and reaching *P* within one second on a straight horizontal trajectory at constant speed. We then manipulated *A*’s and *P*’s post-collision movement which could either be stationary (0), movement continuing *A*’s initial trajectory at half of *A*’s initial speed (1), or movement on the same trajectory at *A*’s full initial speed (2). Both *A* and *P* could display all three movements, with the constraint that *A* could not be faster than *P* after collision because this would imply the objects going through each other. Thus, the

manipulation yielded six conditions which are displayed in Table 1. Conditions 1 and 3 are of main theoretical interest because they manifest the *Blocked* and *Launch* cases to which our main hypothesis refers.

Table 1 also lists several resulting properties of the interactions displayed in each condition. *A\_change* and *P\_change* indicate whether *A* and *P* change their overt tendency in the course of the interaction. *P\_change* is the most important variable for our purpose. Given the pre-collision constellation (i.e., *A* in motion, *P* at rest), as soon as *P* changes its tendency, the case is an instance of *onset causing of motion*, and the NIP is violated. Only if *P* stays stationary, the case becomes an instance of *despite* where the principle is not violated. The remaining properties are further implications of the entities’ post-collision movements. Concordance indicates whether *A* and *P* have a concordant tendency (either of rest or of movement in the same direction) after the collision. Contact indicates whether *A* and *P* remain in direct physical contact after the collision. Finally, Resistance indicates whether *P* displays resistance by not overtaking the pre-collision tendency of *A* in a one-to-one manner. As can be seen in Table 1, this property is not identical to *P\_change*.

Concordance, Contact, and Resistance are listed because they are perfectly confounded with *P\_change* across the two cases of main interest, 1 and 3. Any change in ratings between 1 and 3 could thus just as well be caused by these properties. The remaining four conditions serve to isolate *P\_change* from these confounds.

Table 1: Design of Part 1

Cond	Speed		Resulting properties				
	<i>A</i>	<i>P</i>	<i>A_ch</i>	<i>P_ch</i>	Conc	Cont	Res
1	0	0	1	0	1	1	1
2	0	1	1	1	0	0	1
3	0	2	1	1	0	0	0
4	1	1	1	1	1	1	1
5	1	2	1	1	1	0	0
6	2	2	0	1	1	1	0

*Note.* Cond = condition, Speed = post-collision speed, *A/P\_ch* = *A/P\_change*, Conc = Concordance, Cont = Contact, Res = Resistance. See text for further explanations.

**Specific predictions** Three specific predictions follow directly from our hypothesis. (i) *A* will be rated more negatively than *P* in condition 3 (*Launch*). (ii) *A* will *not* be rated more negatively than *P* in condition 1 (*Blocked*). (iii) *A* will be rated more negatively in 3 than in 1.

The remaining conditions serve to separate the manipulation of the force-dynamic pattern from the properties of Concordance, Contact, and Resistance. If a concordant post-collision tendency is responsible for more positive ratings for *A* in 1 compared to 3, *A*-ratings should also be more positive in 4, 5, and 6. If sustained physical contact is to be made responsible, *A*-ratings should be more positive in 4 and 6. Finally, if the display of resistance by *P* (in not adopting *A*’s pre-collision tendency) is to be made

<sup>1</sup> Three of these 27 trials tested a third hypothesis which is not reported here due to space constraints.

responsible, A-ratings should be more positive in 2 and 4. We predict that none of these alternatives will be the case. Instead, we expect (iv) all control cases to be treated like 3 since they all conform to the *onset causing of motion* pattern. This result would support our hypothesis that the evaluative ratings in 1 (*Blocked*) and 3 (*Launch*) are in fact a function of the underlying force-dynamic pattern as indicated by the variable  $P\_change$ .

**Results and Discussion** The descriptive results are displayed in Figure 2. A global 6 (Condition: 1 to 6)  $\times$  2 (Entity: A vs. P) repeated-measures ANOVA yielded a main effect for Entity ( $F_{1,30} = 9.57$ ;  $p < .01$ ,  $\eta_p^2 = .24$ ), indicating that, across conditions, A was rated more negatively than P. More importantly, the Condition  $\times$  Entity interaction term was significant ( $F_{5,150} = 9.69$ ;  $p < .001$ ,  $\eta_p^2 = .24$ ), showing that A and P were treated differently across conditions. We now turn to the contrasts testing our specific predictions.

(i): In 3 (*Launch*), A-ratings were lower than the P-ratings ( $t_{30} = -3.68$ ,  $p < .001$ ,  $d = -.66$ ). A is thus rated more negatively than P in the launching event as paradigmatic instance of the *onset causing of motion* pattern violating the NIP.

(ii): In 1 (*Blocked*), A-ratings were *higher* than P-ratings ( $t_{30} = 3.63$ ,  $p < .01$ ,  $d = .65$ ). Thus, it seems that A's negative evaluation disappears with an underlying *despite* pattern in which the NIP is not violated. The significant drop in P-ratings was not expected because our predictions only concerned A-ratings. One post-hoc explanation for this phenomenon might be that the agent-patient distinction is not as clear cut in this case as in the *Launch* case (i.e., the agentic cues are distributed more evenly across both entities). Maybe some participants interpreted P as agent due to its capacity to cause change in A, turning the interaction into an *onset causing of rest* pattern (Talmy, 1988) in which P (now the agent) violates the NIP by forcing A (now the patient) to deviate from its intrinsic tendency to motion into a resultant state of rest.

(iii): A-ratings in 1 were higher than those in 3 ( $t_{30} = 3.27$ ,  $p < .01$ ,  $d = .59$ ). Our hypothesis is thus confirmed by comparisons between entities within cases and across cases with different underlying force-dynamic patterns.

Figure 2: Results of Part 1. Error Bars = 95% CI.

(iv): The significant increase in A-ratings only occurred in 1, while, as predicted, the four control conditions generally behaved like 3 (*Launch*). The only exception is condition 4, where the A-ratings were not significantly lower than the P-ratings (although the descriptive trend still holds,  $t_{30} = -1.31$ ). Furthermore, across all six conditions, there seems to be a trend for concordant post-collision movement (i.e., 1, 4, 5, and 6) to yield slightly higher A-ratings than discordant post-collision movement ( $t_{30} = 2.26$ ,  $p < .05$ ,  $d = .41$ ). This might indicate that Concordance is used as an additional cue for the evaluation of A. However, note that this effect is driven mainly by the selective increase of A-ratings in 1 (*Blocked*).

In sum, these findings demonstrate that in clear-cut cases of *onset causing of motion* such as 3 (*Launch*), agents are evaluated more negatively than patients. This is not the case in *despite* cases in which the NIP is not violated. Together, these findings show that people's evaluations of movements are sensitive to underlying force-dynamic patterns. Entities are by default evaluated negatively if they cause other entities to deviate from their intrinsic tendency. This result is consistent with the moral norm in our society to not force others into states in which they would not enter on their own.

## Part 2: Prior Concordance

In this part we will test whether the default evaluations we have discovered are robust enough to be consistently applied to cases in which P is initially not at rest but rather in motion. Imagine a moving P colliding with a faster-moving A, changing the speed and/or direction of its movement after the collision. According to our criteria, P's intrinsic tendency would be to move in exactly the manner manifested prior to collision (including direction and speed parameters). A should thus be identified as causing P to deviate from its intrinsic tendency which constitutes a violation of the noninterference principle (NIP).

Crucially, this should be the case regardless of whether P and A exhibit concordant or discordant pre-collision movement. The direction of forces is not represented in Talmy's (1988) framework so that two entities moving on the same trajectory at different speed are still conceptualized as being in opposition (contrary to Wolff, 2007; see General Discussion). Note that without reference to Talmy's framework of opposing forces it seems a priori plausible that the concordant and discordant cases will be conceptualized differently. Specifically, in the concordant case it may seem as if the faster A *enhances* the slower P in its tendency which could result in A being evaluated positively for "helping" P. According to our theory, however, this should not be the case. If people's default evaluations correspond to Talmy's framework and the NIP, then they should be insensitive to prior concordance: They should evaluate an A making P go faster into the direction of its initial movement similarly to an A making P go into the opposite direction of its initial movement. Both cases violate the NIP.

**Design and Material** The initial state of all animations was an empty stage. After one second, *P* entered the stage from one side at a constant speed on a straight horizontal trajectory, reaching the center of the stage after two seconds. One second after *P*'s appearance, *A* entered the stage at twice the speed of *P*, either from the same side (concordant condition, C+) or from the opposite side (discordant condition, C-). Consequently, in both conditions the collision of *A* and *P* took place in the center of the screen, one second after *A*'s appearance. After the collision, both entities moved in the direction of *A*'s initial movement in all conditions. This implies that in C+, *P* continued in the direction of its initial movement, while in C- it reversed the direction of movement. Similar as in Part 1, we manipulated the post-collision speed of both entities, which could be the initial speed of *P* (1) or *A* (2). Again, *P* had to be at least as fast as *A* after the collision. This yielded three Speed conditions crossed with the two Concordance conditions, resulting in the six experimental conditions summarized in Table 2. Concerning the definition of agentic cues, we refined the criterion of pre-collision movement (a, see above) to *faster* pre-collision movement relative to the other entity. As in Part 1, *A* exhibits at least one more cue for agency than *P* in all conditions.

Table 2: Design of Part 2

Cond	Conc	Speed		Resulting Properties		Cont	Res
		A	P	A_ch	P_ch		
C+1	1	1	1	1	0	1	1
C+2	1	1	2	1	1	0	0
C+3	1	2	2	0	1	1	0
C-1	0	1	1	1	1	1	1
C-2	0	1	2	1	1	0	0
C-3	0	2	2	0	1	1	0

Note. Cond = Condition, Conc = pre-collision Concordance, Speed = post-collision speed, A/P\_ch = A/P\_change, Cont = Contact, Res = Resistance.

**Specific Predictions** (i) Straightforward predictions arise from our model for the evaluation of *A* in all three C- cases. The reversal of *P*'s direction of movement caused by *A* is a clear violation of the NIP which should lead subjects to evaluate *A* negatively relative to *P*.

(ii) Case C+1 is an instantiation of *despite* in which *P* continues manifesting its intrinsic tendency after the collision. *A* should not be evaluated negatively relative to *P* since the NIP is not violated.

(iii) The crucial new conditions are C+2 and C+3. Here, subjects encounter a violation of the NIP preceded by concordant pre-collision movement. *P* is thus merely caused to deviate from its intrinsic (slow) speed, but not to deviate from its intrinsic direction. This could in principle lead subjects to conceptualize *A* as helping *P* to advance faster on its path. However, our theory predicts that subjects will still evaluate *A* negatively for causing a violation of the NIP. The *A*-ratings should also not differ from the *A*-ratings in the C- conditions.

**Results and Discussion** The descriptive results are displayed in Figure 3. A global 2 (Concordance: C+ vs. C-)  $\times$  3 (Speed: 1 to 3)  $\times$  2 (Entity: *A* vs. *P*) repeated-measures ANOVA yielded a main effect for Concordance ( $F_{1,30} = 19.10$ ;  $p < .001$ ,  $\eta_p^2 = .39$ ), indicating that both entities were generally rated more negatively in C- than in C+. Again there was a main effect for Entity ( $F_{1,30} = 28.90$ ;  $p < .001$ ,  $\eta_p^2 = .49$ ), indicating that *A* was generally rated more negatively than *P*. Finally, the Speed  $\times$  Entity and the Speed  $\times$  Concordance interaction terms were significant ( $F_{1,30} = 7.08$ ;  $p < .01$ ,  $\eta_p^2 = .19$ , and  $F_{1,30} = 4.07$ ;  $p < .05$ ,  $\eta_p^2 = .12$ , respectively), showing that post-collision movements of *A* and *P* affected *A*- and *P*-ratings differentially, and that they also had different effects depending on the prior concordance of both entities.

(i) *A*-ratings in the three C- conditions are lower than the respective *P*-ratings ( $t_{30} = -4.02$ ,  $p < .001$ ,  $d = -.72$ ), replicating the result of Part 1 that *A* receives negative evaluations when it clearly violates the NIP.

(ii) *A*-ratings in C+1 are not different from the *P*-ratings in the same condition ( $t_{30} = -.97$ ,  $p = .34$ ). As expected, *A* is again not evaluated negatively if it does not interfere with *P*'s intrinsic tendency.

(iii) *A*-ratings in C+2 and C+3 are lower than the respective *P*-ratings ( $t_{30} = -5.81$ ,  $p < .001$ ,  $d = -1.04$ ), while they do not differ significantly from the *A*-ratings in the C- conditions ( $t_{30} = 1.44$ ,  $p = .16$ ). Both results indicate that our subjects evaluated the concordant cases according to the same principles of opposing force-dynamics that they used in discordant cases, as predicted by our model. As soon as *A* violated the NIP, it was evaluated negatively, regardless of whether *P* was forced to reverse direction of movement or merely to continue faster on its original trajectory.

## General Discussion

In this paper, we have argued that the semantic category of force dynamics (Talmy, 1988) provides a cognitive structure underlying our moral intuitions. We provided evidence that various evaluations of content-free interacting entities can be predicted from force-dynamic properties in combination with a single normative principle (NIP) that

Figure 3: Results of Part 2. Error Bars = 95% CI.

expresses our *prima facie* moral norm not to interfere with others' interests. We thus propose that force dynamics might be part of the missing link between the apprehension of a situation and the automatic generation of a moral intuition. Observed events activate an abstract representation of the force-dynamic pattern which they instantiate. This representation is subjected to a basic normative principle, yielding default evaluative tendencies that are automatically applied to the participants of the observed interaction. We do not claim that the output of this process already represents a full-blown moral intuition. The automatically generated resulting representation could constitute a building block serving as input for higher-level processes (e.g., contextual analysis, inferences from other cues, background knowledge, application of exceptions, etc.) that eventually lead to rich, conscious moral intuitions.

Of course, the present study is only an encouraging first step in our research endeavor. So far we have only demonstrated an association between some force-dynamic patterns and explicit evaluations under maximally impoverished context conditions. It needs yet to be shown that the observed force-dynamic interactions also spontaneously elicit basic evaluations when no explicit test questions are given that request moral evaluations.

It may be seen as problematic that our model does not differentiate between animate and inanimate entities, contrary to many other theories in the field (e.g., Carey, 2009). Instead, our proposal is that force dynamic intuitions underlie event representation across domains as an abstract common code. If we are correct that basic evaluations are automatically elicited on this level of abstraction, this implies that observing one billiard ball launching another should elicit the same evaluative tendencies as observing Jack pushing Jones. Note, for example, that our displays contained no cues to animacy (such as self-propelled motion), and yet evaluations consistent with our model were observed. The postulation of a common code eliciting basic intuitions in both physical and social domains does not rule out that people use additional cues to differentiate between animate and inanimate entities (see Hamlin & Wynn, 2011, for evidence with infants). Force dynamics does not postulate that our representations of physics and psychology are *exhaustively* characterized as interplay of interacting forces. Additional semantic knowledge may of course enrich the force dynamic representation.

A related concern is that our model does not seem to capture all moral intuitions. A force-dynamic analysis of Jack lying to Jones, for example, will probably be less straightforward. We are aware that the practice of our moral judgment is very intricate and involves more considerations than those touched upon here. Our claim is thus not to provide a comprehensive theory of our moral intuitions. However, note that the range of intuitions our approach *does* potentially capture seems remarkable given its simplicity. The abstract nature of force dynamics makes it applicable to heterogeneous morally relevant events (e.g., dictators *oppressing* their people, people *resisting* temptations, etc.).

Another limitation of our approach is that it only predicts evaluations of agents. Yet, patient ratings also varied across our experimental conditions, sometimes independently from agent ratings. This might suggest that additional inferences are drawn from our stimuli which are not captured by our model.

Result (iii) of Part 2 suggests that the default conceptualization of force-related interactions is one of antagonism. It is likely that this default can quite easily be overridden if additional contextual cues are available that activate concepts of cooperation. Wolff (2007), for example, investigated cases in which *P* initially approaches a specific end state and *A* exerts a concordant force on *P*, resulting in *P* reaching the end state more quickly. Such displays reliably elicited concepts of *enable* or *help* in which *A* would presumably receive positive evaluations. We would predict that if a salient end state was provided in our displays, the default conceptualization of *P*'s intrinsic tendency might be replaced by a higher-level goal-directed conceptualization in which *P*'s intrinsic tendency would be *to reach the end state*. Once this more abstract intrinsic tendency would be attributed to *P*, the NIP would no longer be violated. Future studies will need to test these and related predictions for more complex structures with more than two protagonists.

## Abstract

Previous studies reported that language comprehenders tend to preserve the initial incorrect analysis with temporarily ambiguous sentences following structural reanalysis (Christianson et al., 2001; van Gompel et al., 2006). One possible criticism is that the sentences tested in previous studies allow comprehenders to pragmatically infer that the initial misanalysis may be true. It is thus unclear whether the tendency can still be observed where such inferences are not possible. The current study therefore tested the relative clause sentences in Japanese, which are temporarily ambiguous between the main clause and relative clause analysis. Crucially, our sentences differed from those in the past studies in that the correct interpretation following reanalysis makes an interpretation for the initial analysis pragmatically incompatible. The results demonstrated that an interpretation for the initial analysis persists even without pragmatic inference and that such incomplete syntactic representations are most likely due to excessive processing load.

**Keywords:** good-enough representation; garden-path sentence; self-paced reading; eye-tracking; reading

## Introduction

It is known that structurally ambiguous sentences such as *While the man hunted the deer ran into the woods* cause readers to experience difficulty at the point where the structure is disambiguated (i.e., *ran*), which indicates that they initially adopted an incorrect analysis (i.e., the transitive analysis). Past research showed that in processing this type of ambiguous sentences, language comprehenders tend to preserve an interpretation of the initial incorrect analysis even after the structure was fully reanalyzed and they often end up with incomplete, or so-called *good-enough* sentence representations (Christianson, Hollingworth, Halliwell, & Ferreira, 2001; Ferreira, Bailey & Ferraro, 2002). In Christianson et al. (2001), for instance, participants read sentences like (1) and were next shown comprehension questions like (2). Their results showed that participants often answered incorrectly by responding “yes”. Christianson et al. (2001) argued that the reanalysis of ambiguous sentence structures is not always complete and the initial incorrect analysis often remains preserved and not fully suppressed.

- (1) While Anna dressed the baby spit up on the bed.  
(2) Did Anna dress the baby?

However, in their study as well as their follow-up studies (e.g., Christianson, Williams, Zacks, & Ferreira, 2006; Ferreira et al., 2002 for the review), it is arguable that the initial incorrect analysis, even though it was suppressed following reanalysis, may have been re-activated by processing the question sentences. Another criticism for their argument of incomplete representations is an influence of pragmatic inference. For example, even with their items with reflexive verbs such as (1), it is still possible to infer that the baby spit up while being dressed by Anna even though such an interpretation is not syntactically licensed. The first issue was addressed by van Gompel, Pickering, Pearson, and Jacob (2006), who reported an effect of syntactic priming for the initial incorrect analysis. In their study, participants first read a prime sentence that was either structurally ambiguous (3a) or unambiguous with a comma following the subordinate clause verb (3b). Next, they completed a sentence fragment such as *When the doctor was visiti....*

- (3a) While the man was visiting the children played outside.  
(3b) While the man was visiting, the children played outside.

Their results showed that participants produced more transitive sentences following (3a) than following (3b), providing evidence that the initial incorrect analysis remained activated. However again it is possible to infer that in the example (3a) the man was visiting the children who played outside. It is therefore unclear from previous studies that the initial incorrect analysis would still remain activated and its interpretation would persist even where such pragmatic inferences are not possible.

To address this issue, the current study tested Japanese relative clause structure such as (4).

- (4) *Akachan-ga nomimono-o koboshita joyuu-o jitto mitusmeta.*  
Subject [RC object RC verb] RC head adverb MC verb  
Baby-NOM [drink-ACC spilled] actress-ACC fixedly stared at  
'The baby stared fixedly at the actress who spilled the drink.'

In Japanese, relative clauses precede lexical heads without an overt complementizer and without any grammatical marking on the verb. This creates local syntactic ambiguity up to the first verb (*koboshita*, 'spilled'); on hearing the verb, the structure is ambiguous between a main clause (MC, henceforth) and a relative clause (RC). It is known that people initially analyze the first verb as a part of MC and construct a sentence representation of the sentence-initial

NP (*akachan*, ‘baby’) to be the agent-subject of the verb, as in (4a). Upon encountering another noun phrase (NP) following the verb (i.e., *joyuu*, ‘actress’), readers are forced to reanalyze for a correct syntactic structure that the initial verb phrase is a part of an embedded RC that modifies the RC-head NP (4b).

- (4a) [*Akachan-ga nomimono-o koboshita*]  
 (4b) *Akachan-ga [nomimono-o koboshita] joyuu-o*

Crucially, the correct interpretation following reanalysis with Japanese RC sentences makes the interpretation of the initial misanalysis pragmatically incompatible. For the example (4), it is impossible to infer that the baby spilled milk after readers correctly reanalyze the structure. This is because Japanese RC structure does not include an implicit argument and therefore there is no ambiguity about who did the spilling action after reanalysis. On the other hand, English sentences in previous studies always included an implicit argument for the verb, which created ambiguity about the direct object.

Using this structure, we manipulated semantic bias of the direct object noun within the RC. Past research demonstrated that readers integrate non-structural information without delay in processing similar ambiguous sentences (e.g., McRae, Spivey-Knowlton, & Tanenhaus, 1998; Garnsey, Pearlmuter, Myers, & Lotocky, 1997). McRae et al. (1998) showed that when a subject noun is plausible as patient but implausible as agent (e.g., *The crook arrested by the detective was guilty...*), readers were more likely to consider the infrequent RC structure on encountering the verb and the preposition *by* within the RC. Also, Garnsey et al. (1997) demonstrated that plausibility of post-verbal nouns as a direct object immediately affected the processing of temporary ambiguous sentence complement sentences (e.g., *The senior senator regretted the decision/reporter had ever...*). Importantly, the plausibility effect interacted with structural bias of individual verbs; when the verb was biased toward the sentence complement, there was no ambiguity cost irrespective of whether the post-verbal noun was plausible as a direct object or not. These results indicate that the verb introduces possible thematic roles within its event semantics and readers check the fit with those roles for each candidate phrase and assess the probabilities of possible structures. Importantly, as Garnsey et al. (1997) suggests, the verb bias appears to exert a stronger influence than the thematic-fit of postverbal elements in English.

On the other hand, in Japanese, the semantics of any arguments may affect parsing since the head does not appear until the end of a clause/sentence. This is rather likely as many studies now demonstrated evidence for pre-head structural analysis (Kamide, Altmann, & Haywood, 2003; Miyamoto, 2002). In fact, Inoue (2006) observed greater processing difficulty with similar RC sentences when the subject noun was biased toward the MC analysis than when it was not. In the present study, we adopted a similar manipulation on the RC direct object and examine whether the preservation of the initial incorrect analysis would be observed where there is no room for pragmatic inference

and, if it is, whether the difference in processing difficulty due to the manipulation of semantic bias would in any way be related to the tendency to preserve the initial analysis.

## Experiment 1

We conducted a moving window self-paced reading experiment with word-by-word presentation.

### Participants

Twenty-four native speakers of Japanese, recruited from the student community at the University of Tokyo, participated in the experiment in exchange for small remuneration.

### Materials

We created 24 sets of experimental items such as (5). We manipulated semantic bias of the direct object for the two alternative analyses at three levels; *MC-biased* (the RC object is biased toward the MC analysis, 5a), *Neutral* (the RC object is neutral toward either the MC and the RC analysis, 5b), and *RC-biased* (the RC object is biased toward the RC analysis, 5c).

#### (5a) *MC-biased*

*Akachan-ga miruku-o koboshita joyuu-o jitto mitusmeta.*  
 Baby-NOM [milk-ACC spilled] actress-ACC fixedly stared at  
 ‘The baby stared at the actress who spilled the milk.’

#### (5b) *Neutral*

*Akachan-ga nomimono-o koboshita joyuu-o jitto mitusmeta.*  
 ‘The baby stared at the actress who spilled the drink.’

#### (5c) *RC-biased*

*Akachan-ga shanpan-o koboshita joyuu-o jitto mitusmeta.*  
 ‘The baby stared at the actress who spilled the champagne.’

If the manipulation of semantic bias has an influence on processing the RC sentences before the RC head is encountered, the sentences in the MC-biased condition and the Neutral condition should initially be analyzed as a MC and exhibit processing difficulty at the disambiguating region. People may commit more strongly to the MC with the former condition than the latter condition because the MC analysis is highly plausible. In contrast, the sentences in the RC-biased condition may be initially analyzed as a RC or be reanalyzed easier because of the MC analysis is less plausible and the RC analysis is highly plausible.

### Design

Three experimental lists were created using a Latin square design, in which each experimental item appears only once in one condition in each list. Each list contained 72 fillers. The comprehension questions followed all the 24 experimental items and 72 fillers. All the questions following the experimental items inquired about the agent of the event denoted by the relative clauses with two options shown below the questions (e.g., *Who spilled the milk? BABY / ACTRESS* for (5a)).

## Procedure

Before each trial, participants saw a star that appeared on the left edge of the screen. They then pressed the space bar to reveal the first word in the sentence. They pressed the space bar to reveal the next word, following which the previous one was masked again. They continued doing so until they reached the end of the sentence. The experimental session began with two practice items.

## Results

**Reading Times** We removed all trials including a region with a reading time that was either extremely long (8000 ms or over) or extremely short (250 ms or under) (Sturt, Pickering, & Crocker, 1999). This resulted in the exclusion of 5.0% of the whole data. For the remaining data, all reading times over 2.5 standard deviations either side of the mean for each participant and each region were replaced with the cut-off value (Sturt, Pickering & Crocker, 1999). We analyzed the reading times using Linear Mixed Effects models (e.g., Baayen, 2008; Baayen, Davidson, & Bates, 2008), including Semantic Bias as a fixed effect with Number of Characters as a covariate. We also included participants and items as random effects. Furthermore, we checked whether the model improved its fit by adding random slopes for each participant and item with a forward-selection approach. Figure 1 shows the mean reading times in the disambiguating region; the RC head (e.g., actress-ACC) per condition.

Figure 1: Mean reading times for each condition (Experiment 1). Error bars denote 95% confidence intervals.

The analysis on the reading time in the disambiguating region revealed significant differences between the conditions. In the RC-biased condition, the disambiguating region was read faster compared to the other two conditions ( $\beta = -217.9$ ,  $t = 2.94$ ,  $p < 0.01$  for RC biased vs. MC biased;  $\beta = -245.9$ ,  $t = 3.33$ ,  $p < 0.01$  for RC biased vs. Neutral). There was no difference between the MC-biased and the Neutral conditions ( $t < 1$ ).

**Comprehension Accuracy** Table 1 shows the percentage of correct answers for comprehension questions. We analyzed the log-odd of correct answers using LME models with a binomial function following the same model selection procedure as for the reading time analysis.

The results showed no difference between the conditions ( $z < 1$  for MC-biased vs. Neutral;  $\beta = 0.03$ ,  $z = 1.50$ ,  $p =$

0.13 for MC-biased vs. RC-biased,  $\beta = -1.49$ ,  $z = 1.66$ ,  $p = 0.10$  for RC-biased vs. Neutral).

Table 1: Percentage of Correct Answers for the Comprehension Questions.

MC-biased	96.1%
Neutral	95.6%
RC-biased	98.9%

## Experiment 2

In Experiment 1, we observed a difference in reading times due to bias of the RC direct object but failed to observe its effect on the responses to the comprehension questions. One possibility for this is that processing of the RC structure may have been relatively easy despite the difference in the reading times (i.e., a ceiling effect). In Experiment 2, we thus used sentences with the longer ambiguous region in an effort to increase the processing cost by leading participants to commit to the MC analysis for a prolonged period.

## Participants

Thirty native speakers of Japanese were recruited from the same population as in Experiment 1. None of them participated in the previous experiment.

## Materials, Design, and Procedure

The material and design were identical to those in Experiment 1, except that we added two adverbial phrases (underlined) to lengthen the ambiguous region in the relative clause as in (6).

(6a, b, c) MC-biased / Neutral / RC-biased

*Akachan-ga miruku / drink / shanpan-o te-buru-de hade-ni koboshita joyuu-o jitto mitusmeta.*

‘The baby stared at the actress who spilled the milk / drink / champagne wildly on the table.’

## Results

The reading time at the disambiguating region and the responses to the comprehension questions were analyzed following the same procedure as in Experiment 1.

**Reading Times** Figure 2 shows the mean reading time in the disambiguating region; the RC head (e.g., actress-ACC) for each condition.

Figure 2: Mean reading times for each condition (Experiment 2). Error bars denote 95% confidence intervals.

We removed invalid trials with the same criteria as Experiment 1, which resulted in exclusion of 8.3% of the whole data. The results showed that the reading time in the disambiguating region was significantly longer in the MC-biased and Neutral conditions compared to that in the RC-biased condition ( $\beta = -108.78$ ,  $t = 3.63$ ,  $p < .001$  for RC-biased vs. MC-biased;  $\beta = -83.78$ ,  $t = 2.78$ ,  $p < 0.01$  for RC-biased vs. Neutral). There was no difference between the MC-biased and Neutral conditions ( $t < 1$ ).

**Comprehension Accuracy** Table 2 shows the percentage of correct answers for the comprehension questions in Experiment 2. The analysis revealed that participants answered more incorrectly in MC-biased condition than in RC-biased condition ( $\beta = -1.17$ ,  $z = 2.11$ ,  $p < 0.05$ ). No significant difference was observed between the Neutral and RC-biased conditions ( $\beta = 0.94$ ,  $z = 1.64$ ,  $p = 0.10$ ), or between the MC-biased and Neutral conditions ( $z < 1$ ). The results demonstrate that when the RC direct object was biased toward the MC and the RC was relatively long, participants tended to preserve the initial incorrect analysis compared to when it was biased toward the RC. The Neutral condition showed a similar pattern to the MC-biased condition, which may suggest that the difference in plausibility for the RC interpretation (i.e., champagne or drink for an actress) did not influence the persistence of the initial analysis. However, the effect was weaker and did not turn out to be fully significant.

Table 2: Percentage of Correct Answers for the Comprehension Questions

MC-biased	92.9%
Neutral	93.8%
RC-biased	97.1%

### Experiment 3

Experiment 2 revealed both the difference in reading time and that in question accuracy, suggesting that preservation of the initial analysis is related to the processing cost. However, the results from Experiment 1, which showed only the difference in reading time, are inconsistent with this. Since the semantic bias and the length of ambiguous region were not tested in a single experiment, it is not clear if the processing cost was any greater in Experiment 2 than 1. Thus, in the next experiment, we crossed the two factors to examine the interaction of the two manipulations. Also, since people could not make any regressions to earlier regions with the self-paced reading task and it is arguable that people may have adopted some task-specific strategy to deal with the structural ambiguity. The next experiment therefore examined eye-movements in normal reading of these sentences. In this experiment, we focus on the interaction between the semantic bias and clause length and its influence on processing cost. We did not include comprehension questions as unrestrained regressive eye-movements make it unlikely to find a subtle difference in response accuracy.

### Participants

Twenty-eight native speakers of Japanese were recruited from the same population as in experiment 1 and 2. None of them participated in the previous experiments.

### Materials and Design

We created 24 sets of experimental items such as (6) with a  $2 \times 2$  design (Semantic Bias [*MC-biased*, *RC-biased*])  $\times$  RC Length [*Short RC*, *Long RC*]). For the analysis, each sentence was divided into six regions as shown below, separated by vertical lines (|).

#### (6a) MC-biased + Short RC

Akachan-ga | miruku-o | koboshita | joyuu-o | jitto | mitusmeta.  
'The baby stared at the actress who spilled the milk.'

#### (6b) MC-biased + Long RC

Akachan-ga | miruku-o | te-buru-de hade-ni koboshita | joyuu-o | jitto | mitusmeta.  
'The baby stared at the actress who spilled the milk wildly on the table.'

#### (6c) RC-biased + Short RC

Akachan-ga | shanpan-o | koboshita | joyuu-o | jitto | mitusmeta.  
'The baby stared at the actress who spilled the champagne.'

#### (6d) RC-biased + Long RC

Akachan-ga | shanpan-o | te-buru-de hade-ni koboshita | joyuu-o | jitto | mitusmeta.  
'The baby stared at the actress who spilled the champagne wildly on the table.'

### Procedure

Four lists of items were created following Latin square design. Each list included 72 fillers and was presented in pseudo-random order. The eye-movements were recorded using Eye-link II (SR Research) at the sampling rate of 500 Hz. Participants first underwent a brief calibration procedure. Before each trial, participants were required to fixate a square box that appeared in the position of the first character of the sentences, which triggered the presentation of sentences. They pressed the space bar when they finished reading each sentence. Thirty-two comprehension questions were included to keep the participants focused.

### Results

We removed fixations that were either extremely long (1200 ms or over) or extremely short (80 ms or under). For statistical analysis, we focus on two eye-movement measures; first-pass reading times and second-pass reading times. *First-pass reading times* are the sum of the fixations in the region following the first entry in the region until the first fixation outside the region (either to the left or the right). *Second-pass reading times* are the sum of fixations made in a region after the region has already been exited to the right. The former measure did not include trials when the region was skipped (i.e., the value of zero) whereas the latter measure did. It is generally assumed that first-pass reading times reflect the early stage of processing and second-pass the late stage. Table 3 shows mean reading

times from Region 2 to Region 5 per condition. In the LME model, we included Semantic Bias (MC-biased vs. RC-biased) and RC Length (short RC vs. long RC) as well as the interaction of the two factors as fixed factors, and participants and items as random factors. Random slopes of the two fixed factors and of the interaction were included for participants and items.

**First-pass reading times** In Region 2, there was an effect of Semantic Bias ( $\beta = 29.2$ ,  $t = 3.64$ ,  $p < 0.001$ ). Participants read this region slower with the sentences in the RC-biased than in the MC-biased condition. In Region 3, we found an effect of RC Length ( $\beta = 22.6$ ,  $t = 10.86$ ,  $p < 0.001$ ), which simply reflects that the longer region took longer to read. In Region 5, which is the *spill-over* region following the disambiguating phrase, there was an interaction between the two factors ( $\beta = 19.2$ ,  $t = 3.21$ ,  $p < 0.01$ ). Further analysis on the effect of Semantic Bias for each level of RC Length showed that the two simple effects were in the opposite direction and were both marginally significant ( $\beta = -19.2$ ,  $t = 1.93$ ,  $p = 0.06$  for Short RC condition;  $\beta = 18.7$ ,  $t = 9.93$ ,  $p = 0.07$  for Long RC condition); Participants tended to read this region faster in the MC-biased than in the RC-biased condition when the RC was long, but they did slower in RC-biased condition than in MC-biased condition when the RC was short. In fact, the mean fast-pass time in the MC-biased and long RC condition was shortest across conditions and this appears *prima facie* at odds with our prediction. However, an additional analysis on the regression-out rate (the probability of regressive eye-movements) revealed that participants made the highest rate of regressive eye-movements in this region in MC-biased + Long RC

condition (0.42). The analysis with the LME model showed an effect of Semantic Bias ( $\beta = 0.5$ ,  $z = 4.59$ ,  $p < 0.001$ ) showing that there were more regressions in the Long RC condition than in the Short RC condition. There also was a marginally significant effect of Semantic Bias ( $\beta = -0.2$ ,  $z = 1.88$ ,  $p = 0.06$ ), showing that there was more regressions in the MC-biased condition than in the RC-biased condition. This indicates that the shortest first-pass time in the MC-biased + Long RC condition was not a reflection of reduced processing difficulty but on the contrary it reflected the excessive processing difficulty that forced participants to immediately regress to the previous region for reanalysis.

**Second-pass reading times** In Region 2, there was a main effect of RC Length ( $\beta = 61.2$ ,  $t = 4.65$ ,  $p < 0.001$ ). This suggests that in this region participants experienced greater cost for reanalysis when the RC was long than it was short. From Region 3 to Region 5, there were effects of Semantic Bias ( $\beta = -136.9$ ,  $t = 3.41$ ,  $p < 0.01$  in Region 3;  $\beta = -37.9$ ,  $t = 3.22$ ,  $p < 0.01$  in Region 4;  $\beta = -44.2$ ,  $t = 3.60$ ,  $p < 0.001$  in Region 5) and those of RC Length although that in Region 5 was marginal ( $\beta = 455.1$ ,  $t = 8.67$ ,  $p < 0.001$  in Region 3;  $\beta = 36.0$ ,  $t = 3.32$ ,  $p < 0.05$  in Region 4;  $\beta = -41.2$ ,  $t = 3.46$ ,  $p = 0.07$  in Region 5). This suggests that in these regions participants experienced greater cost for reanalysis when the RC direct object was biased toward the MC than when it was toward the RC and also did so when the RC was long than when it was short. Importantly, there was an interaction between the two factors in Region 3 ( $\beta = -86.8$ ,  $t = 2.35$ ,  $p < 0.05$ ). Further analysis revealed that the effect of Semantic Bias was larger when the RC was long ( $\beta = -224.9$ ,  $t = 3.63$ ,  $p < 0.001$ ) compared to when it was short ( $\beta = -50.9$ ,  $t = 2.41$ ,  $p < 0.05$ ).

Table 3: Mean reading times for first-pass and second-pass.

	Region 2 (milk/champagne-ACC)	Region 3* (spilled (wildly on the table))	Region 4 (actress-ACC)	Region 5 (fixedly)
<i>First-pass reading time</i>				
MC-biased + short relative clause	283	260 (56)	262	316
MC-biased + long relative clause	288	701 (54)	265	275
RC-biased + short relative clause	330	283 (62)	283	278
RC-biased + long relative clause	356	735 (57)	265	313
<i>Second-pass reading time</i>				
MC-biased + short relative clause	337	353 (78)	253	239
MC-biased + long relative clause	464	1462 (116)	329	331

RC-biased + long relative clause	403	1006 (79)	249	244

\*Region 3 differs in the number of words across conditions, so that the reading time per character is provided in brackets.

## General Discussion

Experiment 1 showed that participants experienced greater difficulty at the disambiguating information when the direct object in the relative clause was biased toward the main clause compared to when it was toward the relative clause. However, there was no effect of the manipulation on the

responses to comprehension questions. Experiment 2 showed the same pattern of results for reading times when the relative clause was lengthened. Importantly, the results from the comprehension questions showed the effect of semantic biases; participants responded less accurately when the direct object was biased toward the main clause compared to when it was toward the relative clause. In

Experiment 3, the results of eye-tracking reading data showed participants had more difficulty for reanalysis when the direct object was biased toward the main clause than when it was toward the relative clause. It also showed that the reanalysis cost was greater when the relative clause was longer than when it was short. Importantly, the effect of semantic biases was larger when the relative clause was long than when it was short. The results taken together provided evidence that the initial incorrect analysis persisted even in absence of pragmatic inference and that it is related to how much people commit to the initial analysis and how much difficulty they experience for reanalysis. We argue that our results are consistent with previous studies in English which showed that the more committed readers were to the initial analysis, the more difficulty they experienced in reanalysis (i.e., “digging-in” effect, Tabor & Hutchins, 2004; see also Ferreira & Henderson, 1991; Ferreira & Henderson, 1998; Frazier & Clifton, 1998; Warner & Glass, 1987).

In a previous study, there was no clear evidence for the effect of phrase/clause length on the persistence of the initial incorrect structure (Experiment 1 in van Gompel et al., 2006) and also for that of the manipulation of plausibility (Experiment 2 in the same study). One possible reason for this discrepancy is that these two factors were tested independently. Yet, another possibility is that this is due to a qualitative difference in how these ambiguous sentences were processed between English and Japanese. With English, it has been shown that readers adopt an inappropriate transitive analysis even when the post-verbal noun phrase is semantically inappropriate as a direct object (Pickering & Traxler, 1998). It is likely that this is at least partly due to head-driven parsing; speakers of English check the fit as a direct object for a post-verbal noun phrase regardless of the verb type (except unaccusative verbs; see Staub, 2007). On the other hand, in the head-final Japanese, it is possible that the plausibility of arguments influences the pre-head structural analysis independently of the verb. That is, in some trials under the RC-bias condition, participants may have not adopted the main clause analysis even as an initial analysis and this may have resulted in the higher accuracy to the comprehension questions in Experiment 1 and 2 and in the less reanalysis cost compared to the MC-bias condition in Experiment 3.

To summarize, the current study provided evidence that comprehenders tend to preserve the initial analysis even when the sentence structure does not permit pragmatic inferences. Our finding of the effects of semantic biases and clause length revealed that such a tendency is related to the degree of processing difficulty that reflects how much people committed to the misanalysis. The results of eye-tracking data showed that participants indeed experienced excessive processing cost with the sentences when both the semantic bias and clause length encourage the main clause analysis. The current study also provided evidence for pre-head processing in Japanese and also demonstrated that the persistence of initial misanalysis that has been reported in a head-initial language such as English occurs in typologically different head-final language.

## Abstract

The purpose of this study was to investigate the neuropsychological process and timing of appreciating humor upon reading a set of Japanese riddles which were made up of 4 distinct phases: “Given A (1st phase), I’d say B (2nd phase). Do you know why? (3rd phase) It is because X (4th phase).” To investigate how the brain responds when an individual finds the answer to the riddle (“It is because X”) humorous, this study used the fMRI method. We found that when a participant judged the answer to the riddle humorous, the bilateral amygdalae had been significantly activated at the 4th phase. When the participant judged the answer to the riddle banal (non-humorous), by contrast, the left amygdala was found to be significantly activated earlier at the 3rd phase. Therefore, we argue that in both cases, activation of the amygdala is related to the detection of optimal relevance.

**Keywords:** amygdala; detection of optimal relevance; fMRI; process of humor appreciation; Relevance Theory.

## Introduction

Timing control is essential for a type of Japanese riddle in the following example, which has the fixed form of “Given A (target word), I’d say B (response word). Do you know why? (question) It is because X (answer)” (“A *to kakete*, B *to toku*, *sono kokoro wa*, X.”).

“Given ‘the savings,’ I’d say ‘a smile of my wife’. Do you know why? It is because if they disappear, I will be in trouble.”

In this sequence of utterances, two seemingly unrelated items were mentioned by the speaker and the hearer is expected to reason how on earth they are connected. The process of mentally searching for the connection and discovering it finally on the basis of the rationale provided by the speaker yield humorous effects. The sequence has four distinctive phases: the 1st phase introduces the target concept (“Given A”); the 2nd phase introduces the response concept (“I’d say B”); the 3rd phase asks the hearer if he knows the rationale for making connection between the two concepts (“Do you know why?”); and the 4th phase provides the rationale for the supposed connection (“It is because X”). In this functional magnetic resonance imaging (fMRI) study, we presented a set of such sequences to participants, and then asked them to judge whether or not the given riddles are humorous after they heard the rationale.

## Incongruity resolution in humor appreciation

According to a standard humor appreciation model (Suls, 1972; Wyer & Collins, 1992; Yus, 2003; Martin, 2006), incongruities in the content of the utterance must be identified and resolved for it to be humorous. The incongruities are typically caused by violation of a set of expectations stored in “mental schemas” which are “formed on the basis of past experience with objects, scenes, or events and consists of a set of (usually unconscious) expectations about what things look like and/or the order in which they occur” (Mandler, 1979, p. 263). Thus, in humor appreciation, the simultaneous activation of two incompatible schemas is essential (Wyer & Collins, 1992).

In the Japanese riddle, it is structurally controlled. During the 1st and the 2nd phase, two different schemas corresponding to a target word and a response word are likely to be activated. Two incompatible schemas are simultaneously activated between the 2nd and the 4th phase. When incongruities between these schemas are noticed, the hearer of the riddle naturally looks for a novel and interesting way to resolve them. When a rationale for connecting the two seemingly unrelated concepts is provided at the 4th phase, the incongruities get resolved. At that point, the two existing incompatible schemas and a new schema corresponding to the rationale given are likely to be activated simultaneously. The success of the humor relies upon this resolution being inaccessible before it is given, yet obvious with hindsight when given. If either the resolution fails to be logically coherent or is instead too obvious, the riddle is judged banal.

According to Relevance Theory (Matsui, 2000; Sperber & Wilson, 1995; Yus, 2003; Utsumi, 2005), the motivation for appreciating humor comes from search for “relevance,” which is a property of inputs to cognitive processes and is determined by the balance between the cognitive effect and processing effort. An input has cognitive effect if it significantly improves a cognitive environment of an individual. In order to process the input, though, some processing effort is required. Relevance Theory has two fundamental principles. The first, or the cognitive principle of relevance, states that “human cognition tends to be geared to the maximization of relevance.” The second, or the communicative principle of relevance, states that “every act of ostensive communication communicates a presumption of its own optimal relevance” (Sperber & Wilson, 1995, p. 260). The first principle of relevance predicts that an individual has an innate tendency to process an input to yield maximum cognitive effect with least possible processing effort. The second principle predicts that as a hearer, an individual automatically expects that the speaker will provide information which yields enough cognitive effect in return for the processing cost.

A relevance-theoretic view of interpretation of the Japanese riddles is based on the second principle. When encountering the Japanese riddles, an individual, who expects that it would provide enough cognitive effect with least possible processing effort, automatically tries to resolve the incongruities between the two seemingly unrelated schemas corresponding to the target and the response words. When the individual is finally given the rationale for connecting the two unrelated concepts at the 4th phase, he is likely to feel “Aha!” At that point, he is satisfied with the interpretation and stops processing it.

Based on this principle, it was predicted that, if the answer to the riddle was finally judged humorous, there would be little relevance-based understanding in the 3rd phase because no cognitive effect was yet achieved at that time point, and the intensity of relevance-based understanding would go up in the 4th phase because enough cognitive effect was finally achieved then to repay the large

processing effort spent during the 3rd phase. It was also predicted that, if a riddle was finally judged banal (non-humorous), relevance-based understanding would peak at the 3rd phase since the individual already found a rationale satisfying optimal relevance. Since the riddle was in this case resolved already by the 3rd phase, it was predicted that there would be no further relevance-based understanding in the 4th phase.

### **The amygdala as a detector of optimal relevance**

Previous lesion and neuroimaging studies have shown that the amygdala is involved in an evaluation of motivationally relevant events (Sander, Grafman, & Zalla, 2003; Zald, 2003; Bach et al., 2008). Several studies have demonstrated the key role of the amygdala in negative emotion, but a few studies have suggested a corresponding role for the amygdala in both positive and negative emotion (Hamann & Mao, 2002; Burgdorf & Panksepp, 2006). So, the view of the amygdala as a relevance detector has been proposed (Sander et al., 2003; Zald, 2003), and many neuroimaging studies have supported the hypothesis (Bach et al., 2008; Ousdal et al., 2008; Herbert et al., 2009; Bach et al., 2011). In this article, we take the hypothesis a step further and propose that the amygdala extends its function in humans as a relevance detector in ostensive communication. Thus, it was predicted that the amygdala would be activated if relevance-based understanding occurred. It was also predicted that the amygdala would be deactivated if no such relevance-based processing occurred.

Previous neuroimaging humor studies report the activation of subcortical structures including the amygdalae during humor appreciation (Mobbs, Greicius, Adabel-Azim, Menon, & Reiss, 2003; Moran, Wig, Adams, Janata, & Kelley, 2004; Bartolo, Benuzzi, Nocetti, Baraldi, & Nichelli, 2006; Wild, Rodden et al., 2006; Watson, Matthews, & Allman, 2007; Bekinschtein, Davis, Rodd, & Owen, 2011; Kohn, Kellermann, Gur, Schneider, & Habel, 2011). We propose that activation of amygdala in humor appreciation can be interpreted as the result of detecting the optimal relevance in humorous utterances — the “Aha” reaction. Other main common activation areas of these humor studies include the left hemisphere of the cerebral cortex: an area around the left fusiform gyrus or the left temporo-occipital junction (Brodmann’s area [BA] 37) ) to detect incongruity in humorous utterances (Mobbs et al., 2003); the left posterior middle temporal gyrus (BA 21) for semantic comprehension of humor (Moran et al., 2004); the left inferior frontal gyrus including Broca’s area (BA 44/45) to resolve the incongruity or ambiguity in humorous utterances (Mobbs et al., 2003; Moran et al., 2004; Bekinschtein et al., 2011); and the medial frontal cortex (Goel & Dolan, 2001; Mobbs et al., 2003; Kohn et al., 2011).

In this study, we used the fMRI method to investigate the relationship between humor appreciation and its time course that composed two factors: the presence/absence of humor (humorous vs. non-humorous) and the expecting/shown rationale (the 3rd phase vs. the 4th phase). We predicted that

when a participant explicitly judged the answer to the riddle humorous at the end, its relevance would be detected implicitly at the 4th phase. In addition, it was predicted that when the participant judged the answer to the riddle non-humorous at the end because it was banal, its relevance would be detected earlier at the 3rd phase.

## Methods

### Participants

Twenty participants (10 females and 10 males; mean age, 23.3 years; range, 18–37 years) were recruited as paid volunteers for the fMRI experiment. All participants had normal/corrected-to-normal visual acuity, and were right-handed according to the Edinburgh handedness inventory (Oldfield, 1971), and no history of neurological/psychiatric illness. They were educated higher than high-school graduates. Written informed consent in order to take part in this study was obtained following procedures approved by the Ethical Committee of the National Institute for Physiological Sciences, Japan.

### Preparation of task materials

The riddles had the following structure: “Given A, I’d say B. Do you know why? It is because X.” The topics for the riddles were obtained from an article (Nakamura, 2009) and Internet searches by Google (<http://www.google.com>) in order to create candidates for strongly humorous riddles. For example, “Given ‘savings,’ I’d say ‘a smile of my wife,’ Do you know why? It is because if they disappear, I will be in trouble.” Then, we altered the response word of each riddle in order to create candidates for weakly humorous version. For example, “Given ‘savings,’ I’d say ‘a credit card,’ Do you know why? It is because if they disappear, I will be in trouble.”

In order to select well-controlled pairs of riddles, 8 normal volunteers (4 females and 4 males; mean age, 27.0 years; range, 22–44 years) participated in a pilot study. We selected a paired riddle if one of the pair was evaluated humorous by over one third of participants and the other one was evaluated non-humorous by over one third of participants. We obtained 24 topics from the article and created 24 pairs of riddles, but 8 were removed after the pilot study. We also obtained 20 topics from the Internet searches and created 20 pairs of riddles, but 2 were rejected. So, finally, we selected 34 pairs of riddles and used them in the fMRI session.

### fMRI procedures

Prior to the fMRI session, the participants received detailed instructions and an explanation of the task procedure, and were trained with training stimuli that were not used during the fMRI session. All stimuli were prepared and presented using Presentation 14.8 software (Neurobehavioral Systems, Albany, CA) running on a personal computer. Using a liquid crystal display (LCD) projector, the visual stimuli

were projected onto a half-transparent viewing screen located behind the head coil of the magnetic resonance imaging (MRI) scanner. Participants viewed the stimuli via a mirror attached to the head coil. The sentence stimuli were written in Japanese and presented with white letters on a black background. The maximum visual angle was  $7.8^\circ$  (horizontal)  $\times$   $0.9^\circ$  (vertical).

In each trial, the 1st phase was presented on the screen for 1.5 sec followed by a cross-hair for 1.25 sec, then the 2nd phase appeared for 2 sec followed by a cross-hair for 1.25 sec, then the 3rd phase appeared for 0.75 sec followed by a cross-hair for 1.75 sec, after that the 4th phase was presented for 3.5 sec followed by a cross-hair for 2 sec. The length of each phase was adjusted corresponding to the maximum length of presented stimuli because timing control was important for the Japanese riddles, yet the length of the 3rd phase was shortened and the time between the 3rd and the 4th phase was lengthened because of reducing the value of correlation coefficients of regressors in imaging data analyses. Then the participant was required to judge whether or not the riddle is humorous and to press the button after the question mark “?”, which was presented for 1 sec followed by a cross-hair for 5 sec, was presented.

We used an event-related design to minimize habituation and learning effects. The 34 paired riddles were presented in a pseudorandom order. The paired riddles were presented in different sessions. In total, two sessions, each with 17 candidates of humorous riddles and 17 candidates of non-humorous riddles, were run, and the session order was counterbalanced across participants.

All images were acquired using a 3-Tesla MR scanner (Allegra; Siemens, Erlangen, Germany). For functional imaging during the sessions, an ascending T2\*-weighted gradient-echo echo-planar imaging (EPI) procedure was used to produce 34 continuous 4-mm thick transaxial slices covering the entire cerebrum and cerebellum (time repetition [TR], 2000 ms; time echo [TE], 30 ms; flip angle,  $85^\circ$ ; field of view [FoV], 192 mm;  $64 \times 64$  matrix; voxel dimensions,  $3.0 \times 3.0 \times 4.0$  mm). Oblique scanning was used to exclude the eyeballs from the images. Each session consisted of a continuous series of 354 volume acquisitions with a total duration of 11 min 48 sec. For anatomical imaging, T1-weighted magnetization-prepared rapid-acquisition gradient-echo (MP-RAGE) images were also obtained (TR, 2500 ms; TE, 4.38 ms; flip angle,  $8^\circ$ ; FoV, 230 mm; 1 slab; number of slices per slab, 192; voxel dimensions,  $0.9 \times 0.9 \times 1.0$  mm).

After the fMRI session, the participant was asked to select the best reason for the judgment among the given possibilities (Nakamura, 2009) in order to remove the reasons in which we were not interested. The given options for judging non-humorous were “non-understandable,” “banal,” “objectionable” and “too serious.” The given options for judging humorous were “sympathetic,” “convincing,” “to-the-point” and “close to banal.” The total duration of the experiment was under 60 min, including the acquisition of the structural MR images and these responses.

Figure 1: The amygdala as a detector of optimal relevance (an interaction area of the  $2 \times 2$  factorial design).

## Data analysis

**Performance** In this study, we assumed that the judgment about whether or not a riddle is humorous was based on several different reasons, which we separated out using our experimental design. We created paired riddles which contained humorous version and non-humorous version, and we called convincing-banal pairs if one of the pair was judged humorous because it was convincing by a participant and the other of the pair was judged non-humorous because it was banal by the same participant. Only riddles of convincing-banal pairs were included in the following analyses. Other reasons were rejected because they could contain negative values or ambiguous meanings.

**Imaging data** The preprocessing of the imaging data was performed as follows. The first 6 EPI volumes of each session were eliminated to allow for the stabilization of the magnetization, and the remaining 348 EPI volumes per session (a total of 696 EPI volumes per participant for two sessions) were used for the analyses. The data were analyzed using Statistical Parametric Mapping 8 (SPM8; Wellcome Department of Imaging Neuroscience, London, UK; Friston, Ashburner, Kiebel, Nichols, & Penny, 2007). The EPI volumes were realigned to correct for head motion, and corrected for differences in slice timing within each volume. Then, the whole-head MP-RAGE image volume was coregistered with the mean image volume of the EPI volumes, and segmented into the gray and the white matter volumes using the Montreal Neurological Institute T1 image template. The normalizing parameters of the segmentation were applied to the all EPI volumes. After that, the EPI volumes were spatially smoothed in three dimensions using an 8 mm full-width half-maximum Gaussian kernel.

The signal time course for each participant was modeled with a general linear model. Regressors of interest (trial effects) of the 10 conditions (12e, 3e, 4e, 12a, 3a, 4a, 12z, 3z, 4z, and J) were generated using a box-car function convolved with a hemodynamic-response function (Abbreviation: 12, the 1st and the 2nd phase; 3, the 3rd phase; 4, the 4th phase; J, the judgment phase; e, judging humorous (i.e., convincing of convincing-banal pairs); a, judging non-humorous (i.e., banal of the pairs); z, judging as other six reasons in which we were not interested).

The weighted sum of the parameter estimates in the individual analyses constituted the contrast images, which were used for the group analysis with a random effects-model to make population-level inferences regarding the task-related activation. The contrast images obtained by the individual analyses represent the normalized task-related increment of the MR signal of each participant. In total, the data from 15 participants (other 5 contained no convincing-banal pairs) and four different contrasts (3e, 4e, 3a, and 4a) were incorporated into the  $2$  (humor effect)  $\times$   $2$  (its time course effect) factorial design (Friston et al., 2007). As a result of the factorial design, a significant interaction was found in the bilateral amygdalae, which we defined as regions of interest and used as an explicit mask. In order to show the difference of activated timing of the Amygdala, four different contrasts (3e vs. 3a, 3a vs. 3e, 4e vs. 4a, and 4a vs. 4e) were used in the one-sample t-tests with the explicit mask image. In order to check the activation of each phase, six different contrasts against the rest condition (12e, 3e, 4e, 12a, 3a, and 4a) were used in the one-sample t-tests.

The statistical threshold was set at  $p < .05$  with a correction for multiple comparisons at the cluster level.

## Results

### Behavioral performance

During the fMRI experiment, 734 riddles (54.0%) were judged humorous, while 626 riddles (46.0%) were judged non-humorous. After the fMRI session, 231 riddles (17.0%) were judged convincing, while 243 riddles (17.9%) were judged banal. Then, the 43 paired riddles (6.32%) were judged as convincing-banal pairs, which were used in the following imaging data analysis (a random-effects model).

### Group analysis with a random-effects model

In the  $2 \times 2$  factorial design, no significant main effect was found, but a significant interaction was found in the bilateral amygdalae (see Figure 1 for a spread cluster and Table 1 for peak-levels). In the interaction area, the left amygdala was significantly activated in the 4th phase before the riddle was judged humorous and also in the 3rd phase before the riddle was considered banal (non-humorous), while the right amygdala was significantly activated in the 4th phase before the riddle was judged humorous (see Table 2).

Table 1: The amygdala as a detector of optimal relevance (an interaction area of the  $2 \times 2$  factorial design).

Cluster Size	Peak $p$	Z	Coordinates			Location
			x	y	z	
227	.046	4.72	-18	-6	-20	L Amygdala
	.032	4.81	-14	-8	-16	L Amygdala

Table 2: Difference of activated timing of the Amygdala (results of the one-sample t-test in the interaction area).

When the riddle was to be judged humorous in the end, significant activations were found mainly in the left hemisphere of the cerebral cortex: (12e) the bilateral fusiform gyri (BA 37), the bilateral inferior occipital gyri (BA 17–19), the left middle frontal gyrus (BA 9), and the left middle temporal gyrus (BA 21); (3e) the left inferior frontal gyrus (BA 47/45); (4e) the left posterior rostral medial frontal cortex (prMFC; BA 8/6), the left inferior frontal gyrus (BA 9/45), the left fusiform gyrus (BA 37), and the left inferior occipital gyrus (BA 18/19). When the riddle was to be judged banal (non-humorous), on the other hand, significant activations were found mainly in the left hemisphere and left amygdala: (12a) the bilateral inferior occipital gyri (BA 18–19); (3a) the left amygdala; (4a) the left prMFC (BA 8/6) including the left anterior cingulate cortex (BA 32), the left inferior frontal gyrus (BA 9/45), and the bilateral inferior occipital gyri (BA 18/19).

## Discussion

### Performance

There are clear individual differences in the way humor is appreciated. In this study, we were interested in the amygdala detecting the optimal relevance during humor appreciation, and we used convincing-banal pairs in order to strictly cancel out the effects in which we were not interested. In the 3rd and the 4th phase of a paired riddle, same participants read same stimuli, so only effect of the 2nd phase, which was modeled out in the  $2 \times 2$  factorial design, was remained. Thus, a significance level in the following analysis can be reached with data of only 15 participants.

### Neural activation

The present study revealed that the amygdalae are specifically involved in relevance-based understanding, showing that the amygdalae have a key role in appreciating

a riddle humorous through the time course of humor appreciation. We were also able to reproduce the other activations recorded in other studies.

**Relevance-related activation of amygdala** On the basis of a significant interaction in the  $2 \times 2$  factorial design, we argue that the amygdala is a candidate for relevance-based processing. The left amygdala was significantly activated in the 4th phase when the riddle was to be judged as humorous. It was also activated in the 3rd phase when the riddle was to be judged banal (non-humorous). Thus, we claim that the left amygdala functions as a detector of optimal relevance during humor appreciation. The right amygdala was significantly activated only in the 4th phase when the riddle was to be judged humorous, and hence we argue that the right amygdala is a kind of positive value detector.

While previous studies have suggested that the bilateral or the left amygdala activation involves in positive emotion (Bartolo et al., 2006; Bekinschtein et al., 2011; Mobbs et al., 2003; Moran et al., 2004; Watson et al., 2007), our results suggested that the left amygdala activation involves in relevance detection because it was found not only in the 4th phase of judging humorous (i.e., positive emotion) but also in the 3rd phase of judging non-humorous (i.e., non-positive or negative emotion). If same brain parts are activated in both opposite values, the distinction between positive and negative emotion could not be critical feature, but we argue that the common feature of positive and negative emotion, that is, relevance for the organism is more important.

**Humor-related activation of left hemisphere** Our results also reproduced previous neuroimaging studies of humor appreciation. The activation of the left fusiform gyrus in (12e) and (4e) is interpreted as incongruity detection of humor (Mobbs et al., 2003). The activation of the left middle frontal gyrus in (12e) and the left inferior frontal gyrus in (4e) are interpreted as incongruity or ambiguity resolution of humor (Mobbs et al., 2003; Moran et al., 2004). So, the activation of these areas corresponds to the incongruity resolution a la Suls (1972). The activation of the left middle temporal gyrus in (12e) is interpreted as semantic comprehension of humor (Moran et al., 2004).

Considering that the prMFC has been suggested to represent and update the value of possible future actions such as response selection (Amodio & Frith, 2006), the activation of the left prMFC in (4e) and (4a) is interpreted as being involved in judging whether or not a riddle is humorous. The left inferior frontal gyrus is also activated in both (4e) and (4a), so it might be also involved in the selection. Considering the participants of this study looked at written riddles, the activation of the inferior occipital gyrus is interpreted as seeing effects. So, our results correspond well to previous neuroimaging studies.

## Conclusions

Our results highlight the neural substrates for the detection of optimal relevance. When a participant explicitly judges

the answer to the riddle humorous, the relevance of the answer has been detected implicitly as the activation of the amygdala at the 4th phase. On the other hand, when the participant judges the answer to the riddle non-humorous because it is banal, its relevance has been detected as the activation of the amygdala earlier at the 3rd phase. Therefore, we argue that the amygdala is a detector of optimal relevance in the process of humor appreciation.

# The Footbridge Dilemma Reflects More Utilitarian Thinking Than The Trolley Dilemma: Effect Of Number Of Victims In Moral Dilemmas

Kuninori Nakamura (nakamura.kuninori@gmail.com)

## Abstract

Previous studies on moral judgment have assumed that the trolley and footbridge dilemmas (Thomson, 1985) reflect utilitarian and deontologist thinking, respectively. However, on the basis of the “intervention myopia” hypothesis (Waldmann & Dieterich, 2007) and recent findings in analyses of moral dilemmas (Nakamura, 2011), the current study led a somewhat paradoxical prediction: An effect of the manipulation of the number of victims, considered a utilitarian aspect of moral dilemmas, is larger in the footbridge dilemma than in the trolley dilemma. In order to test this prediction, two experimental studies were conducted in which the number of victims in the trolley and footbridge dilemmas were manipulated. Results of the two studies consistently showed an interaction between the dilemma type and the number of victims, thereby indicating that the manipulation of the utilitarian aspect of moral dilemmas has more effect on the footbridge dilemma, which is believed to reflect deontologist thinking.

**Keywords:** trolley dilemma, footbridge dilemma, utilitarian, deontologist

## Introduction

Is it permissible to sacrifice fewer lives to save more? This is a central question in the debate between utilitarianism and deontology. Utilitarians (e.g., Bentham, 1789; 1948) argue that it is indeed permissible because saving more lives results in greater utility for society than saving fewer ones, whereas deontologists (e.g., Kant, 1965) argue that it is not permissible because life is an ultimate right that should not be violated, irrespective of the number benefit yielded by its sacrifice. This debate has drawn the attention of various researchers who have proposed a number of solutions (see e.g., Singer, 1979; Thomson, 1986; Greene & Haidt, 2002; Mikhail, 2009).

The philosophical debate between utilitarians and deontologists concerns the normative theory of moral judgment. However, psychologists are interested in the descriptive aspect of moral judgment: are people utilitarian or deontologist? The answer to this question is, surprisingly, “it depends on the context.” A discrepancy between the trolley and footbridge dilemmas (Thomson, 1985) clearly demonstrates the context dependency in moral judgment. The trolley dilemma can be described in the following manner: A runaway trolley is headed for five people who will be killed if it proceeds on its current course. The only way to save them is to hit a switch that will turn the trolley onto an alternate set of tracks where it will kill one person instead of five. Should one turn the trolley in order to save

five people at the expense of one? Most people answer yes to this dilemma. Then, consider a similar problem, the footbridge dilemma. As before, a trolley threatens to kill five people. You are standing next to a large stranger on a footbridge that spans the tracks, in between the oncoming trolley and the five people. In this scenario, the only way to save the five people is to push this stranger off the bridge, onto the tracks below. He will die if you do this, but his body will stop the trolley from reaching the others. Should one save the five others by pushing this stranger to his death? To this question, most people answer no (with regard to precise data, see Greene & Haidt, 2002).

With regard to the dominant responses in these dilemmas, people appear to be utilitarians when solving the trolley dilemma and deontologists when solving the footbridge dilemma. In the former dilemma, a person’s choice appears to depend on the number of workmen to be saved, whereas people make much of the right of the man on the bridge in the latter dilemma. Thus, it has been considered that the trolley dilemma reflects the utilitarian way of thinking, whereas the footbridge dilemma reflects the deontologist way of thinking (Greene, Sommerville, Nystrom, Darley, & Cohen, 2001; Waldmann & Dieterich, 2007). With regard to this discrepancy in the dominant responses between the trolley and footbridge dilemmas, various theoretical explanations have been proposed such as the dual process theory (Greene et al., 2001), moral grammar theory (Hauser, 2007; Mikhail, 2009), or causal decision theory (Waldmann & Dieterich, 2007).

Although theorists of moral reasoning differ in terms of how to explain the discrepancy between the trolley and footbridge dilemmas, they consistently receive correspondence between the two dilemmas and philosophical way of thinking without any doubt. For example, Greene et al. (2001) said that the dominant response in the footbridge dilemma could be justified in a Kantian (deontologist) vein, but this justification has trouble when considering the trolley dilemma (Greene et al., 2001, p2106). Hauser (2006, p113–4) explained the philosophical implication of the trolley and footbridge dilemmas in terms of whether the utilitarian calculation can justify dominant responses in these dilemmas. Waldmann and Dieterich (2007) also argued that throwing the switch in the trolley dilemma is in line with the utilitarian view, whereas the footbridge dilemma is in line with the deontologist perspective (Waldmann & Dieterich, 2007, p247–8). Although there are differing theoretical explanations for the discrepancy between the trolley and footbridge dilemmas, the theorists in moral reasoning research have no doubt in

the assumption that the trolley dilemma reflects utilitarian thinking, and the footbridge dilemma reflects deontologist thinking.

However, current research proposes another interpretation of the difference between the two moral dilemmas: the footbridge dilemma reflects more utilitarian thinking than the trolley dilemma. Although this hypothesis apparently sounds strange when considering the presumption in related studies, it can be naturally derived from a theoretical explanation (Waldmann & Dieterich, 2007) and recent empirical findings (Nakamura, 2011) in moral dilemmas. In what follows, we explain this interpretation more precisely.

Waldmann and Dieterich (2007) proposed the “intervention myopia hypothesis”, which insists that moral intuitions are influenced by the locus of the intervention in the underlying causal model, and an attentional focus on the victims is highlighted by the intervention, leading to the neglect of other victims located in the background. More specifically, it treats the trolley dilemma as the intervening agent (trolley) and the footbridge dilemma as the intervening potential patient (victim). Thus, attentional focus on the one victim becomes stronger in the footbridge dilemma than in the trolley dilemma, thereby resulting in deontologist judgments being more likely in the former dilemma. Based on this theoretical explanation for moral dilemmas, Waldmann and Dieterich (2007) performed a series of experiments in which the focus of intervention was manipulated. For example, they compared how participants’ moral judgment would differ between “throwing a bomb on the man” and “throwing a man on a bomb” to save many people. In terms of their hypothesis, the former action corresponds to the agent intervention, and the latter action corresponds to the patient intervention. Results of their experiment consistently supported their hypothesis and revealed that sacrificing one victim to save more victims is more permitted in the agent intervention than in the patient intervention.

One crucial aspect of Waldmann and Dieterich’s (2007) hypothesis is that it considers the difference between the trolley and footbridge dilemma as that of attentional focus to causal structure. As stated above, according to this hypothesis, people make more of the patient when considering the footbridge dilemma compared to the trolley dilemma; they do not permit the sacrificing of a man in the footbridge dilemma as they do in the trolley dilemma. This explanation is intuitively natural and appears to match the dominant responses in these two dilemmas.

At the same time, the explanation in terms of attentional focus also leads to an interesting prediction. Many studies (e.g., Slovic, Griffin, & Tversky, 1990; Tversky & Koheler, 1994; Tversky, Sattath, & Slovic, 1988; also see Fischer & Hawkins, 1993) have demonstrated that a given attribute or element carries more weight for decision making when it becomes prominent. Although these studies are varied in their research subjects, such as preference reversal (Slovic et al., 1990; Tversky et al., 1988) or

probability judgment (Tversky & Koheler, 1994), these studies consistently assume that an attribute or element looms larger when it receives attention and its impact on judgment becomes stronger than when it does not receive attention. If so, the following prediction can be drawn from Waldmann and Dieterich’s (2007) hypothesis; *people are more sensitive to a difference in the number of victims in the footbridge dilemma than in the trolley dilemma because the victims are paid more attention in the footbridge dilemma than in the trolley dilemma*. More specifically, the effect of the manipulation of the number of victims is larger in the footbridge dilemma than in the trolley dilemma because the victims in the former dilemma loom larger than in the latter dilemma. As you see, this prediction can be derived from the existing explanation very naturally. However, it contradicts the dominant view that matches the trolley and footbridge dilemmas to utilitarian and deontologist thinking (e.g., Greene et al., 2001).

Although the above prediction appears to be paradoxical, Nakamura (2011) also demonstrates that the footbridge dilemma surely reflects utilitarian thinking more so than the trolley dilemma. He required participants to answer 62 types of moral dilemmas used in Greene et al. (2001) and analyzed the correlation structure of participants’ judgments using factor analysis and structural equation modeling. The results demonstrated that the moral dilemmas used in Greene et al. (2001) can be explained by four factors: rationality, life-dilemma, risk averse, and efficiency (see Nakamura, 2011). Among these four factors, the risk-averse factor contributed to the difference between the trolley and footbridge dilemmas. This factor mainly comprises problems similar to Asian disease problems (e.g., Tversky & Kahneman, 1984) that require participants to consider a trade-off between probability and outcome (“90% chance of causing no deaths at all and has a 10% chance of causing 1000 deaths or an 88% chance of causing no deaths and a 12% chance of causing 10 deaths”). This factor can be interpreted as the calculation of expected value for each alternative that can be thought of as a utilitarian aspect of moral dilemmas. Surprisingly, a result of structural equation modeling in Nakamura (2011) demonstrated that the risk-averse factor had a significant effect on the footbridge dilemma but not on the trolley dilemma, which is in accordance with the entailment of the intervention myopia hypothesis stated above. That is, results of the multivariate analysis that deals with the correlation structure among the moral dilemmas also indicate a relationship between utilitarian thinking and the footbridge dilemma.

The above discussion consistently suggests that the footbridge dilemma reflects utilitarian thinking more so than the trolley dilemma. Considering that previous studies, including both psychological and philosophical ones, have positioned these dilemmas as symbols for utilitarian and deontologist thinking (e.g., Foot, 1978; Greene et al., 2001; Thomson, 1985), this implication is very important because it contradicts the prevailing view of these two dilemmas. Additionally, the suggestion of the above discussion is

drawn from a natural deduction of the existing theoretical approach (Waldmann & Dieterich, 2007) that also supports this prevailing view. Thus, an exploration of the utilitarian aspect of these two dilemmas leads to a clarification of the meaning of “utilitarian” and “deontologist.”

The purpose of this study is to test the hypothesis that the footbridge dilemma is more related to utilitarian thinking than the trolley dilemma. In order to accomplish this, the current research emphasizes the number of victims. Previous studies combined the trolley and footbridge dilemmas with utilitarian and deontologist thinking in terms of whether participants make much of the number of people to be saved or one man’s right to live. In this vein, the number of victims can be considered a utilitarian aspect of the moral dilemmas. The following two studies manipulated the number of victims in both the trolley and footbridge dilemmas and examined its effect on these two dilemmas.

### Study 1

Study 1 aimed to investigate how a manipulation of the number of victims in the trolley and footbridge dilemmas would work under a standard experimental procedure. Many studies on moral dilemmas (e.g., Greene et al., 2001; Hauser, Cushman, Young, Jin, & Mikhail, 2009) have adopted a forced choice paradigm in which participants are required to choose whether sacrificing a victim to save more people would be permissible or not and have analyzed the percentage of participants who answered yes. Thus, Study 1 examined how the percentage of participants would change according to the number of victims in the trolley and footbridge dilemmas.

### Participants and design

Two hundred eighty-five undergraduates who were naïve to the dilemma tasks participated in Study 1 for course credit. We prepared six types of scenarios in which the story (trolley or footbridge) and number of victims (one/two/five) were manipulated, and each participant received one of the six types of scenarios randomly. As a result, in the trolley dilemma condition, the number of participants who were assigned to the one-, two-, and five-victim condition were 49, 49, and 53, respectively. In the footbridge dilemma condition, the number of participants was 43, 58, and 53 (one-, two-, and five-victim condition, respectively).

### Materials and procedure

Participants received a booklet and before they read the booklet, they were told that the study was about moral dilemmas. The instructions on the first page stated that the task was to read descriptions of a situation and to consider an act described in the scene. The second page presented the scenario and included a response format requiring participants to indicate whether the act (“turn the trolley”/“push the man”) was morally permissible.

The following was the first paragraph in both the trolley and footbridge dilemma conditions:

There is an emergency where a trolley runs out of control. Although a driver tries to stop the trolley, it does not appear to stop. Unfortunately, the trolley is rushing toward ten workmen. If the trolley does not stop, it will surely kill all ten workmen.

After this paragraph, participants in the trolley dilemma condition were shown the following scenario:

There is another railway of the trolley, and if you hit the switch, the trolley changes its course, and the ten workmen will be saved. However, there is #\_\_ workman (or men) on the other course, and if you hit the switch, this workman (or men) will surely be killed by the runaway trolley. Is it permissible to hit the switch to save the ten workmen?

After the first paragraph, participants in the footbridge dilemma condition were shown the following scenario:

There is a footbridge on the course of the trolley, and #\_\_ man (or men) standing on this footbridge. If you throw the man on the railway, the trolley will stop because the man’s body becomes a barrier, and the ten workmen will be saved. However, the man (or men) on the footbridge will be killed. Is it permissible to push the man on the footbridge to save the ten workmen?

The blanks shown in the above texts were replaced by numbers (one, two, or five), depending on the conditions of the number of the victims. The descriptions of these two dilemmas comprised only of sentences and did not employ any pictures. All the participants finished the tasks within 10 minutes.

### Results and discussion

Figure 1 depicts the percentage of participants who believed that sacrificing fewer to save more was “morally permissible” in each condition. As this graph demonstrates, the effect of the number of the people on moral judgment differs between the trolley and footbridge dilemmas. In the footbridge dilemma, acceptability for the death of one person to save ten people decreases as the number of lives sacrificed increases, whereas in the trolley dilemma, the percentage of participants who permitted sacrificing the few remains constant. A logistic multiple regression analysis showed that an effect of the number of victims,  $B = -0.25$ , Wald (1) = 5.47,  $p = 0.02$  and interaction between the number of victims and the type of dilemma,  $B = -0.33$ , Wald (1) = 4.33,  $p = 0.37$  were significant, thereby indicating that whether manipulation of the number of people to be sacrificed would affect moral judgment depends on the context of the dilemma. Multiple comparisons among the conditions in the number of the victims indicate significant differences in the footbridge dilemma, (chi-square test:  $P_s < .01$ ), but not in the trolley dilemma ( $P_s > .10$ ). Thus, results of Study 1 supported our prediction that the

Figure 1 Results of Study 1

footbridge dilemma reflects utilitarian thinking more so than the trolley dilemma.

One noteworthy result of Study 1 is that the difference between the trolley and footbridge dilemmas is not significant when one person must be sacrificed to save ten ( $P > .10$ ). As far as I know, this is the first example demonstrating that the ratio of participants who chose “permissible” in the footbridge dilemma was equal to that of the trolley dilemma. One plausible reason for this result is that the current research differs in terms of the number of people to be saved and the number of victims. Most previous studies on the trolley and footbridge dilemmas (e.g., Greene et al., 2001; Mikhail, 2009; Waldmann & Dieterich, 2007) used five and one as the number of people to be saved and number of victims, respectively. In contrast to these studies, in order to examine the utilitarian aspect of the moral dilemma, the current study used ten as the number of people to be saved, and three values (one, two, or five) for the number of victims. It is possible that the number of victims affect the difference between the trolley and footbridge dilemmas, although it requires further study. Study 2 will also address this problem in the results and discussion section.

## Study 2

Study 2 aimed to replicate the findings in Study 1 under a condition where the following two modifications in the experimental procedure were added. First, Study 2 manipulated the number of victims as a within factor to examine whether the results in Study 1 were due to a reflection of individual differences. Second, Study 2 adopted the number of people to be saved as a dependent variable. Although the current research aimed to examine the utilitarian aspects of the moral dilemmas, the permissibility judgment used in Study 1 appears to be somewhat different from utilitarian calculation because “permissibility” sounds like a subjective impression. Thus, it is not certain whether the same trends would be found if participants are required to make a utilitarian calculation for

permissibility to sacrifice few to save more. In order to examine this, Study 2 required participants to estimate the number of people to be saved that seemed to be equal to sacrificing fewer people.

## Participants and design

Fifty undergraduates participated in Study 2 for course credit and were randomly assigned to one of two conditions: the trolley dilemma condition or the footbridge dilemma condition. All the experimental materials and response formats were given in the form of a booklet. The first page contained the same instructions as Study 1, and the second page described the scenario and included a response format. In both the trolley dilemma conditions, participants read the following:

There is an emergency where a trolley runs out of control. Although a driver tries to stop the trolley, it does not appear to stop. Unfortunately, the trolley is rushing toward some workmen. If the trolley does not stop, it will surely kill all the workmen.

There is another railway for the trolley, and if you hit the switch, the trolley changes its course, and the ten workmen will be saved. However, there are *some* workmen on the other course, and if you hit the switch, the workmen on the other railway will surely be killed by the runaway trolley.

As shown, these instructions are almost the same as those of Study 1, except that the number of victims and people to be saved were not stated explicitly. In the footbridge condition, the first paragraph shown to participants was the same as that in the trolley dilemma condition, but the second paragraph was as given below:

There is a footbridge on the path of the trolley, and some men are standing on this footbridge. If you throw the men on the railway, the trolley will stop because the men’s bodies become a barrier, and the workmen will be saved. However, the men on the footbridge will be killed. Is it permissible to push the men on the footbridge to save the ten workmen?

After reading the above texts, participants in both conditions were required to answer the following question under three conditions, where the number of victims were one, two, or five:

Consider that the number of workmen on the other railway (the footbridge) is #\_\_. How many people do you think are enough to justify hitting the switch (pushing them)? Insert a number in the blank.

The blank shown in the response format was replaced by numbers (one, two, or five). All participants finished within 20 minutes.

## Results and discussion

The results of Study 2 depicted in Figure 2 indicate that the slope of the function between the number of victims and the dependent variable is steeper in the footbridge condition than in the trolley condition. A 2 (type of dilemma: trolley/footbridge) by 3 (number of people to be sacrificed: 1/2/5) ANOVA demonstrated significant main effects of the two factors: type of dilemma,  $F(1, 48) = 7.22, p < .01$ ; number of victims,  $F(2, 47) = 16.57, p < .01$ ; and interaction  $F(2, 96) = 6.60, p < .01$ . Analyses of the simple main effect by Ryan's method indicated that the simple effect of the type of dilemma was significant only in the five-person condition,  $F(1, 144) = 18.68, p < .01$ , and the simple main effect of the number of people was significant only in the footbridge condition,  $F(2, 96) = 22.05, p < .01$ . These results replicate the findings of Study 1, which suggest that the effect of the number of victims is stronger in the footbridge dilemma than in the trolley dilemma, thereby supporting our position that the footbridge dilemma reflects the utilitarian aspect of the moral dilemma more than the trolley dilemma. Additionally, Study 2 also failed to find the difference between the trolley and footbridge dilemmas when the number of victims is small. These results replicate the pattern found in Study 1.

Figure 2 Results of Study 2

## General discussion

The results of the two studies consistently demonstrated that the footbridge dilemma was more sensitive to the manipulation of the number of people to be sacrificed than the trolley dilemma. Study 1 demonstrated that as the number of victims increased, the ratio of participants who permitted sacrificing the few in the footbridge dilemma decreased, whereas those in the trolley dilemma did not change. Study 2 asked participants the number of people to be saved to permit a sacrifice and found that the effect of the number of victims was larger in the footbridge dilemma than in the trolley dilemma.

The current results provide the following four theoretical implications. First, this article demonstrates a connection

between the footbridge dilemma and the utilitarian aspect of the moral dilemma. Previous studies (e.g., Greene et al., 2001; Hauser, 2007; Waldmann & Dieterich, 2007) have assumed that the trolley dilemma reflects utilitarian thinking, whereas the footbridge dilemma reflects deontologist thinking. These studies mainly draw this assumption from a pattern of the dominant responses of the trolley and footbridge dilemmas. In contrast to these studies, the current research took into account sensitivity to the manipulation of the utilitarian aspect of the moral dilemma and derived a contradictory view. As far as we know, this is the first example that challenges the prevailing view: “utilitarian” trolley and “deontologist” footbridge. In addition, the current results reveal the reason why people consider pushing the man not permissible in order to save the five workmen in the original footbridge dilemma. It is not because they think the man's right to live should not be violated; rather, people think that five people are not enough to sacrifice one person.

Second, the current results are in line with the perspective that causal structure might be key to understanding moral reasoning (Waldmann & Dieterich, 2007). According to Waldmann and Dieterich's (2007) view, intervention to causal path in moral dilemmas plays an important role for moral reasoning because it changes attentional weights on agent and patient. The hypothesis tested in the current study is naturally derived from this explanation because attention is believed to affect sensitivity to the attribute that it focuses on (e.g., Tversky & Koheler, 1994; Tversky et al., 1988). The results of the two studies consistently support the hypothesis, thus indirectly confirming Waldmann and Dieterich's (2007) proposition. Additionally, the current results also support Nakamura's (2011) implication that the footbridge dilemma is considered more consequential than the trolley dilemma because the risk-averse factor solely affected the footbridge dilemma.

Third, the current research also suggests that moral reasoning processes may be easily influenced by the number of victims. Both Studies 1 and 2 failed to find a difference between the trolley and footbridge dilemmas that have been replicated robustly (e.g., Greene et al., 2001; Greene & Haidt, 2002). The main difference between previous studies and the current study is the number of victims and people to be saved. With regard to the number of people to be saved by sacrificing fewer people, this research used “ten” in Study 1, whereas previous studies used “five.” Study 2 left the number of people to be saved blank and required participants to provide a number that they would be willing to sacrifice. In this vein, there is a possibility that this difference in the numbers used in the scenario might produce a discrepancy in the results between the current research and previous studies. Although this possibility is an issue for future examination, it would be useful to explore the relationship between numerical value and moral judgment.

Fourth, the current research indicates the importance of exploring not only the dominant response but also sensitivity to manipulation when investigating the moral dilemma. The current research focused on the effect of the number of victims and succeeded to derive a somewhat different conclusion by identifying an interaction between the number of victims and types of dilemma. This result might provide an important implication to a methodology of experimental philosophy (e.g., Knobe, 2004, 2007; Knobe & Nichols, 2009). Experimental philosophy attempts to solve philosophical issues not by speculation but by empirical investigation. In doing so, experimental philosophy mainly deals with average responses in moral reasoning problems, as previous studies on moral dilemmas have done (e.g., Knobe, 2003). However, empirical data are not limited to the average. Correlation among the problems (e.g., Nakamura, 2011) or sensitivity to independent variables can also provide interesting information in understanding the nature of a moral issue. Concern for the data analysis method would benefit experimental philosophy and produce results that are applicable to philosophical issues.

This discussion also leads to an examination of “utilitarian” and “deontologist” thinking. The proposition that the trolley dilemma reflects the utilitarian thinking has its basis on the dominant responses to this dilemma, whereas the current research has its basis on examination to the sensitivity to the number of the victims in moral reasoning. Then, some reader may consider a following question; which is the more plausible evidence to determine the utilitarian thinking? I think this question is a fundamental one for experimental philosophy. That is, one more message of the current research is that empirical studies on the moral reasoning should consider not only the meaning of the moral dilemma but also *how* to interpret empirical evidence in the dilemma. As far as I know, there is no study that considers this problem, and I hope this research would be a first step to this problem.

## Abstract

Our world is a dynamic one: many kinds of objects and events change markedly over time. Despite this, most theories about concepts and categories are either insensitive to time-based variation, or treat people's sensitivity to change as a result of process-level characteristics (like memory limits, captured by weighting more recent items more highly) that produce irrational order effects during learning. In this paper we use two experiments and nine computational models to explore how people learn in a changing environment. We find, first, that people adapt to change during a category learning task; and, second, that this adaptation stems not only from weighting more recent items more highly, but also from forming sensible anticipations about the nature of the change.

**Keywords:** categorization, change detection, concepts, dynamics, time dependence, order effects

At no two moments in time are we presented with the same world. Objects move, plants and animals are born and die, friends come and go, the sun rises and sets, and so on. More abstractly, while some of the rules that describe our world – like physical laws – are invariant over the course of our everyday experience, others – like legal rules – are not. Given some appropriate time scale, certain characteristics of an entity or class of entities can change; moreover, they may tend to change in *systematic* ways. Temperature varies cyclically as a function of time of day and time of year; with a gradual rise over the last century. As another example, the features that describe phones have changed considerably over recent decades: not only do modern phones perform many new functions, they are also physically smaller, sleeker, and smoother. People are aware of this temporal structure and adapt their predictions to it: if asked to predict the temperature six months from today, people will give quite different answers than if asked to predict the temperature tomorrow. We do not modify predictions in an *ad hoc* or senseless fashion; instead, we appear to be attuned to particular details of the nature of the dynamic variation in category structure.

One consequence of recognizing the changeable nature of categories is that the time at which observations are made matters. A machine with a rotary dial could very well be a typical phone if it were observed in 1980, but this is much less plausible if the observation dates from 2010. These changes over time introduce strong *order effects* into the classification problem. Order effects in categorization are well-studied, but people's sensitivity to order is generally thought to result from weighting more recent items more highly (generally as a result of poor memory) or inefficient learning rules (e.g., Kruschke, 2006; Sakamoto, Jones, & Love, 2008). Irrespective

of whether these process limitations arise from the use of *ad hoc* (Anderson, 1990) or rationally motivated (Sanborn, Griffiths, & Navarro, 2010) computation strategies, the shared assumption is that people should *not* be sensitive to order information when learning new categories. While this is certainly true in some cases, in other situations order sensitivity might actually be a sensible adaptation. Especially when a category is changing in systematic ways (e.g., phones are getting steadily more complex), a sensible learner should be able to extrapolate about the future in a way that is sensitive to that systematicity. The central question of this paper is whether people can perform this extrapolation, and whether it can be separated from an order sensitivity that arises from simply weighting more recent items more highly.

The structure of this paper is as follows. The first half explores the advantages of being sensitive to order in category learning. This is important because the literature tends to focus on the negative consequences of order sensitivity – namely, irrational order effects when the environment is in fact stationary. However, we present computational modeling highlighting the fact that when the world is actually changing, being sensitive to that change constitutes an enormous advantage. In the second part of the paper, we investigate the nature of human order sensitivity. To what extent does it reflect imperfect memory, and to what extent does it reflect sensible adaptation and extrapolation about systematic change? Experimental and computational results<sup>1</sup> demonstrate that both factors play an important role.

## The importance of order sensitivity

We begin our exploration into the importance of order sensitivity with a prototype model for categorization, which in its standard form is not sensitive to order. In this model, people are assumed to construct a single representation of the prototype, or the central tendency of the category. In its most usual form, if the learner has seen a series of  $t$  items, then the prototype  $\mu_t$  is found by taking the arithmetic mean of the mental representations of the category members:

$$\mu_t = \frac{1}{t} \sum_{i=1}^t x_i \quad (1)$$

where  $x_i$  denotes the mental representation (e.g., co-ordinates in psychological space) of the  $i$ -th category member. If the

<sup>1</sup>Because the paper involves a large number of models (9 in total), we outline the structure of the models only in general terms here: precise specifications are available in the supplementary materials found at [www.compcogscilab.com/dan/](http://www.compcogscilab.com/dan/).

distribution of the category members is normal, then the learner is assumed to keep track the standard deviation of the  $t$  category members around the prototype  $\sigma_t$ . The probability that a new item belongs to the category is proportional to the probability that the category distribution assigns to that item. As noted by several authors (e.g. Ashby & Alfonso-Reese, 1995) this model has an interpretation as a rational model when the category members satisfy certain assumptions – including the assumption that the world does not change.

It is precisely because the world is assumed not to change that all category members are assigned equal weight in Equation 1, regardless of when they were observed. As a consequence, the model predictions on trial  $t$  do not depend on the order in which the preceding items were observed. This order invariance is characteristic of most probabilistic models for category learning, whether they be prototype, exemplar, or cluster-based (see Griffiths, Sanborn, Canini, & Navarro, 2008). As noted by a number of authors (e.g. Sakamoto et al., 2008; Navarro & Perfors, 2009) such models perform poorly as models of human performance when the data presented to people contains strong order effects. To address this, it is commonplace to consider an updating rule that is more sensitive to the changing structure of the data. The general idea is to assume that when the learner encounters a new category member, he or she moves the prototype a little closer to the new category member. This has the effect of weighting new items more than older items. The simplest version of this rule is as follows: if  $x_t$  refers to the feature value(s) for the new item, then the new prototype location at time  $t + 1$  is

$$\mu_t = \phi\mu_{t-1} + (1 - \phi)x_t. \quad (2)$$

One advantage of this rule is that it is simple and easy to implement. Viewed from a computational perspective, it corresponds to an “exponential weighting” scheme, in which the most recent observations are weighted most highly, where the weight decays exponentially as a function of time.<sup>2</sup> In that sense, it is quite similar to the exponential generalization gradients that are typically used in category learning models (Nosofsky, 1984), but applied across time rather than psychological space. Additionally, this weighting function is similar to the shape of the retention function in memory research.<sup>3</sup>

The key feature of this and similar rules is that the learner is constantly adapting the prototype, never converging to a single true value. Because of this, the model is quite sensitive to the recent trends in the data. Learning rules of this form capture human order effects in simple choice tasks (e.g., Yu & Cohen, 2009; Gökyaydin, Ma-Wyatt, Navarro, & Perfors, 2011). Moreover, such rules make sense as a near-optimal inference scheme when there is a constant probability that “something changes”, but the nature of the change is not predictable or systematic (e.g., Yu & Cohen, 2009; Brown & Steyvers, 2009). In the next section, we illustrate how important this sensitivity can be.

<sup>2</sup>The exact equation is  $\mu_t = (1 - e^{-\tau}) \sum_{i=1}^t e^{-\tau(t-i)} x_i + e^{-\tau} \mu_0$ , where  $\tau = -\ln \phi$ , and  $\mu_0$  is the initial location of the prototype. The derivation is included in the supplementary materials, but since Equation 2 is the simpler and more interpretable version, we use it throughout the paper rather than this more explicit exponential form.

<sup>3</sup>Although retention curves are generally have heavier tails than exponentials (e.g. Rubin, Hinton, & Wenzel, 1999), this would likely make little difference to a typical category learning experiment.

Figure 1: The experimental design from Navarro and Perfors (2009). Stimuli varied along a single dimension (line length). Circles denote items belonging to one category, and squares refer to the other category. The two categories consist of the exact same set of 100 stimuli, but are presented in a different order. The shading summarises the human responses: the darker the shade, the more likely people were to select the “circle” category (see Figure 2 for histograms showing the probability of a correct response). Note the large “jump” around trial 60, and the fact that humans quickly adapt to it.

## Modelling adaptation to change

The typical view of “rationality” in a category learning experiment assumes that the world is stationary. Under this assumption, any sensitivity to the order in which items are observed is irrational. However, this view is sometimes expressed even when using experimental designs that *violate* the stationarity assumption. A good example of this is the paper by Sakamoto et al. (2008), which presented results from a simple supervised categorization task in which one category possessed a strong time dependency. In this task, an order sensitive model accounted for human classification decisions better than an order insensitive one. Despite the fact that is sensible to be sensitive to order such a situation, this was argued to be evidence *against* the rationality of human behavior rather than evidence in favor of it.

To explore the extent to which people are sensitive to categories that change over time, Navarro and Perfors (2009) conducted a categorization experiment in which the *only* information that distinguished the categories was the order in which items were presented (the design is illustrated in Figure 1). Human performance was well above chance: participants correctly classified the stimuli on 76% of trials. However, models were not fitted to this data, making it somewhat unclear exactly how badly an order insensitive model would perform on the task, and the extent to which order sensitive models would improve matters.

To address these question, here we fit<sup>4</sup> six different models to that data. Three of the models are not sensitive to order. This includes two variations of a standard prototype model, one assuming that both category distributions have equal variance (i.e., the same value of  $\sigma$ ) and the other allowing unequal variances, and a standard exemplar model (Nosofsky, 1984). The other three models are analogous, but each use an exponential weighting scheme to assign more importance to recent

<sup>4</sup>Throughout the paper we use the ordinary least-squares (OLS) method to estimate model parameters: that is, we minimize the sum squared deviation between model predictions and human classifications, though we exclude the first 10 trials since human and model predictions are both quite variable initially.

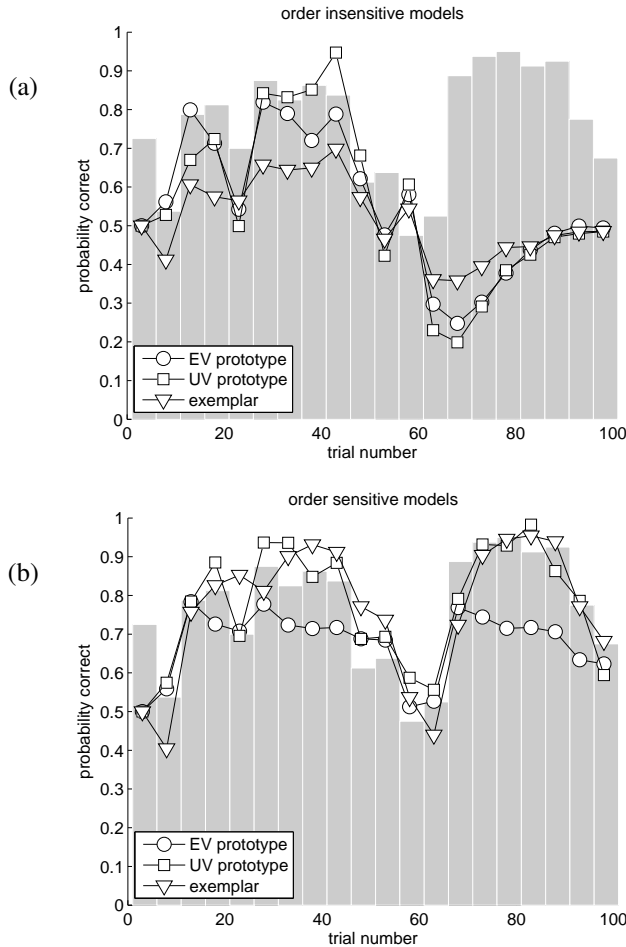

Figure 2: Graphical depiction of the performance of prototype (EV = equal variance, UV = unequal variance) and exemplar models on the classification task, for both the standard order-insensitive versions (panel a) and the order-sensitive versions (panel b). The grey bars plot human performance, and for reasons of visual clarity all plots are averaged over 5 trial blocks. Notice the catastrophic prediction failure for the order insensitive models during the second half of the experiment.

items: this is equivalent to Equation 2 for the prototype models, and is slightly more complex for the exemplar model. The formal details for all models are included in the supplementary materials. None of the models have more than two free parameters in this task.

The important finding here, shown in Figure 2a, is that none of the order insensitive models can mimic human behavior, nor can they achieve good classification performance on the data. No order insensitive model can correctly classify the stimuli at a rate higher than 55%, regardless of what parameter values are chosen. Moreover, none of the models can account for more than 5% of the variance in human responses.<sup>5</sup> The basic problem is evident in Figure 2a: when the task changes at trial 60, no order insensitive model can

<sup>5</sup>We measure this using the Variance Accounted For (VAF) statistic, which is equivalent to an  $R^2$  statistic in regression, but does not estimate an intercept and slope: the model predictions are compared *directly* to human performance.

adapt to it in the way humans do. Viewed as *psychological* models, the inability to describe human behavior is a serious issue. In addition, the inability to achieve an acceptable classification performance makes it clear that none of these models provides a good *rational* standard for the task either.

In stark contrast, all three of the order sensitive models perform reasonably well, as shown in Figure 2b. When fit to the human responses, the exemplar model and unequal-variance prototype model are nearly indistinguishable, accounting for 79% and 80% of the variance respectively. The equal variance prototype model performs slightly worse, accounting for 72% of the variance. This is not surprising: as Figure 1 illustrates, the categories are not equally variable. In any case, the important point is that all three order sensitive models are massively superior to any of the order insensitive models.

This improvement in psychological performance is matched by an improved classification rate. If the parameters are chosen to maximize the classification accuracy rather than to maximize the variance accounted for in human performance, the exemplar model and unequal variance prototype models can both exceed human performance (89% and 82% accuracy), while the equal variance prototype model is slightly worse (68% compared to the 76% of humans). While it would be incorrect to suggest that any of these models provides an exact normative standard for this task, since the data have a rather more complex structure than a simple exponential weighting mechanism suggests, it is clear from the superior classification performance that the order sensitive models are much closer to the required standard than the usual order insensitive models.

We have shown so far that order sensitivity is important in understanding human category learning: standard order insensitive models fail catastrophically when the world changes, both as pure classifiers as well as models of human classification. By contrast, models that use a simple exponential weighting method do surprisingly well in capturing human order sensitivity. But is that the *entire* explanation for how humans respond to time dependence in the input? One possibility is that it is, and that people change over time because they have poor memories and are most likely to recall and use more recent information. The other possibility is that when the changes are systematic, people actively notice and adapt to them, allowing them to extrapolate in a sensible way when making predictions about new items. In the rest of this paper we describe experimental and computational work showing that both possibilities appear to be true: human performance is affected by memory limitations as well as the ability to adapt in a sensible way.

## Learning to predict changes

The central question going forward is whether people's sensitivity to change is the result of memory limitations or to a sensible adaptation to a changing world. To some extent, these explanations are not in conflict: memory is sensitive to the need probability of the information to be recalled, and recent information is more likely to be useful than older information when the world changes (Anderson & Schooler, 1991). Nevertheless, it is possible to make distinctions between the two. For instance, when the world changes in *systematic* ways, it is not usually an optimal strategy to just reweight old informa-

Table 1: An overview of the five models used in the experiment. All models are equal-variance prototype models, but differ in the manner in which the category prototype is estimated. The first column gives the label for the model, the second column indicates whether the model used exponential weighting or not, and the third column indicates what method the model used to anticipate what future changes would occur.

Model	Weighting	Extrapolation
STANDARD	constant	none
RECENCY	exponential	none
RECENCY+BIAS	exponential	constant
REGRESSION	constant	regression
RECENCY+REGRESSION	exponential	regression

tion. Instead, the right strategy is to learn to anticipate those changes, and guess how the world is going to change before the change actually happens. In this section we present a category learning experiment in which people were presented with fairly obvious and systematic temporal changes, and investigate how well people learned to anticipate those changes.

## Method

**Participants** 59 participants were recruited through a mailing list whose members consist primarily of current and former undergraduate psychology students, and paid \$10/hour for their time. The median age was 23, and the participants were predominantly (63%) female.

**Materials & Procedure** The learning task was a standard supervised classification experiment, performed on a computer. Stimuli were little cartoon objects (“floaters”), which were displayed floating above a horizontal line (“the ground”). The height of the floater was the only respect in which the stimuli varied from each other.

On each of 100 trials participants were shown a single floater and asked to predict whether it would flash red or blue. After making their prediction, they would receive feedback for two seconds while the floater flashed the appropriate color. As Figure 3 illustrates, as the experiment progressed, all the stimuli shown to people tended to rise, regardless of which category they belonged to. In the figure, circles correspond to items that belong to the “high” category and crosses correspond to times that belong to the “low” category. Assignment of flash color (red or blue) to category (high or low) was randomized across participants.

The classification rule was such that, if  $x_t$  denotes the height of the stimulus on trial  $t$ , then the optimal response is to select the response option corresponding to the high category if  $x_t > t$ . Such a rule, shown as the solid line in Figure 3, achieves 100% accuracy on the task. However, because most stimuli tend to lie quite close to the classification boundary, the task is relatively difficult even though the general trend is clear. Consistent with this, participants during informal discussions indicated that they detected the upward trend early in the experiment, but still found the task to be quite challenging.

**Models** We fit five models, outlined in Table 1, to the experimental data. For this task a prototype model provides a good description of the category representation, and since the two categories are in fact equal variance we can use the equal

Figure 3: The experimental design. Circles denote stimuli belonging to the “high” category and crosses denote stimuli belonging to the “low” category. Although the classification rule changes over time – that is, the classification boundary is constantly rising – it does so in a regular fashion. The scale on the vertical axis is normalized so that the average “rise” from one trial to the next is 1 unit; on screen, this corresponded to an average rise of approximately 2mm per trial. Note that although it is logically possible to correctly classify all items, in practice the task is quite difficult, since most stimuli lie close to the boundary.

variance prototype model as our basic model.<sup>6</sup> The only differences among the five models lies in how they calculate the location of the prototype  $\mu_t$ ; we systematically vary effects of memory (i.e., how previous items are weighted) as well as anticipation (i.e., what extrapolation method, if any, is used to anticipate future items).

The first two models, STANDARD and RECENCY, do no extrapolation at all: they are identical to the two equal-variance prototype models from in the previous section. The STANDARD model is the order-insensitive model with constant weights as in Equation 1 whereas the recency model captures order sensitivity via the exponential weighting scheme in Equation 2. A third model, which we call RECENCY+BIAS, incorporates this exponential weighting scheme, but also incorporates a component that captures participant adaptation to the experimental design. It does so by shifting the prototype upwards by a constant amount  $\beta$ . In other words, this model not only *follows* where the data are moving (using the exponential weighting scheme), but it *extrapolates* to guess where the data are moving to.<sup>7</sup>

The final two models explore the extent to which people use a different and more optimal extrapolation method. These models estimate an explicit linear regression model for each category prototype, using the trial number as the predictor (i.e.,  $\mu_t = at + b$ ), re-estimating the regression equation after each trial. This is not quite an ideal observer model for the task, but it is extremely close: if we were to allow it to respond deterministically (via the Luce (1963) choice rule, for

<sup>6</sup>We expect that the same pattern would be observed if we used exemplar models or unequal variance prototype models; nothing in the design is specific to the equal variance prototype model.

<sup>7</sup>Note that this is not quite identical to the usual manner in which bias parameters are used in category learning models. The bias in this case alters the underlying category representation (the prototype) rather than the response bias, although in this experimental design the effect is not dissimilar.

Figure 4: Overall performance for humans and models. The qualitatively important characteristics are that humans perform above chance on both categories, but perform better for the high category. This qualitative pattern is captured only by the RECENCY + BIAS model, which extrapolates about the future but also weights more recent items more highly.

instance), it would be able to perfectly classify all items. The fourth model, REGRESSION, uses exactly this linear regression model, while the fifth (RECENCY+REGRESSION) adds an exponential weighting scheme in order to attach more importance to recent observations when estimating the regression equation. In effect, this model assumes that the learner applies a nonparametric regression model (in this case lowess regression; Cleveland & Devlin, 1988) to estimate the location of the prototype, rather than a linear regression model.

The formal specification for all models can be found in the supplementary materials. For now it is sufficient to note that the only free parameters in the models are the  $\phi$  parameter that governs the amount of weighting for the three models that use exponential weighting (Equation 2) and an additional bias parameter  $\beta$  for the RECENCY+BIAS model.<sup>8</sup> The category variances are not free parameters, as these are estimated by the models, though somewhat differently in each case.<sup>9</sup>

## Results

Human performance was significantly above chance for both categories: 76% of the “high” category items and 61% of the “low” category items were classified correctly. Using

<sup>8</sup>Because it turns out that the model with the best performance is also the one with the most parameters, we checked that model complexity was not the source of its superior performance. This was done by calculating the Bayes factors for all models, using a uniform prior over  $\phi$  (which varies between 0 and 1) for the three models that use exponential weighting and a uniform prior over  $\beta$  across the range of 0 to 10. The RECENCY+BIAS model was easily the preferred model: a numerically estimated Bayes factor produced an odds ratio of about  $10^7$  to 1 favoring it over the next best model.

<sup>9</sup>Note that including this as a free parameter would make no qualitative difference to the model predictions: all of the characteristics of the data that we focus on depend only on the classification boundary of the model, which does not depend on the variance at all.

Figure 5: Individual participant data. Each dot represents one participant: the horizontal co-ordinate shows their classification performance on items that belonged to the lower category, and the vertical co-ordinate plots the performance on the higher category. The other markers show the model predictions, as indicated in the legend. The dotted triangular region corresponds to all possible patterns in which classification performance is above chance for both categories, but with the high category showing better performance. The majority of human participants fall within the triangle, as does the RECENCY+BIAS model.

each participant as a distinct data point, a single sample  $t$ -test against chance performance of 50% correct produced significant results for both the high category ( $t_{58} = 19.6$ ,  $p < .001$ ) and the low one ( $t_{58} = 7.3$ ,  $p < .001$ ). The difference between the two categories was also significant: a paired samples  $t$ -test showed that people perform significantly better on the high category than the low one ( $t_{58} = 8.5$ ,  $p < .001$ ). This is illustrated in Figure 4, which also shows the performance of all five models. Only the RECENCY+BIAS model reproduces the human pattern. Of the other four, two of them perform below chance for the low category, and the other two are unable to correctly capture the asymmetry between the categories.

This effect is even more obvious when we plot the data from the individual subjects. Figure 5 shows the classification performance for each of the participants for both the low category (horizontal axis) and the high category (vertical axis). Most human participants fall within the triangular region, in which the high category is classified better but performance is above chance for both categories. Only the RECENCY+BIAS model falls into the same region.

In addition to looking at the data at an individual subjects level, it is useful to examine model performance at an individual stimulus level. That is, how well does each model capture the trial-by-trial changes in performance? The RECENCY+BIAS model captures 39% of the variance at the item level, compared to the 13% of the variance for the RECENCY+REGRESSION model. No other model can explain any of the variability in the human data at the item level.

Finally, since the quantitative evidence for the RECENCY+BIAS model is so strong, it is important to see if the parameter estimates are sensible. The estimated

recency parameter was  $\phi = 0.25$ , meaning that participants weighted each new observation  $x_t$  about one-quarter as strongly as the old prototype  $\mu_{t-1}$  when updating the prototype. The bias parameter of  $\beta = 4.41$  appears to be a substantial upward shift, but as Figure 4 illustrates, it is not quite large enough to overcome the “lag” induced by a reliance on old observations (as per the simpler RECENCY model). In other words, this model still lags a little behind the data.

## Discussion

The experiments and computational modelling in this paper provide evidence that people adapt to changing categories in the world. This adaptation occurs not only because people weight more recent items more highly, but also because they form anticipations about the nature of the change. This work is somewhat preliminary, however, insofar as there are a number of extensions that are important to pursue. Most notable among these are the need to consider other patterns of change besides simple linear trends, and the need to extend the modelling framework to incorporate “relative judgment” approaches to categorization (Stewart, Brown, & Chater, 2002) which encode stimuli in terms of their relationship to recent items. We are currently pursuing both of these avenues.

Nevertheless, the results are interesting even without these extensions. The fact that world changes with time, and our conceptual representations must change with it, carries a number of important corollaries. In situations where the world is not constant over time, then models of category learning that assume a stationary environment are not sensible choices as rational standards for behavior. Indeed, such models do not turn out to be good models for human behavior. This does not invalidate them as good models in the contexts for which they were originally developed, but it sharply limits the generalizations one should draw from them. It is incorrect to conclude that a “rational” model that relies on an assumption of stationarity will apply to a world that changes over time and still remain a rational model in that context. Humans adapt to change, and as illustrated in the second part of the paper, if the structure of the temporal change is regular enough, we can and do learn to anticipate those changes before they occur.

That said, the best model for human performance in the task is not the ideal observer model (REGRESSION). It is instead the one that takes the simple prototype model with recency weighting (Equation 2) and makes the smallest change required to be suitable to the task. The performance of this model suggests that the adaptations that people make to anticipate systemic changes are conservative: they make smaller adjustments than the data warrant, strictly speaking (Phillips & Edwards, 1966). Conservatism itself may be a sensible adaptation (Navon, 1978), but this is not in our view the major point. The key goal is to learn what kinds of changes people are able to detect and anticipate, and how that helps us adapt to a changeable world.

Viewed from this perspective, it is notable that we were led to these results by considering the underlying inference problem that the learner has to solve: category learning in a dynamic world. In that sense, our approach offers a computational analysis, and the models that had an ex-

trapolative component (RECENCY+BIAS, REGRESSION, and RECENCY+REGRESSION) are all inspired by that observation. However, our approach also has much in common with process-level analyses that take seriously the possibility that people must operate within the constraints imposed by memory limitations. Our work helps to bridge the two levels, bringing us closer to a united explanation of how people learn categories within a changing world.

## Abstract

What are the effects of experience on subsequent learning? We explored the effects of language-specific word order knowledge on the acquisition of sequential conditional information. Korean and English adults were engaged in a sequence learning task involving three different sets of stimuli: auditory linguistic (nonsense syllables), visual non-linguistic (nonsense shapes), and auditory non-linguistic (pure tones). The forward and backward probabilities between adjacent elements generated two equally probable and orthogonal perceptual parses of the elements, such that any significant preference at test must be due to either general cognitive biases, or prior language-induced biases. We found that language modulated parsing preferences with the linguistic stimuli only. Intriguingly, these preferences are congruent with the dominant *word order* patterns of each language, as corroborated by corpus analyses. These findings suggest that mechanisms of statistical sequential learning are implicated in language, and experience with language may affect cognitive processes and later learning.

**Keywords:** corpus analyses; experience-dependent learning; implicit learning; prediction; retrodiction; second language acquisition; sensitive periods; sequential learning; statistical learning; transitional probabilities; word order; linguistic typology.

## Introduction

Statistical information has been argued to be an important cue to linguistic structure. For example, sounds within a word are more predictable than sounds across boundaries, which may help infants discover words in fluent speech. Because this type of statistical information is present in all languages, statistical information may be a particularly important cue early in development, one that can be used without requiring prior experience with the native language (e.g., Thiessen & Saffran, 2003).

But while statistical learning may be a universal cue to linguistic structure, it is also the case that the statistical structure across languages differs. If statistical learning fails to adapt to these differences, it is unlikely to be an optimal learning strategy. While much research has examined how statistical learning helps learners adapt to the structure of their native language (e.g., Maye, Werker, & Gerken, 2002; Thiessen & Saffran, 2007), it is unknown whether statistical learning itself adapts to the characteristics of the native language. In this series of experiments, we ask whether experience with language alters the kinds of statistical

regularities that learners detect in ways that are consistent with the predominant statistical structure in their native language.

## Prediction and retrodiction in sequential learning

Recent studies have shown that learners can exploit both predictive and retrodictive relations, operationalized as forward and backward transitional probabilities respectively. For instance, Jones & Pashler (2007) showed participants sequences of shapes governed by probabilistic relations, and then asked them to choose which shape reliably came after a probe shape (prediction test) or before a probe shape (retrodiction test). In experiments where forward and backward probabilities were made informative, they found that both prediction and retrodiction were used effectively for recalling memories. In a similar experiment using a continuous sequence of nonsense syllables, Perruchet & Desaulty (2008) found that participants perceived word boundaries based on backward transitional probabilities as well as forward probabilities equally well. Likewise, Pelucchi, Hay, & Saffran (2009) provided evidence that infants can track backward statistics in speech.

The three studies above tested cases in which forward and backward probabilities were never in conflict. Rather, each cue was made maximally informative in a given experiment, while the other was made uninformative. Yet in naturalistic circumstances, prediction and retrodiction may need to be effectively combined, as when learning the word order of a language. In this respect, a comparison between English and Korean seems particularly appropriate because several word order relations of English are reversed in Korean.

## Prediction and retrodiction in natural languages: Typology and word order tendencies.

In English, the head elements in a phrase come first, while in Korean the head follows the phrase (e.g., '[Door-OBJECT] [close-IMPERATIVE]' = '[You close] [the door]', where square brackets indicate phrase groupings). The English sentence "I saw him go there" is glossed as "I him there go saw". Likewise "Give me the ball" is glossed as "Ball me give"; "Let's go get some food" is glossed as "Food get go let's". Thus, frequent constructions such as transitives, imperatives, and exortatives in English have a reversed word-order in Korean.

English is also prepositional ('to school'), while Korean is postpositional ('school to'). We conjectured that since the

linear word order relations in English and Korean are often specular, different sets of expectancies for predictive and retrodictive dependencies may emerge during learning each specific language: for example, in English the predictive probability of the noun *school* following the preposition *to* ( $p(\text{school}|\text{to})$ ) is lower than the retrodictive probability of *to* preceding *school* ( $p(\text{to}|\text{school})$ ), and vice-versa in Korean.

To corroborate these intuitions, we first conducted large-scale corpus studies of the two languages. Then an ambiguous artificial grammar containing different conflicting cues was presented to Korean and American speakers in a sequence learning task. This grammar is unlearnable from surface statistical regularities alone unless previous biases that favor predictive and retrodictive cues are in place in the system before learners start the experiment. Thus, the grammar was used as a litmus test for assessing potential prior biases on learning. To establish whether the biases should be attributable to experience with language or general sequential biases, we tested sequential learning across speakers of the two languages with opposite word order, and in three different modalities: auditory linguistic (speech), visual non-linguistic (abstract shapes), and auditory non-linguistic (pure tones).

We reasoned that if sequential learning mechanisms are directly involved in language acquisition and processing, as it has been put forth, these mechanisms should show language-specific biases effects when adults are engaged in sequence-learning tasks with speech-like stimuli. We further conjectured that if the bias is due to language experience – and not to some more general temporal processing bias – adult participants engaging in the same sequence task using non-linguistic stimuli (visual shapes and auditory tones), should behave consistently *irrespective* of their language background. Another possibility is that sequential learning mechanisms are shared among perceptual modalities and exhibit inherent a priori biases for sequences of stimuli, for example for predictive relations. In this latter case, we would expect a consistent pattern of preference across languages and modalities. Finally, there may be patterns of preference consistent across languages but differing by modality, in which case any effect may be attributable to modality-specific biases.

## Corpus Analyses

We quantified the hypothesis that word order tendencies in Korean and English generate *opposite* patterns of predictive and retrodictive conditional probabilities that signal phrase cohesiveness and syntactic information.

### Corpora

For English we used the SUSANNE Corpus, consisting of 130,000 words of published American English annotated with part-of-speech (POS) and syntactic information (Treebank)<sup>1</sup>. For Korean we sampled the freely available Sejong Corpus, with a syntactically annotated

subcomponent containing 800,000 words<sup>2</sup>. For each sentence in the corpus, we derived unigram and bigram frequency counts as well as forward and backward transitional probability statistics between any two words. Ngram frequencies in English were sampled from the Google Ngram database for the year 2000 (~4 million unigrams and 60 million bigrams). Korean ngram token frequencies were summed over three different corpora: Sejong, HC Korean (55 million unigrams), and KAIST (70 million unigrams) in order to obtain reliable frequency counts. Finally, for each word pair in a sentence we derived the level of syntactic boundary inherent in the syntactic annotation.

## Corpus Measures of phrase cohesiveness

**Independent Variable I: Ngram frequencies** Because several psycholinguistic studies have shown that humans are sensitive to the logarithm of event frequencies as opposed to raw frequencies, it is customary to consider log-frequencies as opposed to raw frequencies. The logfrequency of a sequence of two words (logBigram) can be taken as an approximation of phrase cohesiveness, following Tremblay et al., 2011. The logfrequency of each individual word can also be useful in predicting headedness, as higher frequency words tend to be heads of phrase constituents (Gervain et al., 2008).

**Independent Variable II: Conditional probability** Another way to measure how likely two words are to occur together is to look at a word and estimate what words are likely to follow it. The likelihood of a given word following is the forward probability of the word pair. For example, for the sequence ‘in Sapporo’:

$$\text{fwdTP}(\text{Sapporo}|\text{in}) = \frac{\text{freq}(\text{in\_Sapporo})}{\text{freq}(\text{in})}$$

The calculation can also be computed in the opposite direction. That is, examine a word and estimate what words are likely to precede it. The likelihood of a given word preceding is known as the backward probability between the two words.

$$\text{bckTP}(\text{in}|\text{Sapporo}) = \frac{\text{freq}(\text{in\_Sapporo})}{\text{freq}(\text{Sapporo})}$$

For example, suppose the word “in” occurs 2853 times in the corpus, but the word “Sapporo” occurs only 9 times and the sequence of words “in Sapporo” occurs 3 times. Since the word “in” occurs 2853 times, and only 3 of those times with the word Sapporo, this pair of words has a very low forward probability (3/2853). However, if we examine the pair from the opposite direction, we see that three out of the nine times the word “Sapporo” appears, it is preceded by the word “in.” Thus, the backward probability is 3/9, or .33.

**Dependent Variable: Phrase structure cohesiveness** To estimate the informativeness of transitional probabilities and frequencies in parsing at the constituent level, we followed Johnson (1965): Sentences from the tree-tagged Susanne corpus and Sejong corpus were divided up into phrasal constituents. For every word pair transition considered

<sup>1</sup> Available at <http://www.grsampson.net/Resources.html>

<sup>2</sup> Available at <http://rocker.snu.ac.kr:8080/search>

linearly from left to right, it is possible to rank-order the level at which a constituent node for that transition occurs. For example, in “[[[The house] [across [the street]]] [is burning]]” the highest node is at transition 5 (*street\_is*), followed in rank by transition 2 (*house\_across*), then transition 3 (*across\_the*). Finally, transitions 1, 4, and 6 are tied on the same rank. Using the syntactically annotated corpora, every bigram in each sentence can be assigned a syntactic rank, following the example above.

Typological studies of the world languages have uncovered important correlations in the linear order of the constituents in different subdomains. For instance, the constituent order of a clause (the relative order of subject, object, and verb); the order of modifiers (adjectives, numerals, demonstratives, possessives, and adjuncts) in a noun phrase; and the order of adverbials and adpositions. Most languages appear to have a preferred word order that is usually most frequent. This ordering of constituents is often represented as a tree where branches can be divided into other minor branches, which may also branch in turn. English is often described as a right-branching language, because it tends to place dependents after the head words. Adjectives follow nouns, direct objects follow verbs, and adpositions are prepositional. This type of branching is also known as head-first order. Left-branching languages, like Korean and Japanese, exhibit the opposite tendency, that is, they tend to place the head element of a phrase to the left. Objects appear to the left of verbs, sentences appear to the left of subordinating conjunctions and noun phrases appear to the left of prepositions (which, for this reason, are often called postpositions in these languages). Since postpositions come after the noun in left-branching languages, our example phrase, “in Sapporo,” would actually be in the opposite order, “Sapporo in.”

We were interested in assessing whether regularities in the word order of English and Korean engender language-specific probabilistic expectations between sequences of adjacent words. For example, considering the sequence “in Sapporo” the forward probability is expected to be low, arguably because many words can follow “in” (Rome, New York, summer, me, the, lovely, etc.). Conversely, the backward probability should be high, because only a few words are expected before “Sapporo” (to, in). Thus a pattern of “forward low-backward high” probability (*LoHi* for short) is expected to run as a sentence unfolds in English. If we express this combined pattern in mathematical terms as the difference between the forward and the backward probability (TPdiff), for any word pair in a sentence we should expect a positive larger TPdiff to indicate a more cohesive phrase unit in the language. Thus, the TP difference could be taken to predict the level of syntactic constituency between any word pair in the syntactically tagged corpora. Notably, for Korean the pattern of transition probabilities is expected to be reversed. For “Sapporo in”, the forward probability should be high relative to the backward probability. Thus, *HiLo* patterns are expected to run as a sentence unfolds in Korean. Using the same

differential measure (TPdiff) between forward and backward probability, this time we can expect a large negative TPdiff to predict more cohesive phrase units in the syntactically-tagged Korean corpus. These predictions “by example” are by no means granted for the whole language. In the syntactic literature it has long been noted that the right-branching/left-branching dichotomy may not hold for an entire language, and in the case of English it is not fully consistent even at the phrasal level (for instance for the word ordering within a Noun Phrase, see Cook and Newson 2007). Thus it is important to evaluate whether these probabilistic biases are significantly and robustly correlated with word order across the two language corpora.

## Results

Ordinal logistic regressions were run to predict the syntactic tree level between any two members of word pairs (word1, word2, e.g., “in Sapporo”) in a sentence. The syntactic tree level was obtained from the syntactic parsing provided in the Susanne and Sejong corpora (henceforth English and Korean corpus respectively). Therefore, the tree level (henceforth *tree*) was the dependent variable to be predicted by the regression models. The following predictors were considered in the following order: log frequency of each bigram, log-frequency of first word, log-frequency of second word, forward probability, backward probability. Because node levels above 6 were very infrequent in both corpora, we considered the first six node levels, accounting for 99.5% of bigrams in the English corpus (109,861 bigrams entered in the analyses) and for 98.1% of bigrams in the Korean corpus (22,382 bigrams entered).

**Model fit** For each corpus, ordinal logistic regression models with different complexity were fitted and compared for goodness of fit. The null model contained no predictors, then increasingly complex models added logBigram, LogFrequency of first word, LogFrequency of second word, Forward Probability, and Backward Probability as predictors. Analyses of deviance between each increasingly complex model indicated that including all predictors except LogFrequency of second word increased the fit of each regression model significantly with respect to the previous less complex model by reducing deviance. This result held for both corpora. Thus, in the following analyses the log-frequency of the second word was excluded as a predictor. All other variables contributed significantly to predict the level of syntactic node between any two adjacent words in a sentence in the corpus. Using the *lrm* function in R we were also able to assess the goodness of fit of the models. As the p-values of the G test statistics are 0 in both language models, the null hypothesis can be rejected that there is no overall significant relationship between the dependent variable *tree* and the independent variables. The predictive ability of the model can also be measured using C, an index of concordance between the predicted probability and the observed response. (if C=0.5 the predictors are random, when it is 1, prediction is perfect). Since C=0.71 for English and C=0.64 for the Korean corpus, we have confidence that

both models have moderate to strong predictive capacity. Somer's  $D_{xy}$  is a rank correlation between predicted probabilities and observed responses. It ranges between 0 (randomness) and 1 (perfect prediction). Since  $D_{xy}=0.43$  (English) and  $D_{xy}=0.30$  (Korean) we have again confidence that both language models have moderate predictive capacity. Kendall's Tau-a rank correlations also assess the correlations between all predicted probabilities and observed response. Here  $\text{Tau-a}=0.26$  (English) and  $\text{Tau-a}=0.16$  (Korean).

**English Corpus** We were particularly interested in the *coefficient sign* of the independent variables across the two corpora. For English, the coefficients for *logBigram* were consistently negative, indicating that the more frequent bigrams are associated with tighter phrase boundaries. Thus, the frequency of a bigram can be used to partially predict phrase cohesiveness, in accord with the psycholinguistic evidence obtained by Tremblay et al. (2011). Most importantly for the hypothesis being tested in this study, lower forward probabilities and concurrently higher backward probabilities (a *LoHi* pattern) were associated with higher phrase cohesiveness, as indicated by a positively valued coefficient for *TPdiff*. Remember that low syntactic levels indicate that the word pair tends to be occurring within the same phrase, or across a transition that is at a lower level up the syntactic tree. In addition, higher frequency of first words was associated with more phrasal cohesiveness, in accord with Gervain et al. (2008).

**Korean Corpus** *LogBigram* frequency was negatively associated with syntactic depth, indicating again that more cohesive phrases tend to be more frequent. Crucially, the coefficient for *TPdiff* was now positive (and reversed with respect to English), indicated that higher forward probabilities and lower backward probabilities (a *HiLo* pattern) were associated with higher phrase cohesiveness.

**Summary** When comparing English and Korean, the patterns of probability that support syntactic parsing are clearly reversed in the two languages, as originally predicted. In particular, phrase cohesiveness correlates with a *LoHi* pattern of transition probabilities in English, and with a *HiLo* pattern in Korean. Below we ask whether these language-specific patterns of probabilities are a source of experience-induced bias when learners group novel stimuli in a sequence learning task.

## Experiment 1

The corpus analyses above provide a rationale for our main hypothesis, namely that the predictive regularities most consistently experienced in one's native language, may impose processing biases on human sequential learning (Table 2). A speech-synthesized stream of syllables was constructed so that two mutually exclusive sets of syllable groupings could possibly be extracted, according to either a bias for a *LoHi* probability pattern (as in English 'to school', Table 2), or a *HiLo* probability pattern (as in Korean 'school to', Table 2). Because the two sets were equally frequent (*HiLo* grouping,  $M=59.2$ ,  $SD=2.9$ ; *LoHi* grouping,  $M=59.3$ ,

$SD=3.2$ ; difference *ns*), a consistent preference for either of them would be indicative of a statistical learning bias developed prior to the experiment.

## Method

**Participants** Thirty-seven English monolingual and 36 native Korean students participated. Korean participants were enrolled in graduate programs at the University of Hawaii, and their scores in the TOEFL test of English as Second Language was high ( $M=252.14$ , out of 300,  $SD=16$ ).

**Stimuli** A seamless 5-min speech sequence of 8 synthesized syllables (*bu, fu, ra, ti, she, zi, ge, ni*) was generated following the forward and backward transitional probabilities in Table 3, with 80 ms for consonants and 260 ms for vowels, and 5 s fade-in and out. We used the Italian diphone set in order to engage participants in a foreign language learning task for both groups. The Italian phonemes we chose had equivalent phonemic realizations in English and Korean, and all syllable sequences were phonotactically legal. No participant knew Italian. No cue to word boundary was present other than the patterns of predictive and retrodictive dependencies (Table 1). Importantly, whenever forward probability was low between any two adjacent syllables, ( $\text{fwdTP}(zi|she=.33)$ ), backward probability was high ( $\text{backTP}(she|zi=1)$ ), and vice versa (Table 1). At test, two groupings corresponding to a pattern of *HiLo* probability and *LoHi* probability were pitted one against the other in a forced-choice task. None of the possible groupings was an actual word in either language. The six test pair trials were presented in random sequential order, while the order within a pair was counterbalanced by repeating each test pair twice.

**Procedure** Participants in each language group were randomly assigned either to the experimental condition that included Training and Test or to a control condition that included the Test phase only (18 English native speakers, 21 Korean native speakers). Participants in the experimental condition listened to the training stream for 5 minutes. Test consisted in 12 two forced-choice task trials between pairs of *LoHi* and *HiLo* groupings. For each pair they were asked to choose which sound sequence formed a grouping in the language they had just heard. All instructions were administered in the native language of participants.

Table 1. The forward [square brackets] and backward (no brackets) transition probabilities associated with any two adjacent stimuli in the training sequence of the three experiments (in Experiments 2 and 3 the syllables were replaced by abstract shapes and tones respectively). For example, given *bu* only *fu* could follow ( $\text{fwd-TP}(fu|bu)=[1]$ ), while given *fu* there was a .33 probability that *bu* preceded it ( $\text{back-TP}(bu|fu)=(.33)$ ). Last three rows:

A sample of the training sequence of Experiment 1. Perceptual grouping boundaries could emerge either when the forward transitional probability between adjacent syllables was high and the backward probability was low (*HiLo* groupings), or viceversa (*LoHi* groupings).

HiLo groupings ... fushe zira funi ziti fuge zibu ...								
LoHi groupings ...fu shezi rafu nizi tifu gezi ...								

## Results

In all three experiments presented participants responses were coded in terms of proportion endorsements for HiLo groupings. Consequently, low endorsement rates for HiLo indicate preferences for LoHi groupings. A 2 (Language: Korean, English) x 2 (Condition: Experimental, Control) ANOVA revealed a main effect of Language ( $F(1,72)=11.22$ ,  $p<0.01$ ), and a Language by Condition interaction ( $F(1,72)=10.67$ ,  $p<0.01$ ). In particular, English native speakers exposed to training consistently preferred the LoHi groupings 62% of times ( $SD=14\%$ ), which was reliably different than chance ( $p < .001$ ). Conversely, Korean native speakers exposed to training preferred HiLo groupings 59% of times ( $SD=13.6\%$ ), which was reliably different than chance ( $p < .025$ ). Thus, English and Korean participants attended to the transitional probabilities that were most predictive of the canonical word order of their native language, as predicted by the corpus analyses. When presented with the Test items alone, no preference emerged for either groupings above or below change (English,  $t(17) = 0.44$ ,  $p = 0.67$ ; Korean,  $t(20) = 1.03$ ,  $p = 0.32$ ), ensuring that the bias in the experimental condition was not due to inherent preferences for certain sound combinations of the test items.

## Experiment 2

In order to further ascertain that the different scores in Experiment 1 were due to language-specific biases, in Experiment 2 we tested whether learning biases would arise when the same miniature grammar was implemented with non-linguistic stimuli in the visual modality. As discussed previously, sensitivity to forward and backward probabilities has been demonstrated in non-language domains, including visual processing (Fiser & Aslin, 2002; Jones & Pashler, 2007). However, the two cues were not pitted against each other in those experiments, but rather one or the other was maximally informative in the input. Here, at any stimulus transition the two cues are equally informative, but pitted against each other. Therefore we expected one of two scenarios. A null result would obtain if learners as a group weigh each cues equally, as indeed Jones & Pashler (2007)'s data suggest. Alternatively, if a priori visual preferences are attested in participants' responses, we expect them to be general visual sequential processing

biases not influenced by language experience. Thus, regardless of scenario, we expected no differential preferences based on the language of our participants.

## Method

**Participants** 15 new English and 15 Korean native speakers from the same population as Experiment 1 participated.

**Stimuli** A continuous sequence was generated that had exactly the same structure and length as Experiment 1, with the only exception that the 8 synthesized syllables were now replaced by 8 abstract shapes. Shapes appeared in succession on the screen for 340ms. The sequence had the same statistical properties as the language in Experiment 1.

**Procedure** The same learning and test procedure as Experiment 1 applied. At test participants received a two forced-choice task between pairs of LoHi and HiLo shapes. For each pair they were asked to choose which one formed a grouping in the sequence they had just seen. All instructions were administered in the native language of participants.

## Results

A one-way ANOVA revealed no significant main effect of Language ( $F(1,28)=0.025$ ,  $p=0.87$ ). Moreover, mean test items endorsements did not differ from chance (Korean,  $M = 0.51$ ,  $SD=0.17$ ,  $t(14) = 0.26$ ,  $p = 0.8$ ; English,  $M = 0.51$ ,  $SD=0.16$ ,  $t(13) = 0.03$ ,  $p = 0.97$ ).

## Experiment 3

The results of Experiment 2 indicate that the difference in directional preference between English and Korean speakers does not extend to visual sequences. This is consistent with the hypothesis that what drives the difference between language speakers in Experiment 1 is their experience with language. However, prior research indicates that there are important differences between processing visual stimuli and audio stimuli, due in part to the more transient nature of audio information (e.g., Conway & Christiansen, 2005). As such, it may be the case that the differences between English and Korean speakers are not specific to language, but rather arise from more general differences in auditory processing. To assess this possibility, we created a tonal analog of the input from Experiment 1.

## Method

**Participants** Both English monolinguals ( $N=15$ ) and Korean/English bilingual ( $N=15$ ) who reported Korean as their dominant language participated in this experiment. All English monolinguals were undergraduates at Carnegie Mellon University, as were six of the Korean English bilinguals. The other 9 bilingual participants were recruited via advertising in Pittsburgh churches.

**Stimuli** Each of the syllables in the language used in Experiment 1 was replaced by a unique 330 ms tone (bu = A4, ti = B, ge = C#, zi = D, fu = E, ni = F#, she = G#, ra = A5) in the key of A major. The resulting tonal sequence thus had an identical statistical structure as in Experiment 1.

**Procedure** Participants listened to the tone sequence over headphones. Next, participants were given 12 forced choice questions and asked to indicate, on a response sheet, which of two items sounded “more like” the tone sequence they had just heard. On each of the 12 questions, a tone item with a high-forward, low-backward transitional probability was paired with an item with low-forward, high-backward transitional probability.

## Results

A one-way ANOVA revealed no effect of Language ( $F(1,28)=0.025$ ,  $p=0.87$ ). Both English ( $M = 0.56$ ,  $SD = 0.09$ ,  $t(14) = 2.6$ ,  $p = .01$ ) and Korean-English bilinguals ( $M = 0.58$ ,  $SD = 1.14$ ,  $t(14) = 2.1$ ,  $p = .05$ ) selected test items with high forward transitional probabilities (HiLo items) at a rate above chance. The fact that they performed equivalently in this experiment is consistent with the hypothesis that the differences between these two populations in Experiment 1 are language-specific, and strengthen the claim that they arise from linguistic experience. Unlike adults’ lack of preference for shape test items in Experiment 2, participants did have a consistent preference for test items with high forward transitional probabilities, perhaps because the preference for forward-going items is a domain-general auditory preference, similar to the Iambic-Trochaic Law (e.g., Hay & Diehl, 2007). This preference may be early-developing, and then modified by linguistic experience: strengthened for Korean learners, and contravened by English learners. Alternatively, experience with music may inculcate a bias in both English and Korean listeners; on this account, musical experience is more consistent cross-culturally than linguistic experience.

## Discussion

We tested the hypothesis that adult English and Korean speakers come to the lab having already developed opposite statistical preferences for parsing continuous speech. The results of Experiment 1 supported that hypothesis: where English speakers preferred items with high backward probabilities, Korean speakers preferred items with high forward probabilities. Experiments 2 and 3 suggest that this preference is limited to linguistic materials. This limitation is consistent with the possibility that the preference arises from experience with language. Corpus analyses of English and Korean are consistent with this possibility, as the predominant word order of both languages mirrors the direction preference of English and Korean speakers.

Our findings have implications for understanding processes of second language acquisition. Our Korean participants were advanced second language speakers of English, and were enrolled in graduate programs in the United States. Their sensitivity to the learning bias opposite to that of the English participants suggests that they implicitly used their solidified L1’s learning biases when learning the novel artificial language. Because patterns that conform to those initially learned are further promoted, interference can be most severe with the learning of patterns

that do not conform to those initially learned. We propose that lower-order kinds of transfer involving basic sequential processing biases are at play in second language acquisition, and may have a ripple effect on encoding higher-order processes such as word order structure.

The results suggest that statistical learning changes throughout development by adapting to the characteristics of the native language. This opens many avenues for subsequent research, including understanding the mechanisms and developmental time course through which experience with native language alters subsequent learning.

# Semantic Coherence Facilitates Distributional Learning of Word Meanings

Long Ouyang, Lera Boroditsky, and Michael C. Frank

Stanford University

## Abstract

Computational work has suggested that one could, in principle, learn aspects of word meaning simply from patterns of co-occurrence between words. The extent to which humans can do this distributional learning is an open question – artificial language learning experiments have yielded mixed results, prompting suggestions that distributional cues must be correlated with other cues, such as phonological regularities, for successful learning. We conducted a large-scale experiment comparing how distributional learning is afforded by two different types of cues – phonological regularities and semantic coherence. We found that semantic coherence more strongly facilitates distributional learning than onset-consonant phonological regularities.

**Keywords:** word learning; distributional learning; semantic coherence

## Introduction

How do people learn what words mean? According to the distributional hypothesis (Harris, 1951; Firth, 1957), patterns of word co-occurrence are a powerful source of information about word meaning. It may be possible to acquire some facets of word meaning by simply keeping track of which linguistic contexts words appear in, even without access to any physical or social cues. Computational models have lent quantitative support for the distributional hypothesis. For example, the Latent Semantic Analysis model of Landauer & Dumais (1997) clustered words according to their patterns of occurrence across documents and was able to closely match human performance on synonym tests. The success of early models like LSA led to a proliferation of models that use distributional information to learn word meaning (see Riordan & Jones, 2010 for an overview) as well as other linguistic properties such as syntactic category (e.g., Redington, Chater, & Finch, 1998).

We know that distributional learning is computationally possible, but the evidence of human capacity for distributional learning is mixed. Some research has found that people learn co-occurrence statistics and use them to inform categorization (Mintz, 2002; Gerken, Wilson, & Lewis, 2005; Reeder, Newport, & Aslin, 2010), but other work has reached the opposite conclusion (Braine, 1966; Smith, 1966; Frank & Gibson, 2009). A holistic reading of the literature suggests that learning is more likely to occur when additional cues are correlated with distributional properties. Below, we review two representative findings using the *MNPQ* artificial language learning paradigm (Braine, 1966; Smith, 1966).

The *MNPQ* grammar contains four categories of words – *M*, *N*, *P*, and *Q* – and sentences take one of two forms: *MN* and *PQ*. Early investigations (Braine, 1966; Smith, 1966)

found that subjects recall “grammatical” *MN* and *PQ* sentences but also tend to recall ungrammatical *MQ* and *PN* sentences, suggesting that they learn position regularities (that *M/P* come first and *N/Q* come second) but not co-occurrence regularities (that *M* co-occurs with *N* but not *Q* and that *P* occurs with *Q* but not *N*). *MNPQ* learning has been an important paradigm because it provides an empirical means to consider purely distributional learning of word categories.

Braine (1987) investigated the effect of correlating co-occurrence regularities with natural gender. Subjects acquired an artificial language by learning to name pictures of referents. In the experimental condition, all pictures of men were labeled by *M* words and all pictures of women were labeled by *P* words. Learning of the co-occurrence regularities was significantly higher in the experimental condition than in a control condition where natural gender was not predictive of *M/P* membership. Though Braine’s experiment combined distributional cues with natural gender, he suggested that phonological cues might better serve real-world language learners. For instance, Spanish and Italian speakers might learn grammatical gender categories by taking advantage of the fact that feminine nouns often end with *-a*, while masculine nouns often end with *-o*. Recently, this suggestion received attention in the work of Lany and Saffran (2010), who found that 22-month old infants learned *MNPQ* co-occurrence regularities when they were aligned with the number of syllables in a word – that is, when *N* words were disyllabic and *Q* words were monosyllabic, but *not* when the number of syllables was not predictive of *N/Q* membership.

The defining feature of the artificial language learning paradigm is that, at the outset of the experiment, subjects do not know the meanings of any of the words. Yet, this condition generally does not hold true for real language learners, who typically know the meanings of some words but not others. It is plausible that the presence of known words facilitates distributional learning. If this is true, how effective are such semantic cues, and how do they compare to (e.g.) phonological cues? Here, we report the initial results of the first large-scale study comparing the effectiveness of various correlated cues on distributional learning. We presented subjects with an *MNPQ* language where sentences took the form “*M* and *N*” or “*P* and *Q*”. We hypothesized that distributional learning would be afforded given a certain level of *semantic coherence*, where all *M* and *P* words were familiar and adhered to some semantic organization (e.g., *M* = animal words, *P* = vehicle words). For instance, hearing the four sentences “cat and dax”, “cat and ziv”, “car and wug”, and “car and pif” might allow learners to infer that daxes and zivs belong to the

same category, as both words co-occur with “cat”, and that wugs and pifs belong to the same category, as both words co-occur with “car”.

In Experiment 1, we tested whether semantic coherence facilitated distributional learning. In Experiments 2 and 3, we compared semantic coherence to phonological coherence and semantic incoherence (the presence of known words that *do not* adhere to some semantic organization).

## Experiment 1: Semantic Coherence

We parametrically varied two independent variables: (1) the amount of exposure to the language and (2) semantic coherence – the fraction of known words that adhered to a taxonomic organization ( $M$  = animal words,  $P$  = vehicle words). We then applied three measures of  $MNPQ$  learning – sentence memory, similarity rating, and a referent assignment task.

### Method

**Participants** 654 Amazon Mechanical Turk (MTurk) workers participated in the study. Using MTurk’s worker qualifications we limited participation to workers located in the US and with a previous HIT approval rate  $\geq 90\%$ . We chose MTurk workers because the number of experimental conditions required a large number of subjects.

**Materials** Sentences took the form “ $M$  and  $N$ ” or “ $P$  and  $Q$ ” (see Figure 1). We generated the actual lexical items randomly for each subject.  $N$ ’s and  $Q$ ’s were always novel nonsense words and were drawn without replacement from {*moke*, *thite*, *jiv*, *pif*, *dex*, *wug*}.  $M$ ’s and  $P$ ’s could be either novel or familiar. Novel  $M$ ’s were drawn from {*feeb*, *bim*, *lup*} and novel  $P$ ’s were drawn from {*zabe*, *vap*, *chuv*}. Familiar  $M$ ’s and  $P$ ’s obeyed a taxonomic organization – familiar  $M$ ’s were drawn from {*hamster*, *cat*, *dog*} (animal words) and familiar  $P$ ’s were drawn from {*car*, *bus*, *truck*} (vehicle words). To create the audio files, we input the sentences as “X. and. Y.” (e.g., “*car*. and. *chuv*.”, including periods) into an American English text-to-speech engine using a female voice. The periods between words introduced substantial pauses ranging in length from 150 to 300 ms; piloting revealed that without pauses, it was difficult for participants to distinguish the words. Sentences using only monosyllabic words were around 2 seconds long. Sentences using the sole disyllabic word, *hamster*, were around 3 seconds long.

The referent assignment task involved visual referents. For the context words, we used 128x128 pixel images of a cat, dog, hamster, car, bus, and truck. For the target words, we used 100x100 pixel images of a horse, rabbit, sheep, bear, goldfish, mouse, boat, van, train, motorcycle, plane, and bicycle.

**Design and Procedure** We parametrically varied coherence – the number of familiar  $M$  and  $P$  words. The language for a subject contained either 0/3, 1/3, 2/3, or 3/3 familiar  $M$  and  $P$  words each. We also varied the amount of exposure to the language – subjects heard either 56, 126, 196, or 392 sentences. Before starting the experiment, we asked subjects

Figure 1: The  $MNPQ$  language. Underlined sentences were withheld from exposure in Experiments 1-3.

<u><math>m_1 n_1</math></u>	$m_1 n_2$	$m_1 n_3$	<u><math>p_1 q_1</math></u>	$p_1 q_2$	$p_1 q_3$
$m_2 n_1$	<u><math>m_2 n_2</math></u>	$m_2 n_3$	$p_2 q_1$	<u><math>p_2 q_2</math></u>	$p_2 q_3$
$m_3 n_1$	$m_3 n_2$	<u><math>m_3 n_3</math></u>	$p_3 q_1$	$p_3 q_2$	<u><math>p_3 q_3</math></u>

to turn on their speakers and click a button, which played a spoken English word. Subjects were required to correctly type the word to continue. The experiment had four phases – exposure, similarity, memory, and referent assign. Below, we detail these phases (for purposes of exposition, we have switched the order of memory and similarity).

**Exposure.** Subjects listened to sentences from the language. We withheld six sentences from exposure (see Figure 1), yielding 14 unique sentences in the exposure set. Each sentence was heard either 4, 9, 14, or 28 times, giving 56, 126, 196, or 392 total trials. We presented the sentences in random order subject to the constraint that there were no repeated words between consecutive trials (pilot testing suggested that repeated words substantially afforded learning). To encourage compliance, subjects had to click a button to hear each sentence.

**Memory.** Subjects listened to sentences and judged on a 5 point scale how confident they were that they had previously heard the sentence during exposure. We tested four types of sentences – *familiar* sentences heard during exposure, *withheld* sentences not heard during exposure but conforming to the  $MNPQ$  structure, *cross-category* sentences of the form  $MQ$  and  $PN$ , and *position-violation* sentences of the form  $MM$ ,  $NN$ ,  $PP$ , and  $QQ$ . Sentences were presented in random order such that there were no repeated words between consecutive trials. In two catch trials, instead of a sentence from the  $MNPQ$  language, we played a non-repeatable audio instruction to press a specific response button. If subjects learned the  $MN$  and  $PQ$  co-occurrence relationships, then we expected that they would rate novel grammatical sentences respecting the co-occurrence relationships as more familiar than the cross-category sentences violating the co-occurrence relationships.

**Similarity.** For each pair of words in the union of  $N$  and  $Q$ , we asked subjects to rate on a 5 point scale how similar they believed the two words to be in meaning. This resulted in within-category judgments (e.g.,  $n_1$  vs.  $n_2$ ) and cross-category judgments (e.g.,  $n_1$  vs.  $q_1$ ). We presented the pairs in a fixed pseudorandom order containing no repeated words between consecutive trials. Though exposure was entirely auditory, for convenience, we presented these similarity questions as text (e.g., “How similar are **pif** and **thite**?”); to facilitate mapping between visual and spoken word forms, the speaker button next to each word played the spoken word when clicked. In two catch trials, subjects were asked to press the response button corresponding to the solution of a simple arithmetic problem. If subjects learned the  $MN$  and  $PQ$

co-occurrence relationships *and* used these relationships as a basis for lexical categorization, then we expected that within-category pairs of words would be rated as more similar than cross-category pairs.

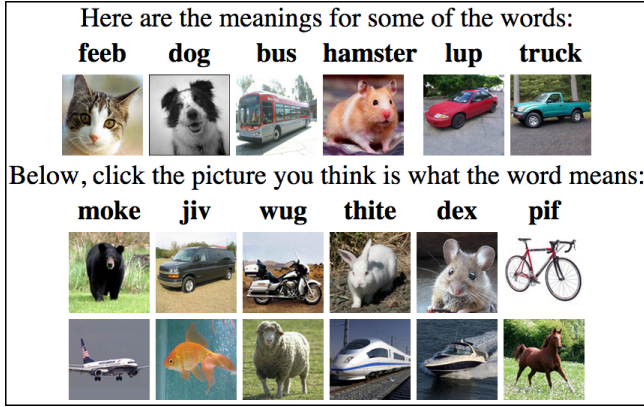

Figure 2: The referent assignment task.

*Referent assignment.* Subjects made 2AFC referent assignments for the  $N$  and  $Q$  words (see Figure 2). At the top of the screen, we displayed the  $M$  and  $P$  words in random order. Under each word, we showed an image of an associated referent. The referents corresponded to the familiar pools for  $M$  and  $P$  words: CAT, DOG, HAMSTER, CAR, BUS, and TRUCK. Familiar words were always associated with the obvious referents (e.g., “dog” was always paired with an image of a dog). Below the “seeded” word meanings, we displayed a row containing the  $N$  and  $Q$  words. Under each word, we displayed a 2AFC referent choice between an animal (the “correct” choice for  $N$  words) and vehicle words (the “correct” choice for  $Q$  words); subjects made a choice by clicking on one of the two pictures. If subjects learned the  $MN$  and  $PQ$  co-occurrence relationships *and* used them to form nascent lexical categories *and* used these lexical categories as a basis for inferences about word meaning, then we expected that referent assignment scores would reflect a tendency to choose on the basis of the taxonomic categories of the co-occurring words (e.g.,  $N$ ’s should be animals because they co-occur with  $M$ ’s, which are known to be animals).

## Results and Discussion

We excluded the 47 subjects who did not correctly answer all of the catch trials. Results are shown in Figure 3. Next, for each dependent measure – memory, similarity, and meaning – we defined a within-subject score representing the sensitivity to the co-occurrence regularities in the language. Memory score was the difference in mean ratings between novel withheld sentences (e.g.,  $m_1-n_1$ ) and novel category violation sentences (e.g.,  $m_1-q_1$ ). Similarity score was the difference between mean ratings of within-category (e.g.,  $N-N$ ) and cross-category (e.g.  $N-Q$ ) ratings. Referent assignment score was the total number of correct choices in the referent assignment task. We analyzed two aspects of the data. First, we were in-

terested in main effects of coherence on score. Second, as one hallmark of statistical learning is sensitivity to the amount of evidence observed, we were interested in the relationship between amount of exposure and score. Accordingly, we looked for exposure  $\times$  coherence interactions. A significant interaction would indicate a difference in how *efficiently* the statistical learning process makes use of evidence at different coherence levels. For all scores, we coded coherence as a categorical variable and analyzed the data using an interactive regression model: score  $\sim$  exposures  $\times$  condition. To examine the differences between the different coherence levels, we used Helmert contrasts analyzing (i) the difference between the 1/3 and 0/3 conditions, (ii) the difference between the 2/3 condition and the 0/3 and 1/3 conditions combined, and (iii) the difference between the 3/3 condition and the 0/3, 1/3, and 2/3 conditions combined. Results of these analyses are shown in Table 1.

Table 1: Regression models

Regressor	$\beta$	$t$	$p$
Memory			
Exposures	< 0.001	2.67	< 0.01*
Condition: 1/3 – (0/3)	-0.003	-0.03	0.97
Condition: 2/3 – (0/3,1/3)	0.101	1.78	0.074
Condition: 3/3 – (0/3,1/3,2/3)	0.154	3.62	< 0.01*
E $\times$ C: 1/3 – (0/3)	< 0.001	0.17	0.86
E $\times$ C: 2/3 – (0/3,1/3)	> -0.001	-0.20	0.83
E $\times$ C: 3/3 – (0/3,1/3,2/3)	< 0.001	2.76	< 0.01*
Similarity			
Exposures	< 0.001	1.82	0.06
Condition: 1/3 – (0/3)	-0.039	-0.36	0.71
Condition: 2/3 – (0/3,1/3)	0.075	1.33	0.18
Condition: 3/3 – (0/3,1/3,2/3)	0.097	2.30	0.02*
E $\times$ C: 1/3 – (0/3)	< 0.001	0.53	0.59
E $\times$ C: 2/3 – (0/3,1/3)	< 0.001	0.42	0.67
E $\times$ C: 3/3 – (0/3,1/3,2/3)	< 0.001	2.66	< 0.02*
Referent assignment			
Exposures	0.001	3.16	< 0.01*
Condition: 1/3 – (0/3)	0.153	1.01	0.31
Condition: 2/3 – (0/3,1/3)	0.183	2.26	0.02*
Condition: 3/3 – (0/3,1/3,2/3)	0.121	2.00	0.04*
E $\times$ C: 1/3 – (0/3)	> -0.001	-0.29	0.77
E $\times$ C: 2/3 – (0/3,1/3)	> -0.001	-0.89	0.37
E $\times$ C: 3/3 – (0/3,1/3,2/3)	< 0.001	1.29	0.19

**Memory** There were significant main effects of exposure and condition, with scores in the 3/3 condition being significantly higher than in the other conditions combined. Additionally, there was a significant exposure  $\times$  condition interaction; the effect of exposures on score was significantly higher in 3/3 than in the other conditions combined, suggesting greater efficiency of statistical learning in 3/3. Thus, more coherent linguistic input (1) bolstered memory for the  $MN$  and  $PQ$  co-occurrence regularities and (2) increased the efficiency of the statistical learning process responsible for learning those regularities, at least in the 3/3 condition.

**Similarity** There was a significant main effect of condition, with scores in 3/3 being significantly higher than in the other conditions combined. Additionally, there was a significant exposure  $\times$  condition interaction; the effect of exposures on

score was significantly higher in 3/3 than in the other conditions combined. Thus, more coherent linguistic input (1) increased the distinction between within-category and cross-category pairs of words and (2) increased the efficiency of the statistical learning process involved in making such distinctions, at least in the 3/3 condition.

**Referent assignment** There were significant main effects of exposure and condition. 2/3 scores were significantly higher than 0/3 and 1/3 scores combined and 3/3 scores were significantly higher than the rest of the scores combined. None of the interaction terms reached significance, indicating that the amount of exposure to the language and greater coherence independently increased the ability to assign *N* and *Q* words to the correct referents. We also computed this model using coherence as a continuous variable; this continuous regressor significantly predicted increases in score,  $\beta = 0.29$ ,  $t(650) = 3.06$ ,  $p < 0.005$ , indicating that *parametrically* increasing coherence resulted in *parametric* increases in referent assignment score.

To summarize, in Experiment 1, we found that higher coherence (1) increased ability to distinguish novel grammatical sentences from sentences violating co-occurrence regularities, (2) sharpened sensitivity to lexical category boundaries related to the co-occurrence regularities, and (3) increased inductive bias in associating words with referents. How does coherence bring about these effects? Frank & Gibson (2009) have shown that *MNPQ* learning can be bolstered by easing working memory demands. Furthermore, there is evidence that novel words tax the memory system more, as they are encoded in terms of smaller phonological units (Treiman & Danis, 1988), so it is conceivable that the presence of semantically coherent known words reduced memory demands and thus improved *MNPQ* learning. We tested for this possibility in our data using mediation analyses. In particular, we tested whether memory scores mediated the effect of coherence on either (1) similarity scores or (2) referent assignment scores. In both cases, we found partial mediation. After controlling for memory, the regression coefficient relating coherence and similarity decreased significantly from 0.28 to 0.12, Sobel  $z = 7.74$ ,  $p < 0.05$ ; this reduced value was significantly greater than zero,  $t(657) = 3.60$ ,  $p < 0.0005$ , indicating partial mediation. After controlling for memory, the regression coefficient relating coherence and referent assignment score decreased significantly from 0.31 to 0.19, Sobel  $z = 5.19$ ,  $p < 0.05$ ; this reduced value was significantly greater than zero,  $t(651) = 3.67$ ,  $p < 0.0005$ , again indicating partial mediation. Thus, improved memory can explain some, but not all, of the increase in similarity and referent assignment scores due to semantic coherence.

Given this result, it is natural to ask whether known words *per se* can sufficiently ease memory demands so as to facilitate *MNPQ* learning, or whether they must have semantic coherence; we consider this question in Experiment 3. A different, though not mutually exclusive, possibility is that any relatively salient type of coherence, such as phonological co-

herence, is sufficient to facilitate distributional learning. We consider this possibility in Experiment 2.

## Experiment 2: Phonological Coherence

As noted previously, Lany and Saffran (2010) found evidence of successful *MNPQ* learning when co-occurrence regularities were perfectly correlated with a phonological property – the number of syllables in an *N/Q* word. We sought to compare phonological coherence with semantic coherence. Thus, in Experiment 2, we measured the result of a phonological manipulation in which all *M* words began with “r” and all *P* words began with “z”.

### Method

**Participants** 157 MTurk workers participated in the study.

**Design** The method was similar to that of Experiment 1. *M*’s were {*rull*, *rudge*, *ruck*} and *P*’s were {*zof*, *zerm*, *zabe*}.

### Results and Discussion

Results are shown in Figure 4. We compared the phonological condition results with the 0/3 and 3/3 conditions of Experiment 1 using a regression model with Helmert contrasts analyzing (i) the difference between the 0/3 and phonological conditions and (ii) the difference between the 3/3 condition and the 0/3 and phonological conditions combined.

**Memory** Phonological scores were not significantly different from 0/3 scores,  $t(466) = 0.96$ ,  $p > 0.05$  and both combined were significantly lower than 3/3 scores,  $\beta = 0.2$ ,  $t(466) = 3.44$ ,  $p < 0.001$ . Phonological efficiency was not significantly different from 0/3 efficiency,  $t(466) = -0.17$ ,  $p > 0.05$  and both combined were significantly lower than 3/3 efficiency,  $\beta = 0.0007$ ,  $t(466) = 2.76$ ,  $p < 0.01$ .

**Similarity** Phonological scores were not significantly different from 0/3 scores,  $t(466) = -0.16$ ,  $p > 0.05$ , and both combined were significantly lower than 3/3 scores,  $\beta = 0.14$ ,  $t(466) = 2.54$ ,  $p < 0.05$ . Phonological efficiency was not significantly different from 0/3 efficiency,  $t(466) = -0.29$ ,  $p > 0.05$ , and both combined were significantly lower than 3/3 efficiency,  $\beta = 0.0008$ ,  $t(466) = 3.2$ ,  $p < 0.005$ .

**Referent assignment** Phonological scores were not significantly different from 0/3 scores,  $t(466) = 1.47$ ,  $p > 0.05$ , and both combined were significantly less than 3/3 scores,  $\beta = 0.2$ ,  $t(466) = 2.35$ ,  $p < 0.05$ . There were no differences in efficiency (recall that this was also the case in Experiment 1). In terms of facilitating acquisition of the *MN* and *PQ* co-occurrence regularities, the phonological manipulation was indistinguishable from the 0/3 condition, and hence was markedly less effective than semantic coherence at the 3/3 level. It must be noted that the phonological regularity we introduced was the onset consonant (*r*- words versus *z*- words) applied to *M/P* words, whereas Lany and Saffran (2010) used syllable length (monosyllabic versus disyllabic words) applied to *N/Q* words, making direct comparison difficult. Presently, we have established that a particular kind

Figure 3: Experiment 1 results. Each plot shows data for one measure (memory, similarity, meaning) in Experiment 1. Dots show condition means, while dashed lines show the best-fitting linear trend.

Figure 4: Experiment 2 and 3 results. Each plot shows data for one measure (memory, similarity, meaning) in Experiments 2 and 3. Dots show condition means, while dashed lines show the best-fitting linear trend.

of phonological regularity (onset consonant of a co-occurring word) is a far weaker correlated cue than semantic coherence.

### Experiment 3: Semantic Incoherence

The *M* and *P* words in Experiment 1 were all known and had semantic coherence. In Experiment 3, we explored whether coherence is necessary for facilitation of distributional learning, or whether the mere presence of known words is sufficient – that is, whether a semantically *incoherent* language facilitates distributional learning.

### Method

**Participants** 151 MTurk workers participated in the study.

**Design and Procedure** The method was similar to that of Experiment 2. The *M* and *P* words were known but did not adhere to any clear semantic organization. The specific *M* and *P* words were drawn from the pool {*shelf*, *glove*, *rain*, *leash*, *card*, *ball*}. In the referent assignment task, these known words were paired with images of the obvious referents, e.g., *card* with a picture of card.

### Results and Discussion

**Memory** Incoherent scores were not significantly different from 0/3 scores,  $t(460) = 0.056$ ,  $p > 0.05$  and both combined were significantly lower than 3/3 scores,  $\beta = 0.23$ ,  $t(460) = 3.95$ ,  $p < 0.0001$ . Incoherent efficiency was not significantly different from 0/3 efficiency,  $t(460) = 0.25$ ,  $p > 0.05$  and both combined were significantly lower than 3/3 efficiency,  $\beta = 0.0006$ ,  $t(460) = 2.55$ ,  $p < 0.05$ .

**Similarity** Incoherent scores were not significantly different from 0/3 scores,  $t(460) = -0.22$ ,  $p > 0.05$ , and both combined were significantly lower than 3/3 scores,  $\beta = 0.15$ ,  $t(460) = 2.47$ ,  $p < 0.05$ . Incoherent efficiency was not significantly different from 0/3 efficiency,  $t(460) = 0.723$ ,  $p > 0.05$ , and both combined were significantly lower than 3/3 efficiency,  $\beta = 0.0006$ ,  $t(460) = 2.54$ ,  $p < 0.05$ .

**Referent assignment** Incoherent scores were not significantly different from 0/3 scores,  $t(460) = 0.82$ ,  $p > 0.05$ , and both combined were significantly less than 3/3 scores,  $\beta = 0.23$ ,  $t(460) = 2.83$ ,  $p < 0.01$ . There were no differences in efficiency (recall that this was also the case in Experiments 1 and 2). The familiar but semantically incoherent linguistic

input appeared to have provided no benefit compared to the novel words of the 0/3 condition, suggesting that the presence of known words by itself does not aid distributional learning.

## General discussion

We have conducted the first large-scale systematic investigation of the effects of exposure and various correlated cues (semantic and phonological coherence) on distributional learning of word meanings. We have shown that semantic coherence aids distributional learning in the *MNPQ* regime far more than phonological (onset consonant) coherence. Additionally, our experiments indicate that *coherence* is necessary – semantically incoherent linguistic input provided virtually no benefit. Additionally, we showed that coherence works in part by alleviating memory limitations, though our data suggests that there may be aspects of distributional word learning not bottlenecked by memory resources.

We conjecture that word learners may be using semantic coherence to infer the topic of discourse and that this gist topic meaning influences the representations of co-occurring novel words (cf. the topic-learning models of Griffiths, Steyvers, & Tenenbaum, 2007). It may be through this process that people know *tort* to be a legal term and *transducer* to be an engineering term, despite not knowing the precise meanings of these words. Under this account, learning would be easier for words that occur in contexts high in semantic information and coherence. Thus, we would expect learning to have a “contiguous” character (faster learning for words occurring in familiar contexts than for words occurring in less familiar contexts), a possibility we plan to test in future work.

Our experiments highlight a limitation of artificial language learning paradigms. Researchers using *entirely* artificial languages may be severely limiting the power of distributional learning mechanisms, which our experiments show to be greatly enhanced by the presence of known words that adhere to some semantic organization.

Our work on distributional learning of semantic properties is in agreement with the extant literature on distributional learning of syntactic properties (viz. grammatical gender). Results from these studies (e.g., Brooks et al., 1993; Frigo & McDonald, 1998) indicate that children and adults fail to learn *MNPQ* categories without correlated cues, but they can learn given (e.g.,) correlated phonological markers. We believe that correlated cues – be they semantic, phonological, or otherwise – serve a common purpose: to reduce the space of possible categories.

## Abstract

The categories named by spatial terms vary considerably across languages. It is often proposed that underlying this variation is a universal set of primitive spatial concepts that are combined differently in different languages. Despite the inherently cognitive assumptions of this proposal, such spatial primitives have generally been inferred in a top-down manner from linguistic data. Here we show that comparable spatial primitives can be inferred bottom-up from non-linguistic pile-sorting of spatial stimuli by speakers of English, Dutch, and Chichewa. We demonstrate that primitives obtained in this fashion explain meaningful cross-linguistic variation in spatial categories better than primitives designed by hand for that purpose, and reflect both universal and language-specific spatial semantics.

**Keywords:** Language and thought; spatial cognition; semantic primitives; semantic universals; linguistic relativity.

## Spatial language and semantic primitives

Languages categorize spatial relations differently, and the significance of this cross-language variation for spatial cognition is a topic of ongoing debate (e.g. Bowerman & Pederson, 1992; Feist, 2000; Hespos & Spelke, 2004; Khetarpal et al., 2010; Levinson & Meira, 2003; Majid et al., 2004; see also e.g. Boroditsky & Gaby, 2010 on spatial structuring of non-spatial domains). This debate has traditionally pitted two views against each other. On the one hand, some have argued (e.g. Majid et al., 2004) that language structures spatial cognition, such that cross-language differences in spatial categorization cause underlying cognitive differences in speakers of those languages. On the other hand, others have suggested (e.g. Levinson & Meira, 2003) that the cross-language variation may reflect different partitions of a universal underlying conceptual representation.

An influential version of the universalist view holds that a set of *semantic primitives* (e.g. Wierzbicka, 1996) is universally available to human cognition, and that spatial categories in different languages can be obtained by composing such spatial semantic primitives in different ways. Feist (2000) proposed a set of spatial attributes characterizing cross-linguistic uses of spatial relations

similar to those expressed by *in* and *on* in English. She demonstrated that these primitives could be conjoined to form the linguistic spatial categories observed in diverse languages, accounting for both universal similarities and variation across languages. Xu and Kemp (2010) have since expanded on Feist's attributes, constructing their own set of universal primitives and demonstrating that conjunctions of these primitives can be used to describe a wide range of variation in the ways that languages partition the semantic space of spatial relations.

Primitive-based accounts have been demonstrated to characterize spatial terms across languages, capturing distinctions in both the intensional meanings and extensional uses of spatial words. However, the central issue in this debate is about cognition—not language. It is unclear whether these primitives accurately characterize the structure of thought as well.

Despite the assumption in the literature that semantic primitives are universal components of spatial cognition, these proposed units of thought have been developed and tested exclusively on the basis of linguistic data. Primitives of spatial cognition are typically inferred top-down from observations of cross-language variation in spatial terms, and evaluated on their ability to explain that variation. Importantly, this is generally done without direct reference to non-linguistic cognition. Consequently, we know little about how the semantic primitives of spatial language relate to spatial cognition.

While the primitives derived from language could plausibly account for variation in spatial cognition, they clearly suggest a subsequent inquiry: would it be possible to infer spatial primitives more directly from measures of nonlinguistic cognition? If so, would these cognitive primitives similarly account for the varying semantic systems across languages? Would they reflect language-specific influences as well?

## Spatial primitives in language and cognition

To determine whether proposals of semantic primitives are supported by direct evidence from nonlinguistic cognition, we would ideally want to obtain both cognitive and linguistic data from speakers of differing languages, extract primitives from the cognitive data of each group of

---

\*The first two authors contributed equally to this work.

speakers, and test the ability of these cognitive primitives to explain the linguistic spatial systems of their own and—most importantly—other languages. We could then compare the descriptive ability of these cognitive primitives to primitives previously proposed on the basis of cross-language data. If cognition-derived primitives from one group of speakers can account *well* for the spatial language of a different group this would provide support for the universalist account of semantic primitives.

However, it is not transparently obvious how to evaluate the performance of a set of primitives. One approach would be to compare their performance to that of previously attested linguistic primitives. However, comparing multiple representations raises the problem of accounting for the flexibility or representational power of differing representational systems. Correspondingly, primitives that accurately capture spatial semantics should explain language well *without* explaining random noise well. This gives us a criterion for testing cognitive primitives; if these primitives perform equally or better than language-derived primitives on a measure that accounts for representational power, then the cognitive primitives are doing well at characterizing *meaningful variation* in spatial semantic systems. Thus, if cognitive features derived from one set of speakers could account for another language's spatial system in such a way, this would support the universalist account.

In addition to testing support for this universal view, it is important to note that our examination is sensitive to linguistic relativity as well. If cognition-derived primitives from a group of speakers tend to explain the language of those speakers better than other languages, this would additionally provide support for linguistic relativity. For this reason, primitive-based proposals need not presume a universalist account. However, a fully relative account would also be difficult to support, as it requires that linguistic data is *always* best explained by cognitive data from speakers of the same language, as similarities in cognition across languages are theoretically limited to the extent that those languages overlap.

To examine the ideas described above, we obtain cognitive and language data through behavioral and linguistic tasks, respectively, in which speakers of various languages partition a set of spatial scenes into disjoint subsets through sorting and naming of the depicted spatial relations. We then infer primitives from the cognitive data in a neutral way, using an unsupervised, bottom-up statistical approach (additive clustering; see Lee, 2002). We evaluate whether these cognition-derived primitives support the semantic primitives account of spatial cognition and language by assessing the ability of cognitive primitives to explain variation in spatial language across a sample of diverse languages, in comparison to language-derived spatial primitives proposed in the literature. Finally, we address general implications for universal and relative views of language and thought, as well as suggestions specific to semantic primitives in spatial cognition.

To preview the results, we find that our spatial primitives

derived from cognitive data (1) explain semantic variation in language better than proposed primitives designed by hand for that purpose, (2) support both universal and relative views on spatial cognition, and (3) express generally coherent, but variably intuitive, semantic components of spatial relations.

## Methods

In order to compare primitives derived from cognition to those inferred from language in the literature, we drew on existing nonlinguistic cognitive data on spatial relations as a source for our primitives. We also incorporated existing spatial naming data, which the primitives attempt to explain. Here we briefly describe the prior collection of the cognitive and linguistic data by Khetarpal et al. (2009, 2010) and by Carstensen (2011). We then explain our process for inferring primitives from these cognitive data, and our procedures for testing the adequacy of these primitives in accounting for linguistic data.

**Participants.** A total of 24 native English speakers (Khetarpal et al., 2010), 24 native Dutch speakers (Khetarpal et al., 2009), and 38 native Chichewa speakers (Carstensen, 2011) took part in both the nonlinguistic and linguistic tasks, administered in their native languages and home countries of the United States, the Netherlands, and Malawi, respectively.

**Cognitive spatial task.** In each of the three studies from which we draw data (Khetarpal et al., 2009; 2010; Carstensen, 2011), participants sorted the 71 scenes in the Topological Relations Picture Series (TRPS; Bowerman & Pederson, 1992; see Figure 1 for examples) into piles based on the spatial relation depicted in each scene. Each scene showed an orange figure object positioned relative to a black ground object and participants were instructed to group the scenes into piles based on this spatial relation, such that the relation was similar for all cards in a given pile. Participants were informed that they could make as few or as many piles as they chose, rearrange their piles as they felt necessary, and could take as much time as they wanted.

**Linguistic spatial task.** In these previous studies (Khetarpal et al., 2009; 2010; Carstensen, 2011), after completing the sorting task, participants were asked to name the spatial relation depicted on each card. Labels picking out the target and ground objects were supplied in the participant's native language and the participant filled in the blank between these labels to complete a sentence specifying the figure's location in relation to the ground.

**Attested linguistic spatial categories.** In the linguistic spatial task, participants supplied terms or short phrases characterizing each spatial relation. Previous studies sanitized these data to collapse over responses that differed only in components without spatial meaning (e.g. variations in verb tense), leaving 88 unique spatial phrases supplied in English, 29 in Dutch, and 70 in Chichewa. For each phrase in every language, we recorded all scenes that the phrase was applied to at least once. These linguistic categories are

used as a target below to evaluate the ability of our primitives in describing categories in language. The attested linguistic categories also provide a standard for groupings of spatial scenes that are coherent and articulable in human language.

**Similarity from partitions of spatial scenes.** We use additive clustering (Lee, 2002) to infer cognitive primitives from nonlinguistic partitions (i.e., pile sorts) of spatial relations. Because this method operates over similarity matrices, we first create similarity matrices for each language based on the frequency with which speakers of that language co-sorted each pair of scenes.

These matrices reflect how often any two scenes were placed in the same pile by speakers of a given language. To create the matrix for language  $L$  for every pair of scenes  $(i, j)$ , we calculate the similarity value  $s_{ij}$  at row  $i$  and column  $j$  by counting the number of times each speaker of  $L$  placed scenes  $i$  and  $j$  into the same pile, and dividing this by  $|L|$ , the sampled number of speakers of language  $L$ .

**Additive clustering to derive primitives.** The spatial primitives proposed to underlie thought and compose categories in language have traditionally been designed by hand. In order to infer primitives from different languages in an unbiased and language-neutral way (e.g. unaffected by the researcher’s native language), we create primitives using an unsupervised clustering algorithm—*stochastic-optimized additive clustering* (Lee, 2002). This algorithm does not require that we assume a particular number of primitives and it has been used in the past to extract meaningful primitives from linguistic semantic partitions (Lee, 2002).<sup>1</sup>

The algorithm approximates  $s_{ij}$  with  $\hat{s}_{ij}$  for all  $i$  and  $j$ , minimizing  $\sum_{i < j} (s_{ij} - \hat{s}_{ij})^2$  under certain assumptions on how  $\hat{s}_{ij}$  is obtained. Specifically, we assume that objects possess a set of  $n$  underlying features, each of which is shared by a subset of the objects, and we assume that each feature has an associated positive weight or salience. The estimated similarity value for two items,  $i$  and  $j$ , is thus the sum of the weights of the features that those two items share (after scaling the weights to be between 0 and 1). That is, let  $\mathbf{1}_k(i)$  be the indicator function for feature  $k$  with weight  $w_k$  (i.e., it has value 1 if its argument has feature  $k$  and 0 otherwise), then  $\hat{s}_{ij} = \sum_{k=1}^n w_k \mathbf{1}_k(i) \mathbf{1}_k(j)$ .

Stochastic-optimized additive clustering uses a stochastic search which grows the set of primitives until the variance explained by adding further primitives fails to outweigh complexity afforded by adding those primitives. Through this process, we generate the features that we treat as cognitive primitives underlying the spatial scenes in the TRPS. That is, each primitive is the set of images defined

by a features indicator function (e.g., see Figure 1 below).

We apply this algorithm to the co-sorting matrices from all three languages, producing a set of primitives based on nonlinguistic cognitive data from speakers of each language. Because the algorithm is stochastic, running it multiple times will return different sets of primitives. To sample the space of potential primitive sets, we create 10 primitive sets for each language’s co-sorting matrix, making for 30 primitive sets in all.

Figure 1: Additive clustering is used to produce a set of primitives which are clusters of “similar” images. Portions of five actual primitives derived from English speakers’ spatial scene sorting are presented above. The pop-out of primitive V shows all four of the 71 TRPS scenes that compose this particular primitive, which appears to characterize spatial relations that involve figure or ground piercing.

**Conjoined primitive sets.** A common assumption is that spatial primitives can be conjoined (e.g., “ $x$  is supported and in contact with  $y$ ”) to produce the spatial categories named by spatial terms in different languages (Feist, 2000; Xu & Kemp, 2010). Accordingly, we examine how the primitives we infer from pile-sort data can be conjoined to explain variation in spatial language across cultures.

We create and denote our conjoined primitive sets as follows. The base primitive set for a language is designated  $F(0)$ . Then,  $F(1)$  is the set of primitives formed by the union of  $F(0)$  and all conjunctions of two primitives from  $F(0)$ . Similarly, we create  $F(2)$  by including all the primitives in  $F(1)$  as well as all conjunctions of three primitives. Finally, we create  $F(3)$  from the union of  $F(2)$  and all conjunctions of four primitives.

**Defining distance.** In order to assess how well cognitive primitives account for spatial language, we need to determine their fit by defining a metric for the distance between sets of binary vectors with the same number of dimensions,  $d$ . First, we define a distance metric between pairs of binary vectors (e.g. primitives and linguistic categories) as being the city-block distance between those two vectors,  $f_1$  and  $f_2$ , which both have  $d$  dimensions (e.g. the 71 TRPS scenes, presence indicated by 1 and absence 0):

<sup>1</sup> Stochastic-optimized additive clustering requires a “precision” parameter describing how precise our similarity measures are, and a parameter that describes how much explanatory power is needed to warrant greater primitive set complexity. Because we used co-sorting as a proxy for similarity, we chose to use the least precise conventionally used value (i.e., 0.15) and the default complexity/simplicity trade-off value of six (Lee, 2002).

$$\text{dist}(f_1, f_2) = \sum_{i=1}^d |f_1(i) - f_2(i)|$$

This counts the scenes present in only one of  $f_1$  and  $f_2$ .

**Best-match analysis.** Though we have defined a distance measure between individual vectors, this does not explain how we measure the distance between *sets* of primitives and categories. Primitives are intended to be composed together to describe variation in linguistic categories across languages. Thus, we would want to create a distance metric that captures good performance on that measure across all primitives in a set.

Suppose that there is a set of primitives,  $P$ , and a set of linguistic categories,  $L$ . While the primitives and linguistic categories that make up these sets have very different interpretations and origins, they share a formal structure. That is, they are both binary vectors over the full set of images. This means that we can use the vector to vector distance as a measure of distance between an individual primitive and a single linguistic category.

Because we are attempting to explain a linguistic categorization system, one reasonable measure for the distance between  $P$  and  $L$  is to take the sum of the distance between the *best matching primitive* in  $P$  for every category in  $L$ . There are no constraints on how often a primitive may be used to explain linguistic categories; thus, this criterion will maximize the explanatory capabilities of  $P$  for  $L$ . Furthermore, each of the 10 primitive sets derived from a language’s pile-sort data will produce a best-match distance with a language  $L$ . We will consider only the value for the run with the lowest distance, since, arguably, by this criterion that run is the best run for explaining  $L$ .

**Primitives in the literature as a benchmark.** Because the description of linguistic spatial categories in terms of proposed universal primitives is a well-visited topic, previous proposed primitives provide a natural benchmark against which to test our cognitive primitives. Xu and Kemp (2010) describe a set of 19 primitives (e.g. “contact”) drawn from the wider literature and define the 71 TRPS images in terms of these primitives. To obtain definitions of scenes in terms of their primitives, Xu and Kemp asked three individuals to state whether each primitive applied to a given scene and assigned primitives to scenes based on majority vote. Using the same 19 primitives and 71 TRPS images, we replicated this procedure with three participants ( $\kappa = .91$ ) to obtain a set of primitives comparable to those described in Xu and Kemp (2010).

We considered both this primitive set and an expanded version consisting of the original 19 primitives together with negated versions of these primitives (i.e. the opposite, complementary set of scenes; e.g. the set of things that are ‘not in contact’) when appropriate, as determined by Xu and Kemp (2010). We found that in all cases the primitives with negation outperformed the simpler set<sup>2</sup>, and we therefore only report the performance of this expanded set. We use this set as a benchmark for evaluating the performance of

our primitives, as these primitives from the literature are hand-designed and generally considered to characterize semantic content across languages.

## Results & Discussion

The universalist account of semantic primitives holds that a set of conceptual primitives is universally available to human cognition, and spatial categories in varying languages can be created from different compositions of such spatial semantic primitives. To assess whether this view is supported directly by evidence from cognition, we derived sets of cognitive primitives from speakers of a sample of three diverse languages. We tested the ability of these cognitive primitives to explain variation in spatial language against previous proposals designed and tested on their ability to characterize such cross-linguistic data.

After creating 10 sets of primitives per language from the nonlinguistic pile-sorting of English, Dutch, and Chichewa speakers, we identified the best-scoring set of primitives from each language, making for three base sets of cognitive primitives. The fourth base set considered was the best-performing set of spatial primitives (with negations) from the literature (specifically from Xu and Kemp, 2010). From each base set, we derived a sequence of increasingly complex sets of features, by allowing increasing numbers of primitives to be conjoined together, as described above. We then recorded the distance of each primitive set in each sequence to the linguistic spatial systems of English, Dutch, and Chichewa, as a measure of how closely each primitive set characterizes variation in these languages.

Figure 2 shows that the distance scores for all four primitive base sets improve (i.e. provide a closer fit to the linguistic data) with the addition of conjunctions, affirming Xu and Kemp’s (2010) finding that conjunctions of primitives (linguistic in their case, cognitive in ours) can indeed provide for closer approximations to the categories in language. (Note, however, that because each further level of conjoined primitives contains the previous level, decrement was impossible and improvement very likely.) Although our primitives were derived from cognition and not hand-designed, like the language-derived primitives, their performance is generally comparable to these previously proposed primitives, substantially improving with the inclusion of the first level of conjunctions, but rapidly tapering off as more features are conjoined.

Notably, our primitives consistently outperform those from the literature in the base case or with pairs of intersections, revealing that they themselves are closer to the attested linguistic categories. At greater depths (i.e. with more conjunctions, and thus at the cost of representational complexity), the primitives from the literature are able to more closely approximate the linguistic categories of one of

<sup>2</sup> Interestingly, while Xu & Kemp (2010) did not find improved performance due to the inclusion of negative primitives, we found that in our comparison, including negated primitives offered large improvements over just the simple set of primitives.

Figure 2: Average distance between literature-derived, Dutch, English, and Chichewa pile-sort-derived primitives, and the Dutch, English, and Chichewa spatial categorization systems.

our target languages (Chichewa) than are primitives derived from pile-sorting by speakers of any of the languages we considered. However for the other two target languages (English and Dutch), at least some of the sets of pile-sort derived primitives outperform those from the literature even at greater depths.

However, as previously discussed, representational power is an important mediating factor in the ability of these differing representational systems to account for cross-language variation. Thus, primitives that accurately capture spatial semantics should explain language well *without* explaining random noise well. To determine the amount of *meaningful variation* in spatial semantic systems that each feature set captures, we must correct for its ability to capture meaningless variation. We indexed this by creating 10 randomly permuted versions of each test language, where the size and structure of “linguistic terms” was preserved, but the specific spatial scenes included in each term were randomly swapped. We then measured the average fit of each feature set to these new nonsense “languages,” and corrected for varying representational power by subtracting the average distance from the feature set to a real language from the average distance between that feature set and the 10 permutations generated from that real language.

From this analysis, presented in Figure 3, it’s evident that the cognition-derived features explain semantic variation in language better than proposed primitives designed by hand for that purpose, in that they characterize considerably more of the *meaningful variation* in language, relative to nonsense variation. It is also apparent that these data provide support for the universal semantic primitives

account: cognition-derived primitives from *all* groups of speakers can account well for the spatial language of the other groups, relative to the comparison feature set hand-designed from cross-linguistic data. Simultaneously, we find that cognition-derived primitives from a given group of speakers *tend* to explain the language of those speakers better than other languages, providing support for accounts of linguistic relativity—although this is not always the case, suggesting some compromise between relative and universal forces in shaping these cognitive primitives.

**Semantic coherence.** Previously proposed spatial primitives were intended to capture cross-language variation, but were also intuitively designed to correspond to meaningful and easily describable semantic components that might underlie spatial cognition. A possible disadvantage of inferring primitives in an unsupervised manner (e.g. by additive clustering) is that this method may propose primitives that lack obviously meaningful interpretations.

Thus, having established that primitives derived from non-linguistic cognitive data can indeed be used to explain cross-cultural variation in linguistic spatial systems, we wished to also examine whether these primitives represent a similarly coherent grouping of spatial semantics. Here, we refer to the distance measures between the primitives themselves (i.e. at depth 0) and our attested categories in language, as an index of semantic coherence.

First, we find that 7.97% of categories in language correspond near perfectly with individual cognitive primitives, in that they either exactly match or have no more than one different scene (distance of 0 or 1). In comparison,

### Semantic Explanatory Power (for Actual Terms - Permutations)

Figure 3: Relative proximity of literature-derived, Dutch, English, and Chichewa pile-sort-derived primitives to the Dutch, English, and Chichewa spatial categorization systems, compared to permuted versions, as a correction for representational power. All primitive sets are closer to real languages; the degree to which they are is the degree to which they can be taken to characterize *meaningful variation* in spatial semantics, rather than flexibly over-fitting noisy data.

the primitives from the literature match language categories near perfectly 5.82% of the time.

Second, the success of cognitive primitives in picking out articulable and coherent components of spatial relations is also apparent from a subjective evaluation of the primitives themselves. Figure 4 illustrates this point with two typical examples of actual cognitive primitives derived from English and Chichewa, which appear to be composed of spatial relations involving full or partial encirclement. While the primitives differ somewhat between languages, both express relatively clear and coherent spatial meanings.

Our analyses suggest the pile-sort-derived primitives represent semantically coherent, articulable components of spatial relations. In fact, these primitives match attested categories in language to a degree comparable with primitives designed by hand and surpass the hand-designed primitives in doing so when representational power is corrected for.

Figure 4: Example primitives derived from English and Chichewa speakers' cognitive data using additive clustering.

## Conclusions & Future Directions

We have shown that spatial primitives derived from non-linguistic pile-sort data account well for spatial terms across three languages. These primitives perform similarly to or better than hand-designed primitives from the literature. Furthermore, despite the unsupervised procedure used to derive them, these primitives reflect relatively coherent, articulable components of spatial cognition.

The present analyses suggest bottom-up inference may be a suitable method for generating spatial primitives. Further, the success of nonlinguistic cognitive data in explaining linguistic variation in spatial semantics supports the argument that universal primitives not only can be used to compose linguistic categories (as demonstrated previously), but may also be able to accurately characterize non-linguistic cognition. As an index of non-linguistic cognition, these primitives provide support for both universal and relative views on spatial cognition in showing that the cognitive primitives derived from one group of speakers can well account for the spatial language in another group, although nevertheless, these cognitive primitives do tend to more closely reflect the language of the speakers from whom they were derived, suggesting a simultaneous role of linguistically relative forces on spatial cognition.

Many questions remain open, suggesting directions for further research. Xu and Kemp (2010) found that allowing weighted primitives gave greater expressive capability to their model, and all distance metrics here were binary. Adapting our approach to weighted primitives, then, could result in improved fits overall, and could alter the general conclusions reached. Additionally, we did have to apply weak parametric assumptions to obtain our primitives, and thus an approach relying on Bayesian non-parametric methods would be beneficial—especially if it could work directly from the pile-sort partition data rather than over similarity matrices derived from the partition data. Finally, we have shown results for only three languages, two of which are from the same family and are closely related within that family. It would be informative to assess these ideas against a broader range of languages.

## Acknowledgments

We thank Asifa Majid and Naveen Khetarpal for kindly sharing their data. We also thank an anonymous reviewer for suggesting the permutation analysis. This work was supported by a Berkeley Fellowship awarded to MP as well as the NSF grant SBE-0541957, to TR and the Spatial Intelligence and Learning Center (SILC).

# Elements of a rational framework for continuous-time causal induction

Michael Pacer (mpacer@berkeley.edu)

Thomas L. Griffiths (tom\_griffiths@berkeley.edu)

Department of Psychology, University of California, Berkeley, Berkeley, CA 94720

## Abstract

Temporal information plays a major role in human causal inference. We present a rational framework for causal induction from events that take place in continuous time. We define a set of desiderata for such a framework and outline a strategy for satisfying these desiderata using continuous-time stochastic processes. We develop two specific models within this framework, illustrating how it can be used to capture both generative and preventative causal relationships as well as delays between cause and effect. We evaluate one model through a new behavioral experiment, and the other through a comparison to existing data.

## Introduction

Causal induction plays a key role in human cognition, allowing people to identify the causal relationships that structure their environment. Recent work in cognitive science has resulted in many successful models of how people infer causal relationships from contingency data (Anderson, 1990; Anderson & Sheu, 1995; Cheng, 1997; Griffiths & Tenenbaum, 2005) and events that unfold in discrete time (Wasserman, 1990; Greville & Buehner, 2007). However, relatively few models have explored events that occur in continuous time. And yet, people regularly and easily reason about causal phenomena that evolve in continuous time (Michotte, 1963; Griffiths & Tenenbaum, 2009). Our understanding of causal inference would thus benefit from a framework capable of explaining human continuous-time causal inferences.

In this paper, we address this challenge by undertaking a rational analysis of continuous-time causal induction, in the spirit of Anderson (1990) and Marr (1982). We formalize the abstract problem posed by continuous-time causal inference, identifying a set of desiderata that a solution to this problem needs to incorporate. We then outline a framework that satisfies these desiderata, based on rational statistical inference over continuous-time stochastic processes. Our framework makes it possible to define both generative and preventative causes that unfold in continuous time, and to take into account delays between causes and effects.

With this framework in hand, we present two case studies from experimental psychology on human continuous-time causal inference. The first case study involves a novel experiment based on an experiment conducted by Griffiths and Tenenbaum (2005), allowing us to show how our framework can be used to infer whether a cause prevents events from occurring. The second case study is a re-analysis of an experiment on the effects of temporal information on human causal inference that was originally conducted by Greville and Buehner (2007). This second case study demonstrates the value of being able to use delay distributions to characterize how the effect of a cause changes over time.

We begin with a brief overview of previous work on the role of time in human causal inference, focusing on Griffiths and Tenenbaum (2005) and Greville and Buehner (2007). We then lay out a set of desiderata for a computational framework for human continuous-time causal inference. We go on to describe formally how we implement these desiderata in our proposed framework. Following this, we apply the framework to our two case studies, evaluating models that use preventative causes and delay distributions. Finally, we conclude and suggest directions for future work.

## Continuous-time causal induction

Studying the role of time in causal induction has a long history in cognitive science. One of the earliest established findings in the study of human causal inference is our ability to perceive causal relations in collisions, which is highly dependent on precise timing (Michotte, 1963). More recently, Buehner and colleagues have been very active in studying causal inference as it interacts with temporal information (e.g., Buehner & May, 2003; Greville & Buehner, 2007). However, while studies of causal induction often present events to participants in continuous time, they are typically analyzed using the discrete trial structure which the researchers used to design the stimuli (e.g., Anderson & Sheu, 1995; Wasserman, 1990).

Nonetheless, it may be enlightening to treat events as if they occurred over continuous time. Models considered by Griffiths and Tenenbaum (2005, 2009) take this approach, treating events that occur in continuous time as existing in a continuous dimension, or analyzing summaries of events as if they had occurred during a continuous interval. Even stimuli that are explicitly designed to convey information in discrete time (e.g., Greville & Buehner, 2007) can be analyzed in terms of continuous time by integrating over the time intervals. In the remainder of this section we summarize results from two studies on causal induction with temporal information, providing context for our later analyses.

### Causal induction from rates

Griffiths and Tenenbaum (2005) showed that people are capable of reasoning about causes that increase the rate at which events occur over continuous time, and their judgments are in close accordance with the predictions of a computational model engaging in continuous-time causal inference. In their experiments, participants observed a series of results that they were told came from physics experiments studying whether different electrical fields cause different radioactive compounds to emit more or fewer particles (the compound always released particles at some rate). For each “experi-

ment”, participants were told how many particles were emitted during one minute when the electrical field was on and one minute when the field was off. Participants then indicated the degree to which they endorse the claim that the field caused the compounds to emit more particles on a scale of 0 (the field definitely does not cause the compound to decay) to 100 (the field definitely does cause the compound to decay).

### Causal induction from tabular displays

Greville and Buehner (2007) demonstrated that the temporal distribution of event occurrences will alter people’s causal judgments, even if the relative frequencies of the occurrence of the effect in the presence or absence of a cause is held constant. Their purpose was to show that “temporal regularity” influences people’s judgments above and beyond mere contingency information. Their experiments used a tabular format to display events that unfolded over five days (split up into five segments of one day each), reporting in which day events occurred. This discretization allows the use of traditional models of causal inference which infer causes on the basis of contingency information.

In each condition of Greville and Buehner’s experiments, participants were shown two groups of 40 bacterial cultures, one group which was exposed to radiation and one which was not. Participants were shown (in tabular format) on which of 5 days each batch of bacteria died (if they died). Participants were asked to rate the effect of the radiation on a scale of –100 to 100 where –100 meant that the treatment was very effective at killing the bacteria, while 100 meant that the treatment was very effective at preventing the bacteria from dying (a rating of 0 meant that the treatment had no effect).

Greville and Buehner asked each participant about 18 pairs of tables, which differed in the frequency and distribution of times of death. In particular, Greville and Buehner varied the number of cultures dead by day five and the distribution over the times at which the bacteria died. They first fixed the number of deaths that would occur in each table. In all conditions, the time distribution for the bacteria not exposed to radiation was such that each of the deaths occurred with equal probability in any of the five days. However, for the bacteria exposed to radiation there were three time-of-death distributions: “strong contiguity”, in which bacteria death was more likely in the first few days after the radiation treatment; “weak contiguity”, in which bacteria died more often later in five day period; and “random”, in which bacteria death was uniformly distributed among the five days. Contingency information was held constant while varying contiguity. The results of the experiments showed that temporal information dramatically affects human causal inference.

### Defining desiderata for the framework

The studies discussed in the previous section illustrate some of the great variety in the phenomena to be considered by a framework for continuous-time causal induction. Thus, it will be helpful to identify the most vital features for allowing the

framework to capture a wide class of these cases. The following sections detail an important set of these properties.

**Intervention.** The framework should be capable of considering interventions in the sense meant in causal graphical models (Pearl, 2000). That is, an intervened upon node is said to be rendered independent of its parent nodes.

**Instantaneous and interval causes.** The framework should include both causes that exist instantaneously as well as over intervals of time.

**Generative and preventative causal relations.** It is vitally important when modeling human causal inference to distinguish between causes that generate effects and causes that prevent effects (Griffiths & Tenenbaum, 2005, 2009). People make dramatically different predictions based on which type of relationship they are looking for. Thus, we would want the framework to be capable of doing the same. In discrete time, Griffiths and Tenenbaum (2005) used the Noisy-OR and Noisy-ANDNOT logic gates to represent a cause that generates or prevents effects with reference to a background rate of the effects’ occurrence. Because these discrete time parameterizations will not hold in continuous time, we will have to redefine what we mean by a generative and a preventative relation for continuous time.

**Delay distributions.** In most models of causation that work in discrete time or over trials in which events occur simultaneously, a cause can only influence an effect if and only if that cause is present. This is undesirable if we are to develop a framework for continuous-time causal inference. Not only would it be useful to track how a cause’s influence changes over time, instantaneous events occur for only an infinitesimal period of time. Thus, in order for such events to have any effect on other variables they must be able to exert influence even after they are no longer present. Thus, we will need to characterize *delay distributions*, which define how a cause’s influence on its effects changes over time.<sup>1</sup>

### A framework based on Poisson processes

To form a rational framework encompassing these desiderata, we draw from the wide literature in statistics and computer science on continuous-time stochastic processes. In particular we pay attention to one class of continuous-time stochastic processes: Poisson processes. Poisson processes provide an excellent starting ground for generalizing causal graphical models (and hence intervention) as they define a series of independent random variables indexed over continuous time, being the continuous analogue of the independent Bernoulli events that take place on a series of discrete trials in many causal graphical models (Griffiths, 2005).

In its simplest sense, a Poisson process is a stochastic process (i.e., a series of random variables) that defines the rate at which instantaneous events occur over continuous time. That rate is determined by the rate function  $\lambda(t)$ . If a set

<sup>1</sup>This notion of change over time is not meant to capture that described in Rottman and Ahn (2009) where the change occurs over successive presentations of the cause, but change associated with temporal distance to one presentation of the cause.

of events are produced by a Poisson process, the probability that a certain number of events ( $k$ ) occurred in a time interval  $[t_0, t_1]$ ,  $0 \leq t_0 < t_1$  is,

$$P[(N(t_1) - N(t_0)) = k] = \frac{e^{-\lambda_{t_0, t_1}} (\lambda_{t_0, t_1})^k}{k!},$$

where  $\lambda_{t_0, t_1} = \int_{t_0}^{t_1} \lambda(t) dt$ .

The rate function defines the distribution of waiting times between events. For example, the waiting time before the first event ( $\tau_1$ ) is distributed  $P(\tau_1 = t) = \lambda(t)e^{-\lambda_0 t}$ .

Poisson processes have several desirable properties. If you have two independent Poisson processes with rates  $\lambda_1(t)$  and  $\lambda_2(t)$ , you can take the union of their event sets and this produces another Poisson process with rate  $\lambda_1(t) + \lambda_2(t)$ . This is a “superposition” of Poisson processes. Now, suppose the existence of some Poisson process  $PP_0$ , which has rate  $\lambda_0(t)$ . Suppose also that you have another function with the same support on  $t$  called  $\pi_1(t)$ , the range of which is a subset of  $[0, 1]$ . Then, for an event produced by  $PP_0$ , cancel that event (i.e., treat it as if it had never occurred) with probability  $\pi_1(t)$ . This procedure is called “thinning” the Poisson process  $PP_0$ , and the resultant Poisson process has rate  $\lambda(t)(1 - \pi(t))$ .

Poisson processes have been used to model aspects of continuous-time causal induction, including both causes that occur instantaneously and over intervals (Griffiths, 2005; Griffiths & Tenenbaum, 2005, 2009). However, this work has focused on generative causes and only explored a limited class of delay distributions. In the remainder of the paper, we show that this framework can address more of these desiderata. First, we define preventative causes within the Poisson process framework, evaluating the resulting model through a new behavioral experiment based on Griffiths and Tenenbaum (2005). We then introduce an extremely general approach to handling delay distributions, which we evaluate using the results of Greville and Buehner (2007).

## Generative and preventative causes

The properties of the Poisson process – specifically invariance of the form of the stochastic process under the superposition and thinning transformations – can be used to characterize generative and preventative causal relations. Suppose that there are  $i$  generative causes ( $\{C_i\}$ ) and  $j$  preventative causes ( $\{C_j\}$ ), and they exist over intervals of time. That is  $\forall C_a \in \{C_i\} \cup \{C_j\}, \exists T_a(C_a = 1) \subset \mathcal{T}$  where  $\mathcal{T}$  is the set of all non-measure-zero time intervals and  $T_a(C_a = 1)$  is the set of intervals during which  $C_a$  occurs. Let the Poisson process  $PP_0$  be a background rate of effect occurrence with an unknown time-invariant rate function  $\lambda_0 > 0$ . Causes assert their influence by altering the base-rate of the effect.

Generative causes will superpose themselves onto the background process, thereby increasing the rate of effect occurrence. That is, we can think of a generative cause  $C_i$  as producing a series of effects on its own, thereby inducing

a Poisson process  $PP_i$  with parameter  $\lambda_i(t)$ , where we assume that the cause only exhibits a non-zero effect when it is present (i.e.,  $t \in T_i(C_i = 1)$ ). That is, when  $C_i$  is present, the rate will be  $\lambda_0 + \lambda_i$ , and otherwise the rate will be  $\lambda_0$ . This is equivalent to a continuous-time version of the Noisy-OR logic gate, used in models of discrete-time causal inference (see Griffiths, 2005; Simma et al., 2008).

We will assume preventative causes will thin all Poisson processes that generate effects including both the background and generative processes. A preventative cause  $C_j$  will have thinning parameter  $\pi_j$  which affects the generative processes if and only if cause is present. Thus, if  $\lambda_{\text{total}}(t)$  is the total rate, when  $C_j$  is absent, the rate be  $\lambda_{\text{total}}(t)$ , but when  $C_j$  is present the rate will become  $\lambda_{\text{total}}(t)(1 - \pi_j)$ . This is equivalent to a continuous-time version of the Noisy-ANDNOT logic gate, which in the discrete-time setting defines the probability that an event will be canceled when the cause is present.

In the case where there are many causes, we will presume that they are independent and thus can be composed with one another, such that you will have a summation of the rates for the generative causes and a product of  $1 -$  the thinning parameters for the preventative causes. The rate function for a case with background rate  $\lambda_0$  and  $i$  generative causes and  $j$  preventative causes is defined as

$$\lambda(t) = \left( \lambda_0 + \sum_i \lambda_i \int_{T' \in T_i(C_i=1)} \delta(t, T') dT' \right) \prod_j (1 - \pi_j \int_{T' \in T_j(C_j=1)} \delta(t, T') dT'). \quad (1)$$

where  $\delta(\cdot, \cdot)$  is the Dirac delta function, which has an infinite spike where the two arguments agree and 0 elsewhere. Note, this does not include a prior for the causes; i.e., we treat these causes as continuous-time interventions.

The situation used as a cover story by Griffiths and Tenenbaum (2005) – determining whether electrical fields change the rate at which radioactive compounds emit particles – involves a system that can be analyzed using this model, where it has one effect (particle emissions) with a background rate and (possibly) one generative cause (the electrical field,  $C_i$ ). Griffiths and Tenenbaum presented participants with information summarizing the number of effect occurrences (particle emissions) that occurred during one minute with the cause on and one minute with the cause off. For each compound, participants rated on a scale of 0 (the electric field definitely does not cause the compound to decay) to 100 (the electric field definitely does cause the compound to decay) their belief regarding whether  $C_i$  was indeed a cause.

To model the participants’ predictions, Griffiths and Tenenbaum (2005) treated the problem as one of model selection between a graphical model  $G_0$  where the cause had no effect (i.e.,  $\lambda_i(t) = 0, \forall t$ ) and a graphical model  $G_1$  where the cause did have an effect (i.e.,  $\lambda_i(t) > 0, \exists t$ ). They parameterized  $G_0$  and  $G_1$  as we have above, as Poisson processes with different rate functions, where generative causes are treated

as we have treated them above. The quantity used to predict human judgments, termed “Causal Support”, was the log likelihood ratio in favor of  $G_1$ , integrating over the values of all of the parameters of the Poisson process. This model performed well at predicting the mean judgments of the participants, with a scaled correlation of  $r = .978, \alpha = .35$ .<sup>2</sup> Other models considered by Griffiths and Tenenbaum (2005) also performed well, with the raw difference in rates  $\Delta R$  (Anderson & Sheu, 1995) giving  $r = .899, \alpha = .05$ , a variant on the Power-PC theory (Cheng, 1997) giving  $r = .845, \alpha = .06$ , and a modified  $\chi^2$  score giving  $r = .980, \alpha = .01$ .

Griffiths and Tenenbaum (2005) considered only generative causes, creating the opportunity to use the same paradigm to evaluate whether the treatment of preventative causes outlined above is effective. We ran a new experiment to address this question. Considering only one preventative cause, we used nearly identical materials to Griffiths and Tenenbaum (2005), only changing the word “increases” to “decreases” and using the following  $(N(c^-), N(c^+))$  pairs (where  $N(c^-)$  and  $N(c^+)$  are the number of particles that were emitted during the minute when, respectively, the cause was absent and was present): (52, 2), (60, 10), (100, 50), (12, 2), (20, 10), (60, 50), (4, 2), (12, 10), (52, 50).

We recruited 18 participants through Amazon Mechanical Turk to participate in our study online. We asked each participant to make the following judgment about each of the nine cases: “Does this field decrease the rate at which this compound emits particles?” Participants responded on a scale ranging from 0 (the electrical field definitely does not decrease the rate of particle emissions) to 100 (the electrical field definitely does decrease the rate of particle emissions).

Following Griffiths and Tenenbaum (2005) we modeled this task as a model selection problem between two graphs  $G_0$  where the cause has no effect and  $G_1$  where the cause has a (preventative) effect on the rate of particle emissions. We used the model defined in Equation 1 with one potential preventative cause with parameter  $\pi_1$  and a background rate  $\lambda_0$  to define the likelihood functions for  $G_0$  and  $G_1$ . We assumed that in  $G_0$ ,  $\pi_1$  is constrained to be equal to 0. To obtain the log likelihood ratio, we need to provide likelihoods in terms of the graphical models (i.e.,  $P(D|G_0)$  and  $P(D|G_1)$  for the observed data  $D$ ). However, as they stand, the Poisson processes associated with these graphical models assume that the parameters  $\lambda_0$  and  $\pi_1$  are known, which is not the case. We thus need to define prior distributions over these parameters. With defined prior distributions, we can use Monte Carlo integration to obtain our marginal likelihoods, corresponding to the probability of the data given just the graphical model. We defined the prior for  $\pi_1$  as  $U(0, 1)$ , i.e., uniformly distributed in the interval  $[0, 1]$ . Griffiths and Tenenbaum (2005) used an improper prior for  $\lambda_0$ , with  $\lambda_0 \sim \frac{1}{\lambda_0}$ . We approximated the previously used prior by sampling  $v_0 \sim$

<sup>2</sup>As is usual in these studies, the authors scaled their model’s values with the non-linear transformation  $y = \text{sign}(x)|x|^\alpha$  where  $\alpha$  is chosen to maximize the linear correlation  $r$ .

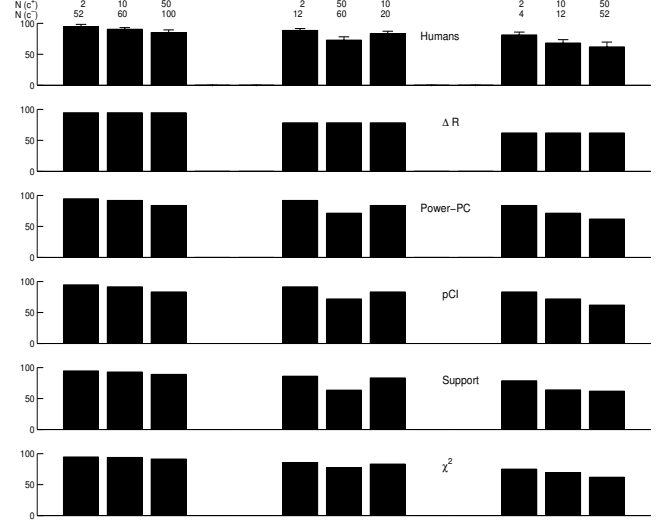

Figure 1: Preventative data for particle emissions: human responses and scaled model predictions. Support is the model that results from our framework.

$U(\log(10^{-6}), \log(10^6))$  and letting  $\lambda_0 = e^{v_0}$ .<sup>3</sup>

Using the log likelihood ratio in favor of the hypothesis that  $\pi_1 \sim U(0, 1)$  ( $G_1$ ) over  $\pi_1 = 0$  ( $G_0$ ) as our predictor of mean human judgments, we see a high scaled correlation with the results of the experiment: Causal Support gives  $r = 0.963, \alpha = 0.23$  (see Figure 1). We also evaluated the models tested by Griffiths and Tenenbaum (2005), which showed similarly high performance,  $\Delta R$  :  $r = 0.780, \alpha = 1.95 \times 10^{-4}$ ; Power PC:  $r = 0.986, \alpha = 0.45$  ; and  $\chi^2$  :  $r = 0.942, \alpha = 1.95 \times 10^{-4}$ . Our purpose is not to claim that the model we have defined is the best model of human inference, but to demonstrate that the assumptions we have made about handling preventative causes in our framework are reasonable. Future work will hopefully clarify whether this model outperforms the other models in cases where their predictions diverge more dramatically.

## Delay distributions

We will now describe how we implement delay distributions in our framework and apply the resultant model to modeling the results of Greville and Buehner (2007) – i.e., the bacteria death studies. We assume that generative and preventative causes have the same representation as above. We will assume that delay functions define what proportion of a cause’s influence remains an arbitrary amount of time after it occurs, where a base parameter defines the maximum influence of the cause.

Let  $f_i^g(\cdot, \cdot; \gamma_i)$  indicate the delay function with unknown parameters  $\gamma_i$  for generative cause  $C_i$ , and  $f_j^p(\cdot, \cdot; \theta_j)$  indicate the delay function with unknown parameters  $\theta_j$  for preventative cause  $C_j$ . Let the set  $\{t_k\}$  be the set of times that instantaneous cause  $C_k$  occurs and  $\{[t_{l,0}, t_{l,1}]\}$  be the set of

<sup>3</sup>To see the approximation, note that  $v_0 = \log(\lambda)$  and  $v'_0 = \frac{1}{\lambda}$  and use a change of variables to find  $f_{\lambda_0}(\cdot)$ .

Figure 2: Model predictions for Greville and Buehner (2007), Experiment 1.

times over which interval cause  $C_l$  occurs. We set  $\lambda_0$  to indicate the underlying rate of an effects' occurrence, and  $\lambda_i$  and  $\pi_j$  to indicate the maximum value of a cause's influence.

The effects of delay distributions can be accommodated by defining a Poisson process with rate

$$\lambda(t) = \left( \lambda_0 + \sum_{C_i^g} \left( \sum_{t' \in \{t_i\}} \lambda_i f_i^g(t, t'; \gamma_i) + \sum_{[t'_0, t'_1] \in \{[t_{i,0}, t_{i,1}]\}} \lambda_i f_i^g(t, [t'_0, t'_1]; \gamma_i) \right) \prod_{C_j^p} \left( \prod_{t'' \in \{t_j\}} (1 - \pi_j f_j^p(t, t''; \theta_j)) \prod_{[t'_0, t'_1] \in \{[t_{j,0}, t_{j,1}]\}} (1 - \pi_j f_j^p(t, [t'_0, t'_1]; \theta_j)) \right) \right)$$

where  $f(t, [t_0, t_1]; \cdot)$  is the convolution of  $f(t, x; \cdot)$  with the boxcar function on  $[t_0, t_1]$  (i.e., the function that takes the value 1 for all  $x \in [t_0, t_1]$  and 0 otherwise). This allows us to keep the expressivity needed to capture our first findings, while allowing greater generality in the types of delay distributions applicable to interval causes.

Modeling the studies in Greville and Buehner (2007) requires further formal specification. Because events in these experiments were deaths they happen only once. As such, we only consider a bacterium to have died on the first arrival in a Poisson process defining the rate of death (i.e.,  $p(\tau_1 = t) = \lambda(t)e^{-\lambda_0 t}$ , where  $\lambda_{a,b} = \int_a^b \lambda(t)dt$ ). But, we do not know the precise time at which the bacterium died, merely the day on which it died. Therefore, the likelihood that bacterium  $i$  died on day  $t_{i,1}$  is  $\int_{t_{i,0}}^{t_{i,1}} \lambda(t) e^{-\lambda_0 t} dt = e^{-\lambda_0 t_{i,0}} - e^{-\lambda_0 t_{i,1}}$ , where  $t_{i,0}$  is the day before  $t_{i,1}$ . Finally, we model the 80 bacterial cultures in each condition as 80 conditionally independent Poisson processes given an underlying graph, i.e.,  $p(D|G) = \prod_{i=1}^{80} \int_{t_{i,0}}^{t_{i,1}} \lambda(t) e^{-\lambda_0 t} dt$ .

Because Greville and Buehner (2007) asked participants to respond on a scale of -100 (the radiation definitely causes

Figure 3: Model predictions for Greville and Buehner (2007), Experiment 2.

death) to 0 (the radiation has no effect) to 100 (the radiation definitely prevents death), we have effectively three graphs to choose from:  $G_g$ , the generative graph (where  $\pi_1 = 0$  and  $\lambda_1 \in \mathbb{R}^+$ );  $G_p$ , the preventative graph (where  $\lambda_1 = 0$  and  $\pi_1 \in [0, 1]$ ); and  $G_0$  the null graph (where  $\pi_1 = \lambda_1 = 0$ ). As in Griffiths and Tenenbaum (2009), we modeled participants' mean responses in each condition as  $P(G_p|D) - P(G_g|D)$ , assuming all three graphs are a priori equally likely.

We assumed a scaled exponential decay function with parameter  $\phi_1$  is used for both generative and preventative causes (i.e.,  $f_i(t, t'; \gamma_i) = f_j(t, t'; \theta_j) = e^{-\phi_1(t-t')}$  where  $t'$  is the time that a cause occurs). Because the radiation is only applied to the bacteria once at the beginning of the five days, for  $G_g$  and  $G_p$ , the only occurrence of the cause is instantaneous and appears at  $t = 0$ . Thus, for the generative graph,

$$\lambda_{0,t} = \int_0^t \lambda_0 + \lambda_1 f_1(s, 0; \gamma_1) ds = t\lambda_0 + \frac{\lambda_1}{\phi_1}(1 - e^{-t\phi_1}),$$

and for the preventative graph,

$$\lambda_{0,t} = t\lambda_0(1 - \frac{\pi_1}{\phi_1}(1 - e^{-t\phi_1}))$$

Similar to before, as a prior for  $\lambda_0$  we used  $v_0 \sim U(\log(10^{-1}), \log(10^1))$  and set  $\lambda_0 = e^{v_0}$ . The remaining priors were defined as  $\pi_1 \sim U(0, 1)$ ,  $\lambda_1 \sim \Gamma(1, \lambda_0)$ , and  $\phi_1 \sim \Gamma(1, \lambda_0)$ , where the priors are defined in terms of  $\lambda_0$  such that they inherit the scale defined by  $\lambda_0$ .

Using Monte Carlo integration, we calculated our model's judgments  $P(G_p|D) - P(G_g|D)$  for the data in Greville and Buehner (2007). Because the experiments used slightly different methods we evaluated our model predictions separately for each experiment but concurrently for all 18 conditions within each experiment. Our model has a scaled correlation of  $r = .910$  ( $\alpha = 2.74$ ) with mean participant responses in Experiment 1 and a scaled correlation of  $r = .957$  ( $\alpha = 1.72$ ) with mean participant responses in Experiment 2. Since submitting this paper, we learned of another model which outperforms our own – namely that described in Buehner (2006).

This was used to analyze the same data and had an excellent linear fit for the two experiments,  $r = .97$  and  $.953$  (Buehner, 2006). In these cases, our models make very similar predictions thus, we will need to explore more complex experimental scenarios (e.g., trials with multiple exposures to the cause at different times). This would put predictions from these models in starker contrast.

## Conclusions and future directions

Continuous-time causal induction is so pervasive that we often go about not even noticing that we are engaging in it. The richness of temporal information surely aids people as they infer causes in their everyday life. Here we have developed a rational framework that makes use of that same wealth of information. The framework is based on an extension to causal graphical models to include continuous-time stochastic processes – specifically Poisson processes. We demonstrate in two case studies that our framework is capable of accurately predicting human judgments in tasks that require reasoning about preventative causes and reasoning about delay functions. This extends previous work on Poisson processes as rational models of continuous-time causal induction.

Continuous-time stochastic processes are a very rich class of mathematical objects, and we expect that the formal framework we have outlined will grow more powerful as further tools are added to it. Fortunately, there are currently many tools being crafted. Our hope is to develop inference algorithms that allow our framework to consider large, complex networks of causal variables and the relations between them, in the vein of Pearl (2000) and Simma and Jordan (2010). Additionally, it will add an additional layer of generality to develop an account for how instantaneous events can alter the states of events that occur over intervals of time. Currently we take the parameters of causes as fixed at all times – it is merely the influence of the cause on the effect that wanes. However, people are very capable of reasoning about causal relations that change their form over time (Rottman & Ahn, 2009), and as such explaining data of that sort may be essential for capturing the full range of human causal reasoning.

Developing a rational framework for continuous-time causal induction could potentially provide insight into other phenomena of human causal judgment. One of the advantages of taking a Bayesian approach to causal induction is its ability to form strong inferences from very small amounts of data. This feature may be essential in explaining why perceptual causality (where one makes a causal inference from a single piece of data) is extremely sensitive to subtle differences in timing (Michotte, 1963; Newman, Choi, Wynn, & Scholl, 2008). Finally, one of the central motivations for studying time in causation is a pervasive belief that the timing of events can unveil the direction of the underlying relationship (i.e., what causes what; Rottman & Keil, 2012). If people do believe this (even implicitly), then characterizing the role of continuous-time in causation would be absolutely necessary if we are to understand the full extent of the human

mind's capacity and propensity for causal inference.

Of course, all of this belies the fact that there are many phenomena on human causal reasoning that have yet to be studied. What any computational-level framework offers is the ability to develop new questions out of the formal principles that originally drove the design – even if those questions did not exist when the framework was formulated. If such an event occurs in the near future, it would be a pleasant thought to think that it could have been the effect of the work presented here; but whether that will occur – only time will tell.

# Musicians are better at learning non-native sound contrasts even in non-tonal languages

## Abstract

It is very difficult for adults to perceive phonetic contrasts in their non-native language. In this study we explored the effects of phonetic training for different populations of people (musicians and non-musicians) and with different kinds of phoneme contrast (timing-based, like the Hindi /g/-/k/ contrast, and pitch-based, like the Mandarin /i/-/i/ tonal contrast). We found that musicians had superior perception for both contrasts, not just the pitch-based one. For both phonemes, training had little to no effect. We consider the implications of this for first and second language acquisition. **Keywords:** phonetic learning; music perception; language acquisition;

## Introduction

Second language learning is a difficult task for a variety of reasons. Adults have difficulty with many aspects of language acquisition, including language processing (Clahsen & Felser, 2006) and certain aspects of syntax (e.g., Birdsong, 2006), but limitations in phonetic perception relative to infants and young children are especially strong and well-documented (e.g., Werker & Lalonde, 1988; Kuhl, 2004; Maye, Weiss, & Aslin, 2008). Phonological deficits can be found not just in perception, but in production and processing as well (e.g., Flege, 1995; Sebastián-Gallés & Soto-Faraco, 1999). Such deficits are sometimes thought to have cascading effects onto other aspects of language (Perani, 2005; Werker & Yeung, 2005; Perfors & Dunbar, 2010).

One striking aspect of adults' poor phonetic perception is that it is quite difficult to overcome it through training. There are various training regimes for teaching adults to learn a phonetic contrast that does not exist in their native language. Some rely on implicit learning of the phonemic categories based on distributional information (Maye & Gerken, 2001, 2002; Shea & Curtin, 2005; Hayes-Harb, 2007), while in others some form of feedback is given (e.g., Jamieson & Morosan, 1989; McCandliss, Fiez, Protopapas, Conway, & McClelland, 2002; Wang, Jongman, & Soreno, 2003; Golestani & Zatorre, 2004; Wayland & Li, 2008; Bradlow, 2008). These training regimes have rarely been compared directly, and are often used for different kinds of phonemes and with different goals. It is therefore still unclear precisely to what extent different kinds of training are effective and why.

Given the importance of phonetic perception, understanding why phonetic training works (to the extent it does) and how it can be improved (to the extent it doesn't) is a matter of some importance. One of the ways to explore this is by investigating the effectiveness of training on different kinds of phonemes as well as in different populations of people. Expanding this exploration is one of the central goals

of this paper. We perform two main manipulations, comparing the effectiveness of the same implicit distributional training method on different populations (musicians and non-musicians) as well as different phonemes (tonal and timing-based). We find that musicians show improved phonetic perception on all phonemes, and that any effects of training are smaller than these population differences. The implications of these findings for language acquisition and representation more broadly are considered in the discussion.

## Different phonemes, different populations

**Tonal vs timing-based phonemes.** A phoneme is the smallest unit in a language that forms a meaningful contrast, like the /b/ in *bat* and the /p/ in *pat*. Many phonemes are distinguished from another based on timing. For instance, one of the differences<sup>1</sup> between the English “g” and “k” sounds is the presence of voicing (i.e., the vibration of the vocal cords). English “g” and “k” differ in their voice onset time, or VOT, which refers to the time at which voicing begins and the vocal cords begin to vibrate. For the English “g” sound, voicing is immediate as soon as the tongue leaves the roof of the mouth; for “k”, there is a time delay between the release of the stop closure and the vibration of the vocal cords.

Hindi makes a further timing-based distinction that does not exist in English. The Hindi /g/ and /k/ differ according to the presence of *pre-voicing*, which is the occurrence of voicing during the silent interval during which the vocal tract is blocked. Because this distinction does not occur in English, both sound like a “g” to a native English speaker. It is possible to train English speakers to hear this distinction, although they are far below native-speaker proficiency even after the best training. One of the simplest techniques, though not the most common for adults, is implicit distributional training (Hayes-Harb, 2007; Maye & Gerken, 2000; Maye et al., 2008). In this type of training, described in more detail later, participants hear a bimodal distribution of phonemes whose peaks are centered around the two phonemes to be learned. Distributional training has been used to teach adults to distinguish these Hindi phonemes given as little as 10 minutes of exposure (Maye & Gerken, 2000; Perfors & Dunbar, 2010).

Another kind of phoneme occurs in tonal languages like Mandarin, which uses pitch to convey meaning. In such a language, the meaning of the syllable changes when it is spoken in a different tone. For instance, in Mandarin, *ma* in the high level Tone 1 ([mā]) and the rising Tone 2 ([má]) means *mother*

<sup>1</sup>The other difference between these two phonemes is aspiration, which refers to the presence of a puff of air after making a sound (/g/ is not aspirated but /k/ is). We do not consider aspiration here.

Figure 1: Distribution of stimuli used in phonetic training, defined along a continuum based on voice onset time in the HINDI condition and pitch in the MANDARIN condition. Tokens 2 and 6 occurred four times as often as tokens 1 and 7.

and *hemp*, respectively. People who are not native speakers of tonal languages process tone differently (Gandour, 1983). As with Hindi phonemes, there is evidence that non-native speakers can be trained to perceive lexical tones (Wang et al., 2003; Wayland, Herrera, & Kaan, 2010; Wong & Perrachione, 2007). However, these training programs generally take longer (days to weeks) and are more intensive than implicit distributional training, with participants being given explicit feedback and sometimes visual help (e.g., pitch graphs).

To our knowledge, no studies have explored the effectiveness of implicit distributional training on lexical tones. Our first goal in this study is therefore to compare the effects of distributional training (and baseline perception) of a Hindi timing-based contrast with a Mandarin tone-based contrast. Are both phoneme types equally easy for native English speakers to perceive? Does implicit training work better or worse with one kind of phoneme?

**Musicians vs non-musicians.** It is well-known that musicians consistently show a superior ability to learn lexical tones (Alexander, Wong, & Bradlow, 2005; Wong & Perrachione, 2007; Wayland et al., 2010). In many ways, this is no surprise: because both music and tonal languages involve pitch, extensive musical training (or superior auditory abilities) may result in increased sensitivity to pitch-related cues.

Much less is known about whether musicianship facilitates the learning of non-native contrasts that are not defined by pitch. While there are few studies investigating this issue, early evidence suggests that it might. For instance, Slevc and Miyake (2006) found that musical ability predicted Japanese speakers' ability to discriminate and produce the English /r/-/l/ contrast, and Sadakata, van der Zanden, and Sekiyama (2010) found that Japanese musicians were better than non-musicians at distinguishing the Dutch vowel /u/. There is also some evidence suggesting that musicians have higher brain-stem plasticity not just for musical stimuli, but for speech stimuli as well (Musacchia, Sams, Skoe, & Kraus, 2007).

For all these reasons, it seems reasonable to think that people with musical training might have superior perception of

timing-based phonetic contrasts as well as tones. However, to our knowledge this question has not been investigated before. Our second goal is therefore to compare the performance of musicians and non-musicians on the Hindi /g/-/k/ contrast. Are musicians better at perceiving that contrast as well as a Mandarin tonal contrast? How much does musicianship help (if it does) in either case? Are musicians more or less responsive to distributional training than non-musicians?

## Goals of the study

This paper addresses two main questions. First, we are interested in comparing performance on two different kinds of phonetic contrast within people given the exact same implicit distributional training. Is one easier than the other? Does training have more of an effect for one than another? Second, we are interested in comparing different populations of adults in their ability to perceive these two kinds of contrasts: namely, musicians and non-musicians. Do musicians have an advantage in perceiving timing-based contrasts as well as pitch-based ones? Does training have more or less of an effect on them than non-musicians?

## Method

There were two phases in this experiment, a training phase and a testing phase. Participants were randomly allocated to either a HINDI or MANDARIN condition. During the training, the participants were exposed to a distribution of sounds from the appropriate language for their condition. All participants participated in the same testing phase, which included two common tests of phoneme discrimination. The testing phase included stimuli from both Mandarin and Hindi, as well as a control set of English phonemes to ensure that they were paying attention. This design allows participants from each condition to serve as each other's control. For instance, the performance of participants in the HINDI condition on Mandarin stimuli reflects performance on those stimuli without having been trained on the Mandarin contrast.

**Participants.** 96 native English-speaking adults from the University of Adelaide and surrounding community participated in the experiment. 48 were classified as musicians according to criteria adapted from Wong and Perrachione (2007) and later slightly loosened in order to recruit enough participants. Musicianship in this study was defined as having had at least five continuous years of formal musical training, starting before the age of 15. The mean duration of musical training was 12.75 years for the musicians and 0.89 years for the non-musicians. There was no significant difference in duration of musical training between the HINDI and MANDARIN conditions ( $t(46) = 0.81, p = 0.4245$ , two-tailed).

**Training.** Participants in the HINDI condition were trained on a distribution of seven stimuli that differed according to voice onset time, while those in the MANDARIN condition were trained on a distribution of seven stimuli that differed according to pitch. The stimuli are described in detail below, but the training procedure is the same in all conditions. As

Figure 2: A seven-step continuum of the Mandarin syllable [ɿ]. Each step differed according to its fundamental frequency ( $f_0$ ) contour. (Figure adapted from Xu et al., 2006)

in Maye and Gerken (2000), we presented subjects with a bimodal distribution of these phonemes, as illustrated in Figure 1; thus, some tokens (e.g., 2 and 6) occurred four times as often as others (e.g., 1 and 7). Participants heard a total of 900 tokens presented in random order and separated by 250 ms each, for a total of approximately 10 minutes of exposure. During stimulus presentation the participants were told not to speak or read, but also that they need not consciously concentrate on the sounds. To alleviate boredom, they were allowed to doodle while listening.

**Testing.** After the training, the participants were presented with two standard discrimination tests, ABX and same/different (S/D); the order of the tests was randomized for each participant. In the ABX test, the participants heard three sounds separated by 1s and were asked whether the third (“X”) was the same as the first (“A”) or the second (“B”). In the S/D test, they heard a pair of sounds separated by 500ms and were asked whether the sounds were the same or not. Performance is given by the percentage of correct answers, and chance is 50% for both kinds of tests. Only tokens 1 and 7 were used in testing, since they most resemble the natural sounds of the language. Both tests consisted of 40 trials presented in random order, with 8 control stimuli corresponding to an English contrast, 16 stimuli corresponding to the Hindi /g/-/k/ contrast, and 16 corresponding to the Mandarin /ɿ/-/i/ contrast. The stimuli are described in more detail below.

**Stimuli.** Each of the two conditions were trained on distributions of stimuli taken from their respective languages – the HINDI condition on a contrast defined by timing, and the MANDARIN condition defined by pitch.

**HINDI.** The contrast used in this study was the unaspirated velar plosive voiced/voiceless contrast (/g/-/k/), which occurs in Hindi but not in English (both phonemes sound like a “g” to an English speaker). The /g/ and /k/ phonemes differ in terms of voice-onset time (VOT), such that /g/ contains a pre-voicing component while /k/ does not. It is therefore possible to gradually convert /g/ tokens into /k/ by successively removing parts of the pre-voicing component. Our training stimuli consisted of the Hindi syllable pairs [gɪ]-[kɪ], constructed by

recording a male native Hindi speaker saying [gɪ] and systematically removing the pre-voicing component using Praat phonetics software. This yields a continuum of seven stimuli from [gɪ] to [kɪ], separated by an average of 19ms in VOT from each other, and identical except for the pre-voicing.

Half of the 16 test trials used the [gɪ]-[kɪ] stimuli, with order of presentation of each and the side of the correct response counterbalanced. The other half of the test trials (also fully counterbalanced) consisted of the same contrast spoken in a different vowel context ([ga]-[ka]) and recorded by a female native Hindi speaker. The continuum of [ga] to [ka] was constructed in the same way as [gɪ] to [kɪ], although only tokens 1 and 7 were used during the test trials. For space reasons, we will report on overall performance among all of the test trials rather than on the two kinds of test trials individually.

**MANDARIN.** Participants were trained on a continuum bridging two tones, one of which is high level (Tone 1) and one of which is rising (Tone 2), as obtained from Xu, Gandour, and Francis (2006) and illustrated in Figure 2. The training stimuli consisted of a continuum between a vowel in Tone 1 ([ɿ]) and the same vowel in Tone 2 ([i]). A male native Mandarin speaker produced the syllable [ɿ], and its fundamental frequency ( $f_0$ ) contour was systematically altered to synthesize tokens on the continuum to Tone 2. This resulted in a seven-equal step continuum, as shown in Figure 2. All tokens have the same offset frequency (130Hz) and were normalized for duration and amplitude. As documented in Xu et al. (2006), three native Mandarin speakers judged tokens 1 and 7 to be good exemplars of the [ɿ] and [i] syllables.

Analogously to the Hindi stimuli, half of the 16 Mandarin test trials used the [ɿ]-[i] stimuli, with the order and side fully counterbalanced. The other half of the test trials consisted of the same tonal contrast spoken by a female Mandarin speaker with a different vowel ([ā] to [á]), constructed by the same method as the [ɿ]-[i] stimuli. As with the Hindi stimuli, we will report on overall performance among all of the test trials rather than on the two kinds of test trials individually.

**CONTROL.** In order to make sure that participants were attending to and understood the task, we included 8 trials of control stimuli during each of the two tests. These corresponded to a phonemic contrast they could already recognize: the dental plosive aspirated/unaspirated voiced/voiceless contrast (/d/-/tʰ/), which sound like “d” and “t” respectively to a native English speaker). Because the /d/-/tʰ/ contrast also exists in Hindi, the phonemes were recorded by the same male Hindi speaker as before.

## Results

Our study used two phoneme discrimination tests, the ABX and the S/D. Performance on these two tests was comparable: there was no significant difference in overall percent correct between discrimination tests (paired-sample  $t(383) = 1.33, p = 0.184$ ), with a mean performance of 70.5% (SD=20.4) in the ABX tests and a mean performance of 69.2% (SD=18.8) in the S/D tests. Moreover, the scores on

Figure 3: Overall accuracy by musicianship and stimulus type. Musicians showed superior performance to non-musicians, and performance was also higher on Mandarin than Hindi stimuli. Moreover, there was an interaction indicating that being a musician helped relatively more for Mandarin than Hindi stimuli.

the two tests were correlated ( $r = 0.50, p < 0.0001$ ). In all of the subsequent analyses we therefore collapse performance on the two tests into one overall accuracy score.

Our first question is whether discrimination performance is different on the Hindi and the Mandarin contrasts: is one easier than the other? Is there a differential effect of musicianship on each? We address this by considering performance on the stimuli for each language, collapsing (for now) any effects of training. As Figure 3 shows, musicians performed better than non-musicians for both types of contrast (two-way ANOVA,  $F(1,380) = 41.5, p < 0.0001$ ) and performance was higher on the Mandarin stimuli ( $F(1,380) = 41.5, p < 0.0001$ ). Moreover, there was an interaction, indicating that being a musician helped more for Mandarin stimuli than for Hindi stimuli ( $F(1,380) = 9.39, p = 0.002$ ).

How did the effects of musicianship play out within each stimulus type, and how did that interact with training? Were musicians or non-musicians helped more by training? Were the effects different depending upon the nature of the contrast in question? To address these issues we evaluate performance on the Hindi and Mandarin stimuli separately.

**Hindi stimuli.** Figure 4 shows overall accuracy on the Hindi test stimuli by musicianship and training. Participants were considered to have been trained on the stimuli if they were in the HINDI condition and untrained if they were in the MANDARIN condition. Musicians performed significantly better than non-musicians (two-way ANOVA,  $F(1,188) = 5.53, p = 0.019$ ), but there was no significant effect of training ( $F(1,188) = 1.71, p = 0.193$ ) and no interaction ( $F(1,188) = 0.049, p = 0.156$ ).

**Mandarin stimuli.** Figure 5 shows overall accuracy on the Mandarin test stimuli by musicianship and training (where people in the HINDI condition were considered to be untrained on the Mandarin stimuli). Here too, musicians performed significantly better than non-musicians (two-way ANOVA,  $F(1,188) = 46.8, p < 0.0001$ ). As before, there was no significant effect of training ( $F(1,188) = 0.001, p = 0.810$ ) and no interaction ( $F(1,188) = 0.71, p = 0.402$ ).

Figure 4: Overall accuracy on the Hindi phonemes by musicianship and training. Musicians did significantly better than non-musicians. Training did not significantly improve performance, although the trend among non-musicians approached significance.

## Discussion

Our overall findings show a strong effect of musicianship on phonetic perception: musicians had superior perception for both timing-based and pitch-based non-native contrasts (although the effect was much stronger for pitch-based contrasts). Interestingly, there was no effect of distributional training. Here we consider some of the implications of these findings for first and second language acquisition in general.

### Why did musicians perform better?

These results are consistent with the extensive literature documenting the fact that musicians have superior performance in linguistic tasks involving lexical tones (Alexander et al., 2005; Wong & Perrachione, 2007; Wayland et al., 2010). However, there is relatively little prior work showing that musicians have an advantage for non-tone-based phonemes, and none that we know of that investigates phonemes defined by differences in voice onset time (Slevc & Miyake, 2006; Sadakata et al., 2010). This suggests that whatever advantage musicians enjoy is not limited to differences in pitch perception, even though the timing-based advantages are smaller. Indeed, we even found a slight difference in performance between musicians and non-musicians on the control stimuli; although both groups performed extremely well (98.7% accuracy for the musicians, 95.2% accuracy for the non-musicians), the difference between the groups was significant ( $t(94) = 2.94, p = 0.004$ ). This is somewhat surprising, but it is true that even the control sounds were potentially confusable than more distinct phonemes would have been, and the difference is small in magnitude.

What is the root of the musician advantage? Consistent with their slightly better performance even on the control trials, one possibility is that musicians simply have a “better ear” in general – that is, they have superior auditory processing abilities overall. While this possibility is consistent with existing research (Schön, Magne, & Besson, 2004; Wong, Skoe, Russo, Dees, & Kraus, 2007; Musacchia et al., 2007), it does not really answer the question: *why* do they have superior abilities? Does musical training itself improve such

Figure 5: Overall accuracy on the Mandarin phonemes by musicianship and training. Musicians did significantly better than non-musicians, and training had no effect on performance.

abilities, or is it simply that people with better auditory processing become musicians in the first place?

This is a hard question to firmly disentangle, but our data provides one way to address it. We find that although the total duration of musical training is correlated with overall accuracy ( $r = 0.306, p = 0.002$ ), this effect is carried by the presence of non-musicians in the sample; there is no effect of duration of musical experience among the musicians only ( $r = 0.012, p = 0.932$ ). This occurs despite the fact that our sample of musicians was fairly diverse, ranging from people with 5 years to 45 years of training ( $M = 12.75, SD = 7.7$ ). It implies that perhaps at least part of the difference between musical and non-musical populations may be due to non-training-related differences in auditory perception. That said, since our participants played a wide range of instruments and were involved with music at different intensities – and any effects of duration are confounded with age – this is at best suggestive and should be interpreted with caution.

Could the better performance by the musicians be due to a motivational difference? While this might explain why the musicians performed better even on the control trials, it seems unlikely. The musicians were not told explicitly that they were being compared to non-musicians; they were only told that we were interested in how musicians learn language in general. It is unclear why they would be more motivated in such a scenario. Furthermore, our findings are consistent with the large amount of previous work showing superior phonetic processing in musicians (Alexander et al., 2005; Slevc & Miyake, 2006; Sadakata et al., 2010; Wayland et al., 2010). That said, in follow-up work we plan to investigate this possibility by recruiting visual artists, who would have the same motivational advantages (if any) that come from being recruited as a member of a special group, but who we would not expect to have superior auditory perceptual abilities.

### Why did training have no effect?

In addition to the musician advantage, our other main finding was that distributional training had no effect on the dis-

crimination of phonemes in our experiment.<sup>2</sup> Although a few previous experiments (Maye & Gerken, 2000; Hayes-Harb, 2007; Perfors & Dunbar, 2010) have found effects of distributional training for Hindi contrasts among non-musicians, these effects were small. Indeed, most training regimes for adults last far longer than 10 minutes and give reinforcement of some type, precisely because it is far more effective to do so (Jamieson & Morosan, 1989; McCandliss et al., 2002; Golestani & Zatorre, 2004; Bradlow, 2008).

The lack of training effect among musicians and for the Mandarin stimuli may have occurred for similar reasons. However, it also may be that implicit distributional training is not an effective means for teaching adults to discriminate pitch-based contrasts like the Mandarin /i/-/i/ distinction. This seems more plausible given the fact that even within the non-musicians – for whom there was non-significant trend of training for the Hindi contrast – there was no effect of training on the Mandarin contrast. But why would distributional training be more effective for one kind of contrast than another? We know that it is *possible* to train non-native speakers to perceive this kind of tonal contrast (Wang et al., 2003; Wayland et al., 2010; Wong & Perrachione, 2007). However, the training programs that have been successful have been far more intensive and explicit than ours was. We can only speculate, but perhaps this sort of instruction is necessary for people to understand the pitch distinctions they should be listening for. In contrast, distributional training may naturally focus people's attention on timing by playing one phoneme after another in rapid succession. That said, since distributional training had no statistically significant effect in any case, the simplest conclusion is that it was insufficient regardless of the nature of the contrast.

A related possibility is that our participants were already performing near their ceiling – that is, near the peak of what would be possible for them without decades of experience distinguishing the sounds in question. Perhaps the benefits of training for non-musicians in Hindi found in previous studies and implied here come from making people aware of the more obvious cues that can be used to distinguish the sounds. Due to their superior auditory skills, musicians may already be aware of those cues; and pitch differences are blatant enough that even non-musicians can hear some of the differences between /i/ and /i/. Of course, the difference between musicians and non-musicians, and between Hindi and Mandarin phonemes, also implies that if there is a ceiling effect, there are probably multiple different ceilings rather than only one.

Is there a ceiling effect? Given the widely-documented difficulty of training adults to recognize non-native contrasts,

<sup>2</sup>We did find that if we performed a post-hoc analysis on only non-musicians in the Hindi contrast, which is the only condition directly corresponding to the previous literature (Maye & Gerken, 2000; Hayes-Harb, 2007; Perfors & Dunbar, 2010), the training effect was significant ( $t(94) = 2.12, p = 0.037$ ). This suggests that had that been the only condition studied – analogous to the previous literature – it would have reached significance. However, since this analysis in our study followed an omnibus ANOVA with no main effect or interaction, it is not statistically appropriate to apply here.

this is certainly possible. After all, native speakers have decades of experience distinguishing between those sounds, and it would be quite surprising if these vast differences in exposure could be eliminated with a small amount of training, even among especially capable subjects like musicians. The notion of a ceiling effect for training is also consistent with the Native Language Neural Commitment hypothesis, which suggests that early experience results in changes in the brain that encode the phonetic contrasts of one's native language (Kuhl, 2004). Because of these neural changes, learning non-native contrasts as an adult is therefore extremely difficult. This would also explain why training made no difference among any of the musicians, who may have been already performing near the limit possible for brains that grew up dedicated to hearing other kinds of contrasts. If there is a ceiling, it has unfortunate implications for second language acquisition. Perhaps it is intrinsically limited by poor phonetic perception abilities, at least without years and years of exposure to the new language. That said, we must remind ourselves that the training approach used in this study was quite simple and short compared to other, more intensive methods, which might very well have more of an effect.

In many ways, this study raises more questions than it answers. Why did distributional training have no effect, particularly for musicians and Mandarin contrasts? What is the root of the musician advantage, and why does it extend to include timing-based contrasts as well as pitch-based ones? These questions are still open, but this work is an important step toward understanding the roots of phonetic perception and its relationship to both first and second language learning.

## Acknowledgments

Thank you to Natalie May, Angela Vause, and Daniel Carabellese for recruiting participants and running the experiments, and to Dan Navarro and the CLCL lab for useful discussions. We especially thank Dr. Jackson Gandour for generously sharing his Mandarin stimuli. AP was supported by ARC grant DE120102378.

# Probability matching vs over-regularization in language: Participant behavior depends on their interpretation of the task

Amy Perfors (amy.perfors@adelaide.edu.au)  
School of Psychology, University of Adelaide, Australia

## Abstract

In a variety of domains, children have been observed to over-regularize inconsistent input, while adults are more likely to “probability match” to any inconsistency. Many explanations for this have been offered, usually relating to cognitive differences between children and adults. Here we explore an additional possibility: that differences in the social assumptions participants bring to the experiment can drive differences in over-regularization behavior. We explore this in the domain of language, where assumptions about error and communicative purpose might have a large effect. Indeed, we find that participants who experience less pressure to be “correct” and who have more reason to believe that any inconsistencies do not correspond to an underlying regularity do over-regularize more. Implications for language acquisition in children and adults are discussed.

**Keywords:** over-regularization; statistical learning; probability matching; language acquisition

## Introduction

In a variety of situations, humans given probabilistic input will tend to *probability match* – that is, they respond differentially in a way that is proportional to those probabilities. In learning theory, this occurs when people (or animals) choose a stimulus proportional to the relative number of times it has been reinforced (e.g., Herrnstein, 1961, 1970; Baum, 1979; Pierce & Epling, 1983; Wearden, 1983). In decision making, this occurs when people are asked to predict the next item in a sequence (e.g., a card drawn from a deck, or a flashing light) and respond by choosing proportionally to the frequency of that item in the past (e.g., Castellan, 1974; Shanks, Tunney, & McCarthy, 2002; Vulkan, 2000). And in language learning, this occurs when people given linguistic input that varies inconsistently (such as an affix or particle occurring only 60% of the time, for no apparent reason) and they produce that particle proportional to its frequency in the input (e.g., Hudson Kam & Newport, 2005, 2009).

Although these cases vary widely in many details, what is interesting in all of them is that an overmatching or maximizing strategy may often be the more sensible one. This strategy, also called over-regularization in the language literature, involves producing or responding to the most frequent item closer to 100% of the time, rather than in a way that is proportional to its probability or frequency. Such a strategy is more sensible for different reasons in different domains. One receives more reinforcement if one always chooses the more frequently-reinforced stimulus; one makes more successful predictions if one always chooses the most frequent item; and one minimizes the burden on the listener as well as the chance of miscommunication by removing linguistic variability when it serves no purpose. Given this, why do people probability match?

One clue may come from the literature on children’s behavior. Although children are less well-studied than that of adults, there is some evidence that preschool-aged children may overmatch or over-regularize more in a decision making or reinforcement learning context (Jones & Liverant, 1960; Derks & Paclisanu, 1967). This is consistent with the small amount of work on children in a linguistic domain suggesting that they are more likely than adults to over-regularize there as well (Hudson Kam & Newport, 2005, 2009). These findings are somewhat limited, since they are based on relatively few studies (especially in the area of language) and generally involve statistical rather than absolute differences: that is, more children over-regularize than adults, but some still do not. Nevertheless, they raise the intriguing possibility that whatever factor causes adults to probability match may play less of a role in preschool-aged children.

What might that factor be? A common hypothesis is that it is related to a cognitive change occurring between childhood and adulthood. One possibility is that preschool children have poorer metacognitive control – that is, they find it difficult to inhibit a previous response (Jones & Liverant, 1960; Weir, 1964), have a harder time monitoring and responding to conflict in their representations (Ramscar & Gitcho, 2007), and/or are more insensitive to the reward structure (Stevenson & Hoving, 1964). Another is that children’s poorer memory and/or processing abilities might result in over-regularization (Hudson Kam & Newport, 2005, 2009).

Although there is support for many of these possibilities, it is also possible that the difference arises, at least in part, for a more prosaic reason: adults and children may be given slightly different tasks, or have different interpretations of the same task. It is natural for minor task differences to arise as a natural by-product of the effort to make the same experiment apply to widely varying age groups. There were indeed small differences in all of the experiments in which differential over-regularization is observed (e.g. Jones & Liverant, 1960; Derks & Paclisanu, 1967; Hudson Kam & Newport, 2005, 2009). However, we are more interested here in the kinds of differences in interpretation that might arise even with precisely the same methodology. That is, different groups (like children and adults) might have different interpretations or different assumptions that they bring to the *exact same* task. As explained below, this may be particularly an issue in linguistic tasks, which are the focus of this work.

This paper explores one main question: is human behavior in a language-learning domain affected by changes in the goal or assumptions underlying the task? It is known that adults can be pushed away from probability matching by

varying the delay between changing a response and reinforcement (Baum, 1975), punishing people for some responses (Bradshaw, Szabadi, Bevan, & Ruddle, 1979), making one response easier (Bradshaw, Ruddle, & Szabadi, 1981), making rewards especially enticing (Shanks et al., 2002), or offering extensive corrective feedback (Shanks et al., 2002). However, none of these possibilities are relevant when the task is linguistic, since language learners generally receive little to no direct feedback or reinforcement, both in the real world (Pinker, 1989) and in this kind of task (e.g., Hudson Kam & Newport, 2005, 2009; Perfors & Burns, 2010; Perfors, 2011).

What goals or assumptions might adults and older children have that younger children do not, which cause the former to probability match but the latter to over-regularize? We hypothesize that adults and older children may feel a strong sense that there is a “right” answer, and a concomitant pressure to be pressure to be “correct” that younger children do not. We noticed in previous studies run in our lab (Perfors & Burns, 2010; Perfors, 2011) that adults reported a strong intuition that there must be some underlying reason behind the inconsistency in the linguistic input they received; for instance, one participant confided that they thought all of the “shiny things” were linguistically marked in the same way. In reality, there were no regularities between the inconsistent items and anything else in the experiment, but the participants did not know that and often tried to produce language in accordance with the regularities they thought they had observed.

Why did our adult subjects have such a strong intuition that there were regularities in the input? One possibility is that this is simply an intuition that all people typically bring to *any* language-learning scenario. It is not an unreasonable assumption; although some phenomena in language are truly arbitrary, much variation does occur for a reason. If people truly do always come to language learning tasks with this assumption, then we would expect adults to show the same behavior regardless of where they thought the language came from or what their goal in the learning task was. Conversely, this intuition may have been caused by, or at least exacerbated by, characteristics of the situation: being in an official lab, presented with stimuli that are clearly designed and non-accidental, and asked to learn about those stimuli all create the strong impression that there actually is some regularity there to learn. By contrast, real linguistic input contains many errors and inconsistencies that arise from the fact that it is produced on the fly, for communication, by real people. If young children are either more blind to the social pressures inherent in a lab-based experiment or more likely to interpret underlying irregularities in the input as errors, then this might be responsible for at least some of the observed difference in over-regularization between children and adults. After all, it is sensible to over-regularize inconsistencies if they do not hide some underlying regularity that you will be judged for missing.

A full test of our hypothesis would require us to manipulate children’s beliefs about the nature of the input they are

receiving and experiment they are in. This is very difficult to do, and it is even more difficult to evaluate whether it has been done successfully. Alternatively, we can test the assumptions underlying our hypothesis by investigating adults. If adults respond to task characteristics that remove a pressure for generating “correct” responses by over-regularizing more, then this offers some support for the idea that at least part of the reason for the different behavior of children and adults might relate to different assumptions about the task.

Therefore, in this paper we explore the hypothesis that adult over-regularization behavior can be changed by changing the pressure for generating “correct” responses. This pressure is manipulated in two ways. First, we vary the cover story to change the assumptions people make about how likely the data is to reflect an underlying regularity of some sort. Second, we vary the goal of the task to emphasize or de-emphasize effective communication. Consistent with our hypothesis, we find that when the pressure for correct communication is reduced, adults over-regularize more. In the discussion we consider the implications of these results for experimental work on over-regularization, probability learning, and language learning more broadly.

## Experiment

**Participants.** 52 adults<sup>1</sup> were recruited from the University of Adelaide and surrounding community and were paid \$10 for their time. Participants were divided randomly into one of two conditions, HIGH PRESSURE and NO PRESSURE (described below). One person in the HIGH PRESSURE condition suffered a computer error causing a failure to save data, and two participants in the NO PRESSURE condition were excluded from the analysis for typing gibberish.<sup>2</sup> This left 25 participants in the HIGH PRESSURE condition and 24 in the NO PRESSURE condition.

**Procedure.** The standard task, which was the same in both conditions, involved a word learning task originally modelled after Hudson Kam and Newport (2009) and Perfors (2011). The original Hudson Kam and Newport (2009) taught a language containing many words taught over multiple days, but the key element for our purposes was that in this language, units (which they called determiners) covaried with the nouns in an inconsistent fashion: participants heard the **main** determiner only 60% of the time. Participants were asked to provide the noun and determiner associated with a scene and sentence and the frequency with which each determiner was produced after each noun was noted.

As in Perfors (2011), we removed extraneous elements of the task so as to focus on the aspect involved in producing the inconsistent units. Our language consists of words composed from 10 stems, all one-syllable consonant-vowel-consonant nonsense words mapped to images representing common ob-

<sup>1</sup>We ran 52 rather than the more round 50 because the HIGH PRESSURE condition required pairs of participants (an even number of people). We matched that number in the NO PRESSURE condition.

<sup>2</sup>This was reflected in their accuracy score, which was over four standard deviations below the mean accuracy for either condition.

jects. Each stem was attached to a by a one-syllable affix: the **main** affix occurred 60% of the time, and each of the four **noise** affixes occurred 10% of the time.<sup>3</sup> The main difference between this study and the previous ones is that while they were entirely auditory in both their presentation of stimuli and the modality of the response, in this study everything was written. This was necessary in order to make the experimental manipulation possible and believable, as explained below. Words were presented with no space between the stem and the affix: thus, participants would see words like PIMUT or JAFIG. They were not told that each of the words was composed from smaller units. The specific image-label mapping and choice of **main** affix was randomized for each participant.

As in Perfors (2011), the task consisted of a total of 200 trials of image-label pairs. On each trial, an image appeared on the computer screen and at the same time the person saw a label written in all capitals below it: for instance, they might see a picture of a baby and read YOKOM. People went to the next trial by clicking a next button. Learning was tested with 20 questions every 100 trials, for a total of 40 test questions. At each test, the participant was presented with an image and asked to enter the label for it. No feedback was given.

**Conditions.** The goal of this experiment was to explore the possibility that adult over-regularization behavior can be affected by changing the pressure for generating “correct” responses. We therefore constructed two conditions, one designed to increase this pressure as much as possible, and one designed to decrease it as much as possible.

**HIGH PRESSURE.** In this condition, we tried to increase the pressure to be correct by pairing each participant with another person who was in the lab at the same time. Each person was informed that the goal of this experiment was to learn a new language, and then successfully use it to communicate with the other person. They were asked to imagine they were scientists who had just discovered a community speaking this language, and they had gotten an informant to label a series of pictures for them. They were to read these labels, and then they would be tested on how well they had learned them by having to fill in the labels for new pictures. Participants sat at different computers and did the standard task individually, but at the end of the standard task each person was given the labels the other person generated during their test questions, and asked to match each of those labels with the correct image. The participants were told that they would get paid proportionally to how many of this final set of questions both of them got right. This created a great deal of social pressure to learn the language correctly, since not only was each individuals’ payment dependent on it, so was their partner’s.

It is important to note that this manipulation *in itself* does not favor either over-regularization or probability matching. Since the affixes did not correlate to the images at all, people could get 100% correct on the test regardless of what they

Figure 1: Accuracy in mapping the stems to the correct item. Both conditions showed high accuracy, and there is no significant difference between conditions. This suggests that any differences in over-regularization probably do not occur because participants were paying different amounts of attention to the stems and affixes.

did with the affixes, as long as the stems were matched to the correct image. Thus, any effect on over-regularization is due to increasing the sense that there is a “right answer” as well as the social pressure to find that right answer – *not* because participants could make more money using one strategy.

**NO PRESSURE.** In this condition, the pressure for being “correct” was reduced in two ways: first, by not pairing participants with a partner and making their payment dependent on performance in any way; and second, by changing the cover story so that people were less likely to believe there was an absolutely correct answer. The cover story in this condition was that we were studying how languages change when multiple people learn it. Thus, a previous participant had learned some words in a fake language, and during the course of the learning they were presented with images and asked to label them with those words. Current participants were told that they were being given the labels that had been generated by the previous participant, and that those labels might be kind of strange if the previous person made errors or did something weird. The participants were asked to just do their best to learn the language, and to provide labels that would then be given to the next participant.

A critical element of this design is that the standard task was *exactly the same* across conditions. All of the data we analyze here is from that standard task (since the partner testing in the HIGH PRESSURE condition was only there to determine payment, and not relevant to our research question). The only difference between conditions that could affect the data we analyze is what participants thought their goal was and how they thought the stimuli were generated.

## Results

The main question of interest is how much participants in each condition over-regularized by producing the **main** affix (or any single affix) more than 60% of the time. However,

<sup>3</sup>Stems were: dut, sil, zeg, mab, yok, pim, ren, jaf, wux, and cov and the affixes were: om, ep, ad, ig, and ut. Objects used were: babies, balls, beds, birds, books, cars, cats, cups, dogs, and shoes.

Figure 2: Proportion of time the most common affix is produced in each condition (after having occurred 60% of the time in the input). Participants in the NO PRESSURE condition over-regularized significantly more than did participants in the HIGH PRESSURE condition.

it is first necessary to determine whether any differences in over-regularization are associated with differences in overall performance or attention between conditions.

**Accuracy.** We can calculate an accuracy score for each condition, based on the percentage of stems that are generated in response to the appropriate item. A stem is counted as correct if it is no more than one letter different from the correct stem; thus, *cav* would be an acceptable variant of *cov*, but *div* would not be.<sup>4</sup> As Figure 1 demonstrates, people in both conditions were highly accurate, and there was also no significant difference between conditions ( $t(47) = 0.807, p = 0.424$ , two-tailed). This suggests that any differences in over-regularization did not result from people in the two groups paying different amounts of attention to learning the stems or affixes.

**Over-regularization.** The main question is if people show different levels of over-regularization in each of the two conditions. To determine this, we calculated the percentage of time that the most commonly-used affix was used by each participant. (For almost all participants, the most commonly-used affix was the **main** one; however, we did not want to presume that it always would be). As with the *accuracy* score, two affixes counted as the same if they differed by no more than one letter.<sup>5</sup>

Figure 2 shows the average percentage of trials in which participants produced the most common affix. It is evident that participants in the HIGH PRESSURE condition approximately probability match, while participants in the NO PRES-

<sup>4</sup>All analyses were also performed with a definition requiring the stem to match exactly; results were qualitatively identical.

<sup>5</sup>We also performed all possible combinations of two additional analyses. In the first, we used a more stringent definition of sameness, such that the affixes had to be identical to be counted. In the second, we considered only the subset of affixes for which the stem had been applied correctly. In all of these cases, participants in the NO PRESSURE condition over-regularized significantly more than participants in the HIGH PRESSURE condition.

Figure 3: Histogram of the number of participants according to how often they produced the most common affix. It appears that in the HIGH PRESSURE condition, there is a unimodal distribution of responses centered near 60%. By contrast, the NO PRESSURE condition appears to have a bimodal distribution of one group that over-regularizes strongly and another group that probability matches.

SURE condition over-regularize significantly more ( $t(47) = -2.250, p = 0.029$ , two-tailed). This sort of population-level analysis can be misleading, however. It is possible that 60% of the people in the HIGH PRESSURE condition produce the most common affix 100% of the time and 40% of the people never produce any affix more than once. Individual performance can also be revealing about to what extent the conditions resulted in different strategies among the participants.

Figure 3 therefore shows the histograms of each of the individual participants. Although such histograms are inevitably somewhat noisy and we should be careful about overinterpreting, they suggest two things. First, the number of participants who over-regularize in an extreme way (by producing the most common affix 80% of the time or more) is noticeably higher in the NO PRESSURE condition. In other words, these population differences actually do reflect the presence of more people who over-regularize strongly. The second interesting thing is that the distribution of participants in the HIGH PRESSURE condition is approximately unimodal: most people produce the most common affix between 40% and 70% of the time, and there are few outliers on either extreme. By contrast, the distribution in the NO PRESSURE condition looks more bimodal: there is one group of people who over-regularize strongly, and another set who do not. We will address some of the implications of this in the next section.

## Discussion

Overall, this work indicates that adults over-regularize inconsistent linguistic input more often when placed in a situation in which the pressure for correct responding is reduced and they have reason to believe that the inconsistency does not correspond to an underlying regularity. Indeed, what strategy is sensible changes depending on whether one believes that the affixes covary according to some hidden regularity, or covary arbitrarily. If there is a regularity, it is sensible to try to find and match it; if not, it is sensible to remove the inconsistency. The NO PRESSURE condition, by emphasizing that the

input came from a previous participant who might have made errors, strongly implied that any variability was random or accidental. In contrast, the HIGH PRESSURE condition, by giving a cover story implying that the participant was a scientist whose job it was to learn the language, and especially by making payment contingent on successful “communication” of that language, created the strong implication that there was some regularity there to learn. It is interesting that increasing communicative pressure did not result in more removal of inconsistency in the language; again, this is probably because the participants thought that the inconsistency reflected an important regularity, even if they weren’t sure what it was.

Our two conditions confound two effects: one is about the different assumptions participants might make about how likely the data is to contain errors, and the other is about how much pressure they feel to match some “correct” standard. We did not try to disentangle these things here because it would be very difficult, since simply knowing that the data might contain errors would decrease the pressure to correctly learn that data. The main point of this research is that differences in the impressions one brings to a task – whatever they may be – can change the degree of over-regularization.

Other than the experimental manipulations, the main implementational difference between this work and previous work is that both the input and the responses were written rather than auditory. However, since *both* conditions were written, the non-auditory nature of the experiment could not explain the difference between the conditions.

What does it mean that only some of the participants adopted an over-regularization strategy in the NO PRESSURE condition? One possibility is that those who did not adopt one still assumed that the inconsistencies may have been associated (perhaps more noisily) with regularities in the data. After all, it is a rather strange pattern of errors to have 10% each of four other kinds of affixes, but no other misspellings or incorrectly used stems. One way to investigate this possibility would be to design an experiment in which the affixes occur less often or there are additional errors in the input. However, since it is known that adults over-regularize more frequently when the inconsistency is less frequent (Hudson Kam & Newport, 2009) and any introduction of other errors would have to also occur in the HIGH PRESSURE condition in order to make the tasks equal, it is not clear that such a manipulation would be very illuminating. Still, this is a possibility we will consider for future work.

A potential limitation of this work is that the differences between the HIGH PRESSURE and NO PRESSURE conditions, although statistically significant no matter how the data is analyzed, are not large. In particular, even in the NO PRESSURE condition, not as many adult participants over-regularized as did children in Hudson Kam and Newport (2005) and Hudson Kam and Newport (2009). For this reason one of the first steps in future work will be to replicate these findings. That said, our results might underestimate the magnitude of the true effect to the extent that our participants didn’t believe the

“error” cover story but more of the children thought or assumed that the language they heard had some errors. Another quite likely possibility is that not all of the difference between children and adults is reducible to their different assumptions. Finally, any effect of naturally different assumptions between children and adults on the same task in Hudson Kam and Newport (2005) and Hudson Kam and Newport (2009) may have been exacerbated by subtle differences in their experimental design. In particular, while both adults and children learned a language called “Sillyspeak”, only the children were told they were learning from someone who did not know the language themselves. It seems plausible that the children were far more likely to conclude that their input contained a lot more error, especially when combined with the very different social assumptions about the nature of laboratory studies that each group may have had.

What do these results mean for research showing that children over-regularize in non-linguistic situations as well as linguistic ones, as in Derks and Paclisanu (1967) and Jones and Liverant (1960)? Any application to non-linguistic domains must be made extremely cautiously, since many of the differences between the HIGH PRESSURE and NO PRESSURE conditions do not translate to a non-linguistic context. For instance, there is no obvious analogue of errors in a deck of cards or reinforcement pattern. In addition, these experiments do not have the learner/teacher dynamic that the linguistic ones do, which might be associated with very different patterns of assumptions. That said, children may still feel less pressure than adults to be “correct” or not look “stupid” to the scientists, so we cannot rule out the possibility that this plays a role even in non-linguistic domains.

Within the area of language, much of the interest in children’s over-regularization arises because children and adults differ in their propensity to over-regularize outside of the lab as well as in it. Deaf children exposed to the inconsistent sign language of hearing parents will over-regularize that language and produce regular grammatical forms (Singleton & Newport, 2004), but adult language learners are known to produce highly variable, inconsistent utterances, even after years of experience with the language and after their grammars have stabilized (Johnson, Shenkman, Newport, & Medin, 1996). If over-regularization in children in these experiments is driven by differences in the assumptions they bring to the task, how do we explain these differences in real life?

In answer, we can only speculate. However, several possibilities present themselves. One is that children’s over-regularization in real life is driven by some of the same factors that we are calling task demands here: that is, perhaps children just assume that more of their input is irregular or full of errors, or they are less bothered by trying to be “correct” or not look like an idiot and therefore focus on simply communicating clearly. Another possibility is that the different assumptions manipulated in the tasks here do not explain all of the differences between children and adults that are found in laboratory experiments. Still another possibility is that the

kind of over-regularization measured in these experimental tasks does not map cleanly onto the over-regularization differences observed in natural language. At a minimum, one of these processes occurs in hours or days, and one takes years. Moreover, children may not bring the same assumptions to real language learning as to this kind of experimental task. Even beyond that, most variation in natural language is consistent in some way (e.g., Chambers, Trudgill, & Schilling-Estes, 2003). Thus, any child/adult differences in learning languages from native speakers<sup>6</sup> may not be traceable to the kinds of over-regularization differences found in these experiments. Thus, the implications for language acquisition must be speculative at this point, and we cannot say at this point for sure how to reconcile these findings with the language acquisition literature. It is important to note, however, that there are many ways they could be reconciled. Pursuing this is a project for future work.

This work may additionally have implications for adult second language acquisition, since it demonstrates that adults may change strategies in response to the nature of the explicit instructions they receive. This too is a project for future work.

The bottom line from this paper is that it is important to be cautious about drawing strong conclusions from existing laboratory studies to differences in how children and adults over-regularize when learning natural language. At the very least, the story is probably complex. For instance, some work shows that infants probability match in a looking time experiment (Davis, Newport, & Aslin, 2011), and even some of the original work in non-linguistic domains showed that children over-regularized the same amount as adults (Weir, 1964) or flipped strategies differentially depending on the nature of the reward (Stevenson & Hoving, 1964). The picture is therefore currently somewhat murky, even as regards the extent to which – and at what ages – children tend to over-regularize more than people of other ages.

In sum, this paper offers some reason to believe that over-regularization behavior can be driven by different assumptions about the goal of the experimental task and the origin of the data. If we are to understand what drives differences between adult and child language learning, we need to determine the extent to which the experimental findings in the literature stem from differences in such assumptions. It is also critical to further explore the extent to which these assumption explain differences in the learning of natural languages. This work is the first step along that path.

## Acknowledgments

Thank you to Natalie May, Angela Vause, and Daniel Carabellese for recruiting participants and running the experiments. Thanks to them as well as Dan Navarro and Irina Baetu for useful discussions. This research was supported by ARC grants DE120102378 and DP110104949.

<sup>6</sup>Pidgins and creoles would be a different story, of course, because there the input might indeed be truly inconsistent. That said, there are many additional complexities in that case as well; for instance, adults receive input from different people than children, and have different goals in their communications in the kind of setting that causes pidgin languages to emerge.

## Abstract

Joint attention has been identified as a foundational skill in human-human interaction. If virtual humans are to engage in joint attention, they have to meet the expectations of their human interaction partner and provide interactional signals in a natural way. This requires operational models of joint attention with precise information on natural gaze timing. We substantiate our model of the joint attention process by studying human-agent interactions in immersive virtual reality and present results on the timing of referential gaze during the initiation of joint attention.

**Keywords:** joint attention; virtual humans; social interaction

## Introduction

Attention has been characterized as an increased awareness (Brinck, 2003) and intentionally directed perception (Tomasello, Carpenter, Call, Behne, & Moll, 2005) and is judged to be crucial for goal-directed behavior. Joint attention builds on attentional processes and has been identified to be a foundational skill in communication and interaction. The term joint attention is often used confusably with shared attention. We follow Kaplan and Hafner (2006) and Tomasello et al. (2005) in using the term joint attention for the phenomenon which presupposes a higher level of interactivity requiring intentional behavior and an awareness of the interaction partner. Joint attention can be defined as simultaneously allocating attention to a target as a consequence of attending to each other's attentional states (Deak, Fasel, & Movellan, 2001). In contrast, we see shared attention (as well as shared gaze) as the state in which interactants are just perceiving the same object simultaneously without further constraints concerning their mental states or their interaction history.

Mundy and Newell (2007) differentiate joint attention behaviors into two categories: *responses* to the bids of others and spontaneous *initiations*. Responding to joint attention refers to the ability to follow the direction of gaze and gestures of others in order to share a reference. On the other hand, to initiate joint attention humans use gestures and eye contact to direct the attention of others to objects, events, and to themselves.

For joint attention, interlocutors have to deliberately focus on the same target while being mutually aware of sharing their focus of attention (Tomasello et al., 2005; Hobson, 2005). To this end, respond and feedback behaviors are necessary. Tasker and Schmidt (2008) argue that to establish joint attention a sequence of behaviors is required which has to meet certain time constraints.

We constructed an operational model of joint attention (Pfeiffer-Lessmann & Wachsmuth, 2009) for our virtual human Max (Lessmann, Kopp, & Wachsmuth, 2006) to create a more natural and effective interaction partner. The model covers four phases: the initiate-act (1), the respond-act (2), the feedback phase (3), and the focus-state (4). However, for Max to appear believable and to use the same behavior patterns in the phases as humans do, investigations on time-frames, human expectations and insights on how humans actually perceive his behavior are indispensable. The topic of concrete reaction and duration times of feedback behaviors during the joint attention process has to our knowledge not been discussed in the area of human-computer interaction yet. The time-frames and expectations of humans for natural interactions are central subject of this paper.

In the section to follow, we provide an overview on related work covering research on joint attention in human-human interaction and in the area of technical systems. In the subsequent "Model" section, a brief summary of our own definition of joint attention is provided. Next, we present a study in immersive virtual reality concerning the exact timing of the first phase, the initiate-act, of our joint attention model. Thereafter, results are discussed and the paper ends with our conclusions and future work.

## Related Work

Staudte and Crocker (2011) raise the question whether joint-attention-like behavior is unique to human-human interaction or whether such behaviors can play a similar role in human-robot interaction. They conclude that their own findings suggest that humans treat artificial interaction partners similar to humans and that it is therefore valid to investigate joint attention in settings with artificial agents.

These artificial agents can consist, on the one hand, of robots (Deak et al., 2001; Imai, Ono, & Ishiguro, 2003; Breazeal et al., 2004; Doniec, Sun, & Scassellati, 2006; Nagai, Asada, & Hosoda, 2006; Yu, Schermerhorn, & Scheutz, 2012; Huang & Thomaz, 2011; Staudte & Crocker, 2011) and, on the other hand, of virtual humans (Peters, Asteriadis, & Karpouzis, 2009; Zhang, Fricker, & Yu, 2010; Bailly, Raidt, & Elisei, 2010).

Kaplan and Hafner (2006) point out that research in robotics concentrates only on partial and isolated elements of joint attention (e.g. gaze following, simultaneous looking or simple coordinated behavior) covering solely the surface of the process but not addressing the deeper, more cognitive

aspects of the problem. The same authors stress that no system achieved true joint attention between a robot and a human or between two robots according to their definition yet. This appears to be still the case, however progress has been made with respect to investigating joint attention behaviors.

A number of researchers in cognitive science and cognitive robotics use developmental insights as a basis for modeling joint attention showing how a robot can acquire joint attention behaviors by supervised and unsupervised learning (Deak et al., 2001; Nagai et al., 2006; Doniec et al., 2006). However, the aspect of intentionality and explicit representation of the other's mental state are not accounted for in these approaches.

Another area of research investigates the impact of artificial agents' joint attention behavior on humans. Here, real interaction scenarios can be distinguished from humans rating video material. Huang and Thomaz (2011) argue that video-based experiments offer the advantage of studying humans' perception of joint attention behaviors without dealing with technical challenges of identifying the humans' behaviors. According to Staudte and Crocker (2011), it has been shown that video-based scenarios without true interaction yield similar results to live-scenarios and can therefore provide valuable insights into humans' perceptions and opinions.

Huang and Thomaz (2011) use videos to investigate humans' judgements of robots initiating and ensuring joint attention behavior. Their results suggest that humans overall preferred robots showing joint attention behavior. Staudte and Crocker (2011) also follow a video-based approach; they conclude that participants robustly follow the robot's gaze and use it to anticipate upcoming referents. Bailly et al. (2010) try to quantify the impact of deictic gaze patterns of their agent. They explicitly instructed participants not to take the agent's behavior into account, but the participants were drastically influenced by the agent's gaze patterns anyway.

In a real interaction scenario, Peters et al. (2009) study how human participants perceive the virtual agent's simple shared attention behavior of non-verbal cuing and how subtle changes of this behavior affect the gaze-following of human participants. Huang and Thomaz (2011) investigate the respond-act of their robot and the resulting impact on a human-robot collaborative task using a task-based metric. They find that the robot responding to referential foci significantly outperforms the one staying focused on the human.

The robot of Breazeal et al. (2004) keeps a representation of its current focus of attention calculated by saliency values. Additionally, it monitors the human participant's focus of attention. It is thereby able to notice when both interactants focus on the same object simultaneously. However, the robot appears to miss feedback mechanisms on a higher level of interactivity covering intentional behavior and the awareness of the interaction partners in the joint attention process.

Many researchers investigating the impact of artificial agents which show joint attention behaviors do not account for the necessary time courses. As an exception, Yu et al. (2012) try to investigate the exact time course of multi-modal

interaction patterns occurring naturally as part of joint attention processes.

In our own approach, we let human participants engage with our interactive virtual agent Max in an immersive virtual environment. As with human-robotic and human-human interactions, the interactants thus share the same three-dimensional environment and reciprocal interactions are possible. However, other than today's robotic systems, the virtual agent has (more than) human-like reaction times and is controlled by a cognitive architecture which goes from basic activation processes up to concepts of epistemic modal logics to model mutual beliefs which are essential for joint attention.

For human-human interactions, Tasker and Schmidt (2008) postulate a time frame of 5 s for the addressee of an initiate-act to respond appropriately. According to them, the duration of the respond-act has to last for at least 3 s in order to establish evidence that the partner's attention has been captured. The focus-state of joint attention has to last for a minimum of 3 s, too. This duration is in accordance to the results found by Vaughan et al. (2003) for maintaining focus on the same object in an episode of joint engagement.

Mueller-Tomfelde (2007) takes a closer look at the research literature to figure out appropriate time scales for referential actions. Since an initiate-act or respond-act could be characterized as such, his results should be highly relevant for natural time-scales of joint attention behaviors. He argues that since a pointing action includes cognitive aspects, it is more than a basic movement-primitive and thus more than a basic physical act constrained by the nature of cognitive operations at a time period of about a  $\frac{1}{3}$  of a second. Therefore, Mueller-Tomfelde (2007) expects an appropriate temporal scale of referential primitives to be greater than 300 ms while being less than the temporal scale of actions of a higher cognitive level with a temporal time window of 2-3 s.

## Model of Joint Attention

The model of joint attention presented here is in agreement with the model of Tasker and Schmidt (2008), except that we do not adopt their time constraints for joint attention. Our model also meets the requirements of Kaplan and Hafner (2006), for a longer discussion see Pfeiffer-Lessmann and Wachsmuth (2009). However, our model differs in that we do not require interactants to perform a certain sequence of behaviors. Instead we define the effects of joint attention behaviors on their mental states. Thereby, different behaviors can be performed counting as joint attention behaviors. However, to realize a natural interaction partner, we are now investigating valid joint attention behaviors performed by humans to be implemented in our artificial agent.

We define four phases characterized by the mental states of the interactants (see Figure 1). In order to engage in joint attention, the interaction partners need to have a certain kind of psychological engagement with each other, which can be described as involving a species of perception as well as a species of emotional responsiveness (Hobson, 2005). This

can be defined as the precondition for joint attention. To establish joint attention, certain behaviors leading to certain mental states need to take place. The first phase can be described as the *initiation-phase*; one of the interactants performs an initiate-act, which the other interactant can recognize. The second phase can be described as the *respond-phase*. Now the addressee of the initiate-act needs to perform a respond-act. The third phase is characterized as the *feedback-phase*; the interactants affirm that they have recognized the interaction attempts of their interaction partners. The forth and last phase consists of the *focus-phase*; now both interactants focus on the object of attention and are aware of the joint attention state (see also Pfeiffer-Lessmann and Wachsmuth (2009) for a formalized definition of the required mental state for joint attention).

Figure 1: Phases of the joint attention process - Initiator (I) and addressee (A) wear hats according to their roles.

The model of Huang and Thomaz (2011) with five steps shares many features with our model except that we define to-be-aware of the interactant as a prerequisite and not a step in the joint attention process and that they concentrate in their step 4 on verifying the response of the addressee whereas we lay more emphasis on the required feedback mechanisms between both interactants.

### Study on the Timing During the Initiate-Act

While the review of related work has brought up timing data on the phases 2 to 4 of our model, little has been found on the internal timing of events during the initiate-act. With the following study, we address the question on the timing of the initiator's referential act in which she first introduces the target of the joint attention process. Additionally, we investigate acceptable response times of the addressee for a referential

Figure 2: In the study, the human participant faces the virtual agent Max in a fully immersive virtual reality environment. Between the two interlocutors is a table with ten objects from a city planning scenario, which serve as reference objects. The eye gaze and the head movements of the human participant are tracked and the line of gaze onto the objects in the virtual environment is computed in real-time.

act to be considered successful. As a first step, we thereby focus on referential acts via eye gaze.

**Scenario** We investigate joint attention in a cooperative interaction scenario with the virtual human Max, where the human interlocutor meets the agent face-to-face in 3D virtual reality (see Figure 2). The human's body movements and gaze are picked up by infrared cameras and an eye tracker (Pfeiffer, 2011). This enables Max to follow the human's head movements and gaze in real-time, the two aspects of human joint attention behavior considered in this study.

### Participants

Altogether data from 20 participants (10 women, 10 men) has been collected. All participants were students or employees of Bielefeld University. The age of the participants was between 21 and 45 years, with a mean of 28 years and a SD of 5.17.

### Method

The participants were invited to our lab and given a brief introduction to the study. At this time, they filled out a short questionnaire and read the written instructions for the tasks. After that, they were equipped with the tracked stereo glasses required for the immersive virtual reality setup. For controlling the experiment, they were given a Wii Remote to step through the trials. After the participants had entered the virtual environment, they had time to get accustomed to the scenario. Finally, the eye-tracking system was calibrated and the participants repeated verbally the procedure of the study. After all questions had been answered, the trials started.

The two possible roles of an interlocutor (initiator or addressee), are reflected by the study design: two blocks I and A are repeated, where the human participant is the initiator

in block I and the addressee in block A. The blocks were repeated three times, for the first ten participants in the order IAIAIA, for the second ten in the order AIAIAI. The tasks within each block are described below. The ten items in block I and block A had a pre-randomized sequence, which was static between participants but different for the first, second and third presentation of the block.

After all blocks were completed, the participants were debriefed. Before departing, all participants received a recompense for taking part in the experiment.

### I: Dwell Time of Referential Gaze Produced by Initiator

The aim of block I is gathering data about the typical dwell time of the referential gaze act of an interlocutor when attempting an initiate-act. During the initiate-act, the interlocutor focuses on the target object for a certain amount of time  $\alpha_r$  ( $r$  for reference) until she checks back by focusing on the face of the interaction partner for time  $\beta_r$ . The total duration of the initiate-act is  $\alpha_r + \beta_r + 2\epsilon_r$ , with  $\epsilon_r$  being the very short time needed to shift the gaze focus.

Figure 3: The sequence of steps for one item in block I. I=initiator (human) and A=addressee (agent)

The interaction scenario described above, with a human interlocutor addressing the virtual agent Max, provides the frame for this task. Max plays the role of an interlocutor, while the participant is instructed to perform an initiate-act for one of the objects located on a virtual table between the participant and Max (see Figure 2). In an orientation phase prior to each initiate-act, Max gets blindfolded and the next target object is highlighted with a red arrow (see Figure 3, step 1). This design has been chosen to make explicitly clear that Max has no prior knowledge of the target object. Once the participant has located the new target object, she has to return her gaze to Max and press a button to start the interaction. This removes the arrow as well as the blindfold of Max. Max then gives a short verbal phrase to provide the context of the joint attention act and the human participant can start her initiate-act. The participant is instructed to use gaze only to try to direct the attention of Max towards the given target object (Figure 3, step 2). She should start while focusing on Max' face, then attempt an initiate-act by focusing at the target object as long as she feels is needed (Figure 3, step 3, while we collect data on  $\alpha_r$ ). She should then interrupt focusing on the target object and check back at Max' face (Fig-

ure 3, step 4). Finally, she should press a button as soon as she feels that Max should have reacted by then (while we collect data on  $\beta_r$ , the expected maximum response time). Because at this point in time we do not want Max to influence the participant's timing behavior, Max does not show any reaction in response to the participant's attempts. The whole procedure is repeated for the remaining objects, until all ten objects have been covered.

### A: Dwell Time of Referential Gaze Accepted by Addressee

In the second part of the study we reverse the roles of the human interlocutor and the virtual agent Max.

Figure 4: The sequence of steps for one item in block A. I=initiator (agent) and A=addressee (human)

Now, it is Max who is performing initiate-acts to achieve joint attention and the human interlocutor observes and evaluates these attempts. During the initiate-act, Max will stop focusing on the interlocutor and move his gaze focus to the target object for an amount of time from a predefined set ranging from 600 ms to 3000 ms in steps of 600 ms (Figure 4, step 2). These values have been selected to comprise typical non-communicative gaze durations and the findings on mean durations from the literature. Max will then focus back at the participant's face (Figure 4, step 3). The participant is asked to watch Max' gaze. Once Max focuses back at the participant, she has to decide whether Max had intended her to follow his gaze. If she decides so, she has to press a button and gaze at the target object (Figure 4, step 4). If not, she has to do nothing. After five seconds, Max will automatically continue with the next item.

During the interaction, one measurement is made. By pressing the button the human participant ascribes Max to have performed a valid initiate-act. We then count the dwell time used by Max from the given set as an acceptable dwell time for an initiate-act,  $\alpha_a$  ( $a$  for acceptance).

## Results

In a post-study questionnaire (seven-point Likert scales (1-7), median score is given here), the participants reported that they felt present in the virtual environment (score 5) and experienced the agent as being even more present (score 6). The naturalness of the communication with the agent, however, was rated 3 (SD 2). The participants also were able to fully concentrate on the task (score 6) and were not hindered by the devices. Overall, they enjoyed the experience in the virtual

Figure 5: Dwell times of referential gaze during initiate-acts produced by the human participants in study part I.

reality (score 5) and had no difficulties with the task (score 3 rating the difficulty).

### I: Dwell Time of Produced Referential Gaze

During block I, 560 initiate-acts were recorded. Overall, the mean dwell time of referential eye gaze ( $\alpha_r$ ) was 1896.82 ms (SD 963.46 ms) and the median was 1796 ms. A histogram of the durations of the referential gaze is depicted in Figure 5. During the orientation phase when the participants had to identify and remember the target object, the mean dwell time of eye gaze was 1559.58 ms (SD 1029.24 ms) and the median was 1390.5 ms. The dwell time during search was significantly shorter than the dwell time of referential gaze (t-Test results in  $t=5.91$  with  $p=0.001$  by 545 DoF, confidence interval 215.75 ms to 430.42 ms).

Overall, the mean duration until the human participant expected a feedback after the production of a referential eye gaze towards the target object ( $\beta_r$ ) was 2556.07 ms (SD 1721.06 ms) and the median was 2247.5 ms.

### A: Dwell Time of Accepted Referential Gaze

In block A, Max produced altogether 600 initiate-acts with referential gaze of different durations (600 ms to 3000 ms in 600 ms steps). The task of the human participant was to decide, whether she accepts the gazing behavior as being intentional in that Max wanted to guide her attention to the target object. The dwell time of accepted referential gaze of the five discrete levels is  $\alpha_a$  with a median of 1800 ms. The histogram of the accepted dwell times is depicted in Figure 6.

A chi-squared test comparing the accepted dwell times  $\alpha_a$  in block A and the dwell times  $\alpha_r$  for referential gaze used by the participants in block I (discretized to the discrete values

Figure 6: Dwell times of referential gaze during initiate-acts produced by Max in study part A, which have been accepted by the human participant as being intentional.

used in block A) shows no significant differences ( $p=0.22$ , see also Figure 5 and Figure 6).

### Discussion

For the presented study we created an immersive virtual environment and let the participants engage in joint attention with a virtual agent to have a realistic but highly controlled experimental setup to run our studies on cognitive models of joint attention. The feedback from the participants regarding their own experience of presence and the presence of the virtual agent renders this approach a success.

With this advanced setup, we aimed at substantiating our knowledge about the timing of referential gaze within the initiate-act. In block I, we found a mean dwell time of referential gaze towards the target object  $\alpha_r$  of about 1897 ms. We take the significant differences of the  $\alpha_r$  from the dwell time on the same target objects during the orientation phase (when the target objects are shown to the participants) as a confirmation of the different nature of gaze use in search and in referential gaze. This also shows that the design of the study is plausible to the participants regarding the different interaction states (orientation phase vs. dialog). Using these timing patterns, Max will learn to arbitrate between gaze search and referential gaze in the future.

If roles are switched and the initiate-act is performed by the virtual agent Max, we found that participants accepted the same kind of gaze patterns as natural as they themselves performed when they had the initiative. This substantiates our findings and at the same time emphasizes the high acceptance of the virtual agent Max as an interaction partner.

A respond-act of the addressee to an initiate-act of the human participant was expected before 2556 ms. This is well

below the 5 s time frame postulated by Tasker and Schmidt (2008) based on human-human interactions. However, as our study focused on the dwell times during referential gaze and Max by design only showed a response when triggered, it was difficult for the participants to decide this threshold. A more thorough investigation of this threshold should use a more complex scenario, were, e.g., Max produces responds with different delays, similar to the design in block A.

## Conclusion

The high acceptance of Max as an interaction partner with human-like capabilities and the comparability of our findings in human-machine interaction with those found in human-human interaction motivate us to follow this line of research further. The 1.9 s dwell time of the referential gaze act is compatible with related findings in human-human interaction. In next steps, we would substantiate our model of joint attention by incrementally increasing the complexity of the interaction scenario until the full process of joint attention can be simulated in real-time in a more natural scenario. This would also allow us to directly compare joint attention behaviors between human-human and human-agent interactions.

Although autonomous behaviors of Max were reduced to a minimum in our controlled setup his naturalness of communication was already rated 3. We believe this rating will increase significantly when he shows his full range of communicative and joint attention behaviors.

## Abstract

It has been argued that real-world structure constrains the semantic representations of verbs, resulting in cross-linguistic convergence of naming patterns for motion events. This study explores the nature of this real-world structure by manipulating individual features of human locomotion in video stimuli and comparing the responses of English and German speakers in an elicitation task. We show that individual features influence naming patterns and that languages encode these features differently. Furthermore, the semantic representations of several German motion verbs sharply contrast with their English equivalents.

**Keywords:** semantic representations; naming; concepts; cross-linguistic diversity; motion verbs; locomotion

## Introduction

Languages divide the world in different ways. Moreover, the boundaries between semantic categories within a particular language are not necessarily fixed. These two factors contribute to a complicated picture in any cross-linguistic comparison of naming patterns. Still, such research has yielded strong evidence of convergent naming patterns across languages in domains such as color (Berlin & Kay, 1969; Kay et al., 1997), emotion (Eckman, 1972), body terms (Majid, Enfield & van Staden, 2006) and events (Majid, Boster, & Bowerman, 2008; Malt et al., 2008). While cognitive biases shared by humans may result in similar construals, humans are also sensitive to salient discontinuities in the world. This real-world structure constrains naming patterns.

Malt et al. (2008) show that structure in the world has a strong influence on the naming patterns of motion events. In a cross-linguistic study in which participants were asked to describe human locomotion, the researchers demonstrate that Dutch, English, Japanese and Spanish speakers uniformly mark a biomechanical distinction between ‘walking’ and ‘running’ gaits when naming these events. However, gait is a cluster of co-occurring features and Malt et al.’s (2008) data do not indicate which of these features are encoded by motion verbs. Also, their study is limited to four languages and should be augmented with data from more languages.

The research we report here manipulates cadence independently from other gait features and shows that it is the latter that influence the category boundary between ‘walking’ and ‘running’ terms, but cadence influences naming on either side of the boundary. Second, it incorporates naming patterns from a German dialect that suggest Malt et al.’s (2008) claim may be too strong. Though some German verbs of human locomotion do encode the biomechanical distinction between ‘walking’ and ‘running’, the term ‘laufen’ (often translated as both *walk* and *run*) does not. This runs contrary to prior predictions. Moreover, the extent to which cadence influences naming may be language-dependent, as some German verbs appear to be less sensitive to manipulations of cadence than their English counterparts.

The present study therefore contributes to research of event categorization in two ways. First, it adds to our understanding of the semantic representations underlying motion verbs by providing a concise picture of the gait features speakers attend to when naming human locomotion. Second, it compares naming patterns of human locomotion in English and German, revealing unexpected patterns not present in previous cross-linguistic comparisons.

## Naming Human Locomotion Events

Continuous human locomotion is particularly interesting due to its biomechanical complexity; it is composed of many co-occurring features. These biomechanical features include but are not limited to stride length, knee bend, elbow bend, and cadence, i.e., the number of steps per unit of time (Kiss, Kocis & Knoll, 2004). Combined, these features can be described as a person’s gait, or their manner of motion. A speaker may draw on several of these gait features when naming a human locomotion event. Importantly, at a particular speed there is a dramatic switch between the clusters of features often categorized as a ‘walking’ gait—a pendulum-type body motion where at least one foot stays on the ground at all times—and a ‘running’ gait—characterized by more elastic, springing movement (Alexander, 1992).

Malt et al. (2008) demonstrate how this real-world structure—namely the dramatic shift in gait—informs the

semantic representations of motion verbs in Dutch, English, Japanese, and Spanish. While viewing stimuli of a woman on a treadmill at varying speed settings and inclines, participants were asked to fill in the blank in the sentence: “What is the woman doing? She is \_\_\_\_.” The striking finding of this study was the uniformity in responses with regard to the 4.5 to 5.5 mph treadmill settings. For each language, ‘walking’ terms always appeared from 4.5 mph and slower (and never over 4.5 mph) whereas ‘running’ terms always appeared from 5.5 mph and faster (and never under 5.5 mph). As mentioned above, this distinction marks an important gait difference. The authors argue that this cross-linguistic convergence is the result of structure in the world exerting strong influence over naming patterns.

This cross-linguistic convergence does not appear to the same extent on either side of the 4.5/5.5 mph boundary. In English, for example, much more within-language variation for lexemes such as ‘jog’ and ‘run’ was found, where use of the latter increases with an increase in treadmill speed (between 5.5 and 8.5 mph), but it is never used 100% of the time.

While the authors acknowledge that there are many features to which speakers may attend, they admit that “the data do not tell us exactly what cues our participants were responding to” (Malt et al. 2008, p. 239). Through a small manipulation of the video stimuli in Study 1 and the addition of a German dialect in Study 2, we demonstrate the detailed nature of speakers’ semantic representations of gait terms and show how individual features, particularly cadence, can be a driving force behind naming patterns. We suggest that naming on either side of the 4.5/5.5 mph boundary is quite sensitive to cadence. Thus, individual features may significantly affect naming patterns in some circumstances (on either side of the 4.5/5.5 mph boundary) and not others (at the boundary marked by other gait elements).

## Study 1: English

The first study had two primary goals. The first was to replicate the English findings of Malt et al. (2008). For this reason, we created stimuli as similar as possible to their original human locomotion study. The second goal was to explore the nature of the semantic representations that may underlie naming patterns in terms of relevant features encoded by motion verbs. This required a manipulation of the video stimuli so as to manipulate cadence while controlling other gait features.

### Stimuli

Stimuli consisted of 21 videos of a college student on a treadmill at varying treadmill settings (1 mph increments from 2.5 to 8.5 mph), in three different playback conditions. Seven of the videos were unmanipulated and shown at Normal Playback. Using Final Cut Express video editing software, the remaining 14 videos were digitally manipulated to be in either ‘slow motion’ or ‘fast motion’. Seven videos were manipulated to Slow Playback, or 20%

slower than Normal Playback. The remaining 7 videos were manipulated to Fast Playback, or 20% faster than Normal Playback.<sup>1</sup>

The Slow and Fast Playback conditions are the critical manipulation in this study. In the Normal Playback condition, all features of human locomotion are coordinated. Digital manipulation disrupts this coordination by altering cadence, i.e., the number of steps per unit of time, while controlling other gait elements. (We recognize that cadence is a sub-parameter of gait, but for the purposes of this study we refer to cadence as separate from gait, where the latter remains a collection of co-occurring features such as stride length, knee bend, elbow bend, etc.). For example, with the 6.5 mph Treadmill Setting at Normal Playback, gait (stride length, knee bend, elbow bend, etc.) and cadence are in sync. In the Slow Playback, all of these elements except for cadence remain constant. The stride length, knee bend, and elbow bend are all identical to the Normal Playback condition. However, the cadence is different. There are fewer steps in the same amount of time. In the Fast Playback condition, there are more stride revolutions than the Normal Playback condition. In other words, this manipulation allows us to ‘mismatch’ cadence with other gait elements.

### Methods

Stimuli were shown to 30 native English-speaking undergraduates at the University of Colorado at Boulder. All undergraduates were monolingual in English with limited experience in a foreign language. Videos were randomized to prevent order biases from previous videos and were displayed using the online survey system Qualtrics. The videos were mixed with 8 distracters featuring the same actor on a treadmill engaging in activities such as crawling and skipping.

Upon presentation of each video, participants were asked to respond to the following question: “What is the man doing? He is \_\_\_\_.” Participants were asked to use as few words as possible when describing the motion, but using more than one word was allowed. Moreover, they were instructed to repeat any word they used as many times as they liked. All participants viewed all videos and the data from all participants was included in the final analysis.

### Results

All responses were grouped based on the head verb. Responses such as ‘running’ and ‘running quickly’ were all grouped as ‘running’. The ‘other’ category includes responses that appeared infrequently (five or fewer times)

---

<sup>1</sup>Prior to the study, naturalness ratings for manipulated videos were obtained. Nine undergraduates at the University of Colorado at Boulder were shown video stimuli and asked to answer the question “How natural is this motion?” by providing a rating on a scale from 1 (not natural) to 5 (very natural). The mean naturalness rating for manipulated videos was 2.8, indicating that while the manipulations were noticeable, they were not unnatural.

within a Treadmill Setting, such as ‘meandering’ or ‘moseying’.

The results of the first study reveal two important findings. First, the Normal Playback condition replicates the results of Malt et al.’s (2008) study. ‘Walking’ terms are used from 2.5 to 4.5 mph and ‘running’ terms are used from 5.5 to 8.5 mph.

Second, playback condition is shown to influence naming patterns on either side of the 4.5/5.5 mph boundary, such that some videos are named differently depending on playback condition. The overall effect of playback condition was confirmed by a binomial test ( $p < .005$ ).<sup>2</sup> Across all Treadmill Settings (2.5 to 8.5 mph), playback speed influences naming patterns. For example, at the Treadmill Setting of 6.5 mph, the term ‘jogging’ is preferred by 83% of the participants for the Slow Playback condition, 40% for Normal Playback, and only 5% for Fast Playback. A comprehensive view of the data can be seen in Figure 1.

Figure 1: The English data from Study 1. Treadmill Settings from 2.5 mph to 8.5 mph and Playback Conditions are Slow (S), Normal (N), and Fast (F).

This provides a very clear picture of the structure that informs English lexemes: cadence seems to be a critical feature in many terms of human locomotion. Even when other gait features remain constant, a change in cadence can result in a change of the most common lexeme for that

<sup>2</sup> To conduct the binomial test, 12 undergraduates from CU Boulder were asked to provide a speed ranking of the lexemes from Study 1 (e.g., ‘running’ was rated as faster than ‘jogging’ by the majority of participants). These speed rankings were then compared to the data in Study 1. Across Treadmill Settings, videos in Slow Playback were more often paired with lexemes that were rated slower than the most common lexemes in Normal Playback (e.g., ‘jogging’ < ‘running’), while videos in Fast Playback were more often paired with lexemes that were rated faster than the most common lexemes in Normal Playback (e.g., ‘running’ < ‘sprinting’). The binomial test compared the number of times the lexeme changed in the predicted direction (e.g. ‘jogging’ < ‘running’ < ‘sprinting’) to the total number times there was a lexeme change due to playback condition.

event. Indeed, the manipulation causes additional semantic categories to appear such as ‘power walking’<sup>3</sup>, which is the most common response for 4.5 mph, but only in Fast Playback. At the very slowest cadence (2.5 mph, Slow Playback), participants are compelled to use a term other than ‘walking’, though there is less agreement as to what that term should be. This accounts for the large ‘other’ category here, consisting of words such as ‘meandering’, ‘sauntering’, and ‘moseying’.

Despite their attendance to the playback manipulation, participants did not use the same lexical item to refer to stimuli on either side of the 4.5/5.5 mph boundary. Rather, at this boundary, other gait features seem to be more critical than cadence. If cadence alone were a determining feature, we might expect to see ‘running’ terms applied to 4.5 mph in Fast Playback, but this is not the case. Increased cadence in this condition did not ‘override’ the category boundary, nor did decreased cadence in the 5.5 mph Slow Playback condition. In the English data, this is without exception.

Study 1 teases apart cadence from other gait elements and shows that a change in cadence influences naming patterns on either side of the biomechanical boundary. While Malt et al. (2008) indicate that strong structure in the world influences naming patterns, they are agnostic in terms of which features are attended to. Our results indicate that there is clearly ample structure to which speakers can selectively attend, and that a single feature can play a central or peripheral role in driving naming patterns.

## Study 2: German

By manipulating cadence while controlling other gait elements, Study 1 provides a concise picture of what external structural elements of human locomotion influence naming patterns. It also opens up the possibility that speakers of other languages will draw upon these structural features differently than English speakers. To explore this possibility, Study 2 replicates Study 1 in a German dialect.

### Stimuli

Study 2 used the same stimuli as Study 1.

### Methods

The videos were shown to 28 speakers of a Bavarian dialect of German known as Rieserisch. This dialect is spoken in the Ries area, the capital of which is the town of Nördlingen. Rieserisch is closely related to the more common German dialect of Schwäbisch, spoken primarily in the state of Baden-Württemberg (Schmidt, 1898). Though there are several important differences between the grammar and lexicon of Rieserisch, Schwäbisch, and standard German, specific contrasts between semantic

<sup>3</sup> ‘Power walking’ was not considered a modified form of ‘walking’, but rather a compound lexical term, in part because ‘power’ in this case does not pattern with other adverbial modifiers of ‘walking’, e.g., ‘quickly’, which can occur pre- or post-verbally.

representations of human locomotion verbs in these dialects remain largely unexplored. It is possible that Study 2's results could extend to speakers of more standard German, but this hypothesis requires further investigation.

Speakers ranged in age from 17 to 48. Participants viewed the videos on their own computers through the use of the survey system Qualtrics. Data from 4 speakers were discarded due to incompleteness. Of the remaining 24, all but 2 claimed to have relatively good knowledge of English. An additional 13 claimed knowledge of a third language, and 4 claimed knowledge of a fourth. Therefore, only 2 or the 24 participants could be described as monolingual. All, however, identified themselves as native speakers of the Rieserisch dialect.

Upon presentation of each video, participants were asked to respond to the following question: "Was macht der Mann? Er \_\_\_\_." (*What is the man doing? He is \_\_\_\_.*). Again, participants were asked to use as few words as possible when describing the motion, but using more than one was allowed. They were instructed to repeat any word they used as many times as they liked. All participants viewed all videos.

# Results

Again, all responses were grouped based on the head verb. The 'other' category includes responses that appeared infrequently (five or fewer times within a Treadmill Setting), such as 'spazieren' (*stroll*) and 'bummeln' (*saunter*).

To begin, use of the term 'laufen' gives rise to four noteworthy observations. First, contrary to Malt et al.'s (2008) predictions, the term 'laufen'—translated as both *walk* and *run*—was used to refer to stimuli on either side of the 4.5/5.5 mph boundary (see Figure 2). Close analysis indicates that 6 speakers used 'laufen' across the boundary, 14 used 'laufen' but did not cross the boundary, and 4 speakers did not use the lexeme at all. Therefore, usage of 'laufen' across the 4.5/5.5 mph boundary does not seem to be idiosyncratic or limited to one speaker. Second, the use of 'laufen' seems to be most common at 5.5 mph.

Figure 2: Comparison of English 'walking' and 'running' with German 'laufen' in Normal Playback.

Third, 'laufen' is used at every Treadmill Setting. While never the most frequent term in any given condition, 'laufen' is used with high frequency overall, equal to that of terms such as 'gehen' and 'joggen'. Fourth, 'laufen' does not appear to be affected by the cadence manipulation. Hypotheses concerning these observations will be addressed in the General Discussion.

The effect of playback condition for verbs other than 'laufen' was confirmed by a binomial test ( $p < .05$ ), indicating that a change in cadence affected the choice of lexeme.<sup>4</sup> The verb 'gehen' (translated as *go* or *walk*) seems to behave differently than English 'walk'. At 2.5 mph, the change in cadence did little to change naming patterns (as seen in Figure 3). The same is true for 4.5 mph: where English speakers designate a category of 'power walking' for 4.5 mph in the Fast Playback condition, German speakers do not seem to agree on a motion lexeme in this same condition. This suggests that 'gehen' may not encode cadence in the same way 'walk' does, and therefore its underlying representation may be qualitatively different.

Cadence effects for other verbs were similar to their English counterparts. The verbs 'joggen' (*jog*), 'rennen' (*run*), and 'sprinten' (*sprint*) were sensitive to the change in cadence. For example, at 6.5 mph, 'joggen' was used by 58% of the participants in the Slow Playback condition, 42% of participants in Normal Playback, and 17% in Fast Playback.

With the exception of 'laufen', German naming patterns align with those in other languages that mark the biomechanical distinction between 'walking' and 'running'. The term 'gehen' only appears at 4.5 mph and slower; terms such as 'joggen' and 'rennen' only appear from 5.5 to 8.5 mph. As in English, the cadence manipulation did not cause speakers to break this boundary.

Figure 3: The German data from Study 2. Treadmill Settings from 2.5 mph to 8.5 mph and Playback Conditions are Slow (S), Normal (N), and Fast (F).

<sup>4</sup> Lexical rankings for the binomial test were provided by 3 additional native Rieserisch speakers who did not contribute to the elicitation task in Study 2.

## General Discussion

Both Study 1 and Study 2 bring relevant observations to bear on the nature of the real-world structure that informs semantic representations of human locomotion. They also help support and inform the findings of previous studies. We show that cadence is a structural feature to which English and German speakers attend and that this salience is reflected in naming patterns. Presumably, underlying concepts of these verbs will also highlight cadence in this way.

Both studies show the relative roles of cadence and other gait elements in naming patterns of continuous human locomotion. First, previous hypotheses that the biomechanical distinction between a ‘walking’ and ‘running’ gait (the 4.5/5.5 mph boundary) is the primary structure influencing speakers’ lexeme choices are strongly confirmed. The manipulation of Playback (and thus cadence) did not cause any speakers to use a ‘walking’ term from 5.5 mph and higher or a ‘running’ term from 4.5 mph and lower. Clearly, the biomechanical gait distinction is a critical aspect of speakers’ semantic representations of these human locomotion verbs at this point in the continuum of motion.

However, results also indicate that some English and German lexemes are extremely sensitive to the manipulation of cadence. In other words, digitally manipulating playback causes people to change the lexeme they use to describe the event (with respect to Normal Playback). This has important implications. First, it demonstrates that, though the 4.5/5.5 mph biomechanical distinction is of great importance, so too are cues of cadence. Moreover, the relative weight given to these features when naming depends on where individual events occur in the continuum of motion. At the 4.5/5.5 mph boundary, motion verbs are distinguished by gait features rather than cadence. On either side of this boundary, however, cadence drives naming patterns to some extent. This is not to say that *only* cadence drives naming patterns in these regions. Rather, it seems that the conjunction between cadence and gait elements (e.g., stride length, knee bend, elbow bend, etc.) is important in the encoding of motion verbs. That is, the semantic space is multidimensional, with cadence (perhaps perceived as speed) set against other gait elements. The combinatory nature of these dimensions gives rise to particular semantic categories, e.g., ‘jog’ is the conjunction between self-propelled, bounce-and-recoil gaits at medium cadence (see Malt et al., 2011 for similar treatments of this multidimensional space). Furthermore, contextual dimensions are undoubtedly critical (see Labov, 1973). For example, people may also attend to the weight of the person (under, average, or overweight), where the locomotion is taking place (indoors, outdoors, on a treadmill), or what they are wearing (casual or sports clothes, etc.). Therefore, subsequent studies in this domain should take into account the complicated nature of semantic representations. Rather than assume a priori that certain structure in the world will determine naming patterns, we suggest that descriptions of

semantic representations should proceed by induction, testing how the possible dimensions of semantic space may be encoded in a given language.

The German verb ‘laufen’, a difficult term for English speakers, is of particular note. It is commonly translated as both *walk* and *run*. However, as can be seen in Study 2, this translation is not accurate. There is little overlap in terms of the semantic space encoded by English ‘walk’ and ‘run’ in comparison to ‘laufen’. Therefore, direct translation is problematic or even impossible.

Though such a verb is not present in their data, Malt et al. (2008, p. 239) suggest that it may be “possible that some [languages] do not have separate words for walking and running gaits.” While German clearly does have words that mark the biomechanical distinction, ‘laufen’ is a frequent verb that crosses the 4.5/5.5 mph boundary. In fact, ‘laufen’ seems to be used most often at these treadmill settings, perhaps indicating a grouping of 4.5 and 5.5 mph to the exclusion of speeds such as 2.5 and 8.5 mph. This is in contrast to previous predictions regarding such a grouping.

One possible interpretation of this finding is that ‘laufen’ is a term of general motion. There are at least two reasons why this explanation is not likely. First, use of ‘laufen’ is used most frequently at 5.5mph. If it were a term of general motion, then it should be distributed evenly across all treadmill settings. Second, ‘laufen’ features similar metaphorical extensions as the English manner verb ‘run’, not of general motion verbs such as ‘go’. This is demonstrated in (3) and (4):

(3) Die Maschine läuft (*The machine is running*).

(4) Das Wasser läuft (*The water is running*).

These reasons are compelling evidence to dismiss the characterization of ‘laufen’ as a verb of general motion. A second response is that ‘laufen’ is not a manner verb at all. Instead, it is aspectual, meaning “put into motion without delay” (Cadiot et al. 2006, p. 182). Again, the metaphorical extensions above argue against this treatment, as ‘laufen’ is used to denote a continuous state, rather than indicating the placement of the event in time. Second, participants only viewed videos in which motion had already begun. The lack of transition from a non-motion state to a motion state in the videos runs counter to this aspectual reading. In other words, the videos do not indicate that the subject was ‘put’ into motion.

We propose, instead, that ‘laufen’ is a specific manner verb of continuous human locomotion that simply draws upon different structure than verbs in English, Dutch, Japanese and Spanish. However, due to the lack of response to the cadence manipulation, we are unable to posit which features in particular figure prominently in its semantic representation.

These results also have important implications with regard to so-called ‘manner’ and ‘path’ languages (Talmy, 1985). With these studies, we show that ‘manner of motion’ is not an unanalyzable primitive, as has been assumed in the

Linguistics literature (Slobin, 1996; Talmy, 1985) and the Psychology literature (Gennari et al., 2002; Papafragou & Selimis, 2010). Rather, ‘manner’ has a fine-grained structure, and the current studies are an attempt to tease apart this structure (following efforts of e.g., Ikegami, 1969).

## Conclusion

As close follow-ups to previous studies of motion verbs, the two studies presented here have confirmed prior findings while adding to our understanding of the cues to which speakers may attend when naming human locomotion. By manipulating cadence while controlling for other gait elements, Studies 1 and 2 demonstrate that cadence is a critical feature driving naming patterns in addition to the biomechanical distinction between ‘walking’ and ‘running’ gaits. The addition of German data provided unexpected results in the form of the lexeme ‘laufen’, which does not follow the trends found in previous literature. This finding highlights the importance of including as many languages as possible when analyzing semantic representations.

This study has concentrated on the semantic representations of human locomotion verbs. We believe, however, that these semantic representations may have important implications for underlying conceptual representations, as defined by Levinson (1997). It is possible that the differences in how people talk about human locomotion events may also influence how they think about these events. Therefore, this work can inform current research (e.g., Malt et al., 2011) on the relationship between semantic representations and underlying concepts.

## Acknowledgments

This work was supported by a student research grant from the Institute of Cognitive Science at The University of Colorado at Boulder. We thank Dr. Bhuvana Narasimhan, Dr. Gary McClelland, Jill Duffield, Dr. Les Sikos, Michael Thomas, Alison Hilger, Shaw Ketels and David Harper for support, advisement and discussion. German data collection was made possible by our contact in Germany, Brigitte Ulbricht. We would also like to thank the anonymous reviewers of the previous draft who pointed us to important research related to the current study.

## Abstract

Purely statistical models have accounted for infants’ early ability to segment words out of fluent speech, with Bayesian models performing best (Goldwater et al. 2009). Yet these models often incorporate unlikely assumptions, such as infants having unlimited processing and memory resources and knowing the full inventory of phonemes in their native language. Following Pearl, et al. (2011), we explore the impact of these assumptions on Bayesian learners by utilizing syllables as the basic unit of representation. We find a significant “Less is More” effect (Pearl et al 2011; Newport 1990) where memory and processing constraints appear to help, rather than hinder, performance. Further, this effect is more robust than earlier results and we suggest this is due a relaxing of the assumption of phonemic knowledge, demonstrating the importance of basic assumptions such as unit of representation. We argue that more cognitively plausible assumptions improve our understanding of language acquisition.

**Keywords:** language acquisition; Bayesian modeling; cognitively plausible learning; less is more; statistical learning; word segmentation

## Introduction

Knowledge of words plays a crucial role in language acquisition but requires a child to identify words out of fluent speech. Children seem to accomplish this word segmentation very early (~7.5 months (Jusczyk & Aslin 1995; Echols et al. 1997; Jusczyk et al., 1993a)), and therefore many strategies have been proposed for this early success. One popular explanation for initial language learning relies purely on distributional information, rather than language-specific biases. This idea is bolstered by findings that infants keep track of the statistical regularities in speech (Saffran et al. 1996), and because languages vary greatly in their cues to word boundaries which would weaken the use of language specific knowledge. One very successful, purely distributional, learning approach uses Bayesian inference (Goldwater, Griffith & Johnson 2009 (GGJ), Pearl, Goldwater & Steyvers 2011 (PGS)). However, these Bayesian models incorporate modeling assumptions that are unlikely to be true. Both have assumed that the basic unit of representation available to the infant is the phoneme. We will argue from experimental evidence that syllables (or syllable-like representations) are a more natural representation for infants at this stage of acquisition. In

addition, GGJ conducted an ideal learner analysis, which assumes unlimited processing and memory resources for the learner. PGS investigated the impact of this assumption, finding a limited “Less is More” effect (Newport 1990) where cognitive resource limitations help, rather than hinder, some Bayesian learners. We examine the effect of the phoneme assumption in addition to these cognitive resource assumptions. We find not only that syllable-based Bayesian learners can do well at word segmentation but also a much more robust “Less is More” effect in our constrained Bayesian learners. This suggests that the unit of representation for models of language acquisition plays a crucial role. Here, using more cognitively plausible assumptions showcases a surprising learning effect, the “Less is More” effect that has been hypothesized to explain language acquisition success in children.

## The syllables as the representational unit

The first evidence that infants possess categorical representations of syllabic units appears at 3 months: Eimas (1999) finds that infants have categorical representations of syllables whereas infants at this age have no categorical representation of phonemes. Since word segmentation first occurs around 7.5 months (Jusczyk & Aslin 1995), it is likely that infants have robust access to syllables at this age. In contrast, knowledge of phonemes does not occur until approximately 10 months (Werker & Tees 1984) making it unlikely the learner has adult knowledge of their native language phonemes during the initial stages of word segmentation. Although it is possible that word segmentation and phoneme learning bootstrap from one another, we consider a more conservative approach which assumes infants only have access to syllabic information.

While the success of previous statistical word segmentation models is heartening, how dependent is their success on the assumption of the phoneme as a representational unit? With this question in mind, we modify existing phoneme-based statistical models of word segmentation that use Bayesian inference (GGJ, PGS) to operate over syllables. All of our modified Bayesian learners treat syllables as atomic units in the same way phonemes are thought of as atomic units. This mimics the performance of infants who are able to discriminate between syllables such as /ba/, /bu/, and /lu/, but who are unable to

recognize the phonemic similarity between /ba/ and /bu/ which does not exist between /ba/ and /lu/ (Jusczyk & Derrah 1987).

Utilizing syllables alleviates the learning problem somewhat because it reduces the number of potential boundary positions (e.g., a baby has three syllables but five phonemes). However, a potential sparse data problem then surfaces: A model operating over English phonemes must track statistics over approximately 40 units; a model operating over English syllables must track statistics over approximately 4000 units, while using less data than a phoneme-based model since there are fewer syllable tokens than phoneme tokens. This increases the statistical difficulty of the task tremendously. Additionally, because syllables are treated as atomic, almost all phonotactic information about English is lost in the model. Although previous work (e.g. Gambell & Yang 2006) shows that heuristic syllable-based models can perform quite well, it is unclear a priori whether a distributional learner with phonemes or syllables will produce better results for Bayesian word segmentation, due to the tradeoffs just mentioned.

In changing our unit of representation, we attempt to create a more psychologically faithful model of word segmentation. To foreshadow our results, we show that successful Bayesian word segmentation does not depend on the phoneme assumption. Moreover, by utilizing a more cognitively plausible unit of representation, we find a much more robust “Less is More” effect. The success of our models demonstrates the effectiveness of this purely statistical approach. Replicating and extending results from PGS concerning the surprising utility of processing constraints for Bayesian word segmentation. This suggests that the task of word segmentation may be structured to be more easily learned with strong memory limitations, such as those that infants have. Moreover, Bayesian models may be on the right track with respect to the kind of strategies infants are using during early word segmentation, since the learners demonstrate this “Less is More” behavior, and infants are thought to as well. In addition, the fact that this pattern of results was only hinted at by the phoneme-based models of PGS means that the unit of representation for models of language acquisition has a strong, non-trivial effect on the results found.

## Methods

### Corpus

We test our syllable-based models using English child-directed speech from the Pearl-Brent corpus (CHILDES: MacWhinney, 2000). This modification of the Brent corpus contains 100 hours of child-directed speech from 16 mother-child pairs. We restrict ourselves, however, to child-directed utterances before 9 months of age, leaving 28,391 utterances (3.4 words per utterance, 10.4 phonemes per utterance, 4.2 syllables per utterance, on average).

While there are many ways to syllabify a corpus automatically, we opted for a two-stage approach. First,

where we have human judgments of syllabification we used them; second, when not, we automatically syllabify our corpus in a language-independent way. We take human judgments of syllabification from the MRC Psycholinguistic Database (Wilson 1988), but not all words in the Pearl-Brent corpus have syllabifications in the MRC dictionary. To solve this problem we used the Maximum-Onset Principle to syllabify all remaining words. This principle states that the onset of any syllable should be as large as possible while still remaining a valid word-initial cluster. We use this principle out of convenience for the kind of syllabification that infants might possess. Given a lack of experimental evidence as to the exact nature of infant syllabification, this representation is likely only an approximation. Approximately 25% of lexical items were syllabified automatically. Only 3.6% of human judgments on our items differ from automatic syllabification. Each unique syllable is then treated as a single, indivisible unit losing all sub-syllabic phonetic (and phonotactic) information.

### Models

Bayesian models are well suited to questions of language acquisition because they explicitly distinguish between the learner’s pre-existing beliefs (prior) and how the learner evaluates incoming data (likelihood), using Bayes’ theorem:

$$P(h|d) \propto P(d|h)P(h)$$

The Bayesian learners we use are those of GGJ as well as the constrained learners of PGS. All learners are based on the same underlying hierarchical Bayesian models developed by GGJ. The first of these models assumes independence between words (a *unigram* assumption) while the second assumes words depend only on the word before them (a *bigram* assumption). To encode these assumptions into the model, GGJ use a *Dirichlet Process* (Ferguson, 1973), which supposes that the observed sequence of words  $w_1 \dots w_n$  is generated sequentially using a probabilistic generative process. In the unigram case, the identity of the  $i$ th word is chosen according to:

$$P(w_i = w | w_1 \dots w_{i-1}) = \frac{n_{i-1}(w) + \alpha P_0(w)}{i-1 + \alpha} \quad (1)$$

where  $n_{i-1}(w)$  is the number of times  $w$  appears in the previous  $i-1$  words,  $\alpha$  is a free parameter of the model, and  $P_0$  is a *base distribution* specifying the probability that a novel word will consist of the phonemes  $x_1 \dots x_m$ :

$$P(w = x_1 \dots x_m) = \prod_{j=1}^m P(x_j) \quad (2)$$

In the bigram case, a *hierarchical Dirichlet Process* (Teh et al. 2006) is used. This model additionally tracks the frequencies of two-word sequences and is defined as in:

$$P(w_i = w | w_{i-1} = w', w_1 \dots w_{i-2}) = \frac{n_{i-1}(w', w) + \beta P_1(w)}{n_{i-1}(w') + \beta} \quad (3)$$

$$P_1(w_i = w) = \frac{b_{i-1}(w) + \gamma P_0(w)}{b_{i-1} + \gamma} \quad (4)$$

where  $n_{i-1}(w', w)$  is the number of times the bigram  $(w', w)$  has occurred in the first  $i - 1$  words,  $b_{i-1}(w)$  is the number of times  $w$  has occurred as the second word of a bigram,  $b_{i-1}$  is the total number of bigrams, and  $\beta$  and  $\gamma$  are free model parameters.

In both the unigram and bigram case, this generative model implicitly incorporates preferences for smaller lexicons by preferring words that appear frequently (due to (1) and (3)) as well as shorter words in the lexicon (due to (2) and (4)). The ideal learner based on this model is fit using Gibbs sampling (Geman & Geman 1984), run over the entire corpus, sampling every potential word boundary 20,000 times. GGJ found that their bigram ideal learner performed better than their unigram ideal learner, so we begin by examining this distinction in our syllable-based Bayesian learners. In addition, we will consider the constrained learners that PGS investigated—incorporating processing and memory constraints.

The Dynamic Programming Maximization (DPM) learner incorporates a basic processing limitation: linguistic processing occurs online rather than in batch after a period of data collection. Thus, the DPM learner processes one utterance at a time, rather than processing the entire corpus at once. This learner uses the Viterbi algorithm to converge on the optimal word segmentation for the current utterance, conditioned on the utterances seen so far. In all other aspects, the DPM learner is essentially identical to the Ideal model: it has perfect memory for previous utterances and unlimited processing resources.

The Dynamic Programming Sampling (DPS) learner is similar to the DPM learner in processing utterances incrementally, but is additionally motivated by the idea that infants, and human beings in general, are not ideally rational. This could mean that infants do not *always* select the best segmentation. Instead, infants select segmentations probabilistically. So, they will often choose the best segmentation but occasionally choose less likely alternatives, based on the likelihood of the various segmentation alternatives. To implement this, the DPS learner uses the Forward algorithm to compute the likelihood of all possible segmentations and then chooses a segmentation based on the calculated distribution.

The Decayed Markov Chain Monte Carlo (DMCMC) learner also processes data incrementally, but uses a DMCMC algorithm (Marthi et al. 2002) to implement a memory constraint. This learner is similar to the original GGJ ideal learner in that it uses Gibbs sampling. However, the DMCMC learner does not sample all boundaries; instead, it samples some number  $s$  of previous boundaries using the decayed function  $b_a^{-d}$  to select the boundary to sample, where  $b_a$  is the number of potential boundary locations between  $b$  and the end of the current utterance  $a$  and  $d$  is the decay rate. Thus, the further  $b$  is from the end of the current utterance, the less likely it is to be sampled.

Additionally, larger values of  $d$  indicate a stricter memory constraint. All our results here use a set, non-optimized value for  $d$  of 1.5, which was chosen to implement a heavy memory constraint. Having sampled a set of boundaries, the DMCMC learner can then update its beliefs about those boundaries and subsequently update its lexicon.<sup>1</sup> Because of the decay function, the DMCMC's sampling is biased towards boundaries in recently seen utterances and thus the DMCMC learner implements a recency effect.

In addition to comparing our syllable-based learners against the original phoneme-based learners, we also compare our learners against other syllable-based learners. The first baseline is the Transitional Probability (TP) model based on Gambell & Yang (2006), which calculates TPs over syllables and places boundaries at all local minima. Our second baseline is a “Syllable=Word” learner which simply assumes that all syllables are words (a strategy that can be very useful in languages containing many monosyllabic words, like English).

## Results

We measure our results in terms of precision, recall and F-score, where precision is defined as (5) and recall is defined as (6):

$$Precision = \frac{\# correct}{\# guessed} \quad (5)$$

$$Recall = \frac{\# correct}{\# actual} \quad (6)$$

F-score is the harmonic mean of the two:

$$F - score = \frac{2 * Precision * Recall}{Precision + Recall} \quad (7)$$

Precision and recall are considered jointly, through the harmonic mean, because it is possible for learners to succeed on one measure while failing on the other. For instance, a learner that posits only a single boundary scores 100% on precision if that boundary is correct. In comparison, the same learner will have just over 0% recall. Similarly, a learner could posit boundaries at every position, producing a 100% recall with very low precision because many of the boundaries were false. As the F-score balances these two measures, a high F-score indicates the learner is succeeding at both precision and recall. We can make these measurements over individual word tokens, word boundaries, and lexical items.

In order to prevent overfitting, we train each learner on 90% of the corpus and then test the learner on the remaining 10%. This train-test validation was done five times for each learner. Given the probabilistic nature of our learners, all

<sup>1</sup> All DMCMC learners sample  $s=20,000$  boundaries per utterance. According to PGS, this works out to approximately 89% less processing than the original ideal learner in GGJ, which samples every boundary 20,000 times.

results presented here are averaged over the five iterations to ensure the validity of each learner’s performance.

Table 1 shows the F-score for word tokens over all of the syllable-based learners. First, we observe that, in all cases, the Bayesian bigram learners outperform their unigram equivalents. In the unigram case, all constrained learners (DPM, DPS, DMCMC) significantly outperform the ideal learner; in contrast, in the bigram case this is true for the DMCMC learners only. This indicates that constrained learning helps generally if statistics cannot be tracked across words. However, if bigram statistics can be tracked, a memory constraint is only beneficial for the DMCMC strategy. Additionally, all learners outperform the TP baseline learner and all bigram learners outperform the Syl = Word baseline.

	Unigram	Bigram
Ideal	53.12	77.06
DPM	<b>58.76</b>	75.08
DPS	<b>63.68</b>	77.77
DMCMC	<b>55.12</b>	<b>86.26</b>
TP	43.98	
Syl=Word	72.41	

Table 1. Word token F-scores across all syllable-based models. Constrained Bayesian learners that significantly outperform their ideal counterpart ( $p < .05$ ) are in bold.

	Syl-U	Phon-U	Syl-B	Phon-B
Ideal	53.1	<b>54.8</b>	<b>77.1</b>	71.5
DPM	58.8	<b>65.9</b>	<b>75.1</b>	69.4
DPS	<b>63.7</b>	58.5	<b>77.8</b>	39.8
DMCMC	55.1	<b>67.8</b>	<b>86.3</b>	73.0

Table 2. Token F-scores for syllable-based (Syl) vs. phoneme-based (Phon) models, comparing Unigram (U) and bigram (B) learners. Learners in bold outperform their baseline counterparts.

Clearly our syllable-based learners perform well, but are syllables a better unit of representation than phonemes for this task? Table 2 compares our syllable-based learners with the original phoneme-based models of PGS. We see that in the unigram case, phoneme-based learners outperform their syllable-based counterparts, except in the case of the DPS learner. In the bigram case, however, all syllable-based models outperform their phoneme-based equivalents. This suggests that the bigram assumption is crucial to a syllable-based learner. We speculate that this is due to an additional source of information that the bigram learner has access to. In particular, because the unigram learner assumes that words are independent of one another, the TPs between syllables are the only source of boundary information. Because there are roughly 4000 syllables, there will often be cases where a problem of sparse data arises. In contrast, the bigram learner has access to the boundary information

inherent in word bigrams, in addition to TPs. These word bigrams may help supplement the sparseness of the TP data.

A desired behavior for all learners is undersegmentation since children are known to undersegment the input they receive (Peters 1983). All of our Bayesian learners exhibit this behavior. This can be seen by comparing the values of boundary precision and recall. High boundary precision (indicating the boundaries are often correct) but low recall (indicating not enough boundaries are put in) indicates general undersegmentation, whereas high boundary recall (indicating a lot of boundaries are put in) but low boundary precision (indicating the boundaries are not often correct) indicates oversegmentation. Although this trend of undersegmentation exists for both unigram and bigram learners, we present data only on our bigram learners since the results are qualitatively similar. Table 3 shows the boundary precision and recall for all Bayesian bigram and comparison learners. The Syl=Word baseline learner tends to oversegment, so although it performs much better than the TP learner and the Bayesian unigram learners, its error pattern does not match what we expect from infants. In contrast, all of our Bayesian learners are producing more undersegmentations than oversegmentations. Table 4 presents sample segmentation errors from the Ideal and DMCMC bigram learners.

	Boundary Precision	Boundary Recall
Ideal	<b>96.50</b>	80.45
DPM	<b>96.49</b>	76.21
DPS	<b>95.78</b>	79.72
DMCMC	<b>94.11</b>	91.57
TP	<b>90.00</b>	53.14
Syl = Word	76.26	<b>100</b>

Table 3. Boundary precision and recall for all bigram Bayesian and comparison learners.

Bigram Ideal	Bigram DMCMC
<i>putit</i> away	put it away
<i>Iloveyou</i>	I love you
<i>Let’ssee</i> what that <i>feltlike</i>	Let’s see what that <i>feltlike</i>
<i>If youdon’t</i> like it	<i>Ifyou</i> don’t like it

Table 4. Example output from Bigram Ideal and DMCMC learners. Undersegmentation is marked in italics.

To explain the difference between our ideal and constrained learner results, we can examine the token and lexicon item recall scores, as shown in Table 5. We observe that both the DMCMC learners identify fewer word types than their ideal learner counterparts, as shown by their comparatively low lexicon recall scores. The token recall score for the DMCMC learners, however, is higher than their ideal learner counterparts. Since this requires the DMCMC learners to identify more word tokens from a smaller stock of lexical items, it can be inferred that these

DMCMC learners are identifying more frequently occurring words than the ideal learners.

	Token Recall	Lexicon Recall
Uni-Ideal	44.96	73.44
Uni-DMCMC	48.09	68.9
Bi-Ideal	72.47	79.69
Bi-DMCMC	85.43	76.84

Table 5. Token and lexicon recall for the Ideal and DMCMC learners. Lower lexicon recall with higher token recall implies that the DMCMC learners identify more frequently occurring words.

## Discussion

Our results support two broad findings. First, we find that memory-constrained learners outperform their “ideal” equivalents, which we take as support for the “Less is More” hypothesis (Newport 1990). In particular, limited cognitive resources, rather than hurting learner, seem to help word segmentation. Second, because this effect was obscured in the phoneme-based learners of PGS, we argue that the unit of representation posited by a model of language acquisition has a crucial impact on the results found. In particular, making more cognitively plausible assumptions may yield answers to the puzzling behaviors we observe—namely, that children, who are more cognitively limited than adults, nonetheless are far more successful at language acquisition.

What exactly is causing the “Less is More” effect here? Perhaps it is due to the properties of online vs. batch unsupervised probabilistic learning algorithms. Liang & Klein (2009) show that for unsupervised models using Expectation-Maximization, online models not only converge more quickly than batch models, but, also in cases as varied as word segmentation, part-of-speech induction and document classification, can actually outperform their batch equivalents. However, this explanation fails to account for our results in two ways: (a) the most direct online equivalent of our batch model (the DPM learner) actually performs worse than the Ideal model, and (b) this does not explain the performance boost caused by sub-optimal segmentation (the DPS learner).

Perhaps the answer lies in the kinds of words these models identify. We find, as in table 5, that our ideal bigram learner segments 72.5% of the words in the input, building a lexicon that contains 80% of the actual word-types it encounters. Yet we find that a learner with memory constraints (the DMCMC learner) can successfully segment 85% of the words in the input, although this makes up only 76.8% of the word-types encountered. This suggests that while an ideal learner identifies more lexical items, the memory-constrained learner identifies more *frequent* lexical items. Not only is this true in both the unigram and bigram syllable-based learners, but it is also true of the equivalent phoneme-based learners of PGS. The robustness of this

phenomenon suggests that, irrespective of the representational unit, memory-constrained learners are biased towards identifying more commonly occurring units, a potentially useful bias in language acquisition.

In effect, this strategy in word segmentation may help in learning the *important* things. Although this has been hypothesized by the literature on “Less is More” in artificial language learning (Kersten & Earles 2001; Cochran et al. 1999), we are unaware of experimental support for why constrained processing helps in real language acquisition. The fact that we can help to explain, from a computational perspective, why “Less is More” is beneficial highlights a very major contribution computational modeling can make to developmental research more generally.

For our claim regarding the impact of the unit of representation, we can compare the syllable-based learner results with those of phoneme-based learners. Table 2 highlights a number of crucial distinctions. First, and most basically, syllable-based learners perform well, and in the bigram case better than phoneme-based learners. This suggests that the tradeoff between number of potential boundaries and number of potential transitional probabilities works out in favor of the syllable-based learner. This underscores the utility of a Bayesian inference strategy for the initial stages of word segmentation – without access to phonotactics, stress, acoustic cues, or innate linguistic knowledge, a learner can be very successful at segmenting words from fluent speech.

Still, there is a major difference in the performance of the sub-optimal (DPS) learner – the syllable-based DPS learner has comparable performance to the Ideal learner while its phoneme-based equivalent suffers greatly. We speculate that this is due to the number of potential segmentations the phoneme-based learner considers, compared to the syllable-based learner since the DPS learner chooses a segmentation probabilistically, the phoneme-based learner may be more easily led astray in the initial stages of segmentation, and never recover. In addition, we also notice a strengthening of the “Less is More” effect in the syllable-based learner, compared to its phoneme-based counterpart (Ideal vs. DMCMC). By making more realistic assumptions about the learner’s unit of representation, we also create a learner that exhibits the kind of behavior that infants show. This highlights one benefit of pursuing more cognitively plausible computational models, as opposed to models that are more idealized.

In that vein, there are a number of areas where we could improve the existing syllable-based Bayesian learners. First, some segmental cue information is likely available to infants such as phonotactics or articulatory cues. Similarly, suprasegmental cues such as primary stress are known to affect infant word segmentation (Jusczyk et al. 1999) and there is evidence that stressed and unstressed syllables are represented separately in infants (Pelucchi, Hay, & Saffran 2009). Finally, the exact form which infants use to represent syllables is unclear. While it is our view that syllabification must be learned by infants, we make no attempt here to

explain by what means this occurs. When one looks cross-linguistically, languages treat syllabification in very different ways. In addition, languages vary significantly on the number of syllable types they have – languages such as English number their unique syllables in the thousands, while some languages, like Japanese, have very few unique syllables. To ensure that our pattern of results is truly representative of word segmentation *generally* and not just in English, syllable-based word segmentation models must be tested across multiple languages.

In conclusion, this study highlights the benefits of using empirical research from psychology to inform decisions on how to model language acquisition: not only can we identify the strategies that are likely to be used by children, but we may also discover potential explanations for existing, sometimes puzzling, observations about child language acquisition, as with the “Less is More” hypothesis.

### Acknowledgments

We would like to thank Caroline Wagenaar and James White for their help on syllabifying the Pearl-Brent corpus. In addition, we are very grateful to Robert Daland, Constantine Lignos, and the audiences at the Psycho-Computational Models of Human Language Acquisition 2012 and the Linguistic Society of America meeting in 2012 for their helpful comments.

## Abstract

Human cognitive capacity includes recursively definable concepts, which are prevalent in domains involving lists, numbers, and languages. Cognitive science currently lacks a satisfactory explanation for the systematic nature of recursive cognitive capacities. The category-theoretic constructs of initial  $F$ -algebra, catamorphism, and their duals, final coalgebra and anamorphism provide a formal, systematic treatment of recursion in computer science. Here, we use this formalism to explain the systematicity of recursive cognitive capacities without ad hoc assumptions (i.e., why the capacity for some recursive cognitive abilities implies the capacity for certain others, to the same explanatory standard used in our account of systematicity for non-recursive capacities). The presence/absence of an initial algebra/final coalgebra implies the presence/absence of all systematically related recursive capacities in that domain. This formulation also clarifies the theoretical relationship between recursive cognitive capacities. In particular, the link between number and language does not depend on recursion, as such, but on the underlying functor on which the group of recursive capacities is based. Thus, many species (and infants) can employ recursive processes without having a full-blown capacity for number and language.<sup>1</sup>

**Keywords:** systematicity; category theory; endofunctor,  $F$ -(co)algebra; (final) initial algebra; universal construction; catamorphism; anamorphism; classicism; connectionism

## Introduction

Many cognitive domains include recursively definable concepts (i.e., concepts defined with reference to themselves), such as domains involving lists, or languages. In card games, for example, a deck of cards can be defined (recursively) as a top card (perhaps turned face up to reveal its value) and a (remaining) deck of cards. To include finite decks, the definition has an alternative clause specifying an empty deck; that is, a deck is either empty, or contains a top card and a (smaller) deck. Operations on recursively defined concepts may also be defined recursively. For example, removing jokers from a deck of cards can be defined (recursively) as removing the top card if it is a joker and then removing jokers from the remaining deck of cards. Given that you don't find people who can remove the jokers from a hand of seven cards without being able to remove jokers from a deck of fifty-three, recursion-related capacities are further instances (see below) of the systematic nature of human cognition.

Systematicity is a property of human cognitive architecture (i.e., the basic processes and modes of composition that

together afford cognition) whereby cognitive capacity is organized around groups of related abilities. A standard example since the original formulation of the problem (Fodor & Pylyshyn, 1988) has been that you don't find people with the capacity to infer John as the lover from the statement *John loves Mary* without having the capacity to infer Mary as the lover from the related statement *Mary loves John*. An instance of systematicity is when a cognizer has cognitive capacity  $c_1$  if and only if the cognizer has cognitive capacity  $c_2$  (see McLaughlin, 2009). So, e.g., systematicity is evident where one has the capacity to remove the jokers if and only if one has the capacity to remove the aces (assuming, of course, one has the capacity to identify jokers and aces).

The classical explanation for systematicity has two components: (1) combinatorial syntactically structured representations; and (2) processes that are sensitive to (i.e., compatible with) those syntactic structures. In a classical cognitive architecture, mental representations of constituent entities (e.g., *John*, *Mary*) are tokened (instantiated) whenever the mental representations of their complex hosts (e.g., *John loves Mary*) are tokened, with the meaning of a complex host representation obtained (recursively) from the meaning assigned to its constituent mental representations and their syntactic relationships. By analogy to language, this form of mental representation is called a *language of thought* (LoT) (Fodor, 1975).

The three aspects of systematicity, i.e., *systematicity of representation*, *systematicity of inference*, and *compositionality of representation* (Fodor & Pylyshyn, 1988), can often be derived from classical cognitive architectures, because the same component processes are often used for each and every member of a group of systematically-related capacities. For instance, a classical system has the capacity to represent *John loves Mary* if and only if the system has a capacity to represent *Mary loves John* when the common component process is something like a production rule:  $S \rightarrow \text{Agent loves Patient}$  (where *John* and *Mary* are produced from *Agent* and *Patient* by other production rules)—systematicity of representation. Likewise, a classical system has the capacity to infer John as the lover in *John loves Mary* if and only if it has the capacity to infer Mary as the lover in *Mary loves John* given a common process that is sensitive to the syntactic structure whereby the lover constituent is represented by the first token—systematicity of inference. And, again, the capacity

<sup>1</sup>This paper is a short version of Phillips and Wilson (2012).

to assign the semantic content of John being the lover of Mary to the representation *John loves Mary* if and only if there is the capacity to assign the semantic content of Mary being the lover of John to the representation *Mary loves John* derives from the tokening principle (above) mediating classical representations and processes: the process for juxtaposing tokens (symbols) *John*, *loves*, and *Mary* to form *John loves Mary* with corresponding semantic content is the same process that is used to form *Mary loves John* with corresponding content.

Classical compositionality would seem to provide an elegant explanation for systematicity with regard to recursive capacities, even though it fails to provide a full account of systematicity generally (Aizawa, 2003).<sup>2</sup> For recursive definitions, like the deck of cards, one self-referencing rule typically covers all cases (bar the terminating case, such as the empty deck). For example, removing jokers from a single hand, or an entire deck invokes the same component process. The two tasks only differ in the number of recursive steps.

### Classical, but not systematically recursive

However, the classical explanation with regard to recursive capacities still suffers the same general problem that it suffers for non-recursive capacities. To illustrate, suppose one card game requires removing the lowest value card in the hand dealt, while another card game requires removing the highest value card. Suppose the following recursive procedure, *lowest*, for identifying the lowest valued card in a deck of cards (containing at least one card):

$$\begin{aligned} \text{lowest}(c : cs) &= \text{lower}(c, \text{lowest}(cs)) \\ \text{lowest}(c : []) &= c \end{aligned}$$

where a deck of cards  $c : cs$  is represented by a recursively defined list with  $c$  as the top card and  $cs$  as the remaining deck,  $[]$  is the empty deck, and *lower* returns the lower of two cards. Suppose, also, the following classical non-recursive procedure, *highest*, for identifying the highest valued card:

```
highest(cs) = (i, high) ← (0, undefined)
while i < n do
    (i, high) ← (i + 1, higher(high, csi))
return high
```

where deck  $cs$  is represented by an array of  $n$  cards with position indexed by  $i$  (i.e.,  $cs_i$  is the  $i$ th card), *high* maintains a representation of the (currently) highest card, *higher* returns the higher of two cards (*undefined* is some value guaranteed to be lower than any card), and  $\leftarrow$  indicates variable-value assignment. Clearly, the two procedures do not share

<sup>2</sup>Classical theory fails to provide a complete explanation because one can construct syntactically compositional systems that support some but not all members of a group of systematically-related cognitive capacities. Additional (*ad hoc*) assumptions are needed to derive only those classical cognitive architectures that support systematicity (Aizawa, 2003). This problem echoes the one originally raised against connectionism as a *theory* of cognitive architecture (Fodor & Pylyshyn, 1988; Fodor & McLaughlin, 1990).

any component processes, and so do not provide a basis for systematicity, even though systematicity could be supported when both tasks are implemented in either the first style only, or the second style only. Notice that we are not unfairly stressing classical theory by apportioning capacity at the level of constituents—systematicity concerns “molecular”, not “atomic” capacities (Fodor & Pylyshyn, 1988). Rather, given constituent capacities *lower* and *higher*, classical theory admits two independent compositional forms, as the example illustrates.

In this paper, we extend our category theory explanation to recursive capacities using universal constructions called an *initial F-algebra* and a *final F-coalgebra*, which have been extensively developed in computer science as a theoretical basis for recursive computations (Manes & Arbib, 1986). Our previous work (Phillips & Wilson, 2010, 2011) dealt with non-recursive domains using a kind of universal construction called *adjoint functors*—a *functor* is a way relating categories, which can be viewed as a way of constructing objects and morphisms from one category based on those in another. The current work uses *endofunctors*, which relate categories to themselves, hence their relevance to recursion.

### Category theory: *F*-(co)algebras

A category theory treatment of recursion starts with the concept of an *F-algebra* constructed on an endofunctor  $F$ .<sup>3</sup>

**Definition (*F*-algebra).** For an endofunctor  $F : \mathbf{C} \rightarrow \mathbf{C}$ , an *F-algebra* is a pair  $(A, \alpha)$ , where  $A$  is an object and  $\alpha : F(A) \rightarrow A$  is a morphism in  $\mathbf{C}$ .

For example, if  $F(A) = A \times A$ , then the addition operator  $+: A \times A \rightarrow A$  is an *F-algebra*.

**Definition (*F*-algebra homomorphism).** An *F-algebra homomorphism*  $h : (A, \alpha) \rightarrow (B, \beta)$  is a morphism  $h : A \rightarrow B$  (in  $\mathbf{C}$ ) such that the following diagram *commutes*:

$$\begin{array}{ccc} F(A) & \xrightarrow{\alpha} & A \\ F(h) \downarrow & & \downarrow h \\ F(B) & \xrightarrow{\beta} & B \end{array} \quad (1)$$

That is,  $h \circ \alpha = \beta \circ F(h)$ .

**Definition (*F*-algebra category).** For endofunctor  $F : \mathbf{C} \rightarrow \mathbf{C}$ , an *F-algebra category*  $\mathbf{Alg}(F)$  has *F-algebras*  $(A, \alpha)$  for objects, and *F-algebra homomorphisms*  $h : (A, \alpha) \rightarrow (B, \beta)$  for morphisms.

**Definition (*Initial algebra*).** An *initial F-algebra*  $(A, in)$ , also called *initial algebra*, is an *initial object* in the category

<sup>3</sup>We omit definitions of *category*, *functor*, and *initial object* (see Phillips & Wilson, 2010, 2011, for introductions tailored to the systematicity problem—short versions appear in CogSci10/CogSci11 proceedings). An example category is **Set**, whose *objects* are sets, *morphisms* are functions, and *composition* of morphisms is function composition. Functors are like generalized functions, but map morphisms to morphisms as well as objects to objects. An *endofunctor* is a functor whose domain and codomain are the same category.

of  $F$ -algebras  $\mathbf{Alg}(F)$ . I.e., there exists a unique  $F$ -algebra homomorphism from  $(A, in)$  to every  $F$ -algebra in  $\mathbf{Alg}(F)$ .

**Definition (Catamorphism).** A *catamorphism*  $h : (A, in) \rightarrow (B, \beta)$  is the unique  $F$ -algebra homomorphism from initial  $F$ -algebra  $(A, in)$  to  $F$ -algebra  $(B, \beta)$ . That is,  $h \circ in = \beta \circ F(h)$ , and the uniquely specified  $h$  for each such  $\beta$  is denoted  $\text{cata } \beta$  (i.e.,  $h = \text{cata } \beta$ ). In Diagram 1, replace  $\alpha$  with  $in$  and  $h$  with  $\text{cata } \beta$  for a commutative diagram indicating a catamorphism.

Hence the importance of initial algebras to the systematicity of recursive capacities: every algebra (process) factors through an initial algebra in a category  $\mathbf{Alg}(F)$  that has one.

Duals:  $F$ -algebra, initial algebra, and catamorphism have dual constructs called *F-coalgebra*, *final coalgebra*, and *anamorphism* (respectively), which we shall also use.

### Systematicity: List-related capacities

Returning to the example raised as a problem for classical theory: a common task is to select the smallest or largest item in a collection. Systematicity, in this case, means that if one has the capacity to distinguish the relative sizes of items, and one has the capacity to identify the smallest item in a list, then one also has the capacity to identify the largest item in a list. (Notation:  $1_A$  is the identity morphism for  $A$ ;  $1_v$  is a constant function returning  $v$ .) List-related capacities are constructed from the functor  $F_A : S \mapsto A \times S, f \mapsto 1_A + 1_A \times f$ . ( $\phi : x \mapsto y$  means  $\phi(x) = y$ .) The algebras are the pairs  $(S, [1_v, f])$ . An initial algebra for lists is the pair  $(L, [\text{empty}, \text{cons}])$ , where  $L$  is a set of lists, and  $[\text{empty}, \text{cons}] : 1 + A \times L \rightarrow L$  is the list-constructing morphism, consisting of the constant function  $\text{empty} : 1 \rightarrow L$  for constructing the empty list  $[]$ , and the function  $\text{cons} : A \times L \rightarrow L; (a, l) \mapsto a \cdot l$  for constructing the list with element  $a \in A$  prepended  $(\cdot)$  to list  $l \in L$ . Here  $1 + A \times L$  is the disjoint union of a 1-element set with the cartesian product of  $A$  and  $L$ . If, for example,  $A$  is the natural numbers  $\mathbb{N}$ , then  $L$  is the set of all finite natural number lists. Catamorphisms from this initial algebra have the form  $\text{foldL}[1_v, f] : L \rightarrow S$ , where  $\text{foldL}[1_v, f] :$

$$\begin{aligned} [] &\mapsto v \\ (a, l) &\mapsto \text{foldL}[1_v, f](l) \end{aligned}$$

The catamorphism for identifying the smallest number is  $\text{foldL}[1_\infty, \text{min}]$ , where  $\text{min} : (x, y) \mapsto x$ , if  $x \leq y$ , else  $y$  returns the smaller of two items, indicated in commutative diagram

$$\begin{array}{ccc} 1 + \mathbb{N} \times L & \xrightarrow{[\text{empty}, \text{cons}]} & L \\ \downarrow 1_1 + 1_{\mathbb{N}} \times \text{foldL}[1_\infty, \text{min}] & & \downarrow \text{foldL}[1_\infty, \text{min}] \\ 1 + \mathbb{N} \times \mathbb{N} & \xrightarrow{[1_\infty, \text{min}]} & \mathbb{N} \end{array} \quad (2)$$

E.g.,  $\text{foldL}[1_\infty, \text{min}](2, 1, 3) = \text{min}(2, \text{min}(1, \text{min}(3, \infty))) = 1$ . By replacing  $\text{min}$  in Diagram 2 with  $\text{max} : (x, y) \mapsto x$ , if  $x \geq y$ , else  $y$ , and  $\infty$  with 0 (or,  $-\infty$  for lists of integers or reals), we have the catamorphism that corresponds to identifying the largest number. For example,  $\text{foldL}[1_0, \text{max}](2, 1, 3) =$

$\text{max}(2, \text{max}(1, \text{max}(3, 0))) = 3$ . Since the two computations have the morphism  $[\text{empty}, \text{cons}]$  as the common component, this arrangement accounts for systematicity with respect to these capacities. Since the catamorphisms are uniquely determined, we have an account of systematicity without further (*ad hoc*) assumptions.

### Systematicity: language-related capacities

In this domain, we use an artificial grammar (for arithmetic expressions) to illustrate our explanation for systematicity with regard to language-related capacities. Artificial grammars are often used, because their forms are more easily adapted to the question at hand. Up to this point, we have addressed systematicity with respect to inference, e.g., why the capacity to infer the smallest list item is systematically related to the capacity to infer the largest list item—*systematicity of inference*. This aspect of systematicity assumes that the cognitive system also has the capacity to systematically represent the entities from which such inferences are made—*systematicity of representation*. Here, we also provide a category theory explanation for systematicity of representation, using the closely related, dual notion of an  $F$ -coalgebra.

### Arithmetic expressions: systematicity of inference

The example in this section is based on Hutton (1998), but adapted to model cognitive capacity for evaluating numerical expressions. The category of  $F$ -algebras that includes language-related capacities is constructed from the functor  $F_A : S \mapsto A + S \times S, f \mapsto 1_A + f \times f$ . The  $F$ -algebras for the category  $\mathbf{Alg}(F_A)$  are the pairs  $(S, [f, g])$ , where  $[f, g] : A + S \times S \rightarrow S$ ,  $f : A \rightarrow S$  is a unary function, and  $g : S \times S \rightarrow S$  is a binary function. An initial algebra in this category is  $(T, [\text{leaf}, \text{branch}])$ , where  $T$  is the set of trees of type  $A$ ,  $[\text{leaf}, \text{branch}] : A + T \times T \rightarrow T$ ,  $\text{leaf} : A \rightarrow T; a \mapsto \langle a \rangle$  returns a tree consisting of a single leaf  $a \in A$ , and  $\text{branch} : T \times T \rightarrow T; (l, r) \mapsto \langle l, r \rangle$  returns a tree consisting of a left branch  $l$  and a right branch  $r$ , where  $l, r \in T$ . For example, a binary tree of numbers  $\langle \langle 1 \rangle, \langle \langle 2 \rangle, \langle 3 \rangle \rangle \rangle$  has a leaf 1 as its left branch, and a tree, with left leaf 2 and a right leaf 3, as its right branch. A catamorphism from initial algebra  $(T, [\text{leaf}, \text{branch}])$  to an arbitrary  $F$ -algebra  $(S, [f, g])$  in  $\mathbf{Alg}(F_A)$  is the recursive function  $\text{foldT}$  (i.e., fold for trees), defined as follows. The (higher-order) function  $\text{foldT}$  takes a unary function  $f : A \rightarrow S$  and a binary function  $g : S \times S \rightarrow S$  and returns the recursive function  $\text{foldT}[f, g] : T \rightarrow S$ , where

$$\begin{aligned} \langle a \rangle &\mapsto f(a) \\ \langle l, r \rangle &\mapsto g(\text{foldT}[f, g](l), \text{foldT}[f, g](r)) \end{aligned}$$

and  $T$  is a set of trees of type  $A$ , indicated in diagram

$$\begin{array}{ccc} A + T \times T & \xrightarrow{[\text{leaf}, \text{branch}]} & T \\ \downarrow 1_A + \text{foldT}[f, g] \times \text{foldT}[f, g] & & \downarrow \text{foldT}[f, g] \\ A + S \times S & \xrightarrow{[f, g]} & S \end{array} \quad (3)$$

Suppose participants are given arithmetic expressions involving a particular operator, say, *addition*, e.g.,  $(1 + 2) + (2 + 3)$ , which they are required to evaluate. Given that participants can correctly evaluate such expressions, there is a host of other capacities that are also afforded provided that they have some other basic knowledge. For example, given knowledge of another binary operator, say, *subtraction*, participants can also evaluate the related expression  $(4 - 2) - (2 - 1)$  as 1. The specific catamorphism for the addition case is given by replacing  $A$  in Diagram 3 with the set of numbers  $N$ ,  $f$  with identity morphism  $1_N$ , and  $g$  with addition  $+$ . For the case of *subtraction*, the binary operator  $(+)$  for addition is replaced with  $(-)$  in Diagram 3. Hence, the second task is computed as  $\text{fold}T[1_N, (-)]$ . The universal construction common to these two capacities is the morphism  $[leaf, branch]$ . So, the explanation for systematicity is essentially the same as the explanations we provided for list- and number-related capacities, albeit based on a different underlying functor—the capacities for evaluating expressions involving addition and subtraction contain  $[leaf, branch]$  as the common factor.

### Arithmetic expr.: systematicity of representation

Evaluating trees is an example of *systematicity of inference* (Fodor & Pylyshyn, 1988; Aizawa, 2003; Phillips & Wilson, 2011). However, such expressions are not given to the cognitive system in tree-form. Typically, such trees are assumed to be constructed from an input (list of characters) by another process. The input may take on several different formats: e.g., numeric/symbolic, as in “1+(2+3)”, or word form, as in *one plus (two plus three)*, which correspond to the same tree. Again, these two forms are systematically related: one has the capacity to represent the expression “1+(2+3)” if and only if one has the capacity to represent the expression *one plus (two plus three)* assuming, of course, a person knows that *one*, *two* and *three* denote the same things as 1, 2 and 3 (respectively), and *plus* denotes the same thing as  $+$ . This form of systematicity is called *systematicity of representation* (Fodor & Pylyshyn, 1988; Aizawa, 2003; Phillips & Wilson, 2011). In this section, we show how systematicity of representation is addressed using coalgebras.

Constructing trees from lists is achieved by a dual construction called an *F-coalgebra* (Hutton, 1998). The explanation for systematicity in this case proceeds in a “dual” manner: i.e., every morphism in a category of *F-coalgebras* with a terminal (dual to initial) object, called a *final coalgebra* (dual to initial algebra) is composed of a unique *anamorphism* (dual to catamorphism) and a common final coalgebra.

Final coalgebras derive from their dual definitions of initial algebras in the category of *F-algebras*  $\mathbf{Alg}(F_A)$  on the functor  $F_A : \mathbf{Set} \rightarrow \mathbf{Set}; S \mapsto A + S \times S, f \mapsto 1_A + f \times f$ . A final coalgebra in this category is  $(T, (p_{\langle \rangle} \rightarrow \text{fmleaf}, \text{fmbranch}))$ , where conditional  $p_{\langle \rangle} \rightarrow \text{fmleaf}, \text{fmbranch}$  consists of a condition  $p_{\langle \rangle} : T \rightarrow \mathbf{Bool}$  that tests whether  $t \in T$  is a leaf (i.e.,  $t = \langle a \rangle, a \in A$ ), or a branch (i.e.,  $t = \langle l, r \rangle, l, r \in T$ ), and associates functions  $\text{fmleaf} : T \rightarrow A, \langle a \rangle \mapsto a$ , for retrieving a value from a leaf, and  $\text{fmbranch} : T \rightarrow T \times T, \langle l, r \rangle \mapsto (l, r)$ ,

for retrieving a pair of left and right subtrees from a branch. The dual category  $\mathbf{CoAlg}(F_A)$  has *F-coalgebras*  $(S, (p \rightarrow f, g))$  as objects, and *F-coalgebra homomorphisms* as morphisms. The anamorphism associated with this final coalgebra is called *unfoldT* (i.e., unfold for trees), defined recursively as  $\text{unfold}T(p \rightarrow f, g) : S \rightarrow T$

$$\begin{aligned} s &\mapsto \langle f(s) \rangle && \text{if } p(s) \\ s &\mapsto \langle \text{unfold}T p? (p_1 \circ g(s)), \text{unfold}T p? (p_2 \circ g(s)) \rangle && \neg p(s) \end{aligned}$$

where  $p?$  abbreviates  $(p \rightarrow f, g)$ . The final coalgebra and anamorphism are indicated in commutative diagram

$$\begin{array}{ccc} S & \xrightarrow{p \rightarrow f, g} & A + S \times S \\ \text{unfold}T p? \downarrow & & \downarrow 1_A + \text{unfold}T p? \times \text{unfold}T p? \\ T & \xrightarrow{p_{\langle \rangle} \rightarrow \text{fmleaf}, \text{fmbranch}} & A + T \times T \end{array} \quad (4)$$

Diagram 4 indicates the general form of the anamorphism from which we specify a particular  $p?$  (i.e.,  $p \rightarrow f, g$ ) for our domain of arithmetic expressions. That is, we need to define the test function  $p : L \rightarrow \mathbf{Bool}$ , where  $\mathbf{Bool} = \{\text{True}, \text{False}\}$  that determines whether an expression indicates a simple (value) or complex expression, and associated functions  $f : L \rightarrow N$  and  $g : L \rightarrow L \times L$  for transforming simple and complex expressions into numbers and expression pairs (respectively).

Specifications of  $f$  and  $g$  (in Diagram 4) are obtained from case analysis. Examples of simple expressions, which indicate values, are: “1”, “(2)”, and “((3))”, i.e., any well-formed expression that does not contain the “+” character. A complex expression is any well-formed expression that is not simple. So,  $p$  is the function  $\text{isVal} : l \mapsto “+” \notin l$ . Since  $f$  is associated with  $p(l)$  being true, we require a function to convert a string into a (internal) representation for the corresponding number, i.e.,  $f$  is the function  $\text{str2num} : L \rightarrow N$ . Finally, we need a function  $g$  for complex expressions. Examples of complex expressions include: “1+2”, “1+(2+3)”, “(1+2)+3”, “(1+2)+(3+4)”, and so on. The purpose of  $g$  is to split an expression into two subexpressions, one corresponding to the left branch of the tree, and the other to the right branch. That is,  $g$  must split the expression at the topmost operator into two subexpressions containing the strings before and after the “+” symbol, after stripping off the outer brackets. Identifying the split point is also determined by case analysis: Basically, the split point is the first instance of “+” in the absence of an unmatched right bracket “)”. So, one simply maintains a counter, starting from 0 (i.e., no unmatched brackets, or top level), which is incremented/decremented on every occurrence of a left/right bracket, when read from left to right. So,  $g$  is the function  $\text{split} : L \rightarrow L \times L$ . Thus, the function for parsing expressions into trees is the anamorphism  $\text{unfold}T(\text{isVal} \rightarrow \text{str2num}, \text{split})$ .

Systematicity of representation (in this example, constructing trees) is obtained in the same way as systematicity of inference (“destructing” trees). To represent the same tree from

the expressions in word form, one simply replaces the argument  $isVal \rightarrow str2num, split$  as appropriate. For example, the function  $str2num$  is replaced with, say,  $word2num$  which converts numbers in word form (e.g., “one”, “two”, etc.) to their corresponding internal representation of number. In any case, the resulting anamorphism factors through the same universal morphism, i.e.,  $p_{\langle \rangle} \rightarrow fmleaf, fmbranch$  from Diagram 4.

Given initial algebra  $in : F(A) \rightarrow A$  in a category  $\mathbf{Alg}(F)$ , the corresponding final coalgebra  $fin : A \rightarrow F(A)$  is guaranteed to exist, because  $F(A) \cong A$ , so  $in$  has as inverse  $fin$ . Thus, further (*ad hoc*) assumptions are not required to guarantee a correspondence between expressions and evaluations since they are indivisibly bound by the (final) initial (co)algebra. By contrast, classical theory assumes that the processes for constructing syntactically compositional representations and the processes for systematically transforming those representations correspond (Phillips & Wilson, 2011).

## Discussion

Our explanation in regard to recursive domains employs the same category theory construct (i.e. universal construction) as our previous explanations for (quasi-)systematicity in regard to non-recursive domains (Phillips & Wilson, 2010, 2011), albeit with different kinds of functors: here, for recursive domains, the universal constructions involved endofunctors (i.e., where the domain and codomain are the same category), whereas for non-recursive domains, the universal constructions involved adjoint functors (which are reciprocating, though not necessarily inverse, functorial maps between categories that are not necessarily the same. Every composition of left and right adjoints is an endofunctor, but not every endofunctor can be decomposed into a pair of adjoint functors. So, having some (primitive) form of systematicity over a recursive domain does not imply having systematicity for non-recursive domains. Nor, for that matter, does having the systematicity property for one recursive domain (e.g., numbers) imply the having the systematicity property for another recursive domain (e.g., lists), when the universal constructions involve functors not related by a natural isomorphism (Manes & Arbib, 1986)—this distinction also applies to non-recursive domains. This functorial distinction has implications for comparative and developmental psychology (discussed later).

## Limitations

Our theory may be incomplete at two points: one point is where competence meets performance, such as when supposed systematically related capacities span memory or cognitive complexity limits. The other point is where systematic cognition meets non-systematic cognition: not all cognition is regarded as systematic; idioms (e.g., *John kicked the bucket*—i.e., he died—is not systematic with *Mary kicked the bucket [with her foot]*) are a paradigm (Fodor & Pylyshyn, 1988). We discuss our theory in the context of both cases.

Competence versus performance: In the case of lists where the morphism  $f$  is not associative (e.g., subtraction), comput-

ing with a right-fold version of list fold means keeping all list items in memory (if presented once only), so systematicity would not extend beyond lists of more than a few items. Such cases are generally not regarded as evidence against the systematicity property—human cognition is *ceteris paribus* (e.g., memory requirements being the same) largely systematic (see McLaughlin, 2009). Nonetheless, a more complete theory will address both aspects of cognition. Category theory may also provide independent principles for performance, since cognitive development-related limits in children were identified with the arity of the (co)product underlying the task (Phillips, Wilson, & Halford, 2009): e.g., the ability of children older than the median age of five years to perform transitive inference and class inclusion in the more difficult condition versus children younger than five was related to (co)product arity, i.e., binary versus unary (co)products. Note that here, too, the difference in “complexity” of the endofunctors for number (no/unary product of functors, not given), list (binary product of constant and identity functors) and tree (binary product of two identity functors). However, performance related differences are beyond the scope of our theory as it currently stands.

Systematic versus non-systematic cognition: Category theory also provides a principled means for joining two cognitive (sub)systems via (co)products of categories, where one category models systematic cognitive capacity and the other non-systematic capacity, and (say) the coproduct category models both. However, as Aizawa (2003) explains, the required explanatory standard for hybrid theories is higher, because one must also explain why/when component theories are invoked. A possible reason is efficiency. A primitive form of addition is supported (systematically) by the category of  $F$ -algebras that included number-related capacities via  $foldN$  (not presented here), where the number of iterations is proportional to the size of the addends. The time needed to add numbers can be reduced by memorizing the addition table for small numbers, which is what children are taught to do. However, addition via memorized associations is not a systematic process: one can memorize part of a table without memorizing the other part; this is an analog of the phrase-book example in language (Fodor & Pylyshyn, 1988). Utility may drive the cognitive system to employ a faster, but non-systematic process, but it is also outside the scope of our current theory.

## Perspective

At the core of our category theory explanation for systematic recursive capacity is a special pair of dual constructions: an (final) initial (co)algebra in a category of (co)algebras on a polynomial functor  $F$ . Although one can reverse the direction of any collection of arrows to form a dual, such duals may not exist in the category of interest (e.g., some categories have initial objects but no final objects). Yet, for categories of (co)algebras on a polynomial functor (final) initial (co)algebras are guaranteed to exist (Manes & Arbib, 1986), and an initial algebra  $in : F(A) \rightarrow A$  is guaranteed to have an inverse  $fin : A \rightarrow F(A)$ , because the component objects are

isomorphic (i.e.,  $A \cong F(A)$ ), which constitutes a final coalgebra for the domains we have investigated. So, the systematic relationship between representation and inference is guaranteed without further (*ad hoc*) assumptions, in contrast to the classical explanation where the link between the two is just assumed (Phillips & Wilson, 2011). Notice that this dual relationship between systematicity of representation and systematicity of inference is more general (and more useful) than an inverse. In the arithmetic expressions example, lists were represented as trees (systematicity of representation), but trees were evaluated as numbers (systematicity of inference). This form of duality goes beyond the simple inverse relationship between sentence recognition and generation found in parsing/production rules in a classical approach to language.

The capacity for recursion has been a contentious issue in the broader interests of cognitive science, which includes comparative and developmental psychology. Some argue that recursion is specific to humans and depends on language (Hauser, Chomsky, & Fitch, 2002); more particularly, a fully inductive (recursive) basis for number is specific to adults and distinct from infants' non-inductive basis (Rips, Bloomfield, & Asmuth, 2008). In contrast, others claim a human language-like capacity for recursion in songbirds (Gentner, Fenn, Margoliash, & Nusbaum, 2006) (but, see Corballis, 2007), and that adult understanding of number (in its fully induced form) is founded on a more primitive infant conception (Carey, 2009). See also Gelman and Butterworth (2005), for a review of the debate over the link between number and language. Our category theory treatment of recursive cognitive capacities provides a different perspective on this issue: specifically, the particular systematic capacities for recursion depend on the underlying functor, not a general capacity for recursion, as such. In particular, one can have a basic recursive capacity for number without having a full-blown capacity for language, because the functor underlying recursive number-related capacities does not provide a systematic basis for recursive language-related capacities, though by our account language-related recursive capacities afford number-related recursive capacities. Analysis of the songbird evidence (Gentner et al., 2006) for supposed center-embedded recursion suggested that these birds were using a simple *counting* strategy (Corballis, 2007), which accords with our  $F$ -(co)algebraic basis for recursion in cognition, where simple counting involves a fold for numbers, not trees. Thus, other species (and infants) can have elementary recursive capacities without a full-blown capacity for number and language as available in adult humans.

The classicist's approach to cognitive architecture is fundamentally limited not in advocating syntax, but in placing syntax at the foundation of their theory. Given the often *ad hoc* and idiosyncratic choices that go into programming language design, computer scientists in recent decades have turned to category theory for a deeper syntax-free understanding of the principles of computation. Cognitive science, as couched within the framework of computationalism, can likewise do

better than lay foundations on the shifting sands of syntax.

## Abstract

There have been several computational alternatives to the cloze task (Taylor, 1953) intended to approximate word predictability effects on eye movements during reading. In this study, we implement a computational model that instantiates each content word in a sentence as an input that activates semantic concepts in working memory. The predictability of a word is then determined by the extent to which its corresponding semantic representation is associated with the network of concepts already active in working memory from the preceding context. The computation of concept activation is based on a connectionist model (Landscape model, see van den Broek, 2010). Latent semantic analysis (LSA) is used to establish connections between words and simulate the long-term semantic associations among concepts (Landauer & Dumais, 1997). This model provides a means of investigating how language comprehension and eye movement behavior are affected by the activation of concepts in working memory.

**Keywords:** eye movements; reading; word predictability; latent semantic analysis; Landscape model.

## Introduction

It has been well-established that eye movement behavior is affected by lexical variables such as frequency and predictability (Rayner, 1998; 2009). As such, the eye movement record provides an indication of language processing as it unfolds during normal reading. Rayner and Well (1996; see also Ehrlich & Rayner, 1981) found that the predictability of target words had a strong influence on eye movements during reading. In their experiment, subjects fixated unpredictable target words longer than either highly or moderately predictable target words; highly predictable words were also skipped more often than moderately predictable or unpredictable target words.

Accordingly, in the E-Z Reader model (Pollatsek, Reichle, & Rayner, 2006; Reichle, Pollatsek, Fisher, & Rayner, 1998; Reichle, Rayner, & Pollatsek, 1999; 2003), word predictability within a given sentence context is considered in both first stage processing (i.e., L1, including identification of orthographic form and a familiarity check) and second stage processing (i.e., L2, including

identification of phonological/semantic form and completion of lexical access). The model also maintains that the predictability effect is stronger in L2 than in L1.

Estimates of word predictability are typically derived from a modified cloze task procedure (Taylor, 1953) in which subjects are asked to guess the identity of a word when given the prior sentence context. Most reading studies utilize the cloze task to establish or confirm word predictability manipulations. These experiments use target words that differ substantially in cloze value (the probability with which subjects select the word), often with probabilities of .70 to .90 for highly predictable words and less than .10 for “low” predictability words. As an alternative to necessarily subjective cloze responses, several computational methods have been successfully utilized to approximate degrees of contextual constraint and predict the influence on eye movements during reading; including, transitional probabilities (McDonald and Shillcock, 2003; but see Frisson, Rayner, & Pickering, 2005), surprisal (Boston, Hale, Kliegl, Patil, and Vasissth, 2008; Levy, 2008), conditional co-occurrence probability (Ong and Kliegl, 2008). Additionally, Latent Semantic Analysis (LSA) (Landauer & Dumais, 1997) was used by Pynte, New, and Kennedy (2008) as well as Wang, Chen, Ko, Pomplun, and Rayner (2010), who reported that eye movement behavior during first-pass reading on content words could be predicted using LSA. McDonald and Shillcock (2003) and Wang et al. (2010) used the transitional probability (corpus-based statistical likelihood of encountering a word given the preceding or subsequent word) to categorize predictability conditions; both proposing that predictability effects could be accounted for using only the content word preceding a target. One limitation of these objective measures could be that prior context, before the immediately preceding lexical item, may affect processing of a word in many instances. Wang et al. (2010) also used *all* concepts in the preceding sentence context to compute contextual constraint for targets using the standard weighting from LSA. However, without a clearer understanding of working memory constraints

during comprehension it is difficult to make regarding semantic constraint.

The predictability of a given word can, in large part, be conceptualized as the degree to which the semantic concept represented by the word is associated with the context of preceding lexical items. By treating incoming lexical items as semantic concepts that interactively influence working memory processes, prior context for a word can be represented as inputs which influence the activation of associated concepts and have the potential to facilitate or inhibit the processing of upcoming words. As a result, the higher the activation of a concept when it is encountered, the more processing of the concept is facilitated. Importantly, individuals can allocate their processing attention to only a finite number of linguistic items at a given moment. Thus, any model of language processing and working memory must establish limits to the number of lexical-semantic concepts that can be simultaneously active and exert an appreciable influence on the processing of upcoming lexical inputs.

## A Connectionist Model for Sentence Reading

This study proposes a computational model to monitor the activations of concepts in working memory. The computation of concept activation is derived from a connectionist model (the Landscape model, see van den Broek, 2010). The current model is not connectionist in the sense of having distributed semantic representations; rather, words are represented as localized semantic "concepts" with weighted connections to a network of additional concepts. The semantic connections among concepts in the simulation are computed using LSA cosine values based on the default 300 dimension semantic space, "general reading up to 1st year college", available at the LSA@CU Boulder website (<http://lsa.colorado.edu/>). LSA represents word meaning and computes associations by applying a linear algebra method, singular value decomposition (SVD), to a large corpus of text (see Landauer & Dumais, 1997).

The Landscape model is a connectionist approach to instantiating comprehension using psychologically plausible algorithms that can potentially be used to model several aspects of text comprehension (see van den Broek, 2010; Tzeng, van den Broek, Kendeou, & Lee, 2005). The architecture of the conventional Landscape model assumes that as a reader proceeds through a text in reading cycles (with each cycle roughly corresponding to the reading of a new sentence), concepts fluctuate in activation as a function of four sources of information: the current processing cycle, the preceding cycle, the current episodic text representation, and reader's background knowledge. With the reading of each cycle, particular concepts are activated and added as nodes to the episodic memory representation of the text. If a concept is already part of the text representation and is reactivated, its trace is strengthened. Furthermore, co-

activation of concepts leads to the establishment (or strengthening) of connections between those concepts. The resulting network representation influences subsequent activation patterns. This phenomenon is called the *cohort effect*. These cyclical and dynamically fluctuating activations lead to the gradual emergence of an episodic memory representation and discourse model of the text, in which textual propositions and inferences are connected via semantic relations (such as causal and referential links). Thus, the model captures the fluctuations of concepts during reading (Linderholm, Virtue, Tzeng, van den Broek, 2004), as well as readers' memory representation of text (Tzeng, 2007). As such, this model has prescribed mechanisms that can link the iterative and reciprocal relations between fluctuations of activations and the episodic text representation. However, there are necessary differences with regard to how readers generate and update active discourse representations for the comprehension of an individual sentence, compared to the processing of a longer narrative or expository text. For the comprehension of an individual sentence, a reader must primarily rely on establishing connections between relevant concepts in working memory and pre-existing long-term semantic representations. For a longer text, on the other hand, readers are often able to take advantage of more extensive and detailed context and presumably a more enriched discourse model. Thus, the current computational approach adapts the Landscape Model to a connectionist framework more suitable for capturing sentence reading. The current model utilizes LSA in order to represent pre-existing connections between semantic representations stored in long-term memory (i.e., background or world knowledge).

In the current model, as with the Landscape Model, text inputs are represented by an *input matrix* and each is indexed as a *Mention* (concepts being read from the text). The conventional Landscape model also defines other sources of activation including *Referential* (for building referential coherence), *Causal*, and *Enabling* (for the causal explanation of the current statement), but those activations are as of yet, not implemented here. The input matrix for example sentence: "*The knight uses his sword to fight the dragon*" is shown in Table 1.

Table 1: Input matrix for the *Knight* example.

cycle	knight	use	sword	fight	Dragon
1	1	0	0	0	0
2	0	1	0	0	0
3	0	0	1	0	0
4	0	0	0	1	0
5	0	0	0	0	1

Initially, the sentence is segmented into component concepts: "knight", "use", "sword", "fight", and "dragon"; as, currently, only content words are considered as concepts. The model assumes that each word is fixated and processed

sequentially. In each cycle, the concept of *Mention* receives 1 unit of activation. In addition to the sequential activation of concepts, the influence of semantic knowledge and pre-existing lexical associations between concepts is established using LSA corpus-learned associations. Table 2 presents the *connection matrix* for the example sentence. The values are always between -1 and 1, but are rarely below 0 because of LSA’s high-dimensional space.

Table 2: Connection matrix for the example.

.	knight	use	sword	fight	dragon
knight	1	.01	.64	.15	.28
use	.01	1	.03	-.02	.06
sword	.64	.03	1	.20	.40
fight	.15	-.20	.20	1	.13
dragon	.28	.06	.40	.13	1

The activation values for each concept are represented in an  $m \times n$  *activation matrix*, where  $m$  represents the number of concepts in the sentence and  $n$  represents the number of *cycles*. Each column in the matrix thus represents the status of each concept. The *activation matrix* takes each column of the *input matrix* as raw input and processes it row by row. In our model, the activation during the current reading cycle is defined by Equation (1):

$$A_i^{cycle} = \sum_{j=1}^m \delta A_j^{cycle-1} \sigma(S_{ij}) + \sum_{j=i}^m input_i^{cycle} \sigma(S_{ij}) \quad (1)$$

$A_i^{cycle}$  is the activation of concept  $i$  during the current cycle. Starting from the summation ( $\Sigma$ ) term in Equation (1), for all activated concepts in the previous reading cycle, each activation value is multiplied by a transformation function  $\sigma$  of connection strength ( $S_{ij}$ ) and by the cohort activation parameter  $\delta$ .  $S_{ij}$  is the strength of the relation from concept  $j$  to  $i$ . For the current cycle,  $input_i^{cycle}$  is the activation of concept  $i$  in the *input matrix*. The sum of the net inputs for these  $m$  concepts is multiplied by the transformation function  $\sigma$  of connection strength ( $S_{ij}$ ).

The conventional Landscape model uses a sigmoid function as the transformation function  $\sigma$  to control the possible linear growth of spreading of activation and limit the effect of cohort activation to those strongly related to the concept. Since  $S_{ij}$  is usually between 0 and 1, a linear function with absolute value is used in this model. The value of the cohort activation parameter,  $\delta$ , directly determines the amount of cohort activation and in the future can be used to mimic individual differences in the spreading of activation. Our model assumes that for any concept, its cohort activation can never exceed its input activation. For this reason the model will take the largest of the input and cohort activation values, and *Mention* is the maximum activation a concept can receive. Furthermore, the system parameter- *Activation Threshold* sets any activation below a set threshold to zero.

The working memory constraint is implemented by a parameter *WMC* (*Working Memory Capacity*). When the actual sum of activation exceeds the value of WMC, the activation of each concept is scaled down using Equation (2):

$$A_i^{cycle} = A_{i,Actual}^{cycle} \cdot \frac{WMC}{\sum_{i=1}^m A_{i,Actual}^{cycle}} \quad (2)$$

For the example sentence, the activation matrix is shown in Figure 1. For the 1<sup>st</sup> cycle (in which “*knight*” is processed during first-pass reading), the activation of “*knight*” is 1, from the *Mention* input. There is no cohort effect for the first reading cycle since no previous cycle exists. The activations for “*use*”, “*sword*”, “*fight*”, and “*dragon*” are established by multiplying their connections, .01, .64, .15, and .28 respectively, and the input of “*knight*” (1). The activation of “*use*” does not reach the threshold (set to 0.1) and as a result receives an activation of 0. For the 2<sup>nd</sup> cycle when “*use*” is being processed, the activation of each concept is calculated according to Equation (1). Figure 1 illustrates that the activation of “*dragon*” stays relatively high from cycle 1 to cycle 4 because of relatively strong connections to “*knight*”, “*sword*”, and “*fight*.” Conversely, the activation of “*use*” decreases from cycle 2 to 5 because of relatively weak connections to “*sword*”, “*fight*”, and “*dragon*” (less than .06).

Figure 1: The “landscape” of the activation matrix for the *Knight* example.

The conventional Landscape model updates the connection strengths in its episodic memory using a learning algorithm in order to adjust active discourse representations for the comprehension of a longer text. In this study, we assume that the background knowledge (represented by the connection matrix) is not altered during sentence reading.

In summary, by assuming (a) that words in a sentence are read and processed sequentially, and (b) long-term memory

representations (i.e., background knowledge) are not affected during comprehension; we propose a computational model of sentence processing which takes advantage of an existing discourse comprehension model designed to take into account contextual effects. The proposed model allows us to examine several factors that affect sentence comprehension; namely, (1) semantic activation in working memory, (2) background knowledge, and (3) working memory capacity. To assess the model's ability to reflect linguistic processing we will compare its performance to the cloze task.

## Experiment: Reanalysis of Previous Data

The key objective for this implementation is to disambiguate high from low semantic constraint in sentence contexts. Another objective of this implementation is to demonstrate that the LS model surpasses previously utilized methods as an alternative to the cloze task. In order to demonstrate that the proposed computational model is capable of matching cloze results more accurately than previous approaches, i.e., Wang et al. (2010), we re-analyzed the materials in Gollan, Slattery, Goldenberg, Van Assche, Duyck, and Rayner (2011), in which predictable/unpredictable target words were determined by a norming cloze task. We estimated predictability of a target word by (1) the previous content word, (2) all words in prior context, and (3) the estimates of the proposed connectionist model in this endeavor. We expect that our model can outperform other predictors on differentiating high- and low-constraint contexts and generate higher correlation to cloze values.

**Participants.** Twenty undergraduate students at the University of California, San Diego, participated. All of them were native speakers of English.

**Materials.** There were 90 target words; all target words were embedded in either a high-constraint (HC) or low-constraint (LC) sentence. For example, “*the hockey player moved on the ice on his \_\_\_\_\_*” (S1) was considered HC while “*The little girl was very happy when she unwrapped her brand new \_\_\_\_\_*” (S2) was LC for the target “skates”. The target words in HC context were generated 87% of the time, whereas the ones in LC context were generated less than 3% of the time.

**Procedure.** Participants were presented with the sentences up to the target words, and asked to provide one-word continuations for each sentence.

**Analysis.** The first estimate of predictability of each target word was derived by extracting the LSA connection weight to the previous content word (PreCont) for each target, e.g., the previous content word of S1 is “ice,” while the one of S2 is “new.” The second approach computed the LSA cosine value using all words in the previous context (AllW). The final estimate was derived from Landscape

model of sentence processing described above in the previous section (LS). We manually segmented the sentence into concepts and removed function words such as “a”, “the”, “in”, etc., for instance, “hockey / player / moved / ice” for S1. The parameters of our model were set as following:  $\delta = .7$ , *Mention* = 1, *Activation Threshold* = .1, and *WMC* = 7. The averages and standard deviations of Cloze, PreCont, AllW, and LS for HC and LC are described in Table 4.

Table 4. The averages and standard deviations (in parentheses) of Cloze, PreCont, AllW, and LS for HC and LC conditions.

	Cloze	PreCont	AllW	LS
HC	.87 (.13)	.17 (.16)	.21 (.16)	.66 (.29)
LC	.03 (.03)	.05 (.11)	.04 (.07)	.13 (.20)

## Results

As shown in Figure 2, an operating characteristic (ROC) analysis demonstrates that the area under the curves (AUC) of Cloze, PreCont, AllW, and LS are 1, .70, .87, .91, respectively. The LS model obtains a higher AUC than AllW or PreCont. Furthermore, a correlation analysis demonstrates that the Pearson correlations between Cloze and PreCont, AllW, and LS are .39, .56, and .70, respectively.

Figure 2: ROC curves for Cloze, PreCont, AllW, and LS.

The results suggest that the LS model can simulate much of the linguistic processing subjects perform when

producing cloze responses (and presumably during normal reading). The current objective is not to match cloze probabilities per se, but to successfully demonstrate the model's ability to differentiate highly constrained and unconstrained sentence contexts as well as the conventionally used cloze task. The LS model also demonstrates superiority over objective measures that utilize only the prior content word or LSA connections between content words exclusively.

## Discussion

The current implementation of the model has demonstrated that it is an effective measure of contextual constraint; in that it differentiates high and low-constraint sentence contexts better than previously employed alternatives to the cloze task. Furthermore, model activations for target words correlate with cloze responses more highly than previous objective methods of measuring contextual constraint. We believe this is an initial step toward the ultimate objective of representing both the fluctuating activation of lexical-semantic concepts in working memory during online sentence processing and how the processing of upcoming words can be facilitated by prior context. Discourse-mediated spreading activation across lexical-semantic representations has been proposed as an appreciable source of predictability effects during reading (Morris, 1994; Pynte et al., 2008; Traxler, Foss, Seely, Kaup, & Morris, 2000). Thus, modeling the process whereby linguistic inputs activate concepts in long-term memory and continuously influence working memory operations during sentence comprehension is an important endeavor in psycholinguistics.

As shown by the comparison to standard cloze responses, the current model can be used to reliably derive predictability of word  $n$  given the preceding context. The model generates a specific level of activation for word  $n$ , assuming that each word in the preceding context has been identified and all associated concepts have been engaged in working memory. As demonstrated above, this predicted level of activation correlates to cloze probabilities for a target word ( $n$ ).

Critically, the LS Model is able to reliably differentiate high and low constraint sentence fragments. Moreover, when using the LS model, in many cases the level of activation for word  $n$  will provide a more psychologically realistic measure of word processing difficulty when compared to cloze proportions, especially in neutral or unconstrained contexts. For instance, referencing cloze scores alone, there is no distinction between words that are plausible, yet not highly-predictable, and those that are completely implausible or anomalous given the preceding sentence context. In fact, it is quite feasible for plausible target words in unconstrained sentence frames to receive cloze probabilities at or around zero; however, low cloze probabilities are not necessarily indicative of potential processing difficulty. The manner in which the cloze task is conventionally used produces binary measurements (to the

extent that non-target responses are ignored). In this way, the current computational model may produce a more accurate representation than cloze scores with regard to indexing online word processing difficulty. This is particularly true for low constraint sentence frames. As such, the next logical step is to assess the LS model's goodness-of-fit to reading times and other eye movement data.

By modifying the framework of the conventional Landscape Model to reduce the size of text segments being processed during a reading cycle and situating activated concepts within limited working memory resources, we have attempted a psychologically plausible computational model of semantic effects on sentence comprehension. Crucially, the fluctuating activation of within sentence concepts is not determined merely by summing its cumulative activation across all preceding words; rather, the interactive and co-dependent influence of the prior sequence of words determined the extent to which the prior sentence context results in activation for a particular lexical-semantic concept.

The model is also a useful tool for investigating the number of semantic entities that are generally active in working memory. As well as the upper limits for the number of lexical-semantic entities simultaneously activated. Computationally examination of working memory limitations during reading could provide insight into what linguistic constructions are likely to elicit processing difficulty, result in longer fixation times, and lead to inter-word regressions during sentence reading. Model outputs can also be used to make predictions as to which concepts are likely to maintain relatively high levels of activation in working memory.

While among the most sophisticated computational frameworks in the field of cognitive science, current models of eye movement control during reading do not focus on how prior words render specific words predictable. The more well-developed models of oculomotor behavior and language comprehension represent the predictability of a given word in a sentence using only its cloze probability (Engbert, Nuthmann, Richter & Kliegl, 2005; Reichle et al., 1999; 2003). Our model successfully attempts to represent the cognitive processes that are sensitive to semantic constraint. Future implementations of the LS model will be capable of more thoroughly examining aspects of language processing and eye movement behavior. The *connection matrix* in the LS model can operationalize a variety of linguistic characteristics stored represented in long-term memory. Semantically-based connection weights can be modified to accommodate mediation by parafoveal preview information. In addition, the *connection matrix* could be modified to capture morphological, orthographic, and phonological relationships between lexical items. Currently, the LS model is a computational alternative to the cloze that is sensitive to both strong and subtle changes in contextual semantic constraint; as shown by the reasonable activation of plausible words in low constraint sentence

frames. Ultimately, the model will be expanded in an effort to achieve more comprehensive measurement of lexical-semantic predictability as it affects reading behavior.

## Acknowledgments

Preparation of the article was conducted when the first author held a predoctoral fellowship on Grant T32DC00041 from the Center for Research in Language. The work was also supported by Grant R01EY021802 from the National Eye Institute, USA, to Marc Pomplun and by Grant 97-2410-H-194-090-MY2 from the National Science Council, Taiwan, to Yuhtsuen Tzeng.

## Abstract

One major aspect of successful language acquisition is the ability to generalize from properties of experienced items to novel items. We present a computational study of artificial language learning, where the generalization patterns of three generative models are compared to those of human learners across 10 experiments. Results suggest that an explicit representation of word categories is the best model for capturing the generalization patterns of human learners across a wide range of learning environments. We discuss the representational assumptions implied by these models.

## Introduction

Learning the grammar of a language consists of at least two important tasks. First, learners must discover the cues in the linguistic input that are useful for constructing the grammar of the language. Second, learners must represent their knowledge of the grammar in a form that makes it possible to assess the grammaticality of future input. With an appropriate representation of the grammar, learners can generalize from properties of the small set of experienced items to predicted properties of novel items. This ability for generalization is crucial for language acquisition, as the input for learning is naturally limited. Such generalization should extend to only the novel items that are actually licensed by the language, no more (over-generalization) and no less (under-generalization).

Previous research has offered several hypotheses regarding the cues that learners use and the representations of grammar they form. In the realm of syntactic category acquisition, one hypothesis is that the categories (but not their contents) are innately specified prior to receiving any linguistic input, with the assignment of words to categories accomplished with minimal exposure (e.g. McNeill, 1966). On this view, both the cues and the representations are predefined and independent of linguistic input. A contrasting view states that grammatical categories are learned, though different hypotheses appeal to the importance of different cues or cue combinations during the learning process (such as semantic cues, e.g., Bowerman, 1973). Within this class of non-nativist hypotheses, several studies have suggested that distributional cues may be sufficient for extracting the grammar of the input language (e.g., Braine, 1987; Maratsos & Chalkley, 1980; Mintz et al., 2002). Distributional cues are defined over patterns in the linguistic input, such as token frequencies, co-occurrence statistics, and latent structural dependencies be-

tween linguistic elements. Although studies have shown that human learners and computational models can successfully learn grammatical categories when only these cues are available, the question of representation still remains poorly understood. How do learners represent the knowledge of previously encountered linguistic items in order to generalize to novel ones?

The aim of the present work is to ask what types of representations are used by human learners in an artificial grammar learning (AGL) task that includes many of the distributional properties of spoken language. We focus on how learners induce grammatical categories and assign words to them. Our approach involves computational modeling, comparing the simulated learning outcome of three different models, each of which makes a different assumption about how learners represent the learned grammar. We assess the models by comparing the generalization patterns of each model and those of human learners. Our experimental data come from our previous findings across 10 AGL experiments (Reeder et al., in review; Schuler et al., in prep). In the next section, we first provide a brief summary of these results. Importantly, the goal of our modeling work is not to mirror every detail of human behavior in AGL experiments: to do so, one must consider psychological variables such as memory and attention, which are currently not included in our models. Instead, we are interested in exploring the representational assumptions that human learners have adopted in our experiments.

## Background on Behavioral Results

The behavioral data come from a series of 10 experiments with adult participants in which we created an artificial grammar with the structure (Q)AXB(R). Each letter represents a category of nonsense words. Q and R words served as optional categories that made sentences of the language vary in length from 3 to 5 words and made words of the language observe patterning in terms of relative order but not fixed position. The sizes of the categories varied across experiments, leading to different numbers of possible sentences in the language. For ease of presentation, we will number the experiments. In Experiments 1-4 (Reeder et al., 2009), there were 108 possible sentences that could be created from this grammar; in Experiment 5 (Reeder et al., 2009), there were 576 possible sentences; in Experiments 6-10 (Reeder et al., 2010;

Schuler et al., in prep), there were 144 possible sentences.

Participants in these experiments were first exposed to a carefully selected subset of the possible sentences of the grammar. The exposure strings were chosen to test whether specific distributional cues enabled learners to form a category of lexical items and generalize to novel words, or to allow exceptions that maintain lexical specificity. In particular, different experiments tested learners sensitivity to the *contexts* of individual words and their individual frequencies, the *sparsity* of sampling the language, the *overlaps* among contexts across words, the non-overlap of contexts (or *systematic gaps* in information), and the size of the exposure set. In each experiment, a portion of the possible strings was withheld in order to create different kinds of “gaps” in the input to participants.

After exposure, subjects completed a grammaticality rating task, where they rated strings on a scale from 1-5, with larger values indicating higher grammaticality. The test was comprised of three types of test strings: familiar AXB sentences (presented during exposure), novel AXB sentences (withheld from the exposure set), and ungrammatical strings that violated the AXB word order (i.e., “A1X1A2” or “A1A2B3”). Importantly, in order to understand how learners generalized from training sentences and the type of knowledge representations suggested by their generalization behaviors, we varied the way the presentation set and the gaps occurred in each experimental condition, as summarized in Table 1. In Experiments 1-2, we varied the sparseness of sampling the language, but learners heard all AX and XB bigrams. In Experiments 3-4, we varied the overlap of contexts across X words: each X was heard with only 2 of the 3 As and Bs. Experiments 6-9 included a new X word (called “X4”) that appeared in only one sentence frame in the training subset. The purpose was to test whether learners would generalize to X4 as one of the X words (and therefore able to occur in all X-word contexts), despite its own extremely limited exposure and minimal overlap with the other X-word contexts. Experiment 5 created subcategories in the language, with distinct occurrence privileges for X words and contexts words: half of the X words only occurred with half of the A words and half of the B words, while the remaining X words occurred with the remaining As and Bs.

In experiments 1-9, the bigram statistics were carefully balanced: all grammatical bigrams were presented equally often (with the exception of the X4 bigrams in Experiments 6-9). Under this balanced design, one possible strategy for judging grammaticality could be simply to keep track of bigram statistics. To examine this, we ran Experiment 10, where the bigram statistics were not balanced.

By definition, the generative grammar used in all these experiments is the same: (Q)AXB(R). However, our distributional manipulations across all of these experiments led human subjects under certain circumstances to restrict generalization to be maximally compatible with the input, while in other circumstances to generalize to the full grammar.

Table 1: Descriptions of the sampling bias in each experiment

Experiment	Sampling bias
Expt 1	Uniformly Distributed Gaps, Dense Sampling (1/3 withheld): Every X-word heard with every A- and B-word
Expt 2	Uniformly Distributed Gaps, Sparse Sampling (2/3 withheld): Every X-word still heard with every A- and B-word
Expt 3	Systematic Gaps, Sparse Sampling: Each X-word heard with a subset of possible A- and B-words
Expt 4	Extended Exposure to Systematic Gaps: Same as Experiment 3, but exposure was tripled
Expt 5	Subcategorization: Gaps were inserted such that a clear divide segregated X-words and contexts words into two subcategories
Expts 6-9	Same as Experiments 1-4, but included a very minimally overlapping X-word (X4); X4 seen in just one sentence frame in each condition
Expt 10	Same as Experiment 3, but bigram statistics are not balanced because words varied in frequency

Learners rated novel grammatical sentences as high as familiar grammatical strings in Experiments 1 and 2, showing a strong tendency to generalize across the words within a category. In Experiments 3 and 10, where a systematically-gapped training set was presented (balanced or not), learners became more conservative and treated novel grammatical sentences as somewhat less grammatical than familiar ones (but still more grammatical than ungrammatical ones). Generalization was further reduced in Experiment 4, when the exposure to systematic gaps was increased. In the subcategorization experiment (Experiment 5), learners did not fully generalize across the gaps created by the subcategory structure, indicating that they used the distributional information to learn that there were two subcategories within the X category. Lastly, the results of Experiment 6 showed that when learners were given a dense sampling of a language with almost complete overlap of contexts for several words in the X category, learners generalized a novel word (X4) to the full range of grammatical contexts of the other X-words, even when they heard X4 in only one of those contexts. When contexts were more sparse (Experiment 7) and there were significantly more systematic gaps in the input (Experiments 8 & 9), learners did not fully transfer their knowledge of X-category structure to the minimally overlapping X4 word. In all experiments, ungrammatical sentences were rated significantly lower than any novel grammatical test string.

## Models

We use a generative model-based framework to develop our three models. The structures of these generative models make explicit the assumptions about knowledge representations. The goal of our modeling effort is to understand what elements must be included in the representation of the QAXBR grammar so that the models’ generalization behavior will be

most compatible with human behavior across all 10 experiments. The answer to this question is related to the types of distributional cues that human learners attend to in the experiments. For the models reported in this paper, we make the simplifying assumption that learners only attend to local bigram information in the input, the bare minimum to capture the sequential dependencies within QAXBR sentences (although our models can easily be extended to use other distributional cues). A successful model should assign high probabilities to grammatical sentences and low probabilities to ungrammatical ones. Crucially, a successful model should assign probabilities to novel grammatical sentences that match the ratings of human learners.

### Word Bigram Model

The first model is the *word bigram model*: the probability of a sentence is simply the product of the probabilities of its ordered word pairs, where the probability of each word  $w_i$  is conditioned on the preceding word  $w_{i-1}$ :

$$p(s) = \prod_{w_i \in s} p(w_i | w_{i-1}) \quad (1)$$

Equation (1) can be interpreted to suggest that a word bigram model represents the grammar with a set of multinomial distributions. Each distribution specifies the probabilities that a word will be followed by any other words in the vocabulary. The parameters of these distributions are typically estimated from training data with maximum likelihood estimation (MLE). However, the standard MLE algorithm is insensitive to sample size, which is a crucial variable of interest in several experiments. When comparing Experiments 3 and 4, for example, our subjects exhibited different generalization patterns as a result of the change in the amount of exposure to the same set of training data (i.e., a change in sample size only). Therefore, we adopt a Bayesian approach that is sensitive to sample size. The fully derived form for estimating the probability of a word is:

$$p(w_i | w_{i-1}, \text{all previous bigrams}) = \frac{n_{w_{i-1}, w_i} + \beta}{\sum_k n_{w_{i-1}, w_k} + v\beta} \quad (2)$$

where  $v$  is the vocabulary size,  $n_{w_{i-1}, w_i}$  is the frequency of bigram  $(w_{i-1}, w_i)$ , and  $\beta$  is a free parameter. The  $\beta$  parameter determines whether certain parameter settings of the multinomial distributions are favored. Here, we report results with  $\beta$  set to 1, which is a non-biased prior.

**Simulation Procedure** In each experiment, the word bigram model first estimates its model parameters according to the training sentences. In experiments where the length of exposure is a predictor of interest (Expts. 3, 4, 8 & 9), we duplicate the training data to simulate the effect of extended exposure. Unlike human subjects, however, the model is given information regarding the size of the vocabulary, and does not have memory limitations.

### Word Bigram Mixture Model

The word bigram model implies that there is one single representation that corresponds to the grammaticality of a sentence. Natural languages, however, are usually more flexible: a sentence can have many different types of grammaticality (or ungrammaticality), such as Noun-Verb agreement, as well as lexical restrictions, such as transitive/intransitive verbs. We address this problem by developing a word bigram mixture model, where multiple patterns of grammaticality can be modeled simultaneously. Each component in the mixture is a word bigram model. A grammatical sentence is generated from a component grammar, which is in turn generated from a stochastic process (the model can be viewed as a Dirichlet process mixture model; Ferguson, 1973). We can describe the process of generating a sentence  $s$  in two steps:

- (a)  $p(s \text{ is generated by an existing component } k) = \frac{n_k}{n + \alpha}$   
 (b)  $p(s \text{ is generated by a new component}) = \frac{\alpha}{n + \alpha}$
- If (a),  $p(s = w_1, \dots, w_m) = p(w_1, \dots, w_m | \mathcal{B}_k)$   
 If (b),  $p(s = w_1, \dots, w_m) = p(w_1, \dots, w_m | \mathcal{B}_{new})$

where  $n_k$  is the number of sentences that have been generated as instances of component grammar  $k$ ,  $n$  is the number of sentences that have already been generated,  $\alpha$  is a free parameter of the model (a larger  $\alpha$  leading to more new clusters), and  $\mathcal{B}$  refers to the parameters of a component bigram model (as described in the previous section). Combining these two steps, the probability that  $s$  will be generated by a word bigram mixture model is

$$p(s = w_1, \dots, w_n) = \frac{\sum_k p(s | \mathcal{B}_k) n_k + p(s | \mathcal{B}_{new}) \alpha}{n + \alpha} \quad (3)$$

**Simulation Procedures** Equation (3) describes a generative model, with which we can assess the probability that a sentence is generated by an existing representation of the grammar. However, the learner faces the opposite problem: they must infer the representation given the observed sentences. We used the Gibbs sampling method to infer these parameters (the exact details are not described due to space limits). We run the model on the training data used in the experiments. The first 500 samples of each run are discarded (which may be biased towards initial values). Due to the small scale of our artificial language, the sampler converges quickly, well within the discarded 500 samples. Each of the remaining posterior samples is considered as a candidate representation of the grammar. For experiments with longer exposure, we also run the sampler longer to approximate the effect. The average probability that a sentence is generated by these posterior representations is taken as a measure of the grammaticality of the sentence.

### Category Bigram Mixture Model

A notable feature of the two models presented so far is the lack of explicit representation for grammatical categories.

Figure 1: Grammaticality predictions made by the category bigram mixture model best approximate subject ratings in most experiments.  $R^2$  is calculated by regressing subject ratings against model predictions.

In both models, bigram statistics are based on word tokens. However, a crucial component of language acquisition involves organizing words into grammatical categories and discovering relations between them. To investigate whether human learners were in fact organizing the words into categories, we also developed the category bigram mixture model. The category bigram mixture model preserves the notion of multiple component grammars and introduces a bigram-based word category discovery process nested within each component grammar. In other words, the component grammars in the category bigram mixture model are themselves infinite mixtures of bigram models on categories. Therefore, generating a sentence under the grammar is a two-step process with the second step containing another two-step process:

- (a)  $p(s \text{ is generated by an existing component } k) = \frac{n_k}{n+\alpha}$   
 (b)  $p(s \text{ is generated by a new component}) = \frac{\alpha}{n+\alpha}$
- If (a), for the category of each word,  $c_i$ :
  - (i)  $p(c_{i-1}, c_i \text{ belongs to existing bigram } l) = \frac{n_l^k}{n^k + \alpha_0}$
  - (ii)  $p(c_{i-1}, c_i \text{ is novel}) = \frac{\alpha_0}{n^k + \alpha_0}$
  - If (i),  $p(w_i) \sim \text{MultiNomial}(c_i | c_{i-1})$
  - If (ii),  $p(w_i) \sim \text{MultiNomial}(c_{\text{new}} | c_{i-1})$
- If (b), for the category of each word,  $c_i$ :
  - (i)  $p(c_{i-1}, c_i \text{ belongs to existing bigram } l) = \frac{n_l^{\text{new}}}{n^k + \alpha_0}$
  - (ii)  $p(c_{i-1}, c_i \text{ is novel}) = \frac{\alpha_0}{n^k + \alpha_0}$
  - If (i),  $p(w_i) \sim \text{MultiNomial}(c_i | c_{i-1})$
  - If (ii),  $p(w_i) \sim \text{MultiNomial}(c_{\text{new}} | c_{i-1})$

where in the top-level process,  $n_k$  is the number of sentences that have been generated by component grammar  $k$ ,  $n$  is the total number of generated sentences,  $\alpha$  is the free parameter (as in the word mixture model) influencing the tendency of creating more component grammars. For clarity, we write  $c_{i-1}, c_i$  as the bigram label that each bigram  $l$  is associated with in the nested process:  $n_l^k$  is the frequency of category bigram  $l$  in component grammar  $k$ ;  $n_k$  is the total number of category bigrams in component grammar  $k$ , and  $\alpha_0$  is a free

parameter (a larger value leading to more category bigrams). Finally, the probability that each word is generated from its category  $c_l$ , conditioned on the category of its preceding word  $c_{i-1}$ , is modeled as a multinomial distribution.

**Relation to other models** The problem of discovering categories for word tokens in a language is analogous to the problem of part-of-speech tagging in computational linguistics, which has been under active research for several decades. Our category bigram mixture model is most similar to the Bayesian unsupervised tagging algorithm developed by Goldwater & Griffiths (2007). While our approach is not fully Bayesian (in the sense that hyper-parameters are treated as free parameters), it has the flexibility of discovering multiple part-of-speech sequence patterns (i.e. component grammars) and creating as many part-of-speech tags as needed (due to the nested Dirichlet Process).

**Simulation Procedure** As in the case of the word bigram mixture model, Gibbs sampling is applied to the inference problem to find samples of the posterior distribution. Each of the remaining posterior samples is considered as a candidate representation of the grammar under the category bigram mixture model. The average probability that a test sentence will be generated by these representations is taken as a measure of the grammaticality of the sentence.

## Results and Discussion

Model predictions are in the format of probability estimates. A higher probability estimate means that a sentence is more grammatical. The quality of model predictions is determined by examining how well they correlate with subject ratings. To ensure that subject ratings are maximally comparable with model predictions, we transformed discrete ratings into z-scores within each subject and experiment, so that the ratings of subjects with consistent biases (consistently high or consistently low ratings) were normalized. We computed the  $R^2$  metric for each group using a linear regression where model predictions were used to predict subject ratings. A model with a high  $R^2$  indicates that the particular model explains a significant amount of variance in subject ratings (see Fig 1). Overall, the category bigram mixture model best captures hu-

man behavior across all 10 experiments combined ( $R^2$  Word Bigram = 0.4,  $R^2$  Word Bigram Mixture = 0.35,  $R^2$  Category Bigram Mixture = 0.47).

The general advantage of the category bigram mixture model suggests that our human learners may have acquired a representation of an X category, and not just a set of simple word co-occurrences. In X4-related experiments (Expts. 6-9), we asked whether learners could extend their knowledge of a target category to a very infrequently presented word for which they only had minimal context information. We found that there was a point in learning where hearing just one context for the minimally overlapping X4 word was enough to generalize full category privileges for that word (Expt 6). Simple word co-occurrence and bigram counts will not achieve this outcome. The category bigram mixture model, however, has the appropriate representation for supporting such a learning outcome. Indeed, in Experiment 6, X4 gets assigned to the same category as all other X-words, thus enabling the generalization to novel X4 sentences (the effect of X4 sentences on overall  $R^2$  is reduced by the extremely small number of X4 sentences in the testing phase).

### Limitations of the category bigram mixture model

While the category bigram mixture model best approximates human generalization patterns across the 10 experiments, it does no better than the other two models in capturing human performance in the subcategorization experiment. Indeed, the two mixture models acquire the subcategory structure, but fit human performance no better than the simplest word bigram model. This paradoxical result is due to the experimental design: all bigrams in the training subset conform to the subcategory boundaries and are presented equally often. At test, novel subcategory-conforming items are rated as high as familiar ones because they contain only bigrams that have been presented (thus indistinguishable from familiar ones). Test strings violating the subcategory structure are rated low by the word bigram model simply because they contain one or two bigrams which are never seen in the training data. The balanced presentation of all within-subcategory bigrams enables the word bigram model to distinguish between subcategory conforming and violation items without learning the existence of two subcategories. As a result, even though the two mixture models successfully discover the existence of two subcategories, the additional advantage of such discoveries is minimal.

The category bigram mixture model also tends to overgeneralize in experiments with systematic gaps. This is most clearly demonstrated in Experiments 4 and 9 (see Fig 2). In those experiments, subjects were exposed to a language with frequent systematic gaps in the input. Human learners gave novel grammatical sentences a significantly lower rating than familiar grammatical strings, especially when the training materials were presented multiple times. We view this restriction of generalization as a rational behavior that prevents human learners from over-generalizing when systematic and persistent gaps occur in the input.

### Normalized Grammaticality Rating (y-axis)

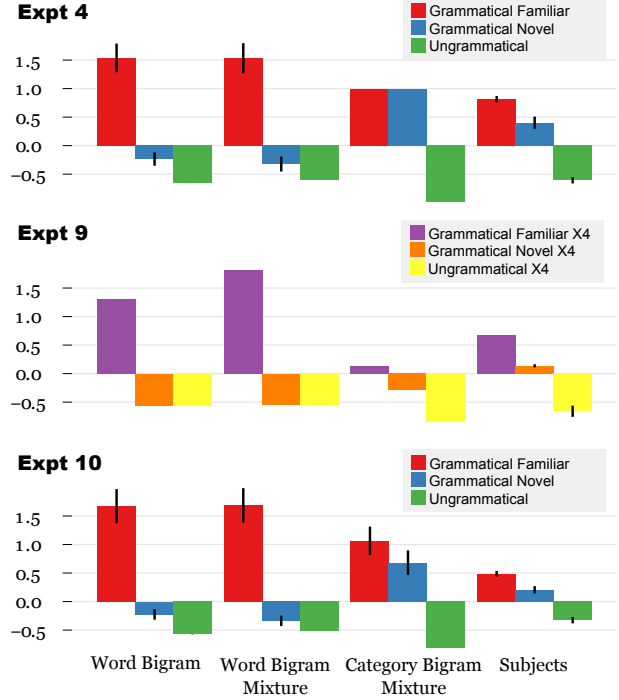

Figure 2: Z-score normalized grammaticality ratings by models and human subjects in 3 experiments where the Category Bigram Mixture model had highest  $R^2$ . Error bars = SE. Regarding the difference between familiar and novel ratings, Expt 4 shows overgeneralization by the category bigram mixture model, Expt 9 shows overly conservative behavior of the category bigram mixture model, and Expt 10 shows the category bigram mixture model best capturing human behavior, despite systematic gaps and variable bigram frequencies.

In the word-based models, the reduced generalization is captured because an increase in the probabilities of observed word bigrams necessarily leads to a decrease in the probabilities of unobserved ones, thus producing restricted generalization. However, this effect is much weaker in the category bigram mixture model, where repeated exposure to training sentences only strengthens the category bigram dependencies. When a novel grammatical sentence is presented to this model, its category bigrams have been observed many times during training and the sentence will receive a relatively high rating as a result (despite this,  $R^2$  is relatively higher in the category bigram mixture model because its predictions are qualitatively closer to subject ratings; see Fig 2). This is an indication that learners have slightly different constraints on learning and/or a slightly different strategy from the category bigram mixture model. We are currently exploring other possible models that build on the idea of an underlying category representation, but incorporate learning constraints that more closely mimic human learning (e.g. incremental models of learning) and lead to the construction of a more restrictive grammar that is still compatible with the input.

This pattern can be contrasted with model performance on Expt 10, where not all grammatical bigrams are seen equally often during exposure. Results from this experiment make clear that the category bigram mixture model is the most robust to manipulations of the bigram distribution (see Fig 2). The other two models rate grammatical novel sentences almost as low as ungrammatical sentences, since novel grammatical sentences contain novel and low-frequency bigrams. By definition, these are less grammatical to the word-based models due to having a lower probability. The category mixture model, on the other hand, is not negatively influenced by the unbalanced design due to the abstraction of word categories.

## General Discussion

Across 10 experiments, we compared the grammaticality predictions of three different models to human subject ratings. Our primary interest was to find the representational elements of the grammar that are most compatible with the generalization behaviors displayed by the learners. Generalization depends on the ability to abstract over categories, which is fundamental to linguistic productivity. A number of researchers have asked whether there is adequate distributional information in the input to form linguistic categories. Previous work uses hierarchical clustering and a computational learning mechanism to attempt to deduce grammatical categories from corpora of child directed speech based solely on distributional analyses of the input (e.g. Mintz et al., 2002; Redington et al., 1998). These models have been able to use co-occurrence statistics among words to achieve relatively good categorization performance for frequent target words, indicating the utility of these types of distributional cues for categorization.

The behavioral experiments that this work is built upon suggest that the patterning of word tokens in a substantial corpus of linguistic input appears to be sufficient to extract the underlying structural categories in a natural language, given an appropriately capable learner. Our modeling results have further explicated the representational assumptions for extracting the knowledge of a grammar. Of the three models, two models are based on simple word bigrams collected from training data. While word bigrams are useful for capturing the lexical dependencies of the grammar, they cannot explain how human learners could generalize from experienced examples to novel items, especially when the prior experience is minimal (i.e., Expts 6-9). Such rapid and automatic generalization behavior calls for a richer representation, in which the grammar of the artificial language is organized around potential categories of vocabulary words. The category bigram mixture model introduces the notion of categories as a representational assumption, which led to model predictions that better approximated the behavior of human learners in almost all experiments. A limitation of the category bigram mixture model, however, is that it overgeneralizes compared to human performance. A fourth type of model could add a

generative component that asks how likely it is that a string is absent given a random sampling process. If that probability is low, then it would penalizes the probability even further by downweighting it in the grammar. We are exploring this direction, in conjunction with other mixture models that may more closely mirror the constrained learning environment that human learners face during natural grammatical category acquisition.

## Abstract

Research on artificial language acquisition has shown that insertion of short subliminal gaps to a continuous stream of speech has a notable effect on how human listeners interpret speech tokens constructed from syllabic constituents of the language. It has been argued that the observed results cannot be explained by a single statistical learning mechanism. On the other hand, computational simulations have shown that as long as the gaps are treated as structurally significant units of the language, a single distributional learning model can explain the behavioral results. However, the reason why the subliminal gaps interfere with processing of language at a linguistic level is currently unknown. In the current work, we concentrate on analyzing distributional properties of purely acoustic representations of speech, showing that a system performing unsupervised learning of transition probabilities between short-term acoustic events can replicate the main behavioral findings without a priori linguistic knowledge.

## Introduction

There is an ongoing debate regarding the degree that distributional learning mechanisms can explain aspects of language acquisition from speech, and the degree that rule-based mental processes are required in the task (e.g., Endress & Bonatti, 2007; Laakso & Calvo, 2011; Peña et al. 2002). Experimental studies with human test subjects have shown that both infants and adults are able to learn statistical regularities in continuously spoken artificial languages and use these regularities to segment speech into word-like units (e.g., Peña et al. 2002; Saffran, Aslin & Newport, 1996). Based on these findings, it has been suggested that the listeners may be using transitional probabilities (TPs) between speech units such as phones or syllables in order to discover statistically regular segments of speech (e.g., Saffran et al., 1996). Computational simulations have also verified that the TPs between signal events can be used to discover word-like units from continuous speech, and that these units do not necessarily need to be linguistic or phonetic in nature (Räsänen, 2011).

Of especial interest is the degree that distributional learning can explain the learning of non-adjacent dependencies in a language. In earlier work, the learning of non-adjacent dependencies has been studied using an

artificial nonsense language consisting of three-syllabic CVCVCV words with the middle syllable being always randomly selected from a pool of “fillers”, but the first and last syllable occurring always together (hence a “*high-probability word*”). It has been found out that when human listeners are familiarized with a continuous stream of such language without gaps between the high-probability words, and then later tested for preference between three-syllabic words that have different TPs between the syllables in terms of the familiarization stream, the listeners seem to prefer words that have occurred with higher internal TPs in the familiarization stream (Endress & Bonatti, 2007; Peña et al. 2002). However, introduction of 25 ms subliminal segments of silence between the high-probability words in the familiarization stream leads to a notable change in the learning outcome: the listeners start to prefer word forms that do not necessarily have the highest TPs across all syllables in the word. Instead, the preferred words may contain partially novel surface form but have dependencies between syllables that can be explained by abstract rules that are also valid for the words in the familiarization stream (Endress & Bonatti, 2007; Peña et al. 2002).

The above finding is somewhat unexpected from the perspective of distributional learning at a linguistic level. The learning results between continuous and gapped familiarization streams should not differ as long as the perceived linguistic units and their ordering in the two conditions do not differ either. The result is also counterintuitive due to the fact that the gaps are tiny in duration in comparison to the other relevant signal segments such as syllables, and since CV-syllable based languages already contain natural silences associated with closures of plosives (e.g., word “#pura#ki”, where # denotes a closure).

Peña et al. (2002) and Endress and Bonatti (2007) suggest that the additional silent gaps provide direct (but unconscious) cues to the segmentation of words from speech, freeing computational resources to structural learning of rule-like relations between constituents of the words. On the contrary, the absence of the gaps necessitates that the segmentation has to be first learned from the data (Endress & Bonatti, 2007; but see also discussion in Laakso & Calvo, 2011). It is therefore argued that the change in learning outcomes after introduction of the gaps provides evidence for non-distributional learning of structural relations between syllabic units (Bonatti & Endress, 2007).

However, a possible auditory processing mechanism for differentiating gaps associated with segmental cues and, e.g., the intra-word gaps related to closures of plosives has not been described in the existing work.

Lately, Laakso and Calvo (2011) have shown that the experimental results of Peña et al. (2002) and Endress and Bonatti (2007) *can* actually be modeled with a single distributional connectionist model when the silent gaps are represented as equally significant units as the consciously perceived syllables. As long as Occam's razor is concerned, the distributional model of Laakso and Calvo (2011) provides a more coherent and simple explanation for the observed data instead of resorting to the more than one mechanisms (MOM) hypothesis of Peña et al. (2002) and Endress and Bonatti (2007). However, the model of Laakso and Calvo also has a shortcoming: it does not explain how the short subliminal gaps end up with an equally large role as the syllabic units in the distributional learning process.

The goal of the current work is to study the distributional learning hypothesis in the context of the artificial language of Peña et al. (2002) by focusing on the analysis of recurring acoustic patterns in a speech stream. Unlike earlier work, we study TPs of short-term acoustic events instead of linguistically or phonetically motivated units such as syllables or segments. This provides a novel perspective to the learning problem by assuming that the listeners may not be directly analyzing the speech stream as a sequence of linguistic units, but may treat the language-learning task as a generic auditory patterning problem. Still, the current approach does not exclude the possibility that the listeners can extract basic recurring units such as syllables or segments from the acoustic speech stream and perceive these as linguistically significant units. We simply show that the behavioral results of Peña et al. (2002) and Endress and Bonatti (2007) can be explained with a single distributional learning mechanism that performs pattern discovery at the level of acoustic signal instead of assuming TP analysis of segments or syllables.

### Motivation for Acoustic Learning

There are multiple reasons to assume that the listeners may utilize generic acoustic patterning instead of purely linguistic coding of input during perception of an artificial language. First of all, test subject preferences towards specific test probe types are typically only slightly above chance level even for extended familiarization periods (Peña et al., 2002; Endress & Bonatti, 2007). If the learning would be based on categorically perceived segments or syllables, one could expect more robust preference for one probe type over another due to the systematically different overall TPs or learned rules for the tokens. Also, the initial preference for specific probe types degrades over longer familiarization periods, suggesting that the low-level distributional properties of the speech stream interfere with the processing of the abstract generalizations. Finally, the introduction of subliminal gaps introduces notable qualitative changes to the learning outcomes. Since these gaps are clearly not

serving any explicit linguistic function but still affect the learning results, it can be taken as evidence that the acoustic level perception, including temporal relationships of acoustic patterns, may play an important role in the process.

Why distributional analysis at the acoustic level would then lead to different results than analysis on the segmental or syllabic level? The major difference comes from temporal relationships between sound events. At the syllabic level, the relevant units and their distances from each other are well defined. Therefore the TP statistics also become well defined after a small number of word occurrences in different contexts. At the acoustic level, a syllable is not perceived as a categorical unit with a well-defined duration, but as a constantly evolving spectrotemporal trajectory that has very low predictability over larger temporal distances. This means that the typical acoustic level dependencies are limited to a time scale much shorter than the tri-syllabic words in the artificial language of Peña et al. (2002). Therefore the acoustic TP analysis must also pay attention to dependencies at a very fine temporal resolution, potentially increasing the relative role of temporal asynchronies caused by the introduction of silent gaps to the familiarization stream.

### Material

The speech material for the experiments was reproduced from the work of Peña et al. (2002). In this material, the familiarization stream of the artificial language consists of three CV-syllable words of form  $A_iXC_i$  so that each word starts with one of three possible syllables  $A_i$  ( $i \in \{1,2,3\}$ ). Importantly, the first syllable always uniquely determines the last syllable  $C_i$  of the word (i.e.,  $P(C_i|A_i) = 1, \forall i$ ) so that there are also three different possibilities for end syllables. Finally, the medial syllable, or *filler*, is chosen randomly from a set of three CV syllables. In total this produces three word templates “pu ... ki”, “be ... ga”, and “ta ... du” where one of the following three fillers are used in the medial position: “li”, “ra” or “fo”.

Based on Endress and Bonatti (2007), four types of probes were used during testing: 1) *words*, i.e., tri-syllable constructs that correspond directly to the ones used in the familiarization (e.g.,  $A_iXC_i$ ), 2) *part-words*, where the sequential order of syllables was from the familiarization data but the word straddles a word boundary (e.g.,  $XC_iA_j$ ), therefore having a smaller overall TPs across the word, 3) *rule words* of form  $A_iX'C_i$ , where the  $X'$  is familiar from the training but has never occurred in the word-medial position, and 4) *class words* of form  $A_iXC_j$  ( $i \neq j$ ) so that all  $A_i$ ,  $X$ , and  $C_j$  are familiar from the familiarization data but the  $A_i$  and  $C_j$  have never occurred in the same word (see Endress & Bonatti, 2007, for detailed word lists).

The familiarization data and test probes were synthesized into speech signals using a Kelly-Lochbaum model based articulatory synthesizer of Rasilo, Räsänen and Laine (in preparation) using articulatory positions of Finnish vowels as targets for the vowel sounds. Sampling rate of the signals was set to 16000 Hz and fundamental frequency of the

Figure 1: Temporal dependencies of acoustic events measured from continuous English speech. The two learning parameter configurations BC and EC are also shown.

speaker was set to 120 Hz. In order to create familiarization data, all words in a training epoch (one occurrence of each word) were concatenated into one long string before synthesis so that the coarticulatory effects were consistent for both intra-word and across-word transitions. In addition to the continuous stream, the gapped familiarization stream of Peña et al. was also created by inserting silent segments of 25 ms between the words. It was also confirmed perceptually that the perception of the gaps was subliminal and no other audible artifacts were introduced to the signals.

## Methods

### Preprocessing

The goal of the preprocessing was to convert synthesized speech signals into sequences of automatically discovered discrete acoustic events for further statistical modeling. This was achieved by extracting Mel-frequency cepstral features (MFCCs) from the signals using a window length of 25 ms and a step size of 10 ms (see, Appendix B in Räsänen 2011a for detailed description). A total of 12 coefficients + energy were used. A random subset of 10000 MFCC vectors from the familiarization data set was then clustered into 64 clusters using the standard k-means algorithm. The obtained cluster centroids were treated as prototypes for the corresponding clusters (“atomic acoustic events”) and each cluster was assigned with a unique integer label  $i \in [1, 2, \dots, 64]$ . Finally, all MFCCs vectors were vector quantized (VQ) by representing the original feature frames with labels corresponding to the nearest cluster centroids for the given frame. This led to a signal representation where the synthesized speech was represented as a sequence of discrete elements, each element being one of the 64 possible choices and one element occurring every 10 ms.

### Discovery of Acoustic Patterns

In order to learn distributional patterns from the artificial speech data, a statistical learning mechanism is needed. In the current work, we utilized the unsupervised word learning model of Räsänen (2011) that has been shown to be able to discover recurring word patterns from real continuous speech. This algorithm will be referred to as the *unsupervised distributional learning algorithm* (UDLA).

The basic principle of the UDLA is to study the TPs between the atomic acoustic events (VQ indices) in order to discover multiple segments of speech that share similar local TP distributions. Unlike typical distributional analysis of syllabic, phonemic, or orthographic units (e.g., Saffran, 1996), UDLA analyzes TPs between short-term acoustic events at several temporal distances (lags) in parallel so that dependencies between non-adjacent acoustic events also become modeled. When recognizing novel patterns, statistical support from all lags is combined in order to provide a uniform and noise robust estimate of familiarity of the pattern. Instead of modeling global TPs, UDLA creates a separate TP model for each novel pattern discovered from the data, where a novel pattern is defined as a sequence of acoustic events whose TPs do not match any of the previously learned patterns.

From the perspective of pattern discovery, it is beneficial to study temporal dependencies up to approximately 200 ms in case of continuous speech. This is because the statistical dependencies between acoustic events diminish to a non-existent level at larger temporal distances and provide no further support for pattern discovery (Räsänen & Laine, 2012). This temporal scale also corresponds to the typical signal integration times measured in human auditory perception in the context of loudness perception or forward masking of speech sounds, suggesting that the integration times in human hearing are matched to the typical temporal structure of acoustic speech signals. As an example, Figure 1 shows the statistical dependencies of short-term acoustic events as a function of temporal distance for continuous English speech measured in terms of mutual information function (MIF; Li, 1990). As can be observed from the figure, majority of the dependencies at the acoustic level are limited to temporal distances shorter than 100 ms.

Since the amount of statistical information diminishes at longer distances, one can hypothesize that the human hearing system would be adapted to process temporal dependencies at such timescale where, on average, dependencies do exist. Therefore, in *baseline configuration* (BC), we use UDLA in a mode in which dependencies are modeled up to 80 ms, capturing approximately 90 % of the statistical dependencies in terms of MIF (Fig. 1). However, we also measure UDLA behavior in the artificial language learning task using TP modeling up to 390 ms. This configuration will be referred to as *extended configuration* (EC). In terms of the current experiments, this means that the TPs were studied at lags  $\mathbf{k} = \{1, 2, \dots, 8\}$  for BC and at lags  $\mathbf{k} = \{1, 3, 5, \dots, 39\}$  for EC, corresponding to the modeling of acoustic dependencies at temporal distances of 10 ms – 80 ms and 10 ms – 390 ms, respectively.

The hypothesis was that, if acoustic and non-linguistic patterning can explain the results of the experiment of Peña et al. (2002), and if human hearing is actually specialized for learning dependencies according the curve shown in Fig. 1, the learning outcomes in the baseline configuration should have better correspondence to the behavioral results than the extended condition. On the other hand, the extended

configuration should show higher preference for part words than class or rule words due to the diminishing role of the gaps in terms of dependencies across all temporal distances.

**Training Phase** The learning process in UDLA proceeds as follows (see also Räsänen, 2011): the sequential discrete familiarization stream  $X$  is analyzed in windows of length  $L_r$  elements and window step size  $L_s$ . For each window position, the TPs between all elements  $a_i$  and  $a_j$  in the window are modeled in parallel for lags  $\mathbf{k} = \{k_1, k_2, \dots, k_K\}$ . For the TPs in the first window position, the first statistical model  $c_1$  is created by storing all transitions at all lags to a transition probability matrix. In the model, the probability of a transition from element  $a_i$  to  $a_j$  at lag  $k$  is defined as

$$P_c^S(a_j | a_i, k) = F_c(a_i, a_j | k) / \sum_{j=1}^{N_A} F_c(a_i, a_j | k) \quad (1)$$

where  $F_c(a_i, a_j | k)$  is the frequency of ordered pairs  $[a_i a_j]$  at distance  $k$  in the context of model  $c$ .

When the window is moved incrementally across the input sequence, all previously learned models are used to recognize the contents of the current window position. First, activation  $A_c(t)$  of each model  $c$  at each moment of time  $t$  is computed by calculating the mean of the TPs over all  $\mathbf{k}$ :

$$A_c(t) = \frac{1}{K} \sum_{k=1}^K P_c^S(X[t] | X[t-k], k) \quad (2)$$

The cumulative activation of each model is then calculated over the window and normalized by the window length:

$$A_c^{cum}(T) = \frac{1}{L_r} \sum_{x=T}^{T+L_r-1} A_c(t[x]) \quad (3)$$

where  $T$  denotes the window position. Now if activation  $A_c^{cum}$  of the most activated model  $c_M$  exceeds a pre-defined familiarity threshold  $t_r$ , the transition frequencies in the current window of analysis  $X_T$  are used to update the statistics of the model  $c_M$  according to Eq. (1). Otherwise, a new model  $c_N$  is created from the window contents using the Eq. (1). This process is repeated for the entire training data set, producing a set of models that incrementally increase their selectivity towards specific structures in the speech signal.

After the familiarization is complete, the learned models are normalized according to

$$P_c(a_j | a_i, k) = P_c^S(a_j | a_i, k) / \sum_{m=1}^{N_C} P_m^S(a_j | a_i, k) - \frac{1}{N_C} \quad (4)$$

where  $N_C$  is the total number of models learned. This changes the nature of the statistics so that now  $P_c$  describes how likely the given transition from  $a_j$  to  $a_i$  occurs in case of pattern  $c$  instead of any other pattern (i.e., *classification* task). The  $1/N_C$  term forces the total activation across all models to zero at all times, ensuring that the total activation level of the system does not increase with increasing number of learned models. Note that the learning process is purely incremental and requires the storage of the previous inputs only up to maximum lag  $K$  (i.e., 80 or 390 ms).

**Recognition Phase** During the testing phase, the test probes were pre-processed into discrete VQ sequences similarly to the familiarization data. Then the instantaneous activation of each model  $c$  at time  $t$  given input probe  $X$  was measured according to

$$A_c(t) = \frac{1}{K} \sum_{k=1}^K P_c(X[t] | X[t-k], k) \quad (5)$$

The total activation induced by the probe was then computed as

$$A_{tot} = \arg_{t,c} \max(A_c(t) | \forall t, c) \quad (6)$$

In other words, the total activation caused by the probe  $X$  was obtained as the maximum instantaneous activation<sup>1</sup> in the pool of all pattern models  $c$ .

## Experiments

In the experiments, UDLA was first used to discover recurring acoustic patterns from the familiarization stream, and then to recognize novel test probes using the learned models. During each test round, the system was shown one token from each of the four possible probe classes and the overall activation caused by each token was measured. A total of 600 probe quartets were generated by randomly sampling one token from each probe class for each quartet.

In all experiments, the UDLA model was run with a familiarity threshold of  $t_r = 0.16$  and window step size  $L_s = 50$  ms (5 frames). The analysis window length was set to  $L_r = 200$  ms and  $L_r = 600$  ms for baseline and extended conditions, respectively, so that multiple transitions at maximal lags would fit to the analysis window. These parameters led to the learning of  $N_C = 26-33$  acoustic patterns depending on the familiarization type (continuous vs. segmented), modeling conditions (baseline vs. extended), and on the duration of the familiarization. Since the number of learned patterns exceeded the number of unique syllables (nine), the system had learned multiple context-sensitive variants of syllable-like units.

Figure 1 shows the mean activation levels of the four different probe types (words, part words, rule words and class words) as a function of familiarization duration for segmented (top) and continuous (bottom) familiarization stream in the baseline condition with temporal dependency modeling up to 80 ms. As can be observed, the insertion of 25 ms gaps between tri-syllable words in the familiarization stream is sufficient to induce a change of preference from part words to rule words and class words. This is in line with the behavioral results of Peña et al. (2002) and Endress and Bonatti (2007) who found out that the use of subliminal

<sup>1</sup> The decoding criterion of probabilities was compared across numerous different possibilities, including, e.g., total activation of all models across the entire probe, temporally integrated maximum activation, and number of models exceeding a pre-defined threshold in activation. However, unlike the used approach in Eq. (6), none of the other criteria were able to replicate the main findings of Peña et al. (2002) and Endress & Bonatti (2007).

gaps in the familiarization stream causes a change of preference from part words to rule words and class words at short familiarization periods.

However, when the TPs between acoustic events are measured beyond the typical dependencies in speech signals, the situation changes notably. Figure 3 shows the mean activation levels of the probes in the extended condition where temporal dependencies are modeled up to 390 ms. Despite the fact that the only difference to the earlier simulation is the distance up to which TPs are measured, there is no sign of difference between the continuous and segmented familiarization streams.

Based on the mean probe activities, it seems that the distributional learning of acoustic patterns without any a priori or intervening linguistic component can explain the experimental results of Peña et al. (2002) and Endress and Bonatti (2007), but only if it is assumed that the system is able to learn acoustic dependencies up to a limited temporal distance defined by typical structure in continuous speech. If the dependency modeling is extended up to much longer delays, the UDLA model is no longer able to replicate the behavioral findings.

In addition to computing overall activations, pair-wise comparisons of probe activities were carried out for all possible probe pairs in the test set in order to simulate behavior in a forced-choice task similar to the one used with human experiments.

Figure 2: The mean activation levels of the four different probe types in *baseline condition* for segmented stream (top) and for continuous stream (bottom). Only relative mean activations of the probes are shown (zero mean).

Figure 3: The mean activation levels of the four different probe types in *extended condition* for segmented stream (top) and for continuous stream (bottom).

More specifically, the relative probabilities of the tokens in each pair were compared separately across all 600 test cases in the baseline configuration. For each pair, a binary flag was used to denote a response for the probe that had the higher activation. Then the distribution of responses was tested against the null hypothesis that the model shows no preference for either probe type (*t*-test). Table 1 illustrates the results from the statistical analysis.

It is evident that the segmented familiarization stream leads to a preference order of *words* > *rule words* > *class words* > *part words* at short familiarization durations. On the other hand, continuous stream leads to order of *words* > *part words* > *rule words* and *class words*. This is largely in line with the results of Laakso and Calvo (2011), confirming that a single distributional learning mechanism can explain the change of preference between the two conditions. However, the previous studies do not always report statistically significant order of preference between all probe types (Laakso & Calvo, 2011), whereas the current simulations show statistically significant order of preference for all learning conditions except for the continuous familiarization stream of 3 minutes. This can be largely explained by the fact that the deterministic nature of UDLA leads to a consistent response pattern across multiple trials even for minor statistical biases between the probe types. In contrast, responses of human test subjects contain additional sources of variation (e.g., fatigue) and are based on a limited number of test trials, possibly rendering minor differences in probe familiarity invisible to statistical analysis.

## Discussion

In Peña et al. (2002) and Endress and Bonatti (2007) it was found that adult test subjects, when familiarized with 10 minutes of continuous stream of speech from an artificial language, prefer words over part words and show no preference between class words, part words and rule words. However, when subliminal gaps were introduced between words in the familiarization stream, the participants started to prefer class words and rule words over part words. Based on these findings, Peña et al. (2002) put forward the MOM hypothesis that the learning of a language might consist of several different processes: a distributional process responsible for discovery of statistically significant patterns and a separate mechanism responsible for modeling of structural relation between the discovered patterns. Endress and Bonatti (2007) provided further support to the MOM hypothesis by failing to replicate the behavioral findings of Peña et al. when modeling the learning task with a distributional system (a recurrent neural network or RNN).

Lately, Laakso and Calvo (2011) showed that RNNs can replicate the main behavioral findings of Peña et al. when the modeling parameters are properly set up, and when the silent gaps between syllables are modeled as separate units with equal importance to syllabic units. Their results undermine the argument for the necessity of multiple mechanisms of learning in this specific context. However, Laakso and Calvo limited their analysis to purely linguistic

Table 1: Pair-wise preference for the four different types of test probes with *segmented* (left) and *continuous* (right) familiarization streams. W stands for word, PW for part word, C for class word and R for rule word.

	segmented			continuous		
	preference	%	<i>p</i>	preference	%	<i>p</i>
3 min	W over PW	82.1	0.0000	W over PW	77.8	0.0000
	R over PW	74.0	0.0000	PW over R	57.1	0.0005
	C over PW	70.5	0.0000	PW over C	64.0	0.0000
	W over R	58.8	0.0000	W over R	89.5	0.0000
	W over C	68.3	0.0000	W over C	90.0	0.0000
	R over C	56.9	0.0032	No pref. R and C	51.4	0.5156
10 min	W over PW	78.4	0.0000	W over PW	71.2	0.0000
	R over PW	70.0	0.0000	PW over R	60.1	0.0000
	C over PW	69.1	0.0000	PW over C	57.0	0.0006
	W over R	68.4	0.0000	W over R	83.4	0.0000
	W over C	74.9	0.0000	W over C	79.0	0.0000
	No pref. R and C	55.9	0.0113	C over R	59.7	0.0000

level, assuming that the learner perceives artificial language as a sequence of syllabic units and silences even though the silences were not consciously perceived by the participants.

Current work studied the hypothesis that the findings of Pena et al. could be based on generic distributional learning at the acoustic level instead of using linguistic level representations. More specifically, we analyzed TPs of short-term acoustic events that were extracted from speech in purely unsupervised manner. Notably, we were able to replicate the behavioral findings related to the change of preference across familiarization conditions by using the UDLA model of word learning from continuous speech, but only when the TP analysis of acoustic events was limited to a temporal window matching to the temporal dependencies of normal continuous speech (Räsänen & Laine, 2012).

If this constraint is violated by exceeding the temporal scale of modeling to several hundreds of milliseconds, the model systematically prefers words over part words, and part words over class words or rule words also in case of segmented familiarization stream. The change of model behavior is driven by the fact that the synthesized speech lacks the acoustic variability and lexical complexity of normal speech, and therefore unnaturally strong long-distance dependencies exist in the speech tokens. By modeling the TPs at increasingly long distances, the relative statistical contribution of the short-term gaps between the words in the segmented condition become too small to affect the preference of word tokens in the testing phase.

This suggests that if human responses in the task are based on acoustic level patterning, it may be the case that the human auditory system is not able to capture dependencies at extended temporal distances. This is closely related to the study of Newport and Aslin (2004) who found that adult listeners are unable to learn dependencies between non-adjacent syllables whereas dependencies between non-adjacent segments (either vowels or consonants) were readily learned when familiarized with continuous stream of artificial language. The inability to learn non-adjacent

syllabic dependencies could be also explained by the finite length temporal integration in the auditory processing. Segmental dependencies with an interleaved random segment in between could be readily captured by a system modeling statistical dependencies up to, e.g., 150 ms, but dependencies across multiple syllables may simply be too distant to be captured by such short-term analysis.

Note that the inability to capture acoustic dependencies at longer temporal distances does not imply that long-range linguistic dependencies would not exist or could not be captured by a distributional learning mechanism. It is well known that such dependencies do exist. However, the huge variability and dimensionality of the acoustic space strongly points towards the necessity of an intermediate representation upon which further analysis and learning can take place. Given the current knowledge of human speech perception, it is early to say whether these units are phones, syllables, morphemes or something else (see Räsänen, 2011), and whether the computations are distributional or structural in nature. The current study does not exclude the possibility that the human listeners are directly utilizing syllable level TPs in the artificial language learning task, but simply shows that the TP analysis at the acoustic level can also explain behavioral observations to a large degree.

## Abstract

Collecting cognitive science data using games has the potential to be a powerful tool for recruiting participants and increasing their motivation. However, designing games that provide useful data is a difficult task that often requires significant trial and error. In this work, we consider how to apply ideas from optimal experiment design to designing games for cognitive science experiments. We use Markov decision processes to model players' actions within a game, and then make inferences about the parameters of a cognitive model from these actions. We present a general framework for finding games with high expected information gain based on this approach. We apply this framework to Boolean concept learning, inferring the difficulty of Boolean concepts from participants' behavior. We show that using games with higher expected information gain allows us to make this inference more efficiently.

**Keywords:** optimal experiment design; Markov decision process; computer games; concept learning

## Introduction

Computer games have become increasingly popular tools for gathering psychological data and for educational purposes (e.g., Michael & Chen, 2005; Von Ahn, 2006; Siorpaes & Hepp, 2008; Klopfer, 2008), providing a way to recruit large numbers of motivated participants. However, creating games that actually result in useful data requires significant engineering, normally based on trial and error. In this paper we propose a method for automating the process of designing games, using ideas from optimal experiment design.

The key problem in designing games for cognitive science research is finding a game that provides as much information as possible about the research question being addressed. For traditional experiments, the field of optimal experiment design seeks to choose the design that will give the most information about the dependent variable (Atkinson, Donev, & Tobias, 2007). We adapt this method to identify the game that will give the most information about the parameters of a cognitive model. By automating the process of game design, we limit the trial and error necessary to find a game that will provide useful data, while still reaping the benefits of using games rather than traditional experiments.

Adapting optimal experiment design methods to game design requires predicting people's behavior within games, which may differ from behavior in traditional experiments. For instance, in a categorization experiment a participant's response to a stimulus may roughly correspond to whether she believes the stimulus is in the category. However, in a game this relationship is complicated by competing incentives. For example, available actions in a game may be contingent on

the success of previous actions, leading to complex strategies. We propose using Markov decision processes (MDPs) to predict people's actions in games. MDPs incorporate the current and future benefit of an action, and thus allow us to take into account the incentive structures and rules of a particular game. By combining MDPs with ideas from optimal experiment design, we create a framework for finding the game that will provide the highest expected information gain.

The plan of the paper is as follows. The next section provides background on optimal experiment design and MDPs. We then show how to combine these ideas in a framework for optimal game design. The remainder of the paper applies this general framework to the specific case of learning Boolean concepts, illustrating the benefits of optimal game design. We introduce a novel concept learning game, and use our approach to optimize the game parameters. Two behavioral experiments show that our optimized game results in more efficient estimation of the difficulty of learning different kinds of Boolean concepts, and that the actual amount of information obtained from players is positively correlated with the expected information gain of the game.

## Background

The optimal game design framework we propose relies on ideas from Bayesian experiment design and Markov decision processes, which we will introduce in turn.

### Bayesian Experiment Design

Bayesian experiment design, a subfield of optimal experiment design, seeks to choose the experiment that will maximize the expected information gain about a parameter  $\theta$  (Atkinson et al., 2007; Chaloner & Verdinelli, 1995). In cognitive science, this procedure and its variations have been used to design more informative experiments that allow for clearer discrimination between alternative hypotheses (Myung & Pitt, 2009). Throughout this paper, let  $\xi$  be an experiment (or game) design and  $y$  be the data collected in the experiment. Then the Bayesian experimental design procedure is as follows:

$$\begin{aligned} \text{maximize } U(\xi) &= \int p(y|\xi)U(y, \xi)dy \\ \text{where } p(y|\xi) &= \int p(y|\xi, \theta)p(\theta)d\theta \\ \text{and } U(y, \xi) &= \int (H(p(\theta|y, \xi)) - H(p(\theta)))d\theta, \quad (1) \end{aligned}$$

where  $H(p)$  is the Shannon entropy of a probability distribution  $p$ , defined as  $H(p) = \int p(x)\log(p(x))dx$ . Thus, the

procedure maximizes the expected utility of an experiment  $\xi$ , defined as the information gain over all outcomes  $y$  weighted by their probabilities  $p(y|\xi)$  under the current prior.

### Markov Decision Processes

The Bayesian experiment design procedure uses  $p(\theta|y, \xi)$  to calculate the information gain from an experiment. This quantity represents the impact that the data  $y$  collected from experiment  $\xi$  have on the parameter  $\theta$ . In a game, the data  $y$  are a series of actions, and to calculate  $p(\theta|y, \xi)$ , we must interpret how  $\theta$  affects those actions. Via Bayes' rule, we know  $p(\theta|y, \xi) \propto p(y|\theta, \xi)p(\theta)$ . We thus want to calculate  $p(y|\theta, \xi)$ , the probability of taking actions  $y$  given a particular value for  $\theta$  and a game  $\xi$ . To do so, we turn to Markov decision processes (MDPs), which provide a natural way to model sequential actions. MDPs and reinforcement learning have been used previously in game design for predicting player actions and adapting game difficulty (Erev & Roth, 1998; Andrade, Ramalho, Santana, & Corruble, 2005; Tan & Cheng, 2009).

MDPs describe the relation between an agent's actions and the state of the world and provide a framework for defining the value of taking one action versus another (see Sutton & Barto, 1998). Formally, an MDP is a tuple  $\langle S, A, T, R, \gamma \rangle$ , where  $S$  is the set of possible states and  $A$  is the set of actions that the agent may take. The transition model  $T$  gives the probability  $p(s'|s, a)$  that the state will change to  $s'$  given that the current state is  $s$  and the agent takes action  $a$ . The reward model  $R(s, a, s')$  describes the probability of receiving a reward  $r \in \mathbb{R}$  given that action  $a$  is taken in state  $s$  and the resulting state is  $s'$ . Finally, the discount factor  $\gamma$  represents the relative value of immediate versus future rewards. The value of taking action  $a$  in state  $s$  is defined as the expected sum of discounted rewards and is known as the Q-value:

$$Q(s, a) = \sum_{s'} p(s'|s, a) \left( R(s, a, s') + \gamma \sum_{a' \in A} p(a'|s') Q(s', a') \right), \quad (2)$$

where  $p(a'|s')$  is the probability that an agent will take action  $a'$  in state  $s'$  and is defined by the agent's policy  $\pi$ . We assume that people's actions can be modeled as a Boltzmann policy, as in Baker, Saxe, and Tenenbaum (2009):

$$p(a|s) \propto \exp(\beta Q(s, a)), \quad (3)$$

where higher values of  $\beta$  mean the agent is more likely to choose the best action, while  $\beta = 0$  results in random actions.

### Optimal Game Design

We can now define a procedure for optimal game design, identifying the game with maximum expected information gain for  $\theta$ . We assume there is an existing game design with parameters to adjust, corresponding to point values, locations of items, or any other factor that can be varied. To apply Bayesian experiment design to choosing a game, we define the utility of a game  $\xi$  as the expectation of information gain over the true value of  $\theta$  and the actions chosen by the players:

$$U(\xi) = E_{p(\theta, \mathbf{a})} [H(p(\theta)) - H(p(\theta|\mathbf{a}, \xi))], \quad (4)$$

where  $\mathbf{a}$  is the set of action vectors for all players. The expectation is approximated by sampling  $\theta$  from the prior  $p(\theta)$ , and then simulating players' actions given  $\theta$  by calculating the Q-values for the MDP and sampling from Equation 3.

The remaining quantity in Equation 4 is  $p(\theta|\mathbf{a}, \xi)$ . Intuitively, this quantity connects actions taken in the game with the parameter of the cognitive model that we seek to infer,  $\theta$ . For a game to yield useful information, it must be the case that people will take different actions for different values of  $\theta$ . Concretely, we expect that players' beliefs about the reward model and the transition model may differ based on  $\theta$ . For instance, in a categorization task with two objects  $A$  and  $B$ ,  $\theta$  might determine the probability that  $A$  is a positive instance and  $B$  is a negative instance of the category. If taking a particular action leads to positive rewards only when a positive instance is observed, then we would expect that the value of  $\theta$  is large if many players take that action when observing  $A$ .

The process of inferring  $\theta$  from actions assumes that each  $\theta$  corresponds to a particular MDP. If this is the case, we can calculate a distribution over values of  $\theta$  based on the observed sequences of actions  $\mathbf{a}$  of all players in the game  $\xi$ :

$$p(\theta|\mathbf{a}, \xi) \propto p(\theta)p(\mathbf{a}|\theta, \xi) \quad (5)$$

$$= p(\theta)p(\mathbf{a}|\text{MDP}_\theta, \xi) \quad (6)$$

$$= p(\theta) \prod_i p(\mathbf{a}_i|\text{MDP}_\theta, \xi), \quad (7)$$

where  $\mathbf{a}_i$  is the vector of actions taken by player  $i$  and  $\text{MDP}_\theta$  is the MDP derived for the game based on the parameter  $\theta$ . Calculating this distribution can be done exactly if there is a fixed set of possible  $\theta$  or by using Markov chain Monte Carlo (MCMC) methods if the set of  $\theta$  is large or infinite (see Gilks, Richardson, & Spiegelhalter, 1996).

Now that we have defined  $p(\theta|\mathbf{a}, \xi)$ , we can use this to find the utility of a game. Equation 4 shows that this calculation follows simply if we can calculate the entropy of the inferred distribution. In the case of a fixed set of possible  $\theta$ ,  $H(p(\theta|\mathbf{a}, \xi))$  can be calculated directly. If MCMC is used, one must first infer a known distribution from the samples and then take the entropy of that distribution. For example, if  $\theta$  is a multinomial and  $p(\theta)$  is a Dirichlet distribution, one might infer the most likely Dirichlet distribution from the samples and find the entropy of that distribution.

We have now shown how to (approximately) calculate  $U(\xi)$ . To complete the procedure for optimal game design, any optimization algorithm that can search through the space of games is sufficient. Maximizing over possible games is unlikely to have a closed form solution, but stochastic search methods can be used to find an approximate solution to the maximum utility game. For example, one might use simulated annealing (Kirkpatrick, Gelatt, & Vecchi, 1983). This method allows optimization of both discrete and continuous parameters, where neighboring states of current game are formed by perturbations of the parameters to be optimized.

Figure 1: Boolean concept structures. In each structure, eight objects differing in three binary dimensions are grouped into two categories of four elements. Each object is represented as a corner of a cube based on its combination of features, and the objects chosen for one category in each problem type are represented by dots.

## Optimal Games for Boolean Concept Learning

We have described a general framework for automatically finding games that are potentially highly informative about model parameters. To test this framework, we applied it to a particular question: What is the relative difficulty of various Boolean concept structures? This question has been studied in past work (e.g. Shepard, Hovland, & Jenkins, 1961; Griffiths, Christian, & Kalish, 2008), so we can compare our results to those produced using more traditional methods. We first describe Boolean concept learning, and then turn to the game we created and the application of optimal game design.

### Boolean Concepts

In Boolean concept learning, one must learn how to categorize objects that differ along several binary dimensions. We focus on the Boolean concepts explored in Shepard et al. (1961). In these concepts, there are three feature dimensions, resulting in  $2^3$  possible objects, and each concept contains four objects. This results in a total of 70 concepts with six distinct structures, as shown in Figure 1. Shepard et al. (1961) found that the six concept structures differed in learning difficulty, with a partial ordering from easiest to most difficult of  $I > II > \{III, IV, V\} > VI$ . Similar results were observed in later work (Nosofsky, Gluck, Palmeri, McKinley, & Glauthier, 1994; Feldman, 2000) although the position of Type VI in the ordering can vary (Griffiths et al., 2008).

To model learning of Boolean concepts, we assume learners' beliefs about the correct concept  $h$  can be captured by Bayes' rule (Griffiths et al., 2008):

$$p(h|\mathbf{d}) \propto p(h)p(\mathbf{d}|h) \quad (8)$$

$$= p(h) \prod_{d \in \mathbf{d}} p(d|h), \quad (9)$$

where each  $d \in \mathbf{d}$  is an observed stimulus and its classification, and observations are independent given the category.

The likelihood  $p(d|h)$  is then a simple indicator function:

$$p(d|h) \propto \begin{cases} 1 & \text{if } h \vdash d \\ 0 & \text{otherwise} \end{cases}, \quad (10)$$

where  $h \vdash d$  if the stimulus classification represented by  $d$  matches the classification of that stimulus in hypothesis  $h$ . We seek to infer the prior  $p(h)$ , which represents the difficulty of learning different concepts and thus gives an implicit ordering on structure difficulty. In our earlier terminology,  $\theta$  is a prior distribution on concepts  $p(h)$ . For simplicity, we assume all concepts with the same structure have the same prior probability, so  $\theta$  is a 6-dimensional multinomial.

### Corridor Challenge

To teach people Boolean concepts we created the game Corridor Challenge, which requires learning Boolean concepts to achieve a high score. Corridor Challenge places the player in a corridor of islands, some of which contain a treasure chest, joined by bridges (Figure 2).<sup>1</sup> The islands form a linear chain and the bridges can be crossed only once, so players cannot return to previous chests. Some chests contain treasure, while others contain traps; opening a chest with treasure increases the player's score and energy, while opening a chest with a trap decreases these values. Each chest has a symbol indicating whether it is a trap; symbols differ along three binary dimensions and are categorized as a trap based on one of the Boolean concepts. Players are shown a record of the symbols from opened chests and their meanings (see the right hand side of Figure 2). Players are told to earn the highest score possible without running out of energy, which is depleted by moving to a new island or opening a trapped chest. When a player runs out of energy, the level is lost and she cannot explore the rest of the level; surviving a level earns the player 250 points. Corridor Challenge games may consist of several levels. Each level is a new corridor with different chests, but the same symbols are used and they retain the same meaning as on the previous level. At the start of each level, the player's energy is restored, but points are retained from level to level.

### Optimizing Corridor Challenge

Applying optimal game design to Corridor Challenge requires specifying the parameters to optimize in the search for the optimal game, formulating the game as an MDP, and specifying the model for how the player's prior on concepts ( $\theta$ ) relates to the MDP parameters. The structure of Corridor Challenge allows for many variants that may differ in the expected information gain. To maximize expected information gain while keeping playing time relatively constant we limited the game to two levels, with five islands per level. We then used optimal game design to select the number of points gained for opening a treasure chest, points lost for opening a trap chest, the energy lost when moving, the symbols that

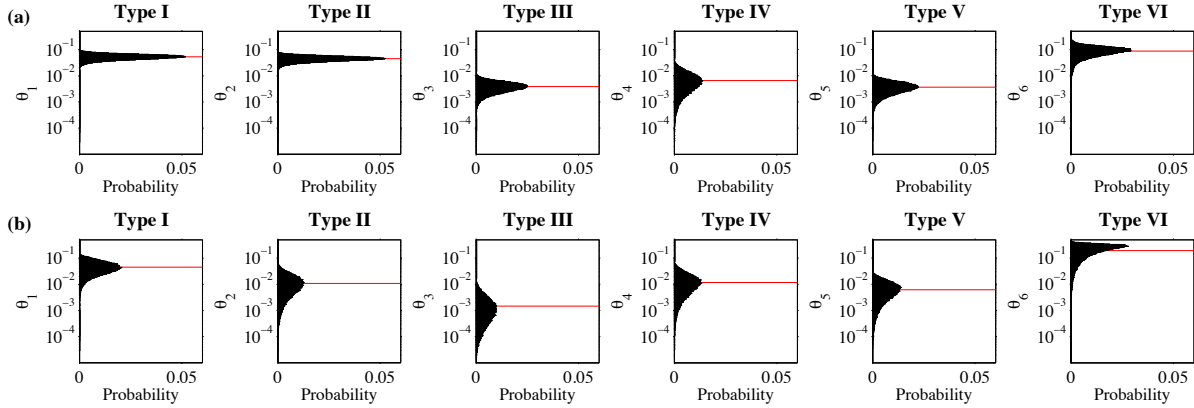

Figure 3: Results of Experiment 1, in the form of posterior distributions on concept difficulty from participants’ responses in (a) the optimized game and (b) the random game; red lines indicate the mean of each distribution. Each panel shows the distribution over the inferred difficulty of a concept with the given structure (Types I-VI), as reflected by its prior probability in the Bayesian model. Concepts with higher prior probability are easier to learn. Note the logarithmic scale.

high information gain had true concepts with different structures. While the information gain found for any given game is approximate, since we estimated the expectation over possible priors with only 35 samples, this was sufficient to separate poor games from relatively good games; we explore this relationship further in Experiment 2.

## Experiment Methods

**Participants.** A total of 50 participants were recruited online and received a small amount of money for their time.

**Stimuli.** Participants played Corridor Challenge with parameters set based either on an optimized game (expected information gain of 3.4 bits) or on a random game (expected information gain of 0.6 bits). The symbols differed along the dimensions of shape, color, and pattern.

**Procedure.** Half of the participants were randomly assigned to each game design, and played the game in a web browser. The participants were shown text describing the structure of the game, and then played several practice games to familiarize them with interface. The first practice game simply had chests labeled “Good” and “Bad”; the next three games used Boolean concepts of increasing difficulty based on previous work. All practice games used different symbols from one another and from the final game. Practice games used the point and energy values from the game chosen for their condition (i.e., the random game or the game found by the search) in order to make players aware of these values, but the symbols in the practice games were identical across conditions. The final game differed by condition. After completing the final game, participants were asked to rate how fun and how difficult the game was, both on 7-point Likert scales. Additionally, they were shown the stimuli and categorization information that they observed during the final game, and asked to classify the remaining stimuli from the game that were not observed.

## Results

Figure 3 shows the inferred distribution over the prior probability of each concept ( $\theta_i$ ) based on participants’ actions

for the optimized game and the random game; if a concept has higher prior probability, it will be easier to learn. These distributions were obtained via MCMC using a Metropolis-Hastings algorithm on both the prior and the noise parameter  $\beta$ . Results show samples generated from five chains with 100,000 samples each; the first 10% of samples from each chain were removed for burn-in.

Qualitatively, the distributions inferred from the optimized game appear more tightly concentrated than those from the random game; this is confirmed by the actual information gain, which was 3.30 bits for the optimized game and 1.62 bits for the random game. This implies that we could halve the number of participants by running the optimized game.

For both games, the ordering of the mean prior probabilities of each type, shown by red lines in Figure 3, is the same as that found in previous work, except for Type VI. Our inferred distributions for Type VI placed significant probability on many values, suggesting that we simply did not gain much information about its actual difficulty. We do infer that Type VI is easier than Types III, IV, or V, which has a precedent in the results of Griffiths et al. (2008).

## Experiment 2: Estimating Information Gain

To verify the relationship between actual and expected information gain, we conducted a second experiment in which players played games with a range of information gains. In order to isolate the impact of the symbols on the chests and the true concept we fixed the point structures to those found for the optimized game in Experiment 1 and conducted new searches over the remaining variables. We then selected games from the search paths that had varying expected information gains, demonstrating that even without changing the incentive structure a range of information gains was possible.

## Methods

**Participants.** A total of 175 participants were recruited online and received the same payment as in Experiment 1.

**Stimuli.** Participants played one of seven new games.

Figure 4: Results of Experiment 2, showing expected versus actual information gains ( $r = 0.72$ ). Each circle represents a game, and the least-squares regression line is shown.

**Procedure.** Procedure matched Experiment 1.

## Results

We compared the actual and expected information gains for the seven new games and the optimized game from Experiment 1, all of which used the same point structure. As shown in Figure 4, we found that expected and actual information gain were positively correlated ( $r(6) = 0.72$ ,  $p < 0.05$ ). This demonstrates that the design of the game does influence how much information we can infer from human players' actions, and that this gain is predicted by our estimates.

## Conclusion

We have presented a general framework for the optimal design of games for cognitive science experiments that adapts ideas from Bayesian experiment design. Our methodology hinges on using Markov decision processes to infer cognitively relevant information from players' actions. By combining this model with a stochastic search method, we were able to find appreciably more informative games for Boolean concept learning. Our experimental results demonstrate that using this framework to infer concept difficulty gives similar results to prior work, and that the expected information gain of a game predicts the actual information gain when the game is played by real players. One of the chief advantages of this framework is its applicability to a wide variety of scenarios, from creating other types of games that examine different psychological questions to designing optimally informative assessments within educational software.

There are a number of ways in which this initial test of a framework for designing games could be expanded. In this work, we ignored the value of information for computational tractability. However, people may consider how their future knowledge will be affected by their current actions, leading to deviations from our model's predictions; compar-

ing the fit of a partially observable Markov decision process model to the fit of an MDP model would help to determine whether this is an issue. In the optimal game design procedure, one might also want to explore other metrics than entropy for measuring a game's expected utility. For instance, one might use a loss metric that considers the distance of samples from the true value of  $\theta$ . Finally, it would be interesting to explore whether there are advantages beyond motivation for using games rather than traditional experiments. While there remain many areas for future exploration, this work gives a starting point for designing highly informative games and gives experimental support that these games can provide meaningful data for cognitive science.

# Cognitive Workload and the Motor Component of Visual Attention

Jason Ralph, Wayne D. Gray, & Michael J. Schoelles  
Rensselaer Polytechnic Institute

## Abstract

Outside the laboratory, the ability to control visual input during multiple task performance by controlling *where the eyes look and when* is an obvious component of multiple task performance. However, inside the laboratory researchers either obviate the control of the eyes by presenting information from one task at a time or are oblivious to the need for *just-in-time* control of the motor component of visual attention. We investigate the effects of cognitive workload on eye movements in a paradigm that controls the demand on the eyes as an input channel while increasing workload by increasing the demand on working memory. Despite constant visual demands, we find that fixations become more scattered with increasing working memory load.

**Keywords:** dual mechanisms of control, cognitive control, cognitive workload

## Introduction

Our ability to switch among multiple tasks has been the subject of extensive research for many decades (Allport, Styles, & Hsieh, 1994; Altmann & Gray, 2008; Broadbent, 1952; Cherry, 1953). People generally exhibit a multitask effect in which they are slower and commit more errors when performing multiple concurrent tasks than a sequential series of the same tasks. Most theories of multitasking propose a resource capacity explanation for this multi-task effect. These theories, including Wicken's multiple resource theory (MRT) (Wickens, 2002; Wickens & Colcombe, 2007), and Salvucci and Taatgen's threaded cognition (Salvucci & Taatgen, 2008; Salvucci & Taatgen, 2011), propose a variety of resources which must be shared by concurrent tasks. They argue that when the capacity of one of these resources is exhausted, the cognitive system must wait for the bottleneck to clear, which causes slower task execution.

MRT identifies input modalities (visual or auditory), response modalities (motor, vocal), and cognition as resources responsible for multi-task effects (Wickens, 2002; Wickens, 1992; Wickens, Goh, Helleberg, Horrey, & Talleur, 2003). For instance, if two tasks require visual processing, performance will be slower because the capacity of the visual processor is limited. MRT has not been instantiated in computational form but its assumptions appear compatible with other capacity theories such that multiple tasks can be performed without interference until some capacity limit is reached (e.g., see Just, Carpenter, & Hemphill, 1996a, 1996b).

Threaded cognition is a model based procedural theory

of task switching, which is implemented within the ACT-R cognitive architecture (Anderson et al., 2004). In this theory, "concurrent multitasking emerges from the interaction of autonomous process threads in conjunction with a straightforward mechanism for resource acquisition and conflict resolution," (Salvucci & Taatgen, 2008, p. 102). Although we see Threaded Cognition as a major advance in the modeling of complex cognition, at present it focuses on the control of task switching per se, not on the control of tasks.

As detailed by the Dual Mechanisms of Control (DMC) theory (Braver, Gray, & Burgess, 2007; Braver, 2012), the brain's ability to prepare ahead of time (proactive control) is limited. Proactive control requires that the strategy and information for a task be kept active. Hence, proactive control places strategies such as the verbal-articulatory loop (Baddeley, 2012) and updating, shifting, and inhibition (Miyake et al., 2000) under control of the PFC and subject to limits in PFC processing. The importance of proactive control depends on the nature of the task being performed. In situations with a limited number of stimuli and responses (i.e., most experimental psychology tasks), then proactive control seems best. However, in tasks that require the subject to respond to one of a number of different stimuli in a number of different ways (e.g., driving on the freeway during rush hour) then reactive processing seems required. Cognitive control is recruited by a mix of proactive and reactive influences, and understanding how this mix changes based on task demands is key to understanding performance of multiple tasks.

We hypothesize that differences between single-task and multi-task performance depend on how the brain manages the demands on proactive control. A major limiting factor in multitasking is our ability to distribute our attention to perform multiple concurrent tasks. In visual tasks, the capacity of the eyes to focus on one part of the visual scene at a time is a factor constraining our performance. Many tasks require the ability to control eye movements to capture required information from the world, or to maintain sustained focal attention.

The ability to control our eyes during task performance is an overlooked but critical variety of control. Unless we assume that pointing-the-eyes at potentially informative areas of visual interest is somehow both automatic and effortless, then the need to control gaze to optimize task performance adds yet another burden to our control mechanisms. Hence, it may be possible to determine when a switch in

control mode has occurred by examining patterns of eye fixations. We hypothesize that effective proactive control results in long, constant fixations on the area of the visual scene related to a task. As the demands on proactive control increase, eye movements should become more scattered, evidenced by short fixation durations spread across a wider area. After presenting our paradigm and results, we return to speculative discussion of this issue in our Discussion section.

## Previous Research

In prior research, we found that performance in a dual-task paradigm was affected by requiring subjects to look in different locations for information needed for different tasks (Ralph, Gray, & Schoelles, 2010). Subjects performed a continuous visual tracking task while concurrently performing an n-back style memory task. (The paradigm will be explained in detail in the methods section below.) Consistent with an MRT prediction, subjects who received information aurally outperformed those who received it visually. However, we could not determine whether auditory instruction relieved the cognitive demands of the task, or simply the visual demands.

The DMC account implies that proactive control of behavior relies on a common set of PFC mechanisms. Viewing the eye as something that needs to be controlled, we hypothesize that it is the extra control of the eye that contributes to the auditory vs visual tasks differences, not necessarily the differences in auditory vs visual processing (as implied by MRT).

To test this hypothesis, the current study compares two visual conditions which share the same visual demands, but differ in the cognitive (working memory) requirements. This differs from most MRT research, which typically increases cognitive load by increasing the difficulty of visual tracking (Wickens et al., 2003). In the current study, differences in eye movement behavior and performance cannot be attributed to increased demands on the eye as these demands are identical across conditions. Thus the focus of the current study is on how increased demands for proactive control affect eye movement strategies and performance in the absence of additional demands for the control of the eye.

## The Study

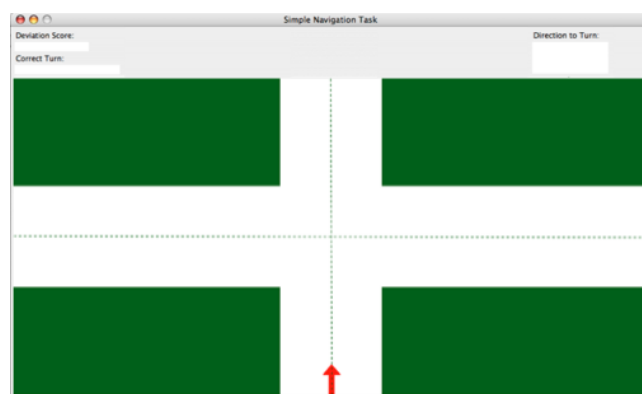

The NavBack paradigm was designed to collect detailed empirical data in a task at the approximate complexity of those used by Wickens in testing MRT (e.g., Martin-Emerson & Wickens, 1992, 1997). The NavBack task combines a tracking task with a working memory task. The tracking task requires the subject to keep an arrow centered as it *jitters* (i.e., moves randomly) from side to side. Concurrently, subjects perform a continuous working memory span task, which is similar to the n-back memory task (Gevins & Smith, 2003; Jaeggi et al., 2010; McEvoy, Smith, & Gevins, 1998). In the high workload conditions, subjects must maintain a

list of instructions in memory of how to *turn* in the next three intersections (e.g., “left”, “right”, or “forward”). After each intersection the subject has to delete the just completed instruction and add a new instruction to the end of his mental list. In the low workload condition, only one instruction must be maintained.

## Methods

### Subjects

22 undergraduate students of Rensselaer Polytechnic Institute (mean age = 19) volunteered to participate in this study for course credit. Eleven subjects were randomly assigned to each of two conditions: *High Memory* or *Low Memory*.

*Figure 1.* Screenshot of the NavBack Paradigm. Subjects must keep the arrow in the center of the road as they receive turn instructions in the box at the upper right corner. The arrow remained at the bottom of the screen, and the “road” scrolled downward, simulating forward movement. Subjects could turn when the arrow was in the intersection.

### Apparatus and Materials

The experiment was run on an Apple Mac Mini computer (running Mac-OS 10.4) at a 1024x768 screen resolution. Eye fixation data were collected using an LC Technologies tracker at a 120 Hz sampling rate. A chin-rest was used to stabilize head movements and ensure a fixed viewing distance of 60 cm. The NavBack software is a custom application implemented in Lispworks 5.1.

### Design

**Between-Subject Condition: Memory Load.** Each memory load condition received a new direction (the turn to make in the future) while traveling through a “city block”. For the *High Memory* condition, the new instruction specified how to turn three intersections in the future. In the *Low Memory* condition, the new instruction specified how to turn at the next intersection. Hence, the memory load for the High vs Low Memory conditions was three versus one items.

### Within-Subject Condition: Instruction Presentation

**Time.** All subjects received the new turn instruction *early*, *middle*, or *late* during their *travel* through a city block. The instruction appeared for 2-s beginning either 1-s, 3.4-s, or 5-s after the arrow exited the intersection and entered the next city block. On any given episode cycle, whether the instruction was presented early, middle, or late was determined randomly.

### Procedure

Each subject completed a 2-min practice session to familiarize them with the demands of the task, followed by eight 5-min experimental blocks. Each 5-min block consisted of a continuous series of episode cycles. Each cycle began when the tip of the arrow left an intersection and entered the next city block (city blocks are the green areas in Figure 1). At one of three randomly chosen times a new instruction appeared in the direction box on the upper right of the screen (see Figure 1). Travel time through each city block was 6-s.

Although, once in the intersection, subjects could turn at any time, minimizing the jitter score required the subject to turn at the exact center of the intersection. The animation for the turn added 1,500 ms to the time spent in the intersection when subjects made left or right turns. During each episode cycle subjects had to do two related tasks: the jitter task and the turn direction task. The jitter task is a visual-motor task requiring constant attention. The turn-direction task requires monitoring for the appearance of a new turn direction while performing the jitter task. Depending on condition subjects needed to hold either one or three turns in memory. Each new episode cycle required them to update the list of items held in memory.

### Jitter Task: Visual-Motor

Subjects were instructed to keep the arrow in the center of the road (on the dotted line in Figure 1) as the arrow *jittered* actively from side to side, every 200 ms, based on a pseudo-random function. Subjects corrected the arrow's horizontal position by pressing the *a* and *d* keys on a standard keyboard. Their goal was to keep the arrow as close to the center of the lane as possible. The arrow's position at the beginning of each city block was determined by the timing of the previous turn. If the previous turn (left or right) was initiated at the exact vertical center of the intersection, then the arrow began the next city block in the center of the lane. If the turn was initiated early or late, it began the next city block deviated from the center by an amount proportional to the distance from the turn point to the center of the intersection. (Ss were not instructed on this aspect of the task.) The computer logged the absolute value of the number of pixels deviated from the center every 200 ms. We refer to this value as "jitter score".

Figure 2. Mean jitter scores for middle instruction city blocks. The gray rectangle denotes when the instruction was on-screen.

### Turn Direction Task: Working Memory Updating

Concurrent with the Jitter Task, subjects were required to keep either one or three turns in memory (e.g., left, right, forward). At the beginning of a 5-min set, high memory subjects were presented with the initial three turns that were to be made in the first, second, and third intersection. After the set began, new turn directions appeared at one of the three times described earlier. The direction presentation time was randomly chosen for each city block.

As discussed previously, success in the high memory condition essentially required subjects to rehearse, update, and maintain a list of three instructions. Subjects had to mentally delete the instruction for the just completed turn and to append a new instruction at the end of their mental list. Subjects in the low memory group had to remember only the most recently presented direction. Feedback on the correctness of the most recent turn was available at the top left of the screen (see Figure 1).

### Results

**Jitter Scores.** An analysis of variance was performed on jitter scores by memory load and instruction time and revealed main effects of memory load  $F(1,20)=7.96$   $p<.02$ , and instruction time  $F(2,40) = 17.31$   $p<.001$ . High memory subjects ( $M=10.42$  pixels  $SD=2.03$ ) had higher mean jitter scores than low memory subjects ( $M=8.38$  pixels,  $SD=1.05$ ). Figure 2 shows the mean jitter scores throughout an average city block (for middle instruction times). Low memory subjects outperformed high memory subjects throughout the city block.

**Turning Task.** The turn results were as expected with the Low Workload group more accurate (94.64%) than the High Workload group (85.31%). These differences were significant ( $F(1,20) = 12.57$   $p<.01$ ) but will not be discussed further in this short report.

**Fixation Locations.** Analysis of the eye data was performed using the areas of interest displayed in Figure 3. Only data recorded while the arrow was within a city block is included (e.g. not in an intersection). The data yielded several differences in fixations between the high vs low memory conditions. Figure 4 shows the proportion of time spent looking at the arrow, direction box, and road areas. High memory subjects spend less time fixated on the arrow and more time looking at the direction box throughout the city block. This difference is most pronounced before the instruction appears (compare Figure 5 top and bottom for those times before the appearance of the instruction), suggesting that low memory subjects employed a more economical strategy to monitor the direction box for the appearance of the arrow. As Figures 4 and 5 demonstrate, compared to low memory subjects, high memory ones devoted proportionately more time looking at the direction box and less time looking at the arrow<sup>1</sup>.

The fixation pattern for low memory subjects likely reflects a proactive strategy designed to maximize time spent fixating on the arrow while maintaining the ability to monitor for instructions. It is a strategy that high memory subjects were either unwilling or unable to pursue.

Figure 3. Areas of Interest used for the analysis of eye fixations. Shaded areas represent the arrow, direction box (upper right), feedback (upper left), and road areas.

#### Eye Movements Reveal Task Priority Differences with Workload.

Figures 4 and 5 limit the data they present to the four task relevant areas shown in Figure 3. We find it both interesting and important that the two conditions spent different proportions of time gazing at screen areas relevant to different parts of the task. The low workload condition spent more time on jitter related areas (e.g. arrow), and the high memory condition spent more time looking at areas relevant to the turning task (e.g direction box, road).

We further examined the degree of task focus by conducting an analysis of the variability of eye fixations throughout the screen area for the two conditions (see Figure 6). For this analysis, we split the screen into 30x30 pixel boxes and computed the standard deviation of the number of fixations

Figure 4. Time spent fixating on the arrow, direction box and road areas, respectively. High Memory subjects spent more time looking at the road and direction box.

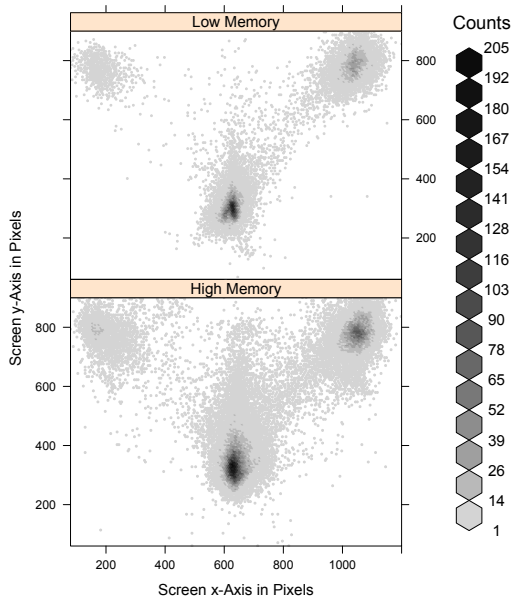

Figure 5. Proportion of time spent fixating on the direction box (top) and arrow (bottom) for middle instruction city blocks. The gray area represents the time period when the instruction is on-screen.

per box for each subject. By this measure, increasing standard deviations show that subjects focus more on some of the pixel boxes than others. The lower the standard deviation, the more evenly spread the fixations are across all pixel boxes. An analysis of variance performed on this measure shows that the fixations of high memory subjects were significantly

<sup>1</sup>Less than 4% of fixations for *high memory* and 3% of fixations for *low memory* subjects were to the *feedback* area with large variations between-Ss within the same group. A one-way ANOVA on that area was not significant.

more evenly distributed (i.e., more scattered) than those of low memory subjects  $F(1,20)=8.31$   $p<.01$ . But, when separated into the relevant areas of interest, individual ANOVAs showed that high memory subjects were more scattered in the *arrow* area  $F(1,20) = 4.18$   $p<.05$ , but not in the *direction box* or *road* areas.

**Figure 6.** Density plot of eye fixations on screen for Low Memory (top) and High Memory (bottom) groups. Scale on the right shows the density count for the number of fixations centered at each pixel of the screen. Note that despite the same nominal task requirements for where-to-look-when the High Memory group scattered their fixations more across the entire screen than did the Low Memory group.

## Discussion

As the jitter and memory tasks do not share any obvious resource conflicts, it is unlikely that resource based theories of multitasking (such as MRT) would predict the effects of memory load on jitter task performance. Likewise, as there are only two tasks being interleaved, it is also unlikely that Threaded Cognition would predict differences in how they are controlled. Yet our results show a significant difference in *inattention* to task relevant areas between conditions.

A general theory of cognitive control must explain the control required to switch among multiple tasks as well as the control required to perform each single task. For many tasks, a bridge between these two types of control may lie in understanding the role of eye movements. In our study, low memory subjects performed better on the jitter task than high memory subjects throughout the average city block. In addition, our microanalysis revealed that visual attention on

the arrow is a very important factor in predicting jitter performance. Jitter performance in both conditions suffered in the time period before instructions were presented (as per Figure 2), as visual attention had to be split between the arrow and direction box.

Eye fixation data suggested major differences in the allocation of control caused by memory load. Low memory subjects were able to remain fixated on the arrow for much longer periods of time than high memory subjects. Fixations to the direction box increased until an instruction appeared for high memory subjects, but remained relatively constant for low memory subjects<sup>2</sup>.

The demands on the proactive working memory system had an impact on the fixation strategy employed. The data suggest that high memory fixations reflect a different proactive strategy meant to focus on the turn instruction at the cost of a loss of focus on the arrow. Despite this difference in strategy, our variability measure showed that memory load also caused the high memory condition to lack focus on the arrow *while they were looking at it*. It can be argued that Increased memory load indirectly affected jitter performance by causing a lack of task focus. Task that require constant focus for optimal performance (like our jitter task) will be particularly susceptible to this effect.

In currently planned studies, we hypothesize that these results are not a special case, but rather a demonstration of how cognitive control affects the use of all the brain's resources. We can no longer assume, as Threaded Cognition does, that task performance is only subject to the control required to switch tasks. We must also consider the effects that overall control demands have on how we perform each task. Recent research points to differences in the use of proactive control in affecting behavior in many tasks, including the attentional blink (Taatgen, Juvina, Schipper, Borst, & Martens, 2009), AX-CPT (Braver et al., 2007), and n-back (Szmales, Verbruggen, Vandierendonck, & Kemps, 2011) tasks. Our future research will focus on the mode of control (e.g. proactive/reactive) to help us explain these complex multitask effects that do not fit into a strict resource (MRT) framework.

Research reported in this paper has been supported, in part, by grant N000141010019 to Wayne Gray from the Office of Naval Research, Dr. Ray Perez, Project Officer. Julia Van Cleve and Matt Nebel assisted in data collection.

<sup>2</sup>We remind the reader that the data presented in Figure 5 is for those trials on which Ss received their instruction in the middle of the city block. These data are representative of the early and late conditions in that those conditions also show increased fixations on the Direction Box until the instruction is presented for both Low and High load conditions with High > Low.

## Abstract

Sequentially observed symptoms in diagnostic reasoning have to be integrated to arrive at a final diagnosis. In our experiments employing quasi-medical problems, four sequentially presented symptoms were consistent with multiple diagnostic hypotheses. We tested whether symptom order creates biases in symptom evaluation. Early symptoms induced a bias towards the initial hypothesis even though an alternative hypothesis was equally supported. In two experiments, stepwise ratings were prompted to explicitly highlight alternative hypotheses. Explicit highlighting eliminated the bias towards the initial hypothesis if only two hypotheses competed, but the bias remained if more than two hypotheses were associated with symptoms in a sequence. Our results are consistent with process models of information integration that specify how early information can frame the processing of later information. Extending previous results obtained with fewer contending hypotheses, we show limits in impartially considering more than two hypotheses.

**Keywords:** Order Effects; Diagnostic Reasoning; Multiple Candidate Hypotheses; Construction Integration Theory

## Introduction

When humans explain observations in their environment, they apply knowledge about possible causes and the effects that each cause can bring about. Explaining observed symptoms by a diagnosis that specifies the most probable cause can be difficult for symptoms which are ambiguous and thus consistent with multiple diagnoses or inconsistent and hard to subsume under a single diagnosis (Johnson & Krems, 2001). Imagine the sequential integration of symptoms in medical diagnosis in its simplest form: You, a physician, become aware of a symptom pointing towards different possible diseases your new patient might have caught. Bit by bit you take notice of a second, third and a fourth symptom. Some of them are unspecific, others strengthen your belief in a diagnosis and weaken

alternatives, but none is decisive by itself. The order in which symptoms are encountered can influence the final diagnosis because the initial diagnostic hypotheses may affect how the subsequent symptoms are weighed and integrated (e.g., Chapman, Bergus & Elstein, 1996). If symptoms are observed in sequence, the initially encountered symptoms trigger diagnostic hypotheses (Mehlhorn, Taatgen, Lebiere, & Krems, 2011).

Sequential symptom processing towards the initial hypothesis demonstrates a confirmation bias (Nickerson, 1998), which would be overcome if all alternative diagnostic hypotheses could be considered in parallel. In previous studies such impartial symptom integration sometimes succeeded for two alternative diagnoses (McKenzie, 1998), but doubts have been raised whether more than two alternative diagnoses can be considered impartially in parallel (Dougherty & Hunter, 2003).

According to normative Bayesian information integration, the order of symptom presentation should not matter. Symptom patterns equally supportive of two alternative diagnoses should produce equal proportions of these diagnoses. However, already updating of a single hypothesis can be biased by the order, in which pieces of evidence are encountered (Wang, Johnson, & Zhang, 2006). Hogarth and Einhorn (1992) specified circumstances under which normative updating of a single belief is possible and no order effects should occur (e.g. stepwise simple evaluation of short and consistent sequences). Yet, models of sequential information integration including the belief adjustment model of Hogarth and Einhorn (1992) typically postulate a disproportionately large influence of early encountered information resulting in a *primacy effect*.

When multiple diagnostic hypotheses compete, such a strong influence of early information can take the form of a bias towards the diagnosis that is most strongly supported by the first symptom. The memory dynamic resulting in a confirmation bias in sequential symptom integration can be described in terms of the construction-integration theory of text comprehension by Kintsch (1998) (Baumann, Mehlhorn, & Bocklisch, 2007). After observing the first symptom, the first construction-integration cycle results in high activation of the candidate hypothesis most strongly supported by the first symptom. Subsequent construction-integration cycles start from this state. Thus, initial symptoms and preliminary hypotheses frame the processing of later symptoms.

Recently, HyGene (Thomas, Dougherty, Spenger, & Harbison, 2008), which models memory processes in hypothesis generation for a specified set of symptoms has been extended to capture effects of sequential symptom processing in detail (Lange, Thomas, & Davelaar, 2012). The activations of symptom representations compete in working memory as symptoms are sequentially encountered, however, framing of symptom processing by preliminary hypotheses is not yet implemented in HyGene.

Our main goal was to study framing of symptom processing by preliminary hypotheses and its effects on final diagnoses in diagnostic reasoning with multiple candidate hypotheses. So, the reported experiments examine sequential diagnostic reasoning with four candidate diagnoses. Differing from previous studies (Koehler, 1991), we will not set a single hypothesis, whose probability has to be rated. Instead, participants have to choose among four candidate hypotheses. We determine effects of symptom order by evaluating proportions of final diagnoses for ambiguous symptom sequences, which equally support alternative diagnoses.

Whereas framing by preliminary hypotheses should bias towards initial hypotheses, increasing the saliency of alternative diagnoses should decrease biased symptom processing. We examine both explicit and implicit highlighting of alternative diagnoses. Alternative diagnoses were explicitly highlighted by asking participants to rate the current support for each possible diagnosis after each symptom. This procedure constantly reminds participants of the competing hypotheses.

Implicit highlighting of alternative diagnoses was attempted by presenting inconsistent symptom sequences. Symptoms inconsistent with the initial hypothesis could increase the salience of diagnostic alternatives. In terms of support theory (Tversky & Koehler, 1994), symptoms inconsistent with the focal hypothesis that strongly suggest

specific alternatives could unpack the complement of the focal hypothesis into specified alternative diagnoses.

## Experiments

Participants were told that they should evaluate symptoms of workers in a chemical plant to determine which of four chemicals had most likely affected each worker. In all four experiments, the diagnostic reasoning tasks referred to the same knowledge about symptoms and causes, which was acquired in a learning phase. Firstly, participants learned which symptoms belonged to which symptom classes and subsequently, with which probability each of the four chemicals caused symptoms from a symptom class (see Table 1).

Each diagnostic reasoning trial consisted of four sequentially presented symptoms after which participants had to respond with a diagnosis. Diagnostic symptoms pointing more strongly to one chemical also pointed weakly to a second chemical. For example, an “Ab”-symptom would point strongly to A and weakly to B. In addition, there were unspecific symptoms, which were caused with equal probability by all four chemicals. These were denoted with “x”. Thus, an Ab-x-Ba-x symptom sequence could induce A as the initial hypothesis but was ambiguous because it contains equal support for A and B. Such a sequence is ambiguous, but it is still consistent because all symptoms are consistent with both A and B.

In Experiment 1, we presented such ambiguous symptom sequences (AB) together with sequences that more strongly supported A (AAB) or B (ABB). The A-diagnosis was strongly supported by the first symptom, which should result in a higher proportion of A- than B-diagnoses for ambiguous AB-items (primacy order effect). In Experiment 2, participants rated the current support for each of the four alternative hypotheses after each symptom. This explicit highlighting of alternative diagnoses should reduce order effects. In Experiment 3, the procedure was identical to Experiment 1, however, inconsistent symptom sequences such as Cd-Ab-x-Ba were presented that may implicitly highlight alternative diagnoses. Finally, in Experiment 4 the inconsistent symptom sequences were presented as in Experiment 2 with ratings of all alternative diagnoses after each symptom to highlight alternative diagnoses explicitly as well.

## Method

**Participants** Forty (28 female; mean age 23.6, SD = 2.8) undergraduate students from the University of Greifswald and 39 (30 female; mean age 22.1, SD = 2.7) undergraduate

students from Chemnitz University of Technology took part in experiments 1 and 2.

Forty (32 female; mean age 21.5, SD = 2.2) undergraduate students from the University of Greifswald and 39 (26 female; mean age 23.5, SD = 3.2) undergraduate students from Chemnitz University of Technology took part in experiments 3 and 4.

**Material** The four alternative diagnoses were introduced as chemicals that cause symptoms when they affect workers. Each chemical caused symptoms from one symptom class (e.g. Eyes) “almost always” (see Table 1). These were symptoms with a strong causal link to the respective chemical. In addition, each chemical caused symptoms from a second symptom class “occasionally”. These were weak symptoms for the respective chemical. As shown in Table 1, there were two pairs of chemicals. Within a pair, strong and weak symptoms did overlap. For example, the symptom class “Eyes” was strong for R and weak for B, “Respiration” was strong for “B” and weak for “R”. Furthermore, there were two unspecific symptom classes that each chemical could cause “occasionally”.

Each symptom class contained two symptoms. For example, the “Eyes”-symptoms were “Tears” and “Eyelid swelling”. The symptom sequences presented in the diagnostic reasoning trials consisted of four symptoms. Table 2 shows the item types and the symptom orders that they subsume. We constructed each symptom order with each chemical in the “A”-role and each possible assignment of symptoms. For example, if “W” was the “A”-chemical, and “K” was the “B”-chemical for “Ab-x-Ba-x”, one possible symptom assignment would be “Rash-Sting-Paralysis-Swoon”.

Table 1: Domain knowledge participants had to acquire at the beginning

Group	Chem.	Strong symptoms concerning	Weak symptoms concerning	Unspecific symptoms concerning
Gasi-form	R	Eyes	Respiration	Circulatory problems, Pain
Gasi-form	B	Respiration	Eyes	Circulatory problems, Pain
Fluid	W	Skin	Neurolog.	Circulatory problems, Pain
Fluid	K	Neurolog.	Skin	Circulatory problems, Pain

*Note.* The original materials were in German.

In each experiment ambiguous AB-items were presented. In Experiments 1 and 2, the additional item types were AAB and ABB. AB, AAB and ABB item types contain Ab- and Ba-symptoms which both could have been caused by A or B. AB items thus are ambiguous, but they are not inconsistent. In Experiments 3 and 4, the additional item types were CAB and ABC subsuming inconsistent symptom sequences (see Table 2). Inconsistent sequences confronted participants with a “Cd”-symptom that could not be caused by A or B and that was strong for C and weak for D. CAB and ABC items are inconsistent and they are ambiguous with regard to A and B.

**Procedure** In all four experiments, participants were first introduced to the cover story and then acquired knowledge about the chemicals and symptom classes. They studied a table of symptom classes and symptoms and were tested until they could assign symptoms to symptom classes with 100% accuracy. Then they studied a table similar to Table 1 and were tested until they could assign the correct chemical or the correct set of chemicals to a symptom-frequency combination with 100% accuracy. Then, the diagnostic reasoning task was explained and participants were told that the symptoms to be diagnosed were caused by exactly one of the four chemicals.

In each diagnostic reasoning trial in Experiments 1 and 3, four symptoms were presented serially in the center of the screen. Each symptom was shown for 2 s followed by a fixation cross shown for 1 s. After the fourth symptom, participants were prompted to enter one of the four chemicals as their final diagnosis. Then, they were asked to rate their confidence from 1 (very unsure) to 7 (very sure). In Experiments 2 and 4, the trial procedure was similar

except that after each symptom participants rated for each chemical how likely it had caused the symptoms seen so far on a scale from 0 to 100. These ratings are not reported in the present paper. We just consider the effect that this procedure had on the final diagnosis.

Table 2: Orders of symptoms related to first (A) and second (B) respectively third (C) and fourth (D) chemicals; included x stands for unspecific symptoms

Experiment	Item type	Order
1 and 2	AAB Consistent	Ab-Ab-x-Ba
		Ab-Ab-Ba-x
		Ab-x-Ab-Ba
1 and 2	ABB Consistent	Ab-x-Ba-Ba
		Ab-Ba-Ba-x
		Ab-Ba-x-Ba
		Ab-Ba-x-Ba
1 and 2	AB Consistent	Ab-x-x-Ba
		Ab-x-Ba-x
		Ab-Ba-x-x
3 and 4	AB Consistent	x-Ab-Ba-x
		x-Ab-x-Ba
		x-x-Ab-Ba
3 and 4	CAB Inconsistent	Cd-Ab-Ba-x
		Cd-Ab-x-Ba
		Cd-x-Ab-Ba
3 and 4	ABC Inconsistent	Ab-Ba-Cd-x
		Ab-Ba-x-Cd
		Ab-x-Ba-Cd

In each experiment, each participant was presented with each of nine symptom orders (see Table 2) with each of the four chemicals in the A-role resulting in 36 trials in total. The assignment of symptoms to symptom orders was chosen randomly and the trials were presented in randomized order. In addition, four training trials were presented in each experiment.

## Results

**Experiments 1 and 2** Mean proportions of final diagnoses are shown in the top half of Table 3 separated by item type. In both Experiment 1 and Experiment 2, the proportion of A-diagnoses decreased from AAB to AB to ABB items reflecting the decrease in relative support of A. Within-subjects contrasts confirmed this decrease in the proportion of A-diagnoses by significant linear trends,  $F(1, 39) = 230.84, p < .001, \eta^2 = .86$ , and  $F(1, 38) = 474.09, p < .001, \eta^2 = .93$ , respectively.

Focusing on ambiguous AB-items, equal proportions of A- and B-diagnoses each about 50% would be expected normatively. In Experiment 1, there was a clear bias towards A-diagnoses compared with B-diagnoses for AB-items, confirmed by a paired t-test,  $t(39) = 4.54, p < .001, d = 0.72$ . Thus, we obtained a clear primacy order effect for

ambiguous AB-items in Experiment 1, whereas in Experiment 2, the proportion of A-diagnoses did not deviate from the proportion of B-diagnoses,  $t(38) = -0.10, p = .924$ . Mean confidence ratings are shown in the top half of Table 4. Space limitations preclude a detailed analysis but it is apparent that confidence was reduced for the ambiguous AB-items.

Table 3: Means of proportions of diagnoses

Exp.	Item type	A (SD)	B (SD)	C (SD)	D (SD)
1	AAB	.91 (.15)	.09 (.15)		
	AB	.65 (.20)	.35 (.20)		
	ABB	.14 (.21)	.86 (.21)		
2	AAB	.83 (.16)	.17 (.16)		
	AB	.50 (.21)	.50 (.21)		
	ABB	.09 (.10)	.91 (.10)		
3	AB	.62 (.26)	.28 (.19)		
	ABC	.60 (.25)	.22 (.17)	.12 (.12)	.06 (.10)
	CAB	.48 (.25)	.20 (.19)	.26 (.20)	.06 (.08)
4	AB	.50 (.21)	.44 (.19)		
	ABC	.45 (.22)	.29 (.15)	.21 (.18)	.06 (.07)
	CAB	.42 (.22)	.39 (.17)	.14 (.12)	.05 (.08)

*Note.* Proportions for AB items in Experiments 3 and 4 do not sum to 1 because proportions of wrong C and D diagnoses are omitted from the table.

**Experiments 3 and 4** In Experiments 3 and 4, the ambiguous item type AB and inconsistent item types ABC and CAB were presented. Note that with respect to A and B, the item types ABC and CAB contain equal support as well. Thus, normatively equal proportions of A- and B-diagnoses should be elicited by all three item types. Mean proportions of final diagnoses are shown in the bottom half of Table 3.

For AB-items the results are similar to Experiments 1 and 2. Without explicit highlighting of diagnostic alternatives in Experiment 3, there was a clear bias towards A-diagnoses compared with B-diagnoses (primacy order effect) confirmed by a paired t-test,  $t(39) = 4.94, p < .001, d = 0.78$ , whereas with explicit highlighting in Experiment 4, the proportion of A-diagnoses did not deviate from the proportion of B-diagnoses,  $t(38) = 1.02, p = .315$ .

For ABC and CAB items, the leading strong symptom took effect in Experiment 3. The proportion of A-diagnoses was higher for ABC than for CAB items,  $t(39) = 3.42, p = .001, d = 0.47$ , and the proportion of C-diagnoses was higher for CAB than for ABC items,  $t(39) = 4.12, p < .001, d = 0.84$ . Nonetheless, A-diagnoses were more frequent than

C-diagnoses for both item types reflecting the superior support by a strong and a weak symptom as opposed to a single strong symptom. Despite equal support for A and B, A-diagnoses were also more frequent than B-diagnoses for both item types suggesting a primacy order effect in ABC and a similar order effect in CAB, in which the Ab-symptom can frame the integration of the later Ba symptom.

In Experiment 4, there was hardly any effect of the leading symptom on A- and C-diagnoses for ABC and CAB. The proportion of A-diagnoses was comparable for ABC and CAB,  $t(38) = 0.65$ ;  $p = .520$ , and the proportion of C-diagnoses was even lower for CAB than for ABC items,  $t(38) = -2.02$ ;  $p = .050$ ;  $d = -0.46$ .

Table 4: Means of confidence ratings of related diagnoses

E. Item type	A (SD)	B (SD)	C (SD)	D (SD)
1 AAB	5.66 (0.96)	4.08 (1.80)		
AB	3.77 (1.19)	3.69 (1.29)		
ABB	4.63 (1.11)	5.47 (1.14)		
2 AAB	5.10 (1.07)	4.06 (1.34)		
AB	3.49 (0.94)	3.38 (1.06)		
ABB	3.54 (1.16)	5.16 (0.95)		
3 AB	4.05 (1.45)	3.36 (1.52)		
ABC	3.52 (1.45)	3.08 (1.40)	2.83 (1.51)	2.33 (1.35)
CAB	3.41 (1.38)	3.23 (1.41)	3.06 (1.52)	2.29 (1.24)
4 AB	4.00 (1.75)	3.80 (1.43)		
ABC	3.64 (1.66)	3.32 (1.38)	3.32 (1.81)	3.08 (1.60)
CAB	3.92 (1.57)	3.39 (1.47)	2.94 (1.47)	3.25 (1.75)

On top of a decreased primacy order effect, which increased A-diagnoses compared to B diagnoses for ABC items, there was a stronger influence of the last diagnostic symptom than in Experiment 3. The proportion of B-diagnoses was higher for CAB than ABC,  $t(38) = -3.02$ ,  $p = .004$ ,  $d = -0.63$ , and the proportion of C-diagnoses was higher for ABC than CAB. B-proportions in ABC could be reduced simply because of a primacy order effect favoring A. The difference in C-proportions, however, is not open to such an alternative explanation and suggests an increased influence of the last diagnostic symptom in Experiment 4.

Mean confidence ratings are presented in the bottom half of Table 4 and show that inconsistent symptom sequences reduced confidence compared to ambiguous AB-items.

## Discussion

We have investigated effects of symptom order in a diagnostic reasoning task with four candidate hypotheses. Ambiguous symptom sequences (AB-items) equally supporting two alternative diagnoses revealed a clear primacy order effect if participants only responded with a final diagnosis (Experiments 1 and 3). Consistent with the processing assumptions of construction-integration theory, the initial hypothesis suggested by the first symptom framed the integration of subsequent symptoms. An equally supported alternative diagnosis was therefore chosen less often. This order effect is in line with the notion that alternative hypotheses are typically not considered impartially in parallel. Instead, symptom processing proceeds with respect to a focal hypothesis if subsequent symptoms are consistent.

Inconsistent symptoms were not an effective means to highlight alternative diagnoses in Experiment 3. There was still a considerable primacy order effect favoring A over B in ABC- and CAB-items despite equal support. Explicit highlighting of alternative diagnoses, however, was effective. In Experiments 2 and 4, participants rated the current likelihood of each candidate hypothesis after each symptom and thus were led to consider alternative diagnoses. This eliminated the primacy order effect for AB-items. As noted in previous studies, impartial consideration of two alternative diagnoses in parallel can succeed under favorable conditions.

Yet, eliciting ratings of all alternative diagnoses after each symptom did not eliminate the primacy order effect if an inconsistent symptom pattern added a third and presumably even a fourth candidate hypothesis to the set of contenders (ABC- and CAB-items in Experiment 4). In these cases, we did not only observe an advantage for the alternative that was supported by a strong symptom before its equally supported rival (A before B), but also an effect of the last strong symptom. Forcing the participants to consider the current support for all alternatives after this last strong symptom before the final diagnosis resulted in a recency effect. The proportion of final diagnoses was increased for the alternative most strongly supported by the last strong symptom for the inconsistent items ABC and CAB in Experiment 4. Our results are consistent with process models of information integration that specify how early information can frame the processing of later information (Kintsch, 1998, Baumann et al., 2007). They are also consistent with descriptive models predicting order effects in belief updating, hypothesis testing, classification, and judgment and decision making (Hogarth & Einhorn 1992, Koehler, White, & Grondin, 2003) and are a further instance

of confirmation bias (Nickerson, 1998). Studies with more than two contending alternatives are rare. Here, we have shown that the number of relevant contenders matters. The primacy order effect was overcome with two competing alternatives by explicit highlighting. With inconsistent items, more than two hypotheses had to be considered. Constrained by working-memory capacity unpacking of the set of alternatives was incomplete and rather the most likely alternatives were taken into consideration (Dougherty & Hunter, 2003).

Our results may not generalize to instances of diagnostic reasoning in everyday life, in which symptoms can be evaluated more thoroughly without time pressure and search for further information is possible. However, there are situations, in which incoming information has to be processed quickly. For example, physicians evaluating case histories are influenced by early emerging hypotheses (e.g., Kostopoulou, Mousoulis, & Delaney, 2009). The difficulties in considering more than two contenders impartially in the present experiments clearly illustrate the limits in diagnostic reasoning with multiple alternative diagnoses in similar situations.

## Abstract

**Abstract** Autism is characterized by atypical use of social communicative cues, such as another person's gaze or point. Despite these real-world difficulties, experimental manipulations often reveal minimal group differences. One factor that may contribute to this failure to find differences is the use of oversimplified and decontextualized social stimuli to examine these behaviors (e.g., a solo floating face). In the current study, we examined whether typical individuals and those with high-functioning autism spectrum disorder would use subtle gaze cues embedded in a natural, real-world scene to aid them in a change detection task using flicker presentation. Each scene contained three changes, and in some pictures, one of those changes was in the direction of gaze of the people in the scene. Even though neither group was aware that gaze cues aided in identification of the change, both groups showed a robust effect of gaze cues in change detection, such that changes in the line of gaze were detected first in a scene more often than those not in the line of gaze. These data illustrate typical use of gaze cues in high-functioning adults with ASD even in the context of a complex, naturalistic scene. Our findings suggest that attention to gaze cues may not be at the root of difficulties with joint attention in adults with autism

**Keywords:** change blindness; joint attention; autism spectrum disorder.

## Introduction

Imagine we are taking a walk in a park and a bird flies overhead. I point to it and look at you, then you look at the bird and you tell me it's a magpie. These simple instances of joint attention, or the intentional coordination of one's own attention with another on an object or topic, occur often in everyday social interactions. Joint attention interactions begin in infancy and provide a robust social learning tool for those who engage in them (e.g., Baldwin et al., 1996; Tomasello, Carpenter, Call, Behne, et al., 2005). Atypical joint attention is a hallmark characteristic in individuals with autism spectrum disorders (ASD) (e.g., Charman, 2003; Mundy & Newell, 2007, but see Gernsbacher, Stevenson, Khandakar, & Goldsmith, 2008) and early joint attention abilities are correlated with atypical language and

social development. While joint attention refers to both the initiation of a bid for joint attention and the response, the focus of the current paper is on processes that may underlie atypical responding. Atypical responding to joint attention could be due to general differences in visual attention (e.g., Brenner, Turner, & Müller, 2007), social attention specifically, for example reduced attention to people, faces, and eyes (Klin, Jones, Schultz, Volkmar, et al., 2002; Pelphrey et al., 2002), and/or a failure to direct one's own attention based on cues from others, to name a few. These various aspects of joint attention behavior have been investigated in a number of different experimental paradigms, however evidence for difficulties with these processes in individuals with autism has been mixed - at least in experimental contexts.

Social attention in autism has been investigated in several ways including the collection of eye-tracking data during viewing of videos, scenes, or pictures of faces and the examination of response patterns during a change blindness paradigm<sup>1</sup>. The first eye-tracking studies to examine whether social attention was atypical in ASD revealed reduced attention to people, and in particular to their eyes, during video viewing (Klin et al., 2002; Pelphrey et al., 2002). While more recent evidence also supports this atypical focus of attention on people within a scene, and on eyes within a face (e.g., Jones, Carr, & Klin, 2008; Dalton et al., 2005; Spezio, Adolphs, Hurley, & Piven, 2007), other evidence does not (e.g., Bar-Haim, Shulman, Lamy, & Reuveni, 2006). Recent studies have capitalized on change blindness methods in order to ask whether attention in a complex scene is prioritized to social aspects of the scene. These studies find that visual attention is prioritized for social agents (New, Schultz, Wolf, Niehaus et al., 2010; Fletcher-Watson, Leekam, Benson, et al., 2009) and eyes (Fletcher-Watson, Leekam, Findlay, & Stanton, 2008) in typical individuals and those with ASD. Thus, among a

---

<sup>1</sup> In a change blindness paradigm participants must identify small change(s) between two images through comparing images side-by-side or through flicker presentation.

high-functioning group of participants with ASD, there is mixed support for problems with social attention, suggesting that either this may not be a source of atypical joint attention (at least by adulthood) or the experimental paradigms used are failing to capture the difficulties.

In a joint attention context social attention is necessary but not sufficient to coordinate attention with another. If I just looked at you pointing to the magpie but didn't look at the magpie I would not have engaged in joint attention with you nor would I have learned the name for that type of bird. Indeed, individuals must use the other person's shift in attention (e.g., through gaze) to redirect their own attention to achieve joint attention. Thus, one hypothesis is that atypical use of gaze, rather than social attention alone, may underlie atypical joint attention. Researchers have examined the effect of gaze cueing on attention in experimental tasks and again find mixed to weak support for an atypical response in autism. However, these studies have been largely devoid of social context. These studies have mostly been conducted through the use of a modified Posner cueing task in which participants are told to push the left or right button when they detect a target on the left or right side of the screen, respectively. A face at the center of the screen shifts gaze just prior to appearance of the target to a location that is either congruent or incongruent with the target location. Greater reaction time for the incongruent than congruent trials suggests reflexive use of the gaze cue information to redirect attention even though participants are told the gaze cue is irrelevant to the task. In a review of 12 experiments, 8 revealed no differences between autism and control groups with this method (review, Nation & Penny, 2008), suggesting reflexive orienting of attention to gaze cues in ASD is fairly typical. As mentioned above, this failure to find a difference could be due to the lack of social context in the stimuli. A study using eye-tracking methods examined attention to objects in a person's line of gaze in a real-world scene. While individuals with autism reliably followed the person's gaze to the objects, they looked less at the objects of attention than controls (Freeth, Chapman, Ropar, & Mitchell, 2010). This study illustrates typical gaze following in ASD individuals, but suggests atypical use of gaze information (i.e., less looking at the objects). One limitation of the study, though, is that the gaze cues were so salient in the scenes that the study may not be tapping into more subtle, real-world difficulties in attention to and use of gaze information to orient attention to relevant aspects in ones environment.

In sum, studies of social attention using eye-tracking or change blindness methods do not examine the effect of gaze on attention reorienting, while gaze cueing paradigms that do examine the effect of gaze have previously used oversimplified stimuli with minimal social context or real-world validity. To overcome these limitations and examine whether the object of another person's attention is prioritized in a complex visual scene, we used a change blindness paradigm in which gaze cues were subtly embedded in a complex, natural scene.

## Methods

### Participants

Eleven adults with autism spectrum disorder (ASD) ( $29.6 \pm 4.2$  years, 8 male) and fifteen typically developing adults (TD) ( $24.4 \pm 5.2$  years, 9 male) participated in this study. All participants gave written informed consent and received monetary compensation for their participation. Two TD subjects were excluded from subsequent analysis, one for having been previously diagnosed with depression and another for an ophthalmologic developmental disorder. Participants entered the study with a diagnosis of autism or Asperger's from their community healthcare provider but in order to confirm a research diagnosis of autism spectrum disorder, an autism behavioral therapist (P.L.M.) who was certified on the Autism Diagnostic Observation Schedule (ADOS) – Module 4 (Lord et al., 2000) administered and scored the ADOS. A psychiatrist confirmed a diagnosis on the spectrum by viewing tapes of the ADOS interview. Of the 11 participants, 8 met criteria for autism (i.e., a combined social-communication score of 10 or higher), the other three 3 met criteria for spectrum (i.e., a combined social-communication score of 7 or greater). Social-communication scores ranged from 7-14 with a mean of 10 (stdev 2.24).

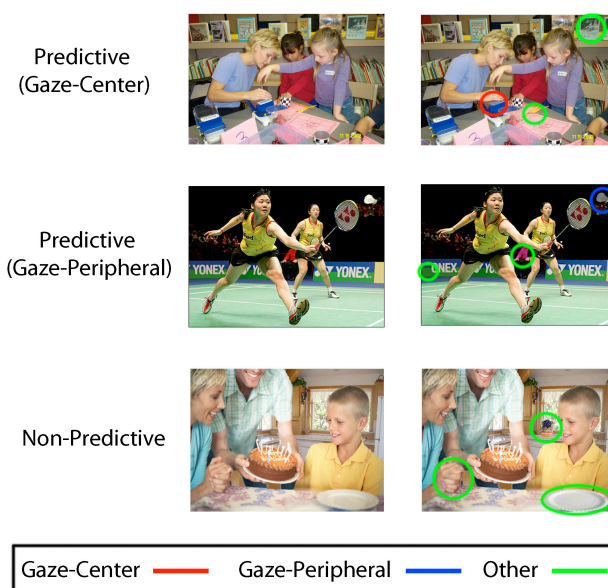

Figure 1: Examples of the picture types (Predictive or Non-Predictive) and change types (gaze-center, gaze-peripheral, non-gaze center, non-gaze peripheral).

### Stimuli

Twenty-nine color photographs of natural scenes were used to create the stimuli. Each photograph included between one and three people with visible faces and several objects. The photographs were edited using Adobe Photoshop. For each photograph, three changes were made to each picture.

Attempts were made to balance the changes in the center and periphery across pictures. Center regions were defined as the area within an oval that is half of the height and width of the entire picture, while peripheral regions consisted of any areas outside of the center regions. Twenty of the photographs had a change that was within the line of direct gaze of the person(s) in the photograph. These twenty photos are labeled 'Predictive' because one of the changes can be predicted by the gaze direction. The other nine photos ('Nonpredictive') were included as fillers so that participants were unlikely to notice the predictive nature of the gaze changes.

### Stimulus ratings

Eight new participants not informed of the purpose of the current study rated each change within the set of predictive pictures as 'center' or 'periphery' based on the definition given above. Additionally, these participants judged whether the change occurred in the foreground or background of the scene. Two changes could not be categorized as center or periphery (50% ratings for each). These two changes were within the same picture so that picture was removed from all further analyses. Thus, out of 19 predictive pictures, 11 changes were rated as in the center and in the line of gaze (gaze-center), 8 were in the periphery and in the line of gaze (gaze-periphery), 15 were in the center and not in the line of gaze (non-gaze center), 23 were in the periphery and not in the line of gaze (non-gaze periphery). All gaze changes were rated as in the foreground of the picture whereas non-gaze changes were a mix of foreground and background, thus the grounding (foreground vs. background) of changes was included as a covariate in the statistical models (below).

### Visual controls

Photographs were analyzed for visual saliency using the saliency toolbox (Walther & Koch, 2006). This toolbox identifies the most salient 'objects' (or locations) in a scene. Saliency was determined based on a combination of intensity, orientation, and color maps. When choosing regions in which to make a change, we attempted to avoid these most salient regions. In order to compare whether saliency values from the pixels that contained a change differed between the change types, a saliency map was generated which contained a saliency value at each pixel. Regions of interest were created for each change region in each picture. Mean saliency value was extracted from within each change region using Matlab. Another potential low-level feature that could have influenced change detection was size of the change. The size of the change was determined by counting the number of pixels in the regions of interest for each change. Two one-way ANOVA's were conducted to examine the effect of saliency and size on change category (gaze center, gaze periphery, non-gaze center, non-gaze periphery). No significant difference in size of the change types was found ( $F(3)=.576, p<.63$ ) but saliency did show an effect of change category

( $F(3)=4.19, p<.01$ ) with changes in the center and line of gaze showing higher saliency values than changes in the periphery. Pairwise contrasts were examined using Tukey's HSD ( $\alpha<.05$ ), and no differences in saliency were found between nongaze-center changes, gaze-center changes, and gaze-periphery changes or between gaze-periphery and non-gaze periphery changes. Saliency and change size were both included as covariates in the model (below).

### Task

The experiment was conducted on an iMac computer with stimuli presented on an auxiliary 19" monitor using Matlab Version 7.7 (R2008b) with Psychophysics Toolbox Version 3. Participants received written and verbal instructions that they would be viewing a series of picture pairs and that these pairs would be presented in rapid alternation and would be identical except for three changes, such as changes in the color or the presence of an object. Participants were asked to identify these changes as quickly as possible and to respond via a button press. Participants were first given a practice task consisting of two trials that were identical to the actual task to ensure that subjects fully understood the task. Each trial began when the subject indicated that they were ready by pressing the mouse button. The subject would then be presented with the original photograph for 1000ms, a blank screen for 200ms, then the altered image for 1000ms, and another blank screen for 200ms. This sequence was looped until the subject indicated via a button press that a change was observed between the photographs. The button press brought up a blank screen. The subjects were required to give a verbal description of the change and to point on the blank screen in the area where the change was observed. The experimenter would record the change on the computer. Accuracy was determined online by the experimenter. When the subject indicated they were ready, this process would continue with the same photograph sequence. The subsequent trial would begin with a new stimulus once all three changes were observed, or until a time limit of 3 minutes was reached. Stimulus order was randomized for each subject.

Figure 2: Timeline of one trial

### Statistical analyses

Separate analyses were conducted on total number of changes detected and on the first change detected in each picture using logistic mixed-effects models as implemented in the lme4 package (Bates, Maechler, & Bolker, 2011) in

the R software package (version 2.14.1; R Development Core Team, 2011). *Gaze* (change in the line of gaze or not), *location* (center or peripheral change) and *group* (ASD or control) were treated as fixed effects using orthogonal contrast coding, and participants and items were treated as crossed random effects, with the maximal random effects structure supported by the data. In addition, change *saliency*, *size*, and *grounding* (foreground or background) were included as centered fixed effect covariates.

Mixed effects models are useful for data such as these because they do not require aggregation across items nor do they require fully balanced data (Jaeger, 2008). Log-transformed response times were analyzed with similar (non-logistic) models. For readability and for purposes of graphical presentation, values are described as proportions (calculated as means of participant means) rather than as log-odds ratios and as raw response times (after excluding times exceeding two standard deviations from each participant's mean response time) rather than log transformed times.

## Results

### Gaze cues facilitate change detection

Participants first detected 53.5% of the changes in the line of gaze compared to only 25.3% of the changes not in the line of gaze; this 28.2% difference was reflected in a significant main effect of gaze (see Figure 3a;  $b = 1.46$ ,  $SE = 0.47$ ,  $z = 3.09$ ,  $p < .01$ ). Unsurprisingly, participants were (marginally significantly) more likely to first detect changes that were larger ( $b = 0.30$ ,  $SE = 0.02$ ,  $z = 1.69$ ,  $p < .10$ ). Although participants first detected numerically more changes in the periphery than in the center (37% vs. 32%), this difference did not reach significance ( $b = 0.64$ ,  $SE = 0.39$ ,  $z = 1.64$ ,  $n.s.$ ). There was, however, a marginally significant effect of location when the covariates of size, saliency, and grounding were not included in the model ( $b = 0.90$ ,  $SE = 0.54$ ,  $z = 1.68$ ,  $p < .10$ ); this likely reflects the fact that center changes were nearly always also foreground changes with higher saliency values than changes in the periphery. (Note that the model does not show concerning levels of collinearity; all variance inflation factors  $< 1.7$ ).

There is evidence that changes in the foreground of pictures are easier to detect than changes in the background (Rensink, O'Regan, & Clark, 1997), however *grounding* did not explain significant variance in change detection or response times, suggesting that these differences were relatively minor.

Analysis of detection times to the first change (Figure 3b) revealed a similar pattern of results.<sup>2</sup> A main effect of gaze showed that participants detected changes in the line of gaze an average of 2.3 seconds faster than changes not in the line of gaze ( $b = -0.30$ ,  $SE = 0.13$ ,  $t = -2.37$ ), a main effect of saliency showed faster detection of more visually salient

changes ( $b = -0.40$ ,  $SE = 0.17$ ,  $t = -2.30$ ), and a marginally significant effect of group ( $b = -0.33$ ,  $SE = 0.18$ ,  $t = -1.82$ ) showed that control participants detected their first change an average of 2.4 seconds faster than ASD participants.

### No effect of group on identification of gaze changes

No other effects or interactions reached significance (all  $ps > .1$ ); in particular, the effect of gaze did not differ for ASD and control participants (29.0% vs 27.6%, respectively).

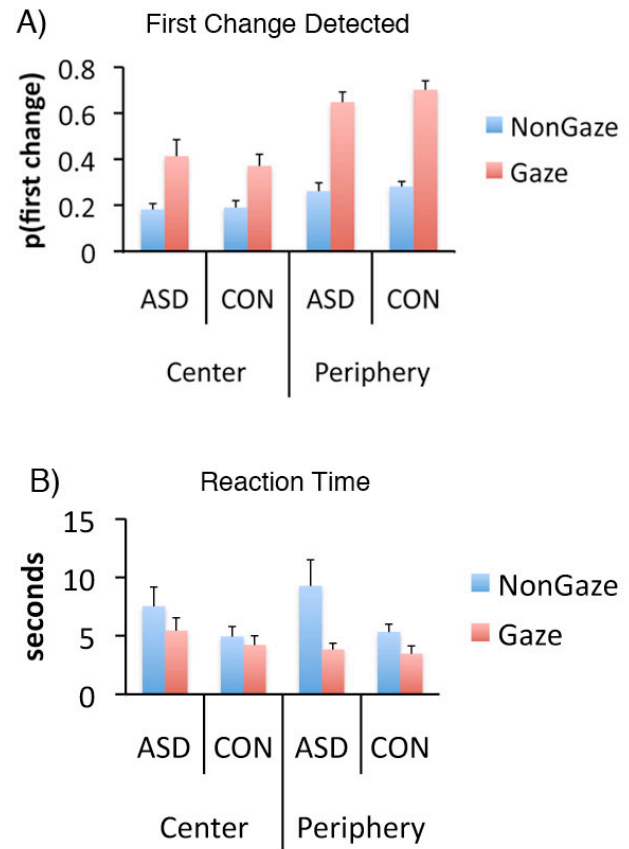

Figure 3: Effect of gaze on first change detected (A) and reaction time to detect change (B).

### Total number of changes detected by group

Overall, ASD participants detected fewer changes than did controls, however this was largely due to the performance of one ASD participant who missed 35% of the changes (compared to an average miss-rate of 5.3% for the rest of the ASD group and 2.8% for the control group). With this participant excluded, ASD participants did not detect significantly fewer changes than did controls (94.7% vs. 97.2% detected;  $b = -0.71$ ,  $SE = 0.75$ ,  $z = -0.95$ ,  $p > .10$ ), although a marginally significant gaze by group interaction ( $b = -2.08$ ,  $SE = 1.22$ ,  $z = -1.71$ ,  $p = .09$ ) showed that ASD participants were more likely to miss changes that were not in the line of gaze (missing 6.6% non-gaze changes vs. 2.6%

<sup>2</sup> The lme4 package cannot currently estimate  $p$  values for  $t$ -statistics in models with random slopes, however common practice is to assume that  $t$  values greater than 2 are statistically significant.

of gaze changes) whereas controls showed a smaller difference, numerically in the other direction (2.4% missed non-gaze vs. 3.6% missed gaze changes).<sup>3</sup> ASD participants also took longer to detect all three changes (when all changes were, in fact, detected) than did control participants (an average of 51.5 vs. 40.1 seconds, respectively;  $b = -0.16$ ,  $SE = 0.05$ ,  $t = -3.00$ ).

## Discussion

### Subtle gaze cues robustly affect visual attention

A robust effect of gaze on change detection was found in both the typical and ASD groups. This effect cannot be explained by low-level visual effects like size or saliency or grounding (foreground vs. background) of the change because the effect of gaze on first change detected and on time to detect the change were significant even with these variables as covariates.

Gaze cueing effects in a change detection paradigm have been demonstrated in typical adults previously (Langton, O'Donnell, Riby, & Ballantyne, 2006) but the gaze cues in those stimuli were highly salient (e.g., one person in the picture at a desk with body facing forward and some objects around him). Our findings provide a stronger test for the role of gaze in object detection through the presentation of multiple changes within a complex scene with multiple people and subtle gaze cues. In fact the cues were so subtle that in a post-test debriefing session, participants reported that they were unaware that direction of gaze provided any information about the location of the changes. Thus, these findings provide strong support that the object of someone's attention is prioritized during visual search – even without explicit awareness of the utility of gaze cues in this context.

### No effect of group on change detection

Surprisingly, no effect of group was found. In fact, there was a trend for individuals with ASD to show a greater effect of gaze on change detection, especially for changes in the periphery. While we predicted an effect of group, this lack of a difference is consistent with several other change blindness studies suggesting normal prioritization of attention to social agents in ASD (Fletcher-Watson et al., 2008; New et al., 2010). Our findings extend previous work by showing normal prioritization of attention to the object of another person's attention in ASD even when the gaze cues were subtly embedded into the scene. These findings suggest that attention to (and use of) gaze information in high-functioning adults with autism may not be impaired and thus are not a determinant of atypical social interactions in adults.

An alternative possibility is that these (and other) findings of a failure to find group differences in offline, experimental contexts suggest that difficulties in social attention and gaze processing are due to inherent difficulties with real-time

social interactions which are not captured by these offline tasks. The unpredictability and fast-pace of live interactions may add sufficient challenges to cause an otherwise capable system of social attention to break down. This conclusion remains speculative however without concurrent data from participants in the context of a real-time face-to-face interaction.

Finally, other factors may have contributed to this lack of a group difference. The participants in this study were high-functioning adults with autism and Asperger's disorder. Thus, their level of social impairment is by definition less severe than the majority of individuals with autism. Second, they have had years to develop strategies for success in social interactions, such as directing attention to the face and eyes. Indeed, atypical gaze processing may be greatest early in life (e.g., Klin, Jones, Schultz, & Volkmar, 2003; Leekam, Hunnisett, & Moore, 1998) but through treatment and compensatory strategies these differences may be minimized by adulthood.

## Conclusions and Future Directions

These data show that normal use of gaze information in high-functioning adults with autism is not restricted to visually simplistic scenes; instead, in complex, real-world scenes with subtle embedding of gaze cues individuals with ASD show normal attentional prioritization to objects in the line of another's gaze. An important question for future research will be to determine when and how adults with autism do show atypical use of gaze information (e.g., see review by Klin, Jones, Schultz, & Volkmar, 2003). Atypical use of gaze information may be the most robust in real-time face-to-face contexts that are unpredictable and quickly changing. However, limited research has been done to investigate spontaneous difficulties with joint attention in adults with autism. This work will be critical to understand the specific difficulties with social interaction experienced throughout the lifespan in autism. For example, factors that underlie atypical social interactions in a toddler may be very different than those of an adult. Understanding how joint social attention is atypical will allow for more targeted interventions and treatments for adults with autism, an area of relatively less investigation (e.g., Autism Speaks Strategic Plan, 2009).

## Acknowledgments

The authors thank Kang Won Choi for discussions on the design of the study. We gratefully acknowledge Rashida Callendar, Joy Ekuta, and Eugenia Luo for assistance with stimuli creation and editing and Ariana Mann for assistance with stimuli creation and pilot testing. This work was supported by funding from the Simons Foundation Autism Research Initiative (SFARI) awarded to J.G. and P.S. and a postdoctoral fellowship awarded from the National Institute of Child Health and Human Development awarded to E.R.

<sup>3</sup> All other analyses are reported over data from all participants, but note that the pattern of results does not change appreciably if this participant is excluded.

## Abstract

Understanding scale is fundamental in science education, but scale comprehension is difficult. One reason difficulties may arise is a disconnect between the linear scale of magnitude and how scale information is cognitively represented. An intervention was designed to foster a linear representation of magnitude, based on the theory that people represent magnitude information in a hierarchically organized structure. The intervention extends principles from the progressive alignment model of analogical reasoning to include hierarchical alignment. Half the students in an undergraduate introductory-level geology class were given multiple opportunities to progressively align time to a constant spatial scale in a linear representation, and locate all previous scales relative to the current scale. The other half of the class received the same content and practice aligning time to space. The intervention group demonstrated a more accurate sense of the relative durations of geological events and a reduction in the magnitude of temporal location errors relative to the control group. These findings suggest that the hierarchical and progressive alignment of geologic time is an effective way to reduce magnitude-based errors in understanding geologic time. These findings are consistent with the category adjustment model, and suggest commonalities between number and time magnitude representation. Educational implications are discussed.

**Keywords:** Scale; Hierarchical alignment; Progressive alignment; analogy

## Introduction

Having a strong conceptual understanding of scale and the relationships between scales is essential for scientific literacy (Tretter, et al., 2006). Fundamental concepts in

many disciplines require understanding scales outside those familiar to human experience. For example, research on geologic time, the atom, the size of the universe, and nanotechnology is all based on phenomena occurring at scales that cannot be directly perceived. Being able to understand important current social issues, such as the U.S. deficit, population growth, and global warming also require an understanding of magnitudes outside of direct human experience. Given the importance of understanding scale, it should be no surprise that the new NRC *Framework for K-12 Science Education* (NRC, 2011) and the *Benchmarks for Science Literacy* (AAAS, 1993) have both identified “size and scale” as fundamental and a unifying theme in science education. “Size and scale” was also identified as one of the “big ideas” at recent nanoscience and education national workshops (Swarat, et al., 2010).

Unfortunately, people consistently have trouble understanding and comparing values of very small or large magnitudes (e.g. Jones, et al., 2008; Libarkin, et al., 2005; Tretter, et al., 2006; Swarat, et al., 2010). Undergraduate students, even those in STEM majors, have difficulty mastering concepts of size and scale (Drane et al., 2008). Size and scale has been described as a critical barrier to learning and higher-level understanding (Hawkins, 1978). While people are more accurate at ranking relative sizes, they struggle assigning, comprehending, and comparing absolute sizes, especially at extreme scales (Jones, et al., 2008; Tretter, et al., 2006). For example, while most students are able to place major geologic events in the correct order, they fail to demonstrate an understanding of the magnitude of time between these events (Libarkin, Kurdziel, & Anderson, 2007).

Difficulties processing extreme sizes and scales may stem from how magnitude information is cognitively represented. Magnitudes at extreme scales are unfamiliar. Activation of representations of unfamiliar magnitudes is less automatic than of familiar values (Kadosh & Walsh, 2009). For example, people possess a weaker association between magnitude and number words for larger quantities than for smaller more familiar quantities (Sullivan & Barner, 2010).

Unfamiliarity with the magnitude and content information associated with extreme scales may lead to the large conceptual categories held by novices (Trend, 2000; Tretter, et al., 2006). While experts working with extreme scales are characterized as having a “detailed, secure, sophisticated, and well developed” mental framework, novices’ mental frameworks are found to be “scant, insecure, and nebulous” (Trend, 2000). For example, even in-service science teachers who teach geologic time represent the roughly 14 billion years of geologic events as only three conceptual categories: extremely ancient, moderately ancient, and less ancient (Trend, 2000). Conceptual boundaries are defined by consistent estimations of events near each other, creating the boundary, and increased variation of estimations of events within each conceptual category across participants.

Huttenlocher and colleagues’ (1988) category adjustment model offers an account for this pattern of estimations. The category adjustment model applies to both objects and events. It suggests that 1D, 2D, and 3D magnitudes, such as location, distance, and duration, are stored as a hierarchical combination of metric and categorical information. A person retrieves needed information at the level required by a question, as well as the boundaries of any associated higher-level units (Huttenlocher, et al., 1988). For example, remembering that dinosaurs first appeared in the Triassic Period implicitly contains information that dinosaurs also first appeared during the Mesozoic Era, which is a larger division that includes the Triassic period.

However, in the absence of exact information, people use boundaries of other objects/events to help make estimations. Variation in estimation, therefore, occurs because of imprecision of boundaries (Shipley & Zacks, 2008; Zacks & Tversky, 2001). As people use object/event boundaries to help make estimations, the more imprecise or the larger the boundaries, the more variation one could expect to find (Huttenlocher, et al., 1988; Shipley & Zacks, 2008). With no information at a lower level, estimations must default to a higher level. Thus, if a student cannot recall which period dinosaurs first appeared, but can recall it happened in the Mesozoic Era, their estimation will range 180 million years, spanning all of the periods that comprise the Mesozoic Era.

The placement of object/event boundaries will systematically distort estimations in predictable ways. Subjective experience of magnitude is influenced by the number of boundaries the person can recall; the more boundaries a person can recall the greater the subjective magnitude, and the converse for recollection of a smaller number of boundaries (Block, 1990). In line with the category adjustment model, when people hold relatively few

conceptual categories, such as at extreme scales, they should underestimate magnitudes. For example, elementary to graduate-level students estimated objects as too small at large scales and as too large at small scales (Tretter, Jones, & Minogue, 2006).

Additionally, because change is usually perceptually salient, and thus plays a role in object/event comprehension and memory, at points of unpredictability humans are more likely to attend to information to permit more accurate future predictions (Shipley & Zacks, 2008). Subsequently, people tend to remember objects/event boundaries by attending to them (Speer, Zacks, & Reynolds, 2007), and recall those objects/events at boundaries more clearly than those in between (Zacks & Tversky, 2001). Therefore, regions sparsely populated with objects/events will tend to elicit more variation in estimation of location and an underestimation of magnitude.

The more organizational structure a person has for the material in memory, the better their recall (Mandler, 1967). Where people have more conceptual categories, perhaps arising from personal experience with the scale, they are more accurate when making judgments. For example, most adults (e.g. Dehaene & Marques, 2002; Dehaene, et al., 2008) and children (Booth & Seigler, 2008) are able to use a proportional linear number line to make estimations for smaller, more familiar numbers, but they fail to do so with larger or unfamiliar numbers. While there currently is a debate about the nature of people’s mental representation of size and scale (e.g. logarithmic, power, scalar variability, or segmented linear model), it is clear that there are compressive effects on people’s estimation of size and scale as magnitude increases to unfamiliar scales. The variation of people’s estimations of quantity increases as a function of the magnitude of the judgment (Dehaene, 2003). A consequence of a compressed number line is that, as magnitudes become less familiar, values will become less discriminable (the distance effect). The distance effect can be seen in slower response times when people make judgments about larger numbers compared to making judgments about smaller numbers (Dehaene, et al., 2008).

If the representation of scale information drives student difficulties in learning about size and scale, then learning interventions designed to address scale representation more directly should improve learning. Effectively teaching reasoning about unfamiliar scale magnitudes should require an intervention that fosters a linear representation of magnitude, populated with boundary information at that scale. An intervention was designed based on the theory that people represent magnitude information in a hierarchically organized structure.

The intervention tested in this study is based on the progressive alignment model of analogical reasoning (Kotovsky & Gentner, 1996). The progressive alignment model has been shown to foster a linear representation of number magnitude (Thompson & Opfer, 2010). The progressive alignment model advocates the comparison of two similar items. The more commonalities that exist

between these items, and the more these commonalities are highlighted, the more salient corresponding relations will be. Comparing two similar items then helps extend the analogy to unfamiliar items (Gentner & Namy, 2006). Furthermore, the act of performing comparisons may change the original mental representations, increasing uniformity between the two representations. Thus, the process of alignment may make higher-order relational similarities more salient. Recognition of higher-order relational commonalities may promote making similar higher-order connections with subsequent unfamiliar items (Kotovsky and Gentner, 1996). The progressive alignment of scales may alleviate the conceptual dissimilarity between human scales and extreme scales by providing greater structural alignment across changes of scale.

The current study uses the Geologic Time Scale, extending from present day back 4.6 billion years. Novices have trouble understanding geologic time, demonstrating a pattern of errors consistent with a hierarchically organized representation of temporal magnitude (e.g. Libarkin, et al., 2005; Trend, 2000). Novices' estimations of when geologic events occurred may differ from the correct magnitude by as much as five orders of magnitude (Catley & Novick, 2008).

A commonly employed classroom exercise to teach students about the magnitude of geological time is to have them align time to a spatial representation. The current study builds on the use of space as an analogy for time. We note that using space to represent time is particularly important in geoscience education because geologically relevant temporal information is often stored in spatial arrays (e.g., as sequences of layers in a sedimentary deposit). In line with the progressive alignment model, the current intervention gives students multiple opportunities to align time to space in a linear representation, progressing from small familiar scales to geological scales. While the amount of time varies, the amount of space remains constant: students align increasing amounts of time to one meter.

Importantly, the current intervention extends the principles of the progressive alignment model to include the hierarchical organization of all previous scales. Every time students align a new temporal scale to space, they locate all previous scales relative to the current scale. This hierarchical organization highlights how each temporal scale is related to the others, helping to populate each scale with boundary information by providing internal structure of magnitude relations within event boundaries.

## Methods

### Participants

Participants consisted of 58 (control group) and 49 (experimental group) students enrolled in an undergraduate introductory-level geoscience course at a major university located in an urban setting. The demographics of participants were consistent with those of a large urban American university.

The geoscience course consisted of twice weekly lectures and a laboratory period. All lectures were given by the same faculty member; the students were divided into different sections for the laboratory period. One TA covered four sections and two TAs covered two sections each. The intervention was conducted by the first author (as a guest lecturer) in the laboratory sections as part of the standard stratigraphy lab. Experimental (intervention) and control conditions were evenly distributed across the TAs to control for instructor-based differences.

**Intervention Design** In the hierarchical alignment intervention, students aligned time to space beginning with a familiar personal time scale, then worked through different historic and geologic timelines, up to the full Geologic Time Scale. For each timeline, students were required to indicate the timeline's length, locate specific events, and locate where all previous timelines would begin on the current timeline (see Fig. 1).

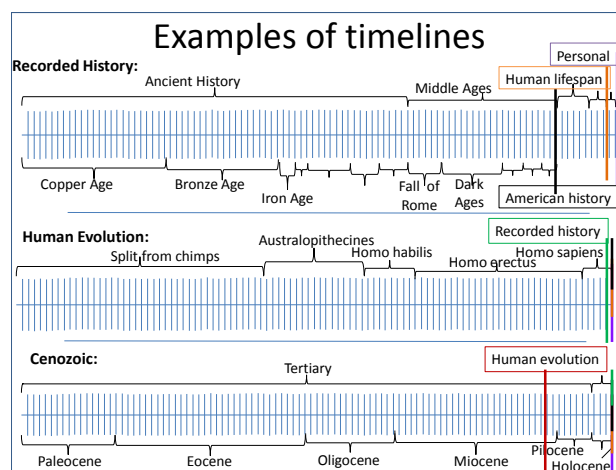

Figure 1: Example of three time lines in the hierarchical alignment intervention. Note that for each time line, all previous time lines are located.

**Procedure** In a two-hour laboratory session, the experimental group participated in the hierarchical alignment intervention (1.5 hr) after a shortened stratigraphy lab (30 min). The control group completed the full stratigraphy lab (2 hr). During the stratigraphy lab, students learned about the age and distribution of rock types and the types of environments in which those rocks are formed by making and examining stratigraphy columns. Importantly, stratigraphy columns involve aligning geologic temporal information to space. Thus, the intervention and control groups both received practice aligning geologic time to space and exposure to magnitude information. The only difference between the intervention and control groups is the way in which the magnitude information was presented (hierarchically or conventionally). Both the intervention and control groups received further instruction on the Geologic Time Scale and concepts explicitly related to geologic time

(i.e. two fossil labs) prior to completing the outcome measures. The fossil labs include identifying fossils from different divisions in time.

**Measures** All students completed outcome measures one month after the stratigraphy lab as part of a laboratory exam. There were two items that assessed understanding of geologic time magnitude. One item came from the Geoscience Concept Inventory, which is a valid and reliable instrument measuring a range of geoscience concept knowledge (Libarkin, et al., 2005). For this item, students were presented with five time lines that had the same geologic events in different locations. Four of the time lines represented common misconceptions students have (response option A. life occurred when Earth formed, B. humans and dinosaurs coexisted, C. dinosaurs appeared much earlier than they did, E. all life formed at the beginning of Earth's history), and one time line showed the events in the correct relative locations (D). Students were asked to choose the most correct time line. Two of the incorrect response options (A/B) reflected relatively small magnitude errors (i.e. they are wrong on the scale of millions of years) and the other two incorrect response options (C/E) reflected relatively large magnitude errors (i.e. they are wrong on the scale of billions of years).

The second item is a new measure of geologic time developed for use with middle school students (Barghaus & Porter, 2010). This item is a multiple-choice item that required students to identify which duration-based statement was true using a conventional diagram of the Geologic Time Scale. The correct choice is the statement: *The Proterozoic Eon lasted much longer than the Phanerozoic Eon*. While numerical information is provided in the diagram, the correct choice may not be obvious to novices in the standard diagram because the spatial intervals of the eons do not proportionally correspond to their temporal lengths. This type of compressed representation is how the Geologic Time Scale is typically depicted. In past work the most commonly chosen incorrect response was a statement that is consistent with the visible spatial intervals (*The Phanerozoic lasted much longer than the Proterozoic*).

A third test item served as a control for other potential group differences (e.g. motivation). This item is a knowledge-based question, asking when mammals were the dominant land animal. This item did not require an understanding of magnitude.

## Results

On the Geoscience Concept Inventory item the intervention group was significantly less likely to make large-magnitude errors than the control group ( $\chi^2(1) = 6.08, p = .01$ ), although both groups were just as likely to choose D, the correct option ( $p > .05$ ). The intervention group was significantly less likely than the control group to choose C, the most common error ( $\chi^2(1) = 7.35, p = .01$ ).

The intervention group was more accurate than the control group on the Geologic Time Scale Diagram item

( $\chi^2(1) = 3.99, p = .05$ ). The groups did not differ significantly on the knowledge-based test item, which did not require an understanding of magnitude ( $p > .05$ ).

Figure 2: Distribution of student responses to Geoscience Concept Inventory item on geologic time. Response option “D” is the correct answer. Incorrect response options reflect common misconceptions: (A) life occurred when Earth formed, (B) humans and dinosaurs coexisted, (C) dinosaurs appeared much earlier than they did, (E) all life formed at the beginning of Earth's history).

Figure 3: Percentage of students making large-magnitude errors. The incorrect response options from the Geoscience Concept Inventory item on geologic time were broken up into small-magnitude errors and large-magnitude errors

## Discussion

The current study found that the hierarchical and progressive alignment of geologic time is an effective way to reduce magnitude-based errors in understanding geologic time. The intervention group demonstrated a more accurate sense of the relative durations of geological events and a reduction in the magnitude of temporal location errors relative to the control group. Importantly, the intervention and control groups did not differ significantly on the knowledge-based item, indicating that the intervention affected understanding the magnitude of geologic time, and did not provide additional content or increase effort or motivation in the intervention group. These findings were attained one month later, suggesting a durable effect.

That the intervention, aimed at fostering a linear representation of geologic time, was successful at reducing magnitude errors suggests that mental representation of magnitude influences understanding of the Geologic Time Scale. Specifically, the increased accuracy on the Geologic Time Scale diagram item and the pattern of errors on the Geoscience Concept Inventory item are consistent with developing a more linear scale of time at large magnitudes. One limitation of the current study is the limited number of measurements assessing geologic time understanding. We are developing new assessments of scale representation that evaluate magnitude understanding in abstract numerical domains as well as spatial and temporal content domains. Such assessments will be important for further development of our understanding the nature of the role of analogical mapping in representing magnitude and scale.

The category adjustment model can be applied to any type of magnitude (e.g. space and time). Currently, there are competing accounts of the nature of the representation of magnitude information. Some researchers advocate a generalized mapping of more/less relations across dimensions (Walsh, 2003), while other researchers maintain separate or asymmetrical representations (e.g., Agrillo, Ranpura, & Butterworth, 2010). Our finding that progressive alignment helps foster a linear representation of magnitude for time, and Thompson & Opfer's (2010) work on numbers indicates that there may be commonalities between number and time magnitude representation. Hierarchical alignment could serve as a valuable technique in future research on the nature of representations of different types of magnitude information.

There are other factors besides those studied here that may contribute to the representation and comprehension of size and scale. Measurement, estimation, perspective, and proportional reasoning may all play some role in understanding size and scale (Jones & Taylor, 2009). For example, proportional reasoning is correlated with students' ability to order objects and assign correct sizes to objects (Jones, et al., 2007). Being able to conceptualize a new unit from existing units (unitizing), and then use that new unit to make comparisons or calculations, are particularly important aspects of proportional reasoning related to understanding size and scale (Lamon, 1994). Further research is needed to examine how these other factors contribute to the understanding of size and scale.

The finding from the current study has clear educational implications. While analogy is one of the most commonly used pedagogical practices (Libarkin, et al., 2007), students still continue to demonstrate difficulties in understanding size and scale information (e.g. Jones, et al., 2008; Libarkin, et al., 2005; Tretter, et al., 2006; Swarat, et al., 2010). It is possible for analogies to fail to bring about conceptual change (Brown & Salter, 2010; Duit, 1991), and even mislead students' understanding of a concept, making misconceptions hard to identify and resolve (Brown & Salter, 2010; Duit, 1991). Two obstacles faced when using analogy in representing scale information include failure of

alignment and unrelated salient features (Gentner, 1983). The hierarchical alignment intervention is specifically designed to control for these issues by keeping everything aligned except for magnitude information. Thus, the hierarchical alignment intervention may be a more effective teaching tool than current practices employing single analogical mapping exercises.

Thus far the research discussed has described representations of large unfamiliar whole numbers compared with relatively smaller more familiar whole numbers. While there has been little research examining scaling and ordering of numbers less than the integer *one*, it is hypothesized that as magnitudes become unfamiliar at both large and small scales, the representation of those magnitudes will become "fuzzy and indistinct" (Tretter, et al., 2006). For example, people also hold a limited number of conceptual categories of extremely small scales (e.g. things we can see versus things we cannot) (Jones, et al., 2008; Tretter, et al., 2006). The increased variation within categories and little to no variation across categories should result in difficulty discriminating among objects/events that are very small. However, in the case of small scales, there is an added complication with the hierarchical alignment intervention: familiar scales are not able to be hierarchically organized within the unfamiliar scales as one progresses towards smaller and smaller scales, as was the case when progressing towards larger and larger scales. A solution may be cycling back up to larger level (or levels) for each smaller scale. In any event, the implications of this complication in cognitive representations and pedagogical practices should be examined in future research.

## Acknowledgments

## Abstract

Human beings infer complex mental states given very little information—a facial expression, a sarcastic tone, or even a simple behavior. Previous work suggests that adults make joint belief and desire inferences based on an actor’s path, and that these inferences are well-explained by a Bayesian framework (Baker, Saxe, & Tenenbaum, 2011). We investigate the development of this ability by assessing mental state inferences made by children ages 3-6 after watching a short movie. Our results suggest that young children spontaneously make inductive inferences about desires or preferences, and that the ability to infer belief from behavior develops between ages 3-6, and possibly throughout later childhood. We formulate three computational models that capture the developmental shift between non-representational and representational theory of mind, and show that these models capture qualitative patterns in the children’s data.

**Keywords:** theory of mind, false-belief task, Bayesian inference, cognitive development

## Introduction

As we move about the world, our actions are the observable manifestation of unobservable intentions: we act to fulfill our hopes and desires in accordance with our beliefs. Adults understand this intuitively. When a girl exclaims “I’m starving—I’m craving a piece of fruit!” and begins to search extensively for an apple in the kitchen even though a pear is in plain sight, adults can infer that the girl wants to eat a fruit, that she has a preference for apples over pears, and that she has a reasonable degree of belief that there is an apple in the kitchen. Our explanation of the girl’s action in terms of inferred beliefs and desires relies on a Theory of Mind (ToM): we understand that agents have a working representation of the world that may or may not reflect reality, that this representation is influenced by perceptual access and priors, and that this representation is the basis for subsequent behavior (Gopnik & Wellman, 1992).

If the girl believes that apples are in the fruit basket, we confidently predict she will look for one there, even if we know that the apples are actually in the cupboard. This ability is assessed by the famous “False-Belief task<sup>1</sup>” (Wimmer & Perner, 1983), on which children typically transition from failure to success between the ages of three and five (Wellman, Cross, & Watson, 2001). Most prior

work studying the development of representational ToM has used versions of the False-Belief task to ask children to predict an agent’s behavior, given the agent’s previously established beliefs and desires. In contrast, there has been less work studying how children solve the *inverse problem*: inferring beliefs and preferences from an observed behavior. Given the girl’s extensive search for a fruit in the kitchen, how do we simultaneously infer her beliefs and preferences? Both kinds of judgments—predicting actions given beliefs and desires, and inferring beliefs and desires given actions—tap similar ToM reasoning abilities. This paper aims to test whether the development of the ability to make ToM inferences parallels the transition to understanding false beliefs, and to provide evidence for a formal account of the knowledge supporting both ToM abilities.

The ability to solve this inverse problem is analogous to solving one equation with two unknowns; our natural ability to consider context, weigh in with priors, and make rational inferences enables us to come up with a good guess on questions we would otherwise not be able to answer. Studying this ability in the social domain illustrates the power of ToM to go “beyond the data” and infer multiple implicit mental states from just one observed action. Prior work by Baker et al. (2011) presented adult participants with an inverse mental-state-inference task and showed that adult mental state inferences are well-explained within a rational probabilistic inference framework. Here, we use an analogous paradigm to measure spontaneous mental state inferences made by children 3-6 years of age and assess which observed behaviors prompt mental state inference. By doing so, we are measuring children’s expectation that all parts of an action should have a sufficient explanation in terms of mental states.

If this inferential ability develops in parallel with the ability to predict behavior given a mental state, we would expect a similar shift in performance between the ages of three to five on inverse problems that require mental state inference. On the other hand, it is possible that the ability to infer mental states from sparse information develops later in life. This process not only requires the ability to take the perspective of another and maintain multiple representations of the world, but it also requires that the viewer spontaneously seeks to understand observed actions in terms of underlying beliefs and desires.

In our experiment, children watched a short 3D animation of a hungry bunny navigating a world to find and eat one of three different fruits. The bunny can take one of three paths: (1) pass the nearest, visible fruit to check around a wall to choose the fruit there (2) take a direct path to the nearest,

<sup>1</sup> “Explicit” vs. “implicit”: Surprisingly, infants succeed in looking-time paradigms tapping analogous notions of perceptual access and false belief representation (Onishi & Baillargeon, 2005).

visible fruit (3) take the longest path, passing the nearest fruit to check around the wall (in sight of the farther fruit), and then turning back to choose the near fruit. These three paths suggest different orders and degrees of preference for the three fruits, according to both our intuition and three computational models. In particular, the third path can only be fully interpreted as rational if children infer that the bunny was “looking for” the missing fruit. We analyze how many children inferred the bunny’s fruit preference, as a function of age and condition (i.e., the bunny’s path). In doing so, we believe we are assessing a sophisticated aspect of ToM reasoning: the ability to make rich inverse inferences from limited data.

## Methods

### Participants

143 children were recruited from a local children’s museum to participate in the study. Out of these, 103 were included in the final sample (70 females, 3-4yo group:  $M=4.02$ ,  $SD=0.62$ ; 5-6yo group:  $M=5.79$ ,  $SD=0.56$ ). 40 participants were excluded; 28 for answering at least one of four memory and control questions incorrectly, 5 for parent or sibling interference, 4 for not answering all of the questions, and 3 for experimenter error.

55 adults were recruited from an MIT human subjects listserv. Out of these, 54 were included in the final sample (30 females,  $M=25.95$ ,  $SD=6.14$ ). 1 participant was excluded for not following task instructions.

### Stimuli and Design

3D animated movies were created using Alice 2.2 programming software (<http://www.alice.org>). Stimuli are available at: <http://saxelab.mit.edu/bunny/>. Each participant watched one movie two times followed by a short ending.

**Movie Introduction** Each movie begins with a bunny standing on a green platform. A brown wall divides the platform—this wall reaches above the bunny’s eye level, obstructing his view of the other side. There is a tree with three different fruit on the bunny’s side of the wall. The fruit varied in shape and color (yellow, red, and orange), and position of the fruit was counterbalanced across children. At the beginning of the movie, the bunny waves and says “Hello!” He then turns to the tree, points at the three fruits (ambiguously), and says, “I’m hungry, I want that one!” He attempts to reach the fruit, and eventually succeeds in knocking all three fruits off the tree simultaneously. While the bunny is still facing the tree, the three fruit fall down and roll away—one lands in plain sight of the bunny (Fruit 3), but the other two roll to the other side of the wall. One of these fruits stays on the other side of the wall (Fruit 2), and the other (Fruit 1) falls off of the platform. In the movies viewed by children, Fruit 1 rolled out of sight. The bunny turns to get his fruit, sees Fruit 3, and takes one of three paths: Check Stay (CS), No Check (NC), or Check Turn (CT) (see below for detailed description).

This introduction was created to allow viewers to understand the bunny’s initial belief state about the world. Before he embarks on one of three paths to find a fruit, participants are provided with evidence that the bunny knows that the three fruit exist, and knows that they rolled away. They are also prompted to understand that the bunny is hungry and has a preference for one fruit over the others. Finally, participants know that the bunny has initial perceptual access to Fruit 3, and some degree of belief that the other fruits might be on the other side of the wall. These priors were similarly built into our computational models.

Between the two movie viewings, participants saw a black screen with the words “Let’s watch one more time!” for 3 seconds. The experimenter read this text out loud to child participants at this time.

**Paths** The bunny’s paths were designed to evoke inferences about the bunny’s preferences and beliefs. Below we describe each path, and note in italics the inferences that each path elicits. While we believe these inferences are intuitive, we also characterize them through three formal computational models (see Computational Models section).

**Check Stay (CS)** The bunny passes Fruit 3, walks to the other side of the wall, and chooses Fruit 2 (see Fig. 1). *Predicted Inferences: all age groups will infer that Fruit 2 is the bunny’s favorite fruit. Passing Fruit 3 is the strongest evidence from which to infer that Fruit 3 is the least favorite fruit. Fruit 1 is underspecified.*

Figure 1: Final frame of Check Stay Condition (red arrow shows path).

**No Check (NC)** The bunny walks directly to Fruit 3 (see Fig. 2). *Predicted Inferences: all age groups will infer that Fruit 3 is the favorite fruit. There is no distinguishing evidence for preference order between Fruit 1 and Fruit 2, so the bunny’s least favorite fruit remains ambiguous.*

Figure 2: Final frame of No Check Condition (red arrow shows path).

**Check Turn (CT)** The bunny passes Fruit 3, walks to the other side of the wall, sees Fruit 2, and goes back to Fruit 3 (see Fig. 3). *Predicted Inferences: Participants who attribute initial uncertainty about the locations of the occluded fruits to the bunny will infer the correct preference order: the bunny’s favorite fruit is Fruit 1, and his least favorite fruit is Fruit 2. Participants who do not consider the bunny’s beliefs will infer that the bunny’s favorite fruit is Fruit 3 and his least favorite fruit is Fruit 2.*

Figure 3: Final frame of Check Turn Condition (red arrow shows path).

**Movie Ending** After children viewed both the introduction and path twice, they viewed a short ending. This ending shows all three fruit roll within sight and reach of the bunny, making it clear that this time, the bunny can choose any of the fruits. All participants were shown a laminated picture of the final frame of this ending, which shows the bunny equidistant from all three fruit. This picture enabled children to respond to questions by pointing, and was placed in front of adults as they filled out the short questionnaire.

All participants sat approximately 12-18” from the movie, which was played on a 15” MacBook Pro. Each participant watched two trials of one condition for a total watching time of 3:11 minutes (CT condition), 2:48 minutes (CS condition), or 2:25 minutes (NC condition).

Adult participants were asked to rank how much the bunny liked each of the fruits on a Likert scale from 1-7 (Not Much-Very Much). They were also asked to explain their rankings (“How do you know?”). All responses were recorded by the participant using pencil and paper.

Child participants were asked two control questions, four test questions, and two memory check questions after watching the movie. The first control question asked the child to identify each fruit by pointing to it on the laminated picture; the order of fruits was counterbalanced across children. The second control question asked, “At the beginning of the movie, how many fruit did the bunny see in the tree?” Children were then asked “Which fruit do you think is the bunny’s favorite?” and “How do you know?” Next, children were asked “Which fruit do you think is the bunny’s least favorite—which one does he not like?” and “How do you know?” Finally, children were asked “During the movie, which fruit fell off and rolled away?” and “During the movie, which fruit did the bunny pick?” The control questions provided reasonable exclusion criteria and enabled us to confidently report that children were engaged by the movie and remembered its content, while the test questions provided us with sufficient information regarding preference understanding (which fruit was favorite, neutral, and least favorite). Most children responded to the favorite and least favorite questions by pointing to the laminated picture (rather than responding verbally). Child testing sessions were recorded using a video camera. Parents were usually in the testing room with the child participants, but were asked to remain quiet during the experiment.

### Computational Models

We model children and adults’ mental state inferences as a kind of probabilistic causal reasoning. One way to approach inverse problems is through Bayesian inference, which describes the process by which people generate and test hypotheses based on their expectations and evidence. The probability of a hypothesized mental state  $H$ , given observed evidence  $E$ , denoted  $P(H|E)$ , depends on  $P(E|H)$ , the likelihood of the evidence, given the hypothesis, and  $P(H)$ , the prior probability that the hypothesis is true, according to Bayes’ rule:

$$P(H|E) \propto P(E|H)P(H).$$

Posed in the context of this study: given the path that the bunny takes and the fruit that he chooses ( $E$ ), what were his initial beliefs and desires ( $H$ )?

To capture the development of the ability to represent and infer mental states, we formulated three models: Outcome-Based (OB), Desire Theorist (DT), and Bayesian ToM (BToM). The Outcome-Based model assigns full preference to the fruit that the bunny chooses; it is not influenced by the bunny’s beliefs or the path that he takes. The DT model is based on the Copy Theorist model of Goodman, et al. (2006). DT is a non-mentalistic model that represents how an agent’s desires and the world state—but not the agent’s beliefs—cause its actions, via the principle of rational action (Gergely et al., 1995). The DT model can infer

straightforward desires that do not depend on the actor's belief state. We expect this model to explain mental state inferences that derive mainly from which fruit the bunny chose. The third model is based on the BToM framework proposed by Baker et al. (2011), which models a mentalistic theory. BToM incorporates a principle of rational belief: the assumption that agents maintain beliefs about the world that are consistent with physical laws and depend on their perceptual access to the world (i.e., visual access to different fruits). This enables simultaneous inference of agents' beliefs and desires, given observations of their behavior.

The DT and BToM models assume that the bunny's actions are guided by his degree of desire (subjective value) for each fruit, which trades off against his expected costs to reach them. The bunny incurs costs for effort (quantified by the number of steps taken per path: 1.5 steps for NC, 2.75 for CT, and 3 for CS) and time (an additional cost of .25 for checking around the wall). The bunny's favorite fruit is assigned a value of 15, the second-favorite fruit a value of 5, and the least favorite fruit a value of 1. This desire scale reflects a strong preference for one fruit and is calibrated to the spatial scale of the environment; changing these approximate values does not alter the trends observed. The OB model also assumes that the bunny's actions are guided by desire, but does not assign incorporate costs or rewards; the chosen fruit is considered the bunny's favorite, and the two unchosen fruits are equally least favorite.

The BToM model attributes initial uncertainty to the bunny about the locations of the two non-visible fruit: both, one, or neither of the two fruits may be available behind the wall. In the BToM model, the bunny's beliefs are updated when he moves to the other side of the wall. The Desire Theorist model, on the other hand, assumes the bunny's actions depend only on the true world state. For BToM, costs incurred to check around the wall are rational if the bunny desires one of the two non-visible fruits and believes it could be there; in the DT model, there is no explanation of why the bunny incurred these costs.

This key difference is most evident in the Check Turn condition, which allows us to assess whether three/four-year olds, five/six-year-olds, and adults incorporate information about uncertainty, planning, and belief updating into their desire inferences. If so, their responses should be better predicted by the BToM model than the DT model. This difference is comparable to the performance shift on the False-Belief task between children who are three and five years old; three-year-old children refer to salient outcomes, actions, and desires, while five-year-old children take beliefs into consideration.

## Data Analysis

Child responses to the four control and memory questions, two preference questions, and two explanation questions were transcribed from the recording of the testing session. From these data we recorded the proportion of participants in each age group (3-4yo, 5-6yo, and adults) who reported each fruit (1,2, and 3) as "favorite" and "least favorite" in

each condition (CS, NC, CT). We binarized adult participant data; the fruit that was assigned the highest number on the Likert scale was coded as the favorite, and the fruit assigned the lowest number was coded as the least favorite. Whereas all participants picked one fruit as the favorite for each condition, participants often reported two fruits as least favorite. In this case, each fruit received half the weight assigned to a single favorite or least favorite fruit (.5).

We used logistic regression to test for main effects of age (a continuous variable), condition (CS, NC, CT), and age by condition interactions on favorite and least favorite fruit choice. We used a Bonferroni correction ( $n=3$ ) for multiple comparisons.

To compare behavioral judgments to the three models, we separated participants into three groups: younger children (age 3-4 years,  $n=56$ ), older children (age 5-6 years,  $n=46$ ), and adults ( $n=54$ ). We calculated the probability of choosing each fruit (3) as favorite or least favorite (2) in each condition (3). We compared the resulting 18 values for each group to the corresponding predictions from each model, using a Pearson's correlation.

## Results

### Check Stay (CS) Condition

This condition is a good measure of spontaneous understanding of preference; the bunny picks Fruit 2 after explicitly passing Fruit 3. We expected that children of all ages as well as adults would correctly identify Fruit 2 as the favorite, as predicted by all three models. We found a positive main effect of the CS condition on choosing Fruit 2 as the favorite fruit ( $p<0.001$ ), and a negative effect of the CS condition on choosing Fruit 2 as the least favorite fruit ( $p=0.043$ ). There were no significant effects of age on fruit choice in this condition. Fig. 4 shows that participant judgments were well predicted by the DT and BToM models across age.

### No Check (NC) Condition

This condition is an interesting measure of how participants understand preference when there is less evidence available. The bunny approaches the only visible (and closest) fruit, Fruit 3, providing weaker evidence for his preference; his choice may reflect efficiency or lack of options, rather than a strong preference. Again, all groups successfully picked Fruit 3 as the most likely favorite. We found a positive main effect of the NC behavior on choosing Fruit 3 as the favorite ( $p<0.001$ ), and a negative main effect of the NC behavior on choosing Fruit 3 as the least favorite ( $p=0.020$ ). There was no significant difference between age groups.

We were specifically interested in whether observers were sensitive to the weaker evidence in NC compared to CS paths; if so, Fruit 1 should be more likely to be chosen as least favorite in the NC condition than in the CS condition (because in the CS condition, the bunny explicitly avoided Fruit 3). Only the BToM model showed this qualitative pattern. Although this difference was not significant in any age group individually, combining across age groups did

Figure 4: Results of “Favorite” and “Least Favorite” judgments across conditions and age groups. The bottom row compares the results of the OB, DT, and BToM models to human judgments, matching the qualitative developmental shift between younger and older participants.

reveal the predicted pattern (25/47 chose Fruit 1 as least favorite in NC, compared to 16/49 in CS,  $p < 0.05$ , Fisher’s exact test).

### Check Turn (CT) Condition

This condition tests spontaneous inference of both the beliefs and preferences of the agent. It requires participants to consider the agent’s actions in terms of preferences (which fruit did he really want?) and counterfactuals (what was he looking for behind the wall, that he could have seen but did not?) rather than outcome (which fruit did he pick?). Given the well-documented shift from failure to success on False-Belief tasks, we expected 3-4 year olds to perform significantly worse than 5-6 year olds and adults on the “favorite fruit” question.

We found a positive age by condition interaction on choosing Fruit 1 as the favorite fruit ( $p = 0.029$ ) and a significant negative age by condition effect on choosing Fruit 1 as least favorite ( $p = 0.021$ ). These results show that as participants got older, their judgments slowly came to better resemble the predictions of the BToM model. The salient fact that the bunny chose Fruit 3 was difficult for younger participants to ignore, as suggested by the OB and DT model predictions. As a result, there was also a positive main effect of the CT condition on choosing Fruit 3 as the favorite ( $p = 0.001$ ) and a negative main effect of condition on choosing Fruit 3 as least favorite ( $p = 0.020$ ).

### Model Comparison

Combining across the three conditions, we compared the responses of each age group to the three models. Judgments made by 3-4 year old children were most strongly correlated with the predictions of the OB model ( $r = .902$ ), followed by the DT model ( $r = .898$ ), and least with the BToM model ( $r = .719$ ). In contrast, judgments made by 5-6 year old children correlated most strongly with predictions made by the DT model ( $r = .898$ ) followed by the BToM model ( $r = .812$ ), and correlated least with the OB model ( $r = .786$ ). Adult preference predictions were most strongly correlated with the BToM model ( $r = .943$ ), followed by the DT model ( $r = .920$ ), and least correlated with the OB model ( $r = .678$ ). These data support the idea that across development, people increasingly incorporate spontaneously attributed beliefs and desires into their understanding of agents’ behavior.

### Discussion

In this study we used a novel ToM task to examine the development of the ability to spontaneously attribute mental states in order to understand an agent’s observed actions, i.e., to solve inverse social inference problems. Our results suggest that this ability emerges gradually, with performance continuing to improve after age 5-6 years.

In particular, on the critical Check Turn condition a sufficient explanation of the bunny’s behavior requires children to infer that the bunny checked behind the wall because he was looking for (and preferred) the missing Fruit 1. This inference depends on recognizing that the bunny

initially didn't know which fruit was behind the wall, and that he couldn't have been looking for Fruit 2, because he subsequently turned back to Fruit 3 (which he initially bypassed). Observers would only make this complex inference if they sought a sufficient rational explanation of the bunny's whole path. Most 3-4 year old children effectively ignored the "checking" path, inferring that the bunny prefers whichever fruit he chooses in the end. This behavior mimicked the prediction of our Outcome-Based and Desire Theorist models. Five and six year olds were somewhat more likely to take the checking path into consideration, recognizing Fruit 1 as the favorite, and adults were even more likely to do so. This created a gradual increase with age in the match between participants' choices and the predictions of the Bayesian Theory of Mind model.

One limitation of the current experiment is that we did not test children older than 5-6 years, so we cannot say whether children's performance on these tasks reaches adult levels by age 7-9 years, or whether there is extended development through adolescence. Another limitation is that children's choices for the "least favorite" fruit were frequently ambiguous (both fruits not identified as favorite were often considered least favorite). We are currently working on an extension in which children provide a full ordering of the bunny's preference for all three fruits.

The current results are amenable to multiple interpretations. First, children may be becoming more sophisticated and adept at thinking about other minds. Simultaneously inferring a belief and a desire may require a more robust ToM capacity than using beliefs and desires to predict actions. If so, these results may be related to the observation that children's ToM brain regions also become increasingly selective after age 5-6 years (Gweon, Dodell-Feder, Bedny, & Saxe, in press). Another possibility is that over development, children become more committed to the idea that agent's actions are rational, and require sufficient rational explanations. Thus, younger children may be less likely to view others' actions as efficient paths toward their goals, and so the bunny's deviant path may not seem to require any explanation. As children expect more efficiency from others, the deviant path may become more salient, and demand an explanation. Finally, a third possibility is that children's ability to focus on and interpret the bunny's path, in addition to his (highly salient) final position, depends not on ToM development per se, but on unmasking of prior competence by the development of executive function (Carlson, Moses, & Breton, 2002; Baillargeon, Scott, & He, 2010).

Another key question is how infants will perform on this task. Recent evidence from looking time suggests that infants have a nascent ToM, and can update representations of agents' beliefs and desires given their perceptual access, in change-in-location and appearance-reality tasks (for a review, see Baillargeon et al., 2010). We believe that if infants make simultaneous inferences about beliefs and desires in the current paradigm, it would be particularly

strong evidence for a mentalistic account of infant ToM abilities.

In sum, the current study is an initial step toward clarifying how we develop the ability to make joint belief-desire inferences in order to understand other minds. It contributes to the current literature on ToM development, suggesting that children develop this ability in parallel with other mentalistic reasoning abilities between the ages of three and five, and could serve as a launching point for future work studying rich social inferences made by infants.

# Expectations About the Temporal Structure of the World Result in the Attentional Blink and Repetition Blindness

Cory A. Rieth & Edward Vul (crieth, evul@ucsd.edu)

## Abstract

We consider how repetition blindness and the attentional blink might arise from prior assumptions about the occurrence of task-relevant states of the world. Repetition blindness and the attentional blink are behavioral deficits in the identification of items during rapid serial visual presentation at varying delays after identifying the first “target.” Here we propose that both of these effects are explained by rational inference given prior expectations about the timing of task-relevant world transitions. While such expectations would be helpful in the natural world, they may result in unanticipated biases in laboratory settings. We show that a rational model using prior expectations of the timing of task-relevant information captures the basic repetition blindness and the attentional blink effects, and also the specific distributions of errors made during the attentional blink.

**Keywords:** Attentional blink; Repetition blindness; Attention; Computational Modeling; Bayesian Models

## Introduction

Repetition blindness and the attentional blink refer to common failures in identifying stimuli shortly after an important event. Both phenomena are typically studied in rapid serial visual presentation (RSVP) tasks, in which many stimuli (often letters or digits) are displayed in quick succession. In the task people are asked to pick out some specific “targets” from the RSVP stream (for instance, letters among digits, or letters cued by a ring). After the first target ( $T_1$ ), a second target ( $T_2$ ) appearing within a few stimuli of the first tends to be misreported – this is called the “attentional blink” (AB; Figure 1, top; Raymond, Shapiro, & Arnell, 1992; Weichselgartner, 1987). If an identical target is presented twice without much time intervening, people tend to not notice the repetition, yielding “repetition blindness” (RB; e.g., the ‘E’ in the bottom section of Figure 1; Kanwisher, 1987).

Although both RB and AB have many surface similarities, they follow a qualitatively different time-course as a function of the “stimulus onset asynchrony” (or lag) – the time between the onset of  $T_1$  and the onset of  $T_2$ . The attentional blink exhibits lag-one sparing – if  $T_2$  appears immediately after  $T_1$ , detection is often not impaired; in contrast, the RB deficit is most pronounced at such short delays. Moreover, when manipulated within one experiment, these effects have independent, dissociable effects (Chun, 1997). Several accounts of RB and AB postulate resource limitations (Shapiro, Raymond, & Arnell, 1997) in individuating items into unique tokens and binding them to type identities (Kanwisher, 1987; Bowman & Wyble, 2007). Moreover, the time-course of these effects has been the target of several computational process models that utilize specific mechanistic dynamics of attention

and memory (Bowman & Wyble, 2007; Olivers & Meeter, 2008).

Here we do not aim to supplant these models, but only to provide a rational account of these dynamics, to explain why the visual system may exhibit AB and RB. We remain agnostic to the particular processes and implementations, and instead seek an understanding of the computational principles that may be in play. We develop a probabilistic model of target identification by *co-occurrence detection*, which aims to infer which item occurred simultaneously with the cue, given temporal uncertainty and expectations about world dynamics. First we describe the derivation of the model based on assumed temporal statistics, then illustrate its application to the basic RB and AB paradigms. Finally, we will apply this model to AB response distributions.

## Attentional Blink

## Repetition Blindness

Figure 1: Repetition blindness and attentional blink paradigms. Each row of letters represents a particular type of trial where the letters appear in rapid succession. Repetition blindness arises when a target repeats, and participants indicate whether it appeared once or twice: performance is worse at short inter-target intervals when the two targets are identical compared to when they are different. The attentional blink occurs when the task requires identifying two designated targets: Participants can report items in quick succession, as in the top attentional blink row (“lag-one sparing”); however, when the second target appears a few items later, participants are less accurate.

## RSVP Identification Model

We assume that people identify targets in an RSVP task via the probability that a given item co-occurred with the cue. Under this assumption, the observer’s task is to infer the letter identity ( $\mathcal{L}$ ) of the second target ( $T_2$ ), by marginalizing over all possible stimuli used in the experiment ( $x_i$ ) that may have coincided with the cue. The probability that the cue

co-occurred with item  $i$  at time  $t$  is the product of the probability that the item ( $\mathbb{X}_i(t)$ ) and cue ( $\mathbb{C}(t)$ ) were present at that time. This quantity is integrated over time to obtain an unnormalized probability of item  $i$  co-occurring with the cue. The core of our model is an assumption that participants use prior expectations about the times when salient or task-relevant events are likely to occur ( $P(\text{any}|t)$ ). The probability of co-occurrence at a given time is thus weighted by the probability the stimulus at time  $t$  will be relevant for the task. Thus, the participant's subjective probability distribution over possible identities of the second target is given by:

$$P(Y(T_2) = \mathcal{L} | S, \Omega) \propto \sum_i P(x_i = \mathcal{L}) \int_{t=0}^{\infty} \mathbb{C}(t) \mathbb{X}_i(t) P(\text{any}|t), \quad (1)$$

where  $P(x_i = \mathcal{L})$  is 1 when  $x_i$  is  $\mathcal{L}$ , and 0 otherwise. To distinguish between the letter identity, or *type*, and a particular instance of a letter, or the *token*, we use  $T_2$  to denote the token of the second target, and  $Y(T_2)$  to denote its type.<sup>1</sup>  $S$  refers to the stimulus sequence of the trial, including the particulars of which items occurred at which points in time, and when the cue occurred.  $\Omega$  includes the set of parameters which our model uses to describe subjective uncertainty and expectations about the task. The following sections describe the parameters used to calculate  $\mathbb{C}(t)$ ,  $\mathbb{X}_i(t)$ , and  $P(\text{any}|t)$ .

### Perceptual Likelihood

In RSVP tasks, participants often misreport item identities (Vul & Rich, 2010; Vul, Hanus, & Kanwisher, 2009) and their presentation order (Wyble, Potter, Bowman, & Nieuwenstein, 2011), indicating that even without RB and AB, there is considerable uncertainty about the relative timing of cues and items. The cue-function ( $\mathbb{C}(t)$ ) and the item-function ( $\mathbb{X}_i(t)$ ), account for this temporal uncertainty: they represent the subjective probability that these stimuli were presented at a given point in time. Both of these functions are obtained by convolving some temporal uncertainty kernel with the physical time series of stimulus presentation. We use the Student's t-distribution as the uncertainty kernel.<sup>2</sup>

Thus, the cue-function ( $\mathbb{C}(t)$ ) and the item-function ( $\mathbb{X}_i(t)$ ), are defined as a boxcar function – representing the physical presence of the stimulus – convolved with a t-distribution – representing perceptual uncertainty about the precise time of stimulus onset and offset:

$$\mathbb{C}(t) = P(\text{cue on}|t) = \text{boxcar}(t | \text{onset}, \text{offset}) \otimes \text{Student}(t | \sigma_c, v_c),$$

<sup>1</sup>In general,  $P(Y(x_i) = \mathcal{L})$  could capture perceptual uncertainty about stimulus identity (to reflect that some letters are more confusable than others), but here we ignore this complication, and assume no pairwise letter confusion, by assigning probability 1 to the actual identity of  $x_i$ , and 0 to all other alternatives.

<sup>2</sup>Our qualitative results do not much depend on the specific functional form of the temporal uncertainty kernel – simple Gaussian distributions are sufficient – but our numerical results are more consistent with human behavior when using a heavy-tailed distribution, like the t-distribution.

where ( $\otimes$ ) is the convolution operator, the boxcar function is 1 between the onset and offset of the cue, and 0 otherwise, and  $\text{Student}(t | \sigma_c, v_c)$  is a scaled Student's t-distribution with mean 0,  $v_c$  degrees of freedom, and standard deviation  $\sigma_c$ . This convolution operation effectively captures uncertainty about the exact onset and offset of the cue. Similarly, the item function can be written as:

$$\mathbb{X}_i(t) = P(x_i | t) = \text{boxcar}(t | \text{onset}, \text{offset}) \otimes \text{Student}(t | \sigma_x, v_x).$$

In the simulations presented later  $v_x = v_c = 2$ ,  $\sigma_x = 30$ , and  $\sigma_c = 75$ . The larger uncertainty for the cue reflects the fact that the cue in a RSVP stream is a rare and unpredictable occurrence relative to the steady stream of items.

### Prior for Task-Relevant Events

Both RB and AB are conditioned on correct detection/identification of the first target ( $T_1$ ) in an RSVP stream. Therefore, we consider expectations about whether any task-relevant stimulus is likely to be visible at time  $t$  after the onset of the  $T_1$ . We write this as  $P(\text{any}|t)$ . Since  $T_1$  is, by definition, task-relevant,  $P(\text{any}|t)$  decomposes into the mutually exclusive probabilities that old task-relevant information is still visible ( $P(\text{old}|t)$ ) and that new task-relevant information has appeared ( $P(\text{new}|t)$ ):

$$P(\text{any}|t) = P(\text{old} \cup \text{new}|t) = P(\text{old}|t) + P(\text{new}|t). \quad (2)$$

To obtain these time-varying probability functions, we must assume a transition distribution for the world, that is: what is the probability distribution of the interval between changes in the world? We write this distribution as  $P(R_1 = t)$ , the probability that the first transition ( $R_1$ ) occurred at time  $t$ . This distribution reflects implicit beliefs about the temporal structure of the world (we will later discuss different choices of this transition distribution). Figure 2 illustrates the derivation of the different elements of  $P(\text{any}|t)$ , from  $P(R_1 = t)$ . Based on this transition distribution, the probability that an old task-relevant stimulus is still visible at time  $t$  is given by the probability that the first transition has not yet happened – that is, the probability that the first transition will happen at a time later than  $t$ :

$$P(\text{old}|t) = P(R_1 > t) = 1 - \int_{t'=0}^t P(R_1 = t') \quad (3)$$

To find the probability that a new task-relevant stimulus has appeared by a given point, we must take into account that not every transition in the world produces a task-relevant stimulus. We define the parameter  $\theta$  as the probability that a transition yields a task-relevant stimulus, and define  $P(\text{new}|t)$  as the sum of a convolution series of transitions. The probability that the  $n$ th transition will occur at time  $t$  ( $P(R_n = t)$ ) is computed as the  $n$ th convolution power of the transition dis-

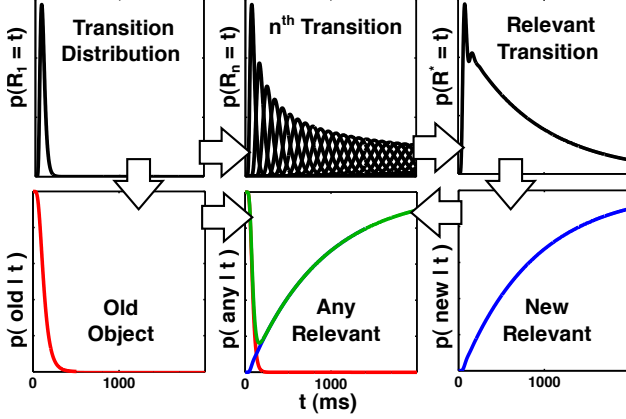

Figure 2: Construction of the prior probability of any task-relevant information at time  $t$  from an assumed transition distribution between world states (see text).

tribution (where  $\otimes$  is the convolution operator):

$$P(R_n = t) = P(R_1 = t) \otimes^n = \underbrace{P(R_1 = t) \otimes P(R_1 = t) \otimes \dots \otimes P(R_1 = t)}_n. \quad (4)$$

Since each transition yields a task-relevant stimulus with probability  $\theta$ , the probability that the first task-relevant stimulus ( $R^*$ ) appears at time  $t$  is given by the probability of any number of non-task-relevant transitions occurring followed by a relevant observation (in other words, the sum of the geometrically weighted convolution series of transitions):<sup>3</sup>

$$P(R^* = t) = \sum_{n=1}^{\infty} \theta(1 - \theta)^{n-1} P(R_n = t) \quad (5)$$

The probability that a new item has appeared at some point before time  $t$  – that is,  $P(\text{new}|t)$  – can be calculated by evaluating the cumulative distribution of  $P(R^* = t)$ :

$$P(\text{new}|t) = P(R^* \leq t) = \int_{t'=0}^t P(R^* = t') \quad (6)$$

### Choice of Transition Distribution

What might be a reasonable form of  $P(R_1 = t)$ ? If we consider world changes to be the result of saccades,  $P(R_1 = t)$  would be a distribution of inter-saccadic intervals, which is well-approximated by a log-normal distribution (Wang, Freeman, Merriam, Hasson, & Heeger, 2012). Alternatively, assuming transitions in the world follow a Poisson process will yield an exponential distribution of transition times. Another approach is to consider transition times to be normally distributed around the rate of the RSVP task itself. This would be the case if subjects were noisily calibrated to the RSVP stream used, which has a regular structure. The insets of Figure 3 illustrate these three possibilities. The larger graphs

<sup>3</sup>In practice, we evaluate this infinite sum numerically by truncating higher order elements of the series (dropping  $ns$  for which the probability of having not yet transitioned to a task-relevant state  $((1 - \theta)^{n-1})$  is less than .001).

Figure 3: The resulting  $P(\text{old}|t)$ ,  $P(\text{new}|t)$ , and  $P(\text{any}|t)$  from several theoretically-motivated possible transition distributions. The probability density of each assumed transition distribution is illustrated in the insets.

show, in green,  $P(\text{any}|t)$  from each of these options. These resulting priors on a task-relevant stimulus being visible (in green) are similar for all three possible transition distribution functions. At short delays from the first target, the probability of a task-relevant object is initially high, since the first transition is unlikely to have yet occurred. However, after the first transition, with  $\theta < 1$ , a new object is not certain to be task-relevant; thus the probability that a new task-relevant item has appeared remains low. With more time, the probability of observing a novel task-relevant item increases. This combination results in the initial dip and later recovery of the prior on task-relevance – this shape of  $p(\text{any}|t)$  is the backbone of our model.

Throughout the results sections, we use the log<sub>10</sub>-normal distribution with  $\mu = 100$  and  $\sigma = .15$ , and  $\theta = .1$ . A higher  $\theta$  results in a smaller dip in the resulting prior, and a smaller RB or AB effect; decreasing  $\mu$  results in a faster time-course, while increasing  $\mu$  results in a slower time-course.<sup>4</sup>

### Modeling Repetition Blindness

In an RB paradigm, participants must decide whether a given stimulus was presented once or twice. In other words, they must decide if there were two tokens of the same type, or just one token (e.g., one or two “E”s in Figure 1). In our notation, the participants challenge is to determine if the two identified targets correspond to only one token ( $T_1 = T_2$ ). This posterior belief is given by:

$$P(T_1 = T_2 | S, \Omega) \propto \begin{cases} \Upsilon(T_1) = \Upsilon(T_2) & \int_{t=0}^{\infty} \mathbb{C}(t) \frac{P(\text{old}|t)}{P(\text{old}|t) + P(\text{new}|t)} \\ \Upsilon(T_1) \neq \Upsilon(T_2) & 0 \end{cases} \quad (7)$$

In words: if the types of  $T_1$  and  $T_2$  are different, then they must be different tokens; if their types are the same, then the

<sup>4</sup>To the best of our knowledge, any transition distribution defined on the support of  $(0, \infty)$  will produce qualitative results similar to RB and AB. This is because  $P(\text{new}|t)$  is defined as the cumulative distribution of a series of convolutions of  $P(R_1 = t)$ , making the prior robust to the specific choice. The time-course of the RB/AB effects will be determined by the median of the transition distribution. In our case, anything with a median of about 100 seems to yield a qualitatively appropriate time course.

probability of them being the same token is given by the probability that the participant perceived the cue before a transition from  $T_1$  was expected.

We assume that participants adopt a soft-max response strategy (effectively sampling from this distribution); thus the expected frequency of correct detections of a repetition is  $P(T_1 \neq T_2 | S, \Omega) = 1 - P(T_1 = T_2 | S, \Omega)$ . The left graph of Figure 4 shows simulation results for a generic RB task with 40 ms targets and 40 ms gaps between items. Overall the qualitative pattern of data is correct. There is no “lag-one sparing”, and the probability of a correct response increases with greater delays.

Figure 4: Model results for the RB, AB, and combination tasks. RB accuracy corresponds to the probability that the target item is a new token. AB accuracy is the probability that the cue is inferred to coincide with the second target item. The middle plot shows the combination of both effects, as in Chun, (1997).

### Modeling the Attentional Blink

In the attentional blink task, the participant needs to determine the identity of the stimulus co-occurring with the cue. Therefore the posterior distribution that the correct  $\mathcal{L}$  was  $P(Y(T_2))$  is given directly by Equation 1. Responses from the posterior are again considered to follow a soft-max rule. That is, the relative frequency of reporting the item  $\mathcal{L}$  as the second target is  $P(Y(T_2) = \mathcal{L} | S, \Omega)$ . The right panel in Figure 4 shows that the time-course of  $T_2$  accuracy matches the typical AB effect: Accuracy for target detection just after  $T_1$  is high (lag-one sparing), and then drops off, recovering after a few hundred milliseconds. The center panel illustrates simultaneous AB and RB effects using the same task and model structure, as has been observed behaviorally (Chun, 1997). Here we can account for both effects as a natural consequence of temporal uncertainty and expectations. While capturing of the qualitative patterns of the AB and RB results is interesting, there are many models that can fit this data (Bowman & Wyble, 2007; Olivers & Meeter, 2008). We now turn to the specific error distributions in the attentional blink to test finer-grained predictions of our model.

### Error Distributions in the Attentional Blink

Our model has the fidelity required to make not only predictions of changes in accuracy as a function of inter-stimulus interval in the attentional blink, but also the error distributions – when  $T_2$  is misreported, which items are reported instead? Vul, Nieuwenstein, and Kanwisher (2008) presented subjects with an RSVP stream containing all 26 English letters at 12 items/sec. Two letters were cued as targets by flashes of an

annulus around the stream (as illustrated in Fig 1). Participants were asked to report the identities of the letters that appeared simultaneously with the cues, in order. Since each english letter appeared only once in the RSVP stream, the authors could identify the exact serial position where the reported letter occurred on each trial; thus they could determine exactly which items, relative to  $T_2$ , tended to be reported in its place (Figure 5). The attentional blink can be decomposed into three changes in error distributions that follow different time-courses (Figure 6): (1) At  $T_1 - T_2$  lags of 100 to 500 ms, participants tend to make more random guesses: their responses are less likely to come from a window around  $T_2$ ; (2) At lags between 50 and 400 ms, responses tend to be more highly dispersed around  $T_2$ : participants are more likely to report letters several items away from  $T_2$ ; (3) At lags shorter than 300 ms, items *preceding*  $T_2$  tend to be misreported in its place, but after 400 ms (and lasting to lags as long as several seconds) errors instead come from items *following*  $T_2$ . We now test whether these three effects and their unique time-courses can also be accounted for by our model based on expectations about temporal structure of the environment.

Figure 5: Response distributions for cues appearing at various positions. Behavioral data are replotted from (Vul et al., 2008). Each curve is the distribution of responses from a second cue appearing at a particular SOA relative to the first target. The dark curves show the correct responses that make up the basic AB effect.

### Error Distributions in the Model

To model error responses, we calculate the model’s prediction about the probability of each possible letter identity  $\mathcal{L}$  being reported (following Equation 1). These error distributions are presented in Figure 5. Each colored curve plots the distribution of responses for a particular delay between  $T_1$  and  $T_2$  as a function of the reported item position relative to  $T_1$ . During the attentional blink, the distribution of responses is distorted by the prior about when task-relevant items occur.

The most notable effect is the reduction in accuracy itself: the items corresponding to  $T_2$  itself are less likely to be reported at  $T_1 - T_2$  lags between 150 to 500 ms. Critically, not only does the model match the accuracy time-course of human data, but it also captures the changes in error distributions. At short delays between  $T_1$  and  $T_2$ ,  $T_2$  errors tend to come from items preceding  $T_2$ , and this pattern reverses at longer delays such that items following the second target are more common intrusions instead. Finally, our model also demonstrates increased variability in which items are reported during the attentional blink. These changes in error distributions are quantified identically to the behavioral data (Vul et al., 2008), and presented in Figure 6.

Figure 6: Summary statistics of  $T_2$  response distributions during the attentional blink, as a function of  $T_1 - T_2$  delay (stimulus onset asynchrony; SOA). Each statistic is computed within a seven item window centered on the position of the second target. Top row: “Suppression” refers to a decrease in the average probability of reports (y-axis) of items within the seven item window around  $T_2$ . Middle row: “Delay” refers to the tendency to report items preceding  $T_2$  at short SOAs, and items following  $T_2$  at long SOAs; the y-axis is the mean position (relative to  $T_2$ ) of reported items within the window. Bottom row: “Dispersion” refers to the increased variance of reported positions within the window around  $T_2$  at SOAs around 150 to 300 msec.

## Discussion

We proposed an account of perception in RSVP paradigms based on probabilistic inference about the co-occurrence of cues and items under expectations about the transitions of interesting items in the world. Our model captures patterns of accuracy in RB and AB, as well as the specific error distributions in AB. The core of this account is the premise that not every world transition brings an important item into view, and a prior constructed based on this premise produces qualitatively similar results regardless of the specific choice of transition distribution.

Why would participants use this prior, since it seems to result in performance deficits? We can only speculate that performance deficits in laboratory RSVP paradigms do not reflect the benefits that such a prior could confer to people in a more natural environment. Recent work has suggested a similar account of inhibition of return (Posner & Cohen, 1984) and immediate priming (Huber, 2008), by demonstrating that the time-courses of these effects are sensitive to learned tem-

poral properties of the environment (Rieth, 2012).

Our account captures a number of other RSVP phenomena. First, because the prior is defined with respect to time, not serial position, the dynamics of lag-one sparing and the detriment to  $T_2$  reports should be constant in time, as has been experimentally shown (Wyble & Bowman, 2005; Vul et al., 2008). Second, because the relative delay of  $T_2$  reports modulates  $T_2$  accuracy, pre-cueing should improve  $T_2$  accuracy, as is the case (Nieuwenstein, Chun, van der Lubbe, Hooge, 2005; Vul et al, 2008). Third, because we assume that perception of particular targets are driven by a *sampling* process (Vul, Hanus, & Kanwisher, 2009), perception of  $T_2$  accuracy will be all-or-none, which appears to be the case (Sergent & Dehaene, 2004). Finally, since we explicitly consider the transition probability from one event to another, our account is consistent with results that the attentional blink facilitates item individuation (Wyble, Bowman, & Nieuwenstein, 2009).

A number of other findings that are not adequately captured by our account provide future challenges. Because we only consider perception of  $T_2$  contingent on  $T_1$  identification, we cannot account for “spreading the sparing” – the finding that multiple cues presented during the “lag-one sparing” interval extend the sparing window to later items (Olivers, van der Stigchel, & Hulleman, 2007) – or whole report errors and order confusion more generally (Wyble, et al., 2009; Nieuwenstein & Potter, 2006). Another challenge is the independence of the *types* of items and the assumed dynamics of the world; because of this independence, our account cannot capture the fact that sometimes words, and sometimes letters, may be treated as the relevant items of interest (Kanwisher & Potter, 1990). Furthermore, additional assumptions would be needed for our account to be consistent with findings that missed second targets in the attentional blink produce semantic priming (Shapiro, Driver, Ward, & Sorensen, 1997). Additionally, there are some aspects of human performance for which the model is quantitatively off. Overall, suppression is smaller in the model (compare the graphs in the top row of Figure 6). For longer SOAs there is less delay in the model, slightly more dispersion, and a less extreme peak in dispersion. Furthermore, in the data – but not the model – the modal response for  $T_2$  at SOAs of four to six items is actually an incorrect answer. Finally, in the AB effect, accuracy for the item just after the first cue is too high relative to other positions.

Despite these challenges, we are encouraged that our rational inference account is consistent with classic type-token theories (Kanwisher, 1987; Chun, 1997): the discrepancy between identifying, and individuating, items in an RSVP stream seems to be of central importance to combining and distinguishing between repetition blindness and the attentional blink, and our account formalizes this intuition in probabilistic inference. Furthermore, the mechanistic dynamics of attention postulated in process models of these phenomena match our prior about task transitions (Bowman & Wyble, 2007; Olivers & Meeter, 2008). We hope that future work

might provide a synthesis of these accounts.

One promising direction for future work is to extend our model to include the perception of  $T_1$ . Because our objective was to demonstrate that RB and AB effects can result from rational use of expectations about world transitions, our current account is conditioned on the identification of the first target; however, a complete model of RSVP perception must include  $T_1$ . This extension might be achieved via an online inference process to account for changing beliefs over the time course of a trial, capitalizing on particle filter approximate inference algorithms (Doucet, Freitas, & Murphy, 2000) and expected duration hidden Markov models (Rabiner, 1989). With an online inference process the model could capture whole report paradigms (Nieuwenstein & Potter, 2006) and might explain the effect of “spreading the sparing” (Olivers, et al., 2007). Moreover, such an extension might help connect our computational level (Marr, 1982) account to previous models of the attentional blink (Bowman & Wyble, 2007; Olivers & Meeter, 2008) by postulating approximate inference algorithms, and their possible neural implementations (Fiser, Berkes, Orbán, & Lengyel, 2010; Vul & Pashler, 2008; Moreno-Bote, Knill, & Pouget, 2011).

## Conclusions

Our results suggest that the attentional blink and repetition blindness are both consequences of rational inference about cue-item co-occurrence given a prior about the rate of transitions to task-relevant items. This framework accounts for the attentional blink and repetition blindness effects as well as the error distributions of in the attentional blink paradigm. The difference between these tasks under our framework supports the intuition that repetition blindness and the attentional blink are two sides of the same coin: both are consequence of rational inference under identical assumptions, but with the observer asked to identify types, or distinguish tokens.

## Abstract

Early word learning is contingent on linguistic input, but a child's linguistic experience is also embedded in the larger, natural structure of everyday life at home. We investigate the activity structure of life in the home of one young child, and link this structure to the child's early word learning. Our analysis is based on the dense, naturalistic, longitudinal corpus collected for the Human Speechome Project. To study activity structure, we apply probabilistic topic modeling techniques to the corpus. The emergent topics capture not only linguistic structure, but also spatial and temporal regularities indicative of coherent activity contexts. We consider the child's word learning with respect to caregiver word usage frequency and word distributions across activity contexts. We find that frequency and consistency of use across context are predictive of age of acquisition. Words that are used more frequently and in more contextually constrained settings are learned earlier, suggesting that activity contexts may be an important aspect of the child's natural learning environment and worthy of further study.

**Keywords:** Language acquisition; word learning; non-linguistic context; topic modeling.

## Introduction

Children's early word learning is a remarkable achievement, the result of powerful learning processes unfolding in the natural setting of a child's first years of life. Cultural and individual variability in children's early environments has led researchers to question the contributions of the child's innate faculties relative to the role of the environment. But to the extent that children are *learning* language, the environment must provide appropriate conditions for learnability: There must be some consistent underlying structure for learning mechanisms to build upon.

In lexical development in particular, the linguistic environment—what words a child hears, and how often—provides essential input for the young learner. Yet the child's natural environment consists of other dimensions in addition to language: spatial, physical and social dimensions, to name a few. Learners are exposed to their input in the rich, multimodal domain of everyday experience. In this work, we begin to investigate the activity structure of day-to-day life and its contributions to early word learning. Based on the idea that words and referents are more predictable in sufficiently constrained situations, we hypothesize that words associated with a limited range of recurrent activities will tend to be learned earlier. That is to say, consistent lin-

guistic input across a narrower range of activities poses a simpler learning problem.

The effect of overall linguistic input on lexical development was investigated by Huttenlocher, Haight, Bryk, Seltzer, and Lyons (1991). They were the first to document positive correlation between the quantity of child-directed speech and a child's vocabulary size and growth rate. For individual words, increased frequency of use was also tied to earlier acquisition of those words; our own (Roy, Frank, & Roy, 2009) and other (Goodman, Dale, & Li, 2008) findings replicate this pattern. In addition to frequency, words presented in single word utterances (Brent & Siskind, 2001) and with prosodic stress (Echols & Newport, 1992; Vosoughi, Roy, Frank, & Roy, 2010) are also acquired earlier.

In addition to studying linguistic input, work in cross-situational word learning has investigated how words can be linked to referents through their consistent co-occurrence across a range of situations. In the face of referential uncertainty, a learner sensitive to the statistics of which words and referents co-occur can learn correct word-referent pairings (Yu & Smith, 2007). But the idea of learning by gradually accumulating word-referent co-occurrences was challenged by Medina, Snedeker, Trueswell, and Gleitman (2011), on the grounds that the sheer number of possible pairings in everyday experience, coupled with memory limitations, leads to an intractable learning problem. Their data suggest a different learning strategy based on early binding between words and referents, with errors corrected through natural processes of forgetting.

While the natural environment is complex, it does provide structure notably absent from many laboratory-based word learning experiments. Bruner (1985) emphasized the importance of naturally occurring, predictable *formats* of interaction that support communication. To study the role of formats in language acquisition, Bruner moved his research into the "clutter of life at home" via naturalistic, observational methods. One format that Bruner studied was the game of "peek-a-boo", a recurring, rule-bound activity that occurs across a wide developmental period. Language works in concert with the game to help reveal the meaning of words.

With Bruner's formats in mind, the goal of the present study is to investigate the activity structure of a child's first years of life, how the child's linguistic input links

to these activities, and how such language in context relates to vocabulary growth. Bruner’s formats are complex, with deep rule-governed structure and social roles, patterns that recur over time during the child’s early life. They are difficult to study in detail, especially since they must be observed and deconstructed from longitudinal observations of natural behavior. To avoid this difficulty, we study a simplified representation of formats: consistent *activity contexts*.

We operationalize the idea of an activity context using data mining and machine learning techniques, applied to the multimodal, dense longitudinal recordings collected for the Human Speechome Project (Roy et al., 2006). We apply Latent Dirichlet Allocation models (Blei, Ng, & Jordan, 2003) to the transcribed speech in the Speechome Corpus, obtaining a set of “topics” that connect groups of related words. Inspection of these topics along linguistic, spatial, and temporal dimensions demonstrates that many correspond to coherent, everyday activity contexts such as **mealtime**, **diaper-change**, and so on. We then consider the child’s vocabulary growth relative to both the standard input frequency and measures of a word’s diversity across activity contexts.

## The Human Speechome Corpus

The Human Speechome Project (HSP) (Roy et al., 2006) was launched in 2005 to study early language development through analysis of audio and video recordings of the first three years of one child’s life. The house of one of the authors (DR, who had a newborn child), was outfitted with eleven omnidirectional cameras, fourteen microphones, and a custom recording system designed for large-scale audio/video recording. The cameras and microphones, embedded in the ceilings, provided near complete coverage of the house while remaining unobtrusive, and the practice of simply turning the system on in the morning and leaving it on all day facilitated adoption of the system and helped to minimize observer effects. The nature of this project required extreme sensitivity to the family’s privacy: They had full control over recordings and the ability to “back-delete” recordings if an embarrassing moment was captured. Audio was recorded using boundary-layer microphones which yield high quality audio, even for whispered speech. Video was recorded at approximately 1 megapixel, 15 frames per second, using high dynamic-range cameras for the wide range of lighting conditions. On average, the family recorded 10 hours per day, from the child’s birth to age three. Altogether, the recordings span roughly 120,000 hours of audio and 90,000 hours of video, capturing an estimated 70% of the child’s waking hours.

## Data Annotation

To date, the focus of our annotation and analysis has been on the subset of data spanning the child’s 9-24

Figure 1: A schematic illustrating how four different dimensions of observable data can depend on a common latent activity context. Viewed as a generative model, the activity context **mealtime** gives rise to the four kinds of observed data.

month age range. For this subset, our long-term goal has been to transcribe *all* speech both heard and produced by the child, but this is a significant challenge using traditional transcription methods. To address this, we have developed BlitzScribe, a new tool for fast, semi-automatic speech transcription (Roy & Roy, 2009). The BlitzScribe system processes raw, unstructured audio and automatically finds speech, segments it into manageable segments, and presents those candidate speech segments to a human transcriber in a simplified user interface. We then use a fully automatic speaker ID system to identify the speaker in an utterance.

Human annotators label which room the child is in (and whether he is awake) over the course of the day. This step ensures that what is transcribed is effectively “child available speech” (CAS), or speech that could be considered linguistic input. Although many studies focus on child-directed speech (CDS) for input-uptake analysis, CDS is much more difficult to obtain at a large scale than CAS. Using BlitzScribe, we have transcribed more than 80% of the CAS audio collected in the 9-24 month age range, which we refer to as the Speechome Corpus. Currently we have transcribed approximately 8 million words, and when fully transcribed we expect the corpus to consist of about 10 million words. However, since some post-processing is required for the latest transcripts, the work described here uses an earlier version of the corpus consisting of approximately 5 million words.

## The Child’s Lexicon

The density and coverage of the Speechome Corpus enables a detailed look at lexical development, including both caregiver speech and the child’s vocabulary over time. In earlier work (Roy et al., 2009), using a smaller version of the corpus, we identified a *word birth* as the first productive use of a word by the child in our transcripts. For our purposes, this served as the age of acquisition (AoA) of each word in the child’s lexicon. We repeated this procedure using the current, larger corpus and identified a large set of candidate word births. We then manually reviewed each of these, removing morphological variations like plurals, dropping invalid word

births, and adjusting birth dates. We identified 670 unique forms in the child’s lexicon at 24 months.<sup>1</sup>

### Activity Contexts

The detailed record of development contained in the Speechome Corpus includes the child’s first words up to multiword utterances. But in addition, the basic routines of daily life are also captured, providing a backdrop for early development. What activities does a child participate in during his first years, and how can they be found in a large, unstructured collection of recordings?

Our approach is to view an *activity context* as a hidden or *latent* variable that explains a set of observable data. An activity such as **mealtime** typically takes place in the kitchen, around noon or in the early evening and involves the whole family, with the speakers often uttering food- and eating-related words. A particular combination of observed *time*, *location*, *words* and *participants* may be best explained by the **mealtime** activity context, illustrated by Figure 1. Thus, an activity context is a latent variable identified by observations across modalities. We wish to identify a set of latent activity contexts from these observables across the entire Speechome Corpus.

Automatic methods for inferring latent variables have been successfully used in data mining applications like document modeling. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is one such technique, which finds a set of latent “topics” that best capture the thematic content of a collection of documents. In LDA, each document is represented as an unordered collection (“bag”) of words; the inferred topics are modelled as distributions over words. Topics group related words together and documents are represented as sparse mixtures of topics. Often, a human can interpret and label the topics simply by inspecting the topic words. As a first exploration of activity structure in the Speechome corpus, we

apply LDA directly to transcripts. We then assess the relationship between LDA topics and activity contexts using data from time and location.

### Applying LDA to the Speechome Corpus

To apply LDA to the Speechome Corpus, we partitioned the transcripts into “documents” using a sliding window procedure. Beginning at the 9-month mark we advanced a 10 minute window over the corpus, shifting the window forward by 10 minutes up to the 24 month mark. All transcribed speech in a window was output as a document for processing by LDA, skipping empty time windows that didn’t contain speech, resulting in 13,672 documents. After some experimentation, we found stemming to be a useful preprocessing step, normalizing word forms to a common root using the Porter stemmer (Porter et al., 1980), and only accepting those words occurring in more than five documents (and occurring more than five times in the corpus.) This yielded a vocabulary of 6,583 unique word types.

In the case of standard LDA, the number of topics to produce is a parameter of the algorithm, and we found 25 topics to be a manageable number while still producing coherent topics. Extensions to LDA such as Hierarchical Dirichlet Processes (Teh, Jordan, Beal, & Blei, 2006) can automatically select the number of topics, and informal experiments with this method also resulted in 20 – 30 topics. To interpret the resultant topics, a common starting point is to review the top words in each topic. We ranked words using the method in (Blei & Lafferty, 2009), which roughly measures the informativeness of the word for the topic relative to the other topics (Figure 2).

### From Topics to Activities

Do topics capture activities? We investigate two methods to make the link: via correlations in time and space, and via human-annotated activities.

**Activities in time and space** LDA outputs topic mixture weights for each document; since documents also have spatial and temporal attributes, we can exploit this to measure how topics are distributed in time and space. Each topic’s time distribution was calculated by weighting the time of day of each document by the topic’s con-

<sup>1</sup>We did not annotate or study *receptive* AoA, which is often documented in diary studies but is much more difficult with a large corpus. Identifying word births is challenging in its own right, since the child’s word form may differ from the adult form. In describing the diary study of her daughter’s early lexical development, Dromi (1987) reviews these and other challenges. In our case, the original audio, video, and access to caregivers were all helpful resources.

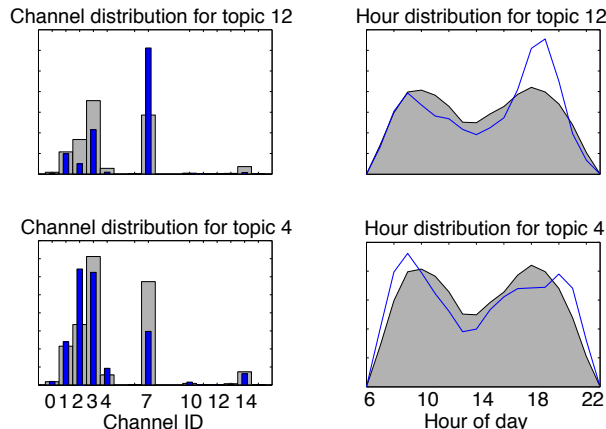

Figure 3: Spatial and temporal distributions for topics 12 and 4. The gray background graphs show overall averages, the blue foreground graphs the “conditional” distributions for the topic (distributions reweighted by the selected topic activity.) The channels of interest here are 7 (kitchen) and 2 (baby bedroom.)

tribution to that document. The spatial distribution of topics across rooms of the house was calculated similarly.

Figure 3 shows the temporal and spatial distributions for topics 12 and 4, relative to the average temporal and spatial distributions. When topic 12 is active, we see that recording channel 7 (the kitchen) is well above average, and the temporal distribution peaks at about 7pm. Inspecting the words in topic 12 shows that it captures food and eating related terms. So, topic 12 appears to be a *mealtime* activity context, or perhaps is more specific to *dinnertime*. Topic 4 is most active, relative to the average, in the early morning and late evening, and in channel 2, the baby’s bedroom. This topic appears to capture the *diaper-change* activity. Thus, at least a subset of topics appear to follow coherent spatial and temporal distributions.

**Human annotated activities** In concert with our efforts to automatically identify activity contexts, we are also manually annotating activities. Using BlitzScribe, annotators now transcribe assignments spanning 15 minutes of “house time,” then list the activities that took place. When we began this annotation project, we gave little instruction to transcribers, asking them to make up their own activity tags as necessary. Nevertheless, we found consistency in the activities that emerged. After conventionalizing tag names, we obtained roughly 30 activities for around 300 annotated assignments. These annotations can provide another means for validating LDA topics as proxies for activity contexts.

To test for relationships between LDA topics and activity contexts, we examined the correlations between individual topics and the human-annotated ac-

Table 1: Coefficients on a multilevel linear regression model predicting age of acquisition (months) on the basis of log frequency in child-available speech, topic entropy of the word, and their interaction.

Predictor	Coefficient	Std. Err.	<i>t</i> -value
Intercept	18.49	0.28	65.83
Log frequency	-0.83	0.12	-7.08
Topic entropy	0.54	0.10	5.44
Log freq $\times$ entropy	0.06	0.13	0.48

tivities. While these correlations remain speculative due to the sparsity of the human-annotated activities, several significant correlations emerged. In the case of the *diaper-change* activity, for example, only topic 4 was significantly correlated (with words like “diaper,” “poo,” and “change” highly active). In the case of *eating*, topics 12, 16 and 0 are significantly positively correlated, with 12 being the strongest (e.g. “chew,” “eat,” and “mango”). For *reading*, a number of topics were active, including 5, 6, 10, and 11, all of which contained words related to different books that were read to the child. And for *crying*, topic 17 (e.g. “daddy,” “blanket,” and “ssh”) was most active. In summary, although at present human annotation of activities is too limited to provide full coverage, the relationships between activities and topics makes us optimistic that our topics are capturing at least some aspects of the varying activity contexts in the child’s environment.

## Word Learning

If LDA topics act as a proxy for activity contexts, then we should be able to use them to test a primary hypothesis of interest: that words that appear in consistent activity contexts are learned relatively earlier than those that appear across a range of contexts. Said another way, words with high *topic entropy*—that do not appear consistently in one or a small set of topics—should be produced later by the child.

We used multilevel linear regression (Gelman & Hill, 2007) to predict age of acquisition (AoA, in months) on the basis of word frequency and topic entropy. AoA measures are described above. For word frequency, we measured the total number of utterances of a target word in our sample up to the age of acquisition of the word, normalized by the number of days of transcripts up until that time to allow these measurements to be compared for words with different AoA.<sup>2</sup> For topic entropy,

<sup>2</sup>We measure only up until the acquisition of the word to avoid a confound: the child’s production of a word could change the adult use of the word. Note that this change, the exclusion of words from the topic model, and several other minor changes make regression coefficients for frequency slightly lower compared with our previous work.

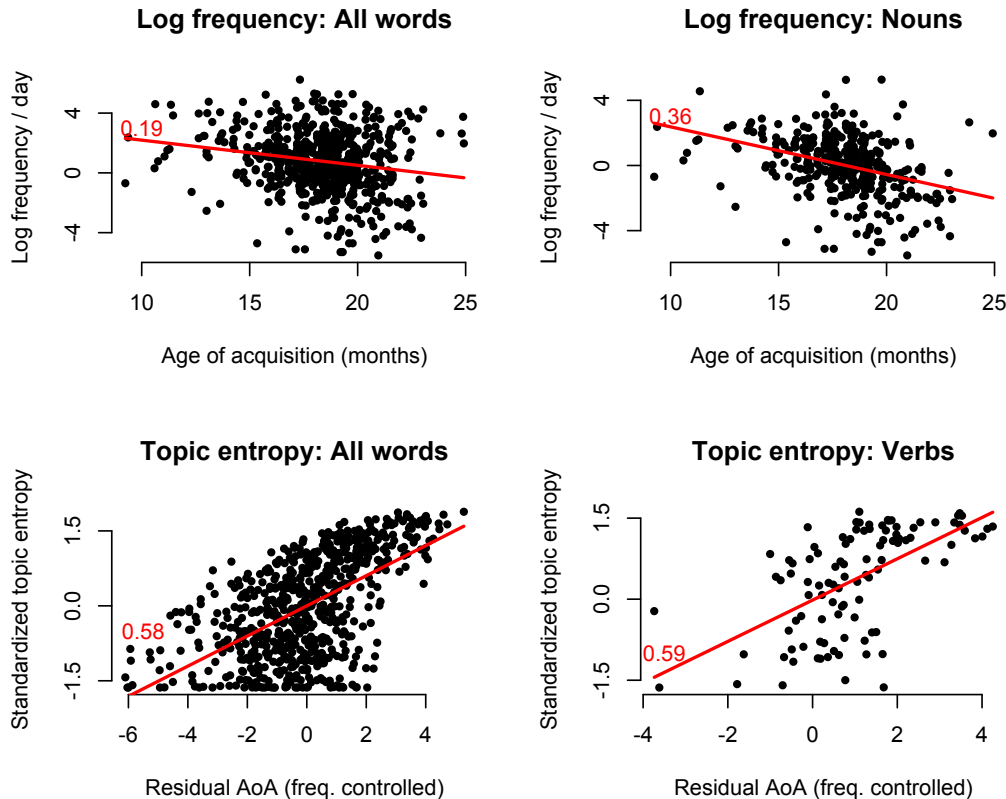

Figure 4: Each plot shows age of acquisition in months for individual words plotted by a predictor. (top) Standardized log word frequency per day (prior to the child’s first production of the word) plotted by age of acquisition for words. Left plot shows all words, right plot shows nouns. (bottom) Standardized topic entropy plotted by residual age of acquisition for words. Left plot shows all words, right plot shows verbs. Red lines show best fitting linear function; numbers indicate correlation coefficients.

we computed the entropy of the word’s weight distribution over the 25 different topics found by the LDA model. We z-scored the units for both of these predictors to be able to compare coefficients for each.

Our model included fixed effects for topic entropy, frequency, and their interaction. The model also included random terms for each syntactic category, and its frequency and topic entropy, and their interaction. Coefficients are shown in Table 1. Coefficient weights can be interpreted as months in AoA per standard deviation in log frequency or topic entropy. We assessed reliability for individual coefficients by testing whether they increased model likelihood. Log frequency had a large negative effect on AoA: more frequent words were learned earlier ( $p < .005$ ). Topic entropy had almost as large an effect: words in more constrained activity contexts (lower entropy) were learned earlier as well ( $p < .005$ ). Their interaction did not significantly increase model fit ( $p = .69$ ).

Figure 4 shows the relationships described by this model. Without regressing out frequency, topic entropy is relatively uncorrelated with age of acquisition. When both terms are entered in a model, however, the effect is

much larger. Figure 4 displays this conditional relationship by plotting topic entropy by residual AoA (controlling frequency).

Topic entropy and part of speech are likely correlated: closed class words like “if” are likely to occur in every topic (topic entropy of 1.3 SDs above mean), while nouns like “pasta” only appear frequently in one context (1.6 SDs below). A key part of this analysis was the use of multilevel models to control for part-of-speech effects. Without including random effect terms for part-of-speech, the interaction between frequency and topic entropy was large, probably because topic entropy and frequency for closed class words is high. Adding the random effects terms eliminated this interaction, however.

To summarize this analysis: we found that the consistency of the contexts within which words appeared was almost as strong a predictor of age of acquisition as pure frequency.

## Discussion and Future Work

Early word learning is a product of powerful learning mechanisms coupled with the rich experience of early childhood. Linguistic input is of critical importance to

lexical development, but it is situated in the larger structure of daily life. The importance of social activity structures was emphasized by Bruner (1985), yet large-scale, quantitative study of their effect on language acquisition has proven difficult. To address this, we used document modeling techniques to operationalize activity contexts. We found evidence that many of the resultant topics captured coherent, interpretable patterns of linguistic, temporal and spatial activity. These activity contexts then provided a useful source of information in modeling lexical acquisition: we found that more contextually focused words were learned earlier.

In future work, we plan to add location, participants, and time to models of latent activity contexts. An interesting question for these extensions is whether some contexts are of more value than others for general word learning or for learning particular words. In addition, a study of episodes of a particular activity may help build intuitions about how activities develop and change over time, and how this progression relates to the child's development.

Our study here represents a first step towards a more complete model of lexical acquisition, one that incorporates elements of social and physical context. In a similar vein, Miller (2011) and Shaw (2011) studied the spatial distribution of language in the Speechome Corpus. Miller (2011) found that more spatially localized words correlated with earlier AoA, noting that many of the most salient locations were directly interpretable in terms of the activities known to take place at those locations. Our work builds on this intuition, targeting activities via their linguistic manifestations. While both of these methods are at best proxies for as-yet-unseen structures, our hope is that by continuing to develop methods for identifying activity contexts, we can gain some insight into the crucial role these social structures play in early language learning.

## Abstract

The increasing use of computational modeling and simulation methods offers interesting epistemic and theoretical challenges for the philosophy of science. One of the main questions discussed in the philosophical literature relates to the explanatory role of false, unrealistic and sometimes even fictional models. In this paper we argue that (i) some fictional models can offer explanations known as structural model explanations, and (ii) at least some variants of realism, such as the information semantic account of scientific models, can consistently hold that this subset of fictional models are explanatory.

**Keywords:** Models; fictional models; explanation; information semantics

## Introduction

For a philosopher of science interested in the philosophical issues of modeling, cognitive science is a wonderful source of case studies. Cognitive science utilizes modeling in a unique way, both methodologically and theoretically. The increasing use of computational modeling and simulation methods offers interesting methodological challenges for scientists, but also philosophers of science find many things of interest in the theoretical and epistemic status of modeling methods.

One of the main questions discussed in the philosophical literature relates to the explanatory role of models. A growing number of philosophers have proposed that explanation of the behavior and capacities of complex systems (such as those found in the cognitive, biological and neurosciences) does not typically involve natural laws, but specific models of particular mechanisms (Bechtel and Richardson, 1993; Craver, 2006, 2007; Machamer, Darden, and Craver, 2000). It has also been argued that this mechanistic account of explanation could be extended to cover explanations in cognitive science (Kaplan & Craver, 2011, Sun, 2008) and computer sciences, as well as computational neuroscience (for instance, Piccinini, 2007).

According to this account, to explain a phenomenon is to construct a model of how a causal mechanism - a hierarchical system composed of component parts, their

properties and their causal relations - gives rise to or produces the phenomenon. Constructing an explanatory mechanistic model involves mapping elements of a mechanistic model to the system of interest, so that the elements of the model correspond to identifiable constituent parts with the appropriate organization and causal powers to sustain that organization.

The mechanistic account of explanation is a typical example of the realist interpretation of scientific models. According to realism, a model explains the behavior of a target system, if and only if it is a correct account of the target's behavior underlying observed phenomena - i.e. the model must correspond to, depict or represent the target system in a sufficiently correct way. In addition, many current realist accounts require that the target systems are actual or real - i.e. have causal power to generate observable phenomena and data.

However, models are always more or less abstract, simplified and idealized descriptions of their real world target systems. Target systems are just too complicated to be studied in a full fidelity, and thus all kinds of assumptions are made to reduce the complexity of a model. Thus most (if not all) models used in science are unrealistic. Often models are nevertheless considered useful, even if they are known to be false, and they are known to contain assumptions that are not even approximately true, but highly idealized. For this reason, it has been argued that this feature of modeling seriously undermines the realist interpretation of models. If all models involve unrealistic elements, how is it possible that they could correspond, depict or describe the real world target system in a correct or truthful way? If they do not, where does their explanatory force come from?

Sometimes models involve assumptions about fictional entities and processes that are known not to exist in the real world. These fictional models describe systems that (i) do not exist in the real world or (ii) have elements that do not exist in the real world. Obvious examples of fictional models in cognitive science are for instance the models of

artificial intelligence<sup>1</sup>. These hypothetical (at the time of their conception) systems offer an example of modeling, which starts with explicitly fictitious entities – non-existing, imaginary cognitive systems – and then converts these fictions into the fact-like platforms from which further research can be done.

Although there is a growing consensus among philosophers that fictions have a legitimate role to play in science, traditionally those philosophers who endorse realism have denied that fictional models could explain. For a realist, the main obstacle to admitting that also fictional model can be explanatory is that it is difficult to imagine how a model without an existing target system could be explanatory. Instead, fictional models have been treated as, for example, only tools for generating and calculating predictions.

However, it seems to us that for example the models offered by AI are more than mere “tools for prediction”. That these fictional models can be converted into real working systems does require that they get some principles of cognition “right” (a fictional AI model that is completely *unrealistic* has little hope of successful implementation). And they do seem to work more like blueprints or instructions for a design than simply devices for predictions. Not only do they offer structural information about the constitution of a model system, but they also restrict and guide the construction process itself – and not in an arbitrary manner.

For this reason it seems intuitively plausible to think that these models do hold a potential to represent or explain something about cognitive systems. In this paper, we argue that (i) these models explain by showing how the structure of a model limits what sorts of objects, properties, states, or behaviors are admissible within that model, and they offer explanations known as structural model explanations (Bokulich, 2008, 2009). In addition, we argue that (ii) at least some variants of realism, such as the information semantic account of scientific models, can consistently hold that this subset of fictional models are explanatory. However, (iii) whether or not a fictional model can be explanatory, depends also on the relationship of the fictional models and the real world<sup>2</sup>.

## Requirements for Realistic Interpretation

Scientific models can be interpreted *realistically* and *instrumentally*. The instrumental interpretation, roughly, holds that scientific models are *instruments for generating predictions about the system's behavior*. According to the instrumentalist interpretation, the models are only used to

produce predictions, and the question whether or not models are realistic or unrealistic, does not arise.

In contrast to instrumentalism, the realist interpretation of explanatory models holds that entities/processes the model posits actually exist and that there is an objective relationship between the model and its target system. In addition, many current realist accounts of explanatory models require that the target system must be actual or real. Following Salmon, many philosophers of science agree that to explain a phenomenon is to describe the actually existing/causal processes that constitute the phenomenon (Salmon, 1984). According to this view, only descriptions of actually existing genuinely causal processes can lead to scientific explanations<sup>3</sup> (Salmon, 1984).

**Aboutness.** A realist typically thinks that the relationship between a model and its target, the *aboutness* of scientific models, is essential to their explanatory power. A scientific model can *explain* the behavior of a target system if and only if it depicts, describes or represents the target system.

For example, the mechanist account of explanation is a typical variant of realism in this sense. According to it explanation involves constructing a model of such mechanisms that correctly depicts or describes the causal interactions among their parts that enable them to produce the phenomena under various conditions. The relationship between a model and its target is seen, for example, as “one of approximate similarity” (Glennan, 2000) in a way, where “the behavior of the system in nature is described (to varying degrees of approximation) by the model's behavioral description and the internal structure of the system is described (again to varying degrees of approximation) by the model's mechanical description”, or as “correspondence” (Craver), because (emphasis added) “in successful explanatory models... (a) the variables in the model *correspond to* components, activities, properties and organizational features *of the target mechanism* that produces, maintains, or underlies the phenomenon, and (b) the... dependencies posited among these variables in the model *correspond to* the... causal relations among the components of the target mechanism” (Kaplan & Craver, 2011; see also Craver, 2006).

Following Giere (1988), both Glennan (2000) and Craver & co (2006, Kaplan & Craver, 2011) seem to think that the relationship – “the aboutness” – is some kind of similarity or correspondence relation. But as Quine (1969) pointed out, similarity is a vague notion, and correspondence is actually not much better. In order to specify these concepts, many philosophers of science have appealed various “morphisms” – iso-, partial- or homomorphisms. However, all these various morphisms, similarities and correspondences are usually discussed only intuitively and philosophically problematic<sup>4</sup>. They have been criticized on logical and

<sup>1</sup> The aim of AI is not only to help us investigate the existing cognitive systems by simulating them, but also to help us to investigate and understand the structure of cognitive systems by producing or to creating artificially new kind of cognitive systems.

<sup>2</sup> Not all fictional models are explanatory, and some of them are useful as calculational devices, other as prototheories and some are useful in generating predictions etc., but not explanation.

<sup>3</sup> For example, the ontic version of mechanistic explanation requires that the mechanistic organization of the target system causally produces the phenomenon to be explained.

<sup>4</sup> There is a huge debate on this issue in philosophy of modeling. See for instance, Suárez, 2003; Frigg, 2006.

substantial grounds<sup>5</sup>. One particularly difficult problem for these accounts is the problem of relevance: a model typically cannot be perfectly “similar” or “isomorphic” with respect to every entity and every relation in the target system, since almost any target system is too complex. This implies that models should be “sufficiently isomorphic” or “sufficiently similar” to the target “in the relevant respects”. However, it is quite tricky to characterize “sufficiency” and “relevance” in a non-circular and precise manner<sup>6</sup>.

There are also some other variants of realism in which the relationship between a model and its target is defined in a different way. According to the information semantic account<sup>7</sup>, models depict, describe, represent or are about their target systems, if and only if there is an appropriate information-content relationship between a model system and its target. The information connection is implemented in a model building process, in which data about the world is incorporated to the model i.e. the information relationship between a model system and its target is implemented in empirical data, which carries the information about the target system into the model.

**The actual existence of target systems.** As the variants of realism typically do, also the information semantic account requires the target systems must be actual or real. Because in information semantics “carrying information” is understood in terms of statistical dependence (Shannon, 1948; Usher, 2001), and statistical dependence is usually understood in causal terms, target systems must be “actual” or “real”: they must have *causal power* to produce the data, which carries the information which is incorporated into the model during the model building process.

To summarize, the realist interpretation of explanatory models requires that an explanatory model (i) represents, depicts or describes the explanatorily relevant features of target systems in a “correct” way, and that (ii) target systems are real and actual. Some variants of realism, such as the information semantic account, require also that (iii) the target systems have appropriate causal properties.

However, most, if not all, models used in science are unrealistic, and sometimes even known to be strictly false because of the abstraction, simplification and idealization and the postulation of fictional entities that goes on in the model building process. This raises the epistemic problem for realism: if models include all these kinds of sources of false assumptions, how can they be explanatory? How, exactly, are these models are used to gain information or knowledge about the real world phenomena?

### The different ways to make a model unrealistic

In practice, when scientists present a model, they offer a model system<sup>8</sup> which is a description of a hypothetical

system, and this model system is, or is thought to be, a hypothetical representation of a real world target system. These model systems are always more or less unrealistic descriptions of their real world target systems, because target systems are too complicated to be studied in every detail. This is typically motivated, rhetorically, on pragmatic grounds. If all the parameters were included in models, they would become too complicated to be understandable, tractable or useful. As McClelland (2009) puts it, “the more detail we incorporate, the harder the model is to understand.”

There are at least four different ways to make models unrealistic: abstraction, simplification, idealization and fictionalization. In practice, this distinction between these types is not always entirely clear. Moreover, these classes are not exclusive. Models can, and often are, abstracted and idealized at the same time<sup>9</sup>. For example, a Turing Machine can be seen as an abstraction of real computations<sup>10</sup>, because it neglects many computationally irrelevant features of computational systems, such as the material basis of the implementing mechanisms. If a Turing Machine is also defined to have properties that are not implemented in any real computational system (unlimited memory, unlimited processing time), it is assumed to never break down and so on, it also involves idealization.

*Abstraction* and *simplification* can be considered to be species of information reduction. Roughly speaking, an abstract model is the result of the process of abstraction, in which information about domain-external factors is disregarded<sup>11</sup> (e.g. a model of a ball rolling on an inclined plane may abstract away the color of the ball, which is not in the domain of Newtonian dynamics). A simplified model is a model, in which some domain-internal factors are given a simplified description (e.g. the ball may be considered a perfect sphere, with the center of gravity in perfectly in the middle). Although abstracted or simplified models do not describe *all* the factors, they describe correctly or approximately certain features of their target systems. Abstracted and simplified models can thus be genuinely explanatory, if they accurately depict the relevant properties of their target systems. These models tell us how phenomena behave in a simpler world than our own<sup>12</sup>, or these models can work as surrogate systems<sup>13</sup> for understanding, how fundamental properties of a system

<sup>9</sup> See Thomson-Jones (2005) for the distinction between abstraction and idealization.

<sup>10</sup> See Piccinini, 2007.

<sup>11</sup> An abstract model is sometimes described as a model, in which *only some factors* or only some of potentially many factors of target system are included into a model system. A simplified model is a model, in which *only some factors of the potentially many factors that are relevant* to the behavior of a target system are included into a model or some factors are given a simplified description.

<sup>12</sup> This idea is explicated by Stephan Hartmann, but the authors did not find the article, in which this idea was presented.

<sup>13</sup> The term “surrogate” is borrowed from Uskali Mäki (2009).

<sup>5</sup> See Suárez, 2003; Frigg, 2006; See also Rusanen and Lappi, 2011.

<sup>6</sup> Suárez, 2003; Frigg, 2006, see also Rusanen & Lappi, 2011.

<sup>7</sup> Rusanen & Lappi, 2011.

<sup>8</sup> The term “model system” is from Frigg (2006, 2010).

generate or produce the certain phenomenon of interest by helping scientists to formulate correct what if- inferences.

However, philosophers of science disagree on the question, whether or not abstracted and simplified models have more explanatory power than non-abstracted models. There are at least two different views about the explanatory power of abstracted models. One of them is the so-called “traditional view”<sup>14</sup>, according to which the more exact, more detailed, more complete and more realistic the model is, better it is. The most explanatory model is the model, which offers the complete description of the phenomenon of interest. The non-traditional view maintains that in some cases the abstracted model can explain better the dominant and significant features of the target system, because it isolates and emphasize the crucial elements in a tractable way.

The third way to make a model unrealistic is *idealization*. In idealization one is not only excluding parameters. Instead, idealization involves distorting theories or models, because at least one of the parameters of the target system is represented in a way that makes the model false. For example, if a model in cognitive science is used to analyze the processing of a perceptual system scientists may stipulate that all processing is described in the model as linear and strictly feedforward<sup>15</sup>, even if in reality the processing would be non-linear and have backforwarding properties.

The fourth way to make models unrealistic is *fictionalization*. *Wide fictionalism*<sup>16</sup> states that idealization and abstraction are subspecies of fiction (Suárez, 2009). However, there are reasons to argue that models that are only simplified, idealized and abstracted representations of real entities (*about* which they make counterfactual claims) should be distinguished from those which refer to fictional entities which do not actually exist. Logically speaking, there is a difference in kind between a representation of real entity and a representation of an imaginary entity (Russell, 1905, Suárez, 2009)<sup>17</sup>.

*Narrow fictionalism* takes it that only those models which involve or describe explicitly fictional or imaginary entities, systems and situations that do not actually exist in real world, are fictional (Suárez, 2009). Such models do not only involve idealization, simplification or abstraction, but they are, and also known to be false, for a further reason: because they describe fictional or imaginary entities, systems and situations that do not actually exist in real world.

---

<sup>14</sup> The terms “traditional view” and “non-traditional” are from Batterman, 2009.

<sup>15</sup> See, for example, McLelland (2009) for a detailed analysis of simplification and idealization of this sort.

<sup>16</sup> About the difference between wide and narrow fictionalism, see Suarez 2009.

<sup>17</sup> As Suárez (2009) has proposed, one way to describe the distinction is to emphasize the difference between “fictional” and “fictive” representations. A fictional representation is a representation of a non-existing entity, and a fictive representation is an inaccurate representation of a real entity (Suárez, 2009).

*Completely fictional models* refer to model systems that do not actually exist in the real world *and do not have any real components*. It is difficult to find a genuine example of a completely fictional model in natural or behavioral sciences, because in these sciences most (and probably all) fictional models include at least some real world elements at some level of analysis.

Actually, fictional models are typically only *partially fictional models*. Often partially fictional scientific models are combinations of real and fictional components. Sometimes these models refer to *real* target systems, but they are fictional, because they include some components or system level descriptions that are taken to represent non-existing entities. For example, the frequency components in the wavelet analysis of EEG components, which are used to explain the synchronization properties of neuron population in neurosciences are typically interpreted as non-existing entities.

Some of partially fictional models consist of realistic constituents, but the combination of constituents is known to be unreal. Some of these model systems may describe systems that are in principle physically possible, or sometimes they are physically impossible, because they violate natural laws etc. Typically these models are used to test the possible behavior of a complex system by creating all kinds of what-if simulations. An example of a model of this sort is the model of xDNA<sup>18</sup>. All of the components of model can be given a real world interpretation, but the combination of these components, xDNA, is unrealistic.

The study of artificial intelligence offers another example of modeling of this sort. For example, if a cognitive scientist wanted to build synthetic brains, she might end up building a model system that does not mimic or simulate any existing brains. Although the design or the computational layout of the artificial brains was novel, the model system might involve elements, which refer to real world entities, such as cells, cell organs, transmitters, or depending on the material implementation, silicon chips, batteries and so on. In addition, if the model system would then be implemented in a concrete way, then a model system of a fictitious entity would have been converted into an actual model organism.

Although the current study of artificial intelligence is not developed to that point, are already existing artificial cognitive systems examples of modeling, which starts explicitly fictitious, non-existing entities – the imaginary cognitive systems - and then convert these fictions into *the fact-like platforms* from which further research can be done. Because these fictional models can be converted into fact-like platforms, fictional models seem to work more like blueprints or instructions for a design than simply devices for predictions. Not only do they offer *structural* information about the constitution of a model system, but they also restrict and guide the construction process itself. For this reason it seems intuitively to think

---

<sup>18</sup> This example is from Michael Weisberg’s presentation in Helsinki in May 2009. Actually, as also Weisberg mentioned in his talk, there is no such a model in biology.

that these models do explain. They seem to explain by showing how the structure of a model limits what sorts of objects, properties, states, or behaviors are admissible within that model. They also show that whatever the system can do is in fact a consequence of that structure and they also offer information about how the converted system will behave *before* it has been converted

## Do Fictional Models Explain?

Alisa Bokulich (2008, 2009) has recently developed an interesting account of scientific explanation, called “model explanations” to describe the sort of explanation that is being offered by fictional models.

Bokulich (2008;2009) characterizes these model explanations as follows: First, the explanans of explanatory fictions must make a reference to scientific model, which involves some idealization and/or fictionalization. Second, that model is taken to explain the explanandum by showing that the pattern of counter-factual dependence in the model mirrors the relevant respects of counterfactual dependences in the target system. Following Woodward (2003), in Bokulich’s account this pattern of counterfactual dependence can be explicated in terms of “what if things have been different- questions”<sup>19</sup>. That is, the explanation must enable us to see what sort of difference it would have made to *explanandum* if the factors cited in *explanans* had been different in various possible ways. The third feature of model explanations is that they must specify what the domain of applicability of the model is and show that the phenomenon in a real world to be explained falls within that domain. If model explanations are characterized in this way, one subspecies of model explanations are structural model explanations (Bokulich, 2009).

A structural model explanation is one in which the the explanandum is explained by showing how the structure of a model limits what sorts of objects, properties, states, or behaviors are admissible within that model, and then showing that the explanandum is in fact a consequence of that structure. A structural model explanation is thus an explanation, in which the explanandum exhibit a pattern of counterfactual dependence on the elements represented in the model, and this dependence is a consequence of the structural features of the model.

It seems to us that *those partially fictional models that are combinations of realistic parts offer structural model explanations* as Bokulich proposes. For example, a model of artificial cognitive system characterizes why certain cognitive processes are possible for a certain kind of cognitive architecture, or how a possible computational structure of certain type architecture will limit its possible cognitive and computational capacities, before the system is actually implemented.

However, Bokulich’s characterization may be a bit too broad. For this reason, we’d like to add one crucial requirement for model explanations. In order to count as genuinely explanatory a model explanation must also be *credible*. Characterizing the credibility is, of course, a challenging task, and there are different suggestions in the literature. For example, according to Sugden (2000) models are artificial “worlds” i.e. “surrogate systems”, and their epistemic dimension is based on inductive extrapolation from these artificial worlds to the real world. In Sugden’s account the relationship between models and the world can be evaluated in terms of similarity; more similar to the real world a model is judged to be, more credible it is. However, similarity alone is usually not sufficient for establishing credibility<sup>20</sup>.

For this reason, credibility considerations must be based on more fundamental claims. According to the information semantic account (Rusanen & Lappi, 2011) the credibility of a model explanation requires that there is, or it is at least possible to imagine, a causally implemented information relationship between a model and its target and a credible data gathering method for that particular model. Information semantic account requires that there is an appropriate information relation between a model and its target. For this reason, if a model is credible, there must exist or it must be possible to imagine a causally implemented information relationship between a model and its target. Because of this, from an information semantic view, completely fictional models, arbitrary models or models, which have only unrealistic constituents, are not explanatory. Instead, only such partially fictional models can offer model explanations, in which the constituents of a model system are realistic. These constituents should (at least to certain extent) refer to/ carry information about real world elements and this information relationship could be, in principle, implemented in data.

So, the final problem is: How is it possible that a fictional model can carry information about the real world? As philosophers of cognitive science know, a structurally similar problem, the problem of uninstantiated properties, plagued the early versions of information semantics in philosophy of mind. In a nutshell, the problem was the following: If A does not carry information about B, it is not a representation of B. So, if B is a non-existing, uninstantiated entity or a property, A cannot carry information about it, and thus A is not, strictly speaking, a representation of B. However, there are still terms, such as unicorns or pegasuses, which clearly have semantic content, even if their referents do not exist. We can attribute properties to these non-existing entities; we can make thought experiments on them and so on. So, if these terms have no existing targets, how do these terms have their semantic properties? What is the basis for the meaning of these terms?

Jerry Fodor proposed (1991) one possible solution for this problem. On his view, these terms, such as “pegasus”, could be seen as complex terms, which can be decomposed into its

<sup>19</sup> While in Woodward’s manipulationist construal explanations are restricted purely to causal explanations, Bokulich adds that not all scientific explanations must be causal.

<sup>20</sup> Kuorikoski and Lehtinen (2009) make a similar point.

constituents (a horse and wings), and these constituents refer to/carry information about the real world components. So, these terms can have a meaning, because the constituents of the terms can carry information about the real world.

Partially fictional models can be treated in a same way. They are complex constructions, which can be decomposed into constituents. If these constituents refer to/carry information about the real world elements, they are realistic. For that reason these models are not completely fictional, although the complex composition of constituents would be fictional. Because the constituents of partially fictional models carry information about/refer to real world elements, these models may indeed offer structural model explanations.

## Concluding Remarks

There are at least four different ways – simplification, abstraction, idealization and fictionalization – to make models unrealistic, not all of them make models false in a way that is problematic for the realist. Even if in practice the difference between these types is not always clear, they should be treated separately. They have different implications for the explanatory power of a model. For example, although simplified or abstracted models do not describe all the factors or all the relevant factors of target systems, they describe certain some features of their target systems. Depending on their degree of truthlikeness they can be more or less explanatory. In this paper we argued that also fictional models may explain by showing how the structure of a model limits what sorts of objects, properties, states, or behaviors are admissible within that model, and they offer explanations known as structural model explanations (Bokulich, 2008, 2009). However, whether or not a fictional model is explanatory, depends also on the relationship of the fictional model and the real world. Only such partially fictional models that have constituents, which can carry information/refer to real world elements, can be explanatory. Completely fictional models, arbitrary models, or models with only unrealistic constituents do not explain.

# Role of Kolmogorov Complexity on Interest in Moral Dilemma Stories

Antoine Saillenfest, Jean-Louis Dessalles

({antoine.saillenfest, jean-louis.dessalles}@telecom-paristech.fr)

Telecom ParisTech, INFRES, 46 Rue Barrault, 75013, Paris

## Abstract

Several studies have highlighted the combined role of emotions and reasoning in the determination of judgments about morality. Here we explore the influence of Kolmogorov complexity in the determination, not only of moral judgment, but also of the associated narrative interest. We designed an experiment to test the predictions of our complexity-based model when applied to moral dilemmas. It confirms that judgments about interest and morality may be explained in part by discrepancies in complexity. This preliminary study suggests that cognitive computations are involved in decision-making about emotional outcomes.

**Keywords:** Kolmogorov complexity; moral dilemma; moral judgment; narrative interest; emotion.

## Introduction

Humans devote a considerable amount of time to producing narratives. Spontaneous conversational narratives constitute a large amount of our conversational time (Norrick, 2000) and fictional narratives constitute a large part of human productions (*e.g.* novels, movies, video games). Modeling narrative interest and emotional impact in narratives, especially in fictional narratives, is of major importance, both scientifically and economically, as there are a variety of potential applications (*e.g.* serious games, film industry, video games). The selection of events that people consider relevant to tell is a not yet fully understood process. Only a small proportion of our experiences passes the selection. Moral dilemma belong to the situations that make good stories.

Previous studies have pointed out that emotional intensity and complexity drop have a decisive influence on narrative interest. The aim of this article is to explore the role of complexity change in the determination of morality and interest in moral dilemma.

## Morality judgments in dilemma

The number of studies on morality and emotion grew steadily in the 1980s and 1990s, and even more during the last decade. Various disciplines now investigate human morality and the interplay of emotion and reason in moral judgment and decision-making.

Moral psychology initially focused on reasoning. During the 1950s and 1960s, mental models and information processing were the preferred framework in psychology. Kohlberg (1958) proposed a six-stage developmental model of moral reasoning which, he thought, drives moral judgment. In the 1980s, however, the idea that moral emotions also play a role has been highlighted. New findings in evolutionary psychology and in primatology pointed to the crucial role of a specific set of emotions. This "affective revolution" has been reinforced during the two last decades. Recent evidence suggests

that moral judgment is more a matter of emotion and affective intuition than of deliberate reasoning (Haidt & Hersh, 2001). Emotion now plays a central role in moral psychology research (Haidt, 2007). Evidence that emotions guide moral judgments comes from brain imagery (Moll et al., 2002; Greene et al., 2004; Moll & Oliveira-Souza, 2007; Koenigs et al., 2007; Decety, Michalska & Kinzler, 2011), philosophy (Roeser, 2006), and psychology (Wheatley & Haidt, 2005; Valdesolo & DeSteno, 2006; Schnall et al., 2008).

Recently, new findings from several areas of cognitive neuroscience have suggested that emotions and reasoning both matter, but that automatic emotional processes tend to dominate (Greene & Haidt, 2002; Greene et al., 2004).

Various elements of particular importance to our study, such as social consensus, proximity (the feeling of nearness), the magnitude of consequences or the probability of effect have been shown to affect our judgment in moral dilemma (Jones, 1991). It has also been shown that people judge permissible to harm people as a side effect but not as a means (Cushman, Young & Hauser, 2006).

## Interest in narratives

Both reasoning and emotions seem to control the intensity of narrative interest. It has been observed that human cognition is sensitive to complexity, in the sense of Kolmogorov (*i.e.* the length of the minimal determination of a situation) (Chater, 1999; Chater & Vitényi, 2003). Simplicity Theory (Dessalles, 2008a; see also [www.simplicitytheory.org](http://www.simplicitytheory.org)) highlighted the role of unexpectedness in the selection of interesting events: a situation is unexpected if it is more complex to produce than to determine. This means that the generation complexity  $C_w$  of an unexpected event is higher than the complexity  $C_d$  of its determination.

$C_w$  measures the minimum quantity of information that must be given for the "world" (as the observer knows it) to make the situation happen. It evaluates the size of the minimal explication of the situation.  $C_d$  measures the quantity of information needed by the observer to describe the situation unambiguously. It evaluates the size of the minimum description of the situation.

Unexpectedness  $U$  is the difference between the generation complexity and the determination complexity ( $U = C_w - C_d$ ). The study of unexpectedness makes good predictions about which parameters control narrative interest in situations such as fortuitous encounters, atypical events, coincidences or rare events (Dessalles, 2008b; see also [www.simplicitytheory.org](http://www.simplicitytheory.org)).

Interest is also a matter of emotions. Emotional intensity plays a crucial role in the selection of narrated events (Rimé,

2005). In what follows, we will present a model in which emotional intensity results from the combination of the emotional category of the event (whether it is about ten deaths or merely about a ten-Euro loss) with unexpectedness. Then we will present an experiment designed to test the model. Finally, we will discuss the validity and the generality of this approach based on complexity.

### A complexity-based model of narrative interest and of moral judgment

The model proposed in this article intends to show that variations of Kolmogorov complexity may contribute to explain both moral judgment and interest in moral dilemma stories.

Any outcome  $i$  comes with an hypothetical emotional intensity  $E_h^i$  ( $> 0$ ) attached to it. This value does not take the valence (positive or negative) of the emotion into account, but only the standard magnitude of the corresponding class of events (sometimes considered to result from social consensus) (e.g. the death of child is supposed to be emotionally more intense than the death of an adult person, all things being equal) (Jones, 1991; Bleske-Rechek et al. 2010).

According to Simplicity Theory, the emotional intensity attached to an event is the sum of the hypothetical emotional intensity and of unexpectedness:  $E = E_h + U$ . Since  $U$  depends on the complexity of the persons involved in the event (with a minus sign), the definition of  $E$  reflects the fact that one is more affected if the victim of an accident is a close acquaintance or a celebrity (as close acquaintances or celebrities require less information to be determined).

When considering the narrative value of an event  $s$  which is the outcome of an action  $a$ , the computation of  $E$  is performed *ex post*:  $E$  is derived from  $E_h$  and  $U$ . In *ex post* calculus,  $C_w(s) = C_w(s|a) + C_w(a)$  in which  $C_w(s|a)$  measures the amount of information the world needs to produce  $s$  from  $a$  (see Figure 1). To judge the moral value of  $a$ , the computation is *ex ante*:  $s$  is evaluated from its emotional intensity  $E$ , from the causal unexpectedness  $U(s|a) = C_w(s|a) - C_d(s|a)$  and from the unexpectedness of action  $a$ .  $C_d(s|a)$  measures what is still to be determined about  $s$  once  $a$  is known. Then the moral evaluation  $E_h^a$  of  $a$  is  $E_h^a(s) = E(s) - U(s|a) - U(a)$ .

We introduce the notion of responsibility:  $R^a(s) = C_w(s) - C_w(s|a)$ . The more  $a$  makes  $s$  easy (resp. hard) to produce, the more  $R^a(s)$  increases (resp. decreases) and the more (resp. less) the actor is judged responsible for  $s$ . We also introduce the notion of targetting:  $T^a(s) = C_d(s) - C_d(s|a)$  which evaluates the contribution of  $a$  in the description of  $s$ .  $T_a(s) = C_d(s)$  means that  $s$  is fully described by  $a$ , the outcome  $s$  is targeted by the actor that does  $a$ . Lastly, we introduce the notion of inadvertence  $F^a = U(a)$  which measures how unexpected the action is. If  $F^a$  is large, then  $a$  has been done inadvertently. Eventually,  $E_h^a = R^a - T^a - F^a$ .

In this paper, we only consider premeditated actions ( $F^a = 0$ ) that do fully describe the outcomes ( $C_d(s|a) = 0$ ). Therefore:

$$E_h^a(s) = E(s) - C_w(s|a)$$

We define the emotional gain  $\Delta E_a$  of a moral dilemma as the difference between emotional intensities for the desired consequences and undesired consequences (see Figure 1).  $\Delta E_a$  estimates how satisfying the consequences of an action appear (note that  $\Delta E_a$  can be negative or positive). The model leads us to the following predictions:

1. The narrative interest  $I$  of a situation increases with its unexpectedness  $U$  of its hypothetical emotional intensity  $E_h$ .

$$I = E_h + U$$

2. The moral judgment  $MJ$ , in the case of an action, increases with the emotional gain  $\Delta E_a$ .

$$MJ = \Delta E_a$$

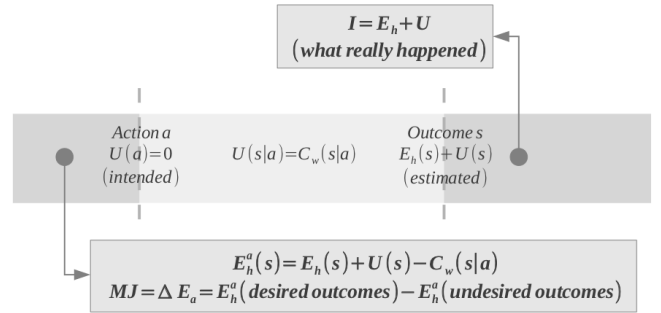

Figure 1: Complexity and Emotional intensity in a cause-to-consequence schema

The model leads to the following particular expectations:

1. A character's actions that have negative outcomes will be less morally approved if they are more direct, because their causal complexity is smaller.
2. The complexification of a causal chain will increase the narrative interest of an event, because it increases the generation complexity of the consequences, which thus appear more unexpected.
3. An action will appear more interesting, but will be less approved, if its negative consequences are simpler. In particular, an action that provokes the death of relatives or family members raises more interest (after the fact) but will be less approved.
4. Unexpected events that alter the normal course of a causal chain will have a positive influence on narrative interest.

### Experiment

Participants were asked to take the perspective of a reader and to evaluate how alternative endings of a moral dilemma story would be globally perceived by other readers on two aspects: narrative interest and moral approval of the character's action. Participants therefore were not supposed to engage their own judgment.

Participants had to read the following story (original in French):

Figure 2: Illustration for the *flooded mine* dilemma

*Tom is a miner who left Scotland, his native country, to go to work in a mine in Argentina. Here is what happened to him two years ago, while he was watching the mining site upstream. The river flooded suddenly. It was flooding one of the two tunnels of the mine. Tom knew that there were five people in this tunnel (tunnel A). In the other tunnel (tunnel B), there was only one person. The water level was rising fast, and the current in the tunnel A was increasing. The trapped persons were going to drown. Tom knew that by interrupting the current in one tunnel, one would flood the other one and provoke the death of people in it. The current cannot be interrupted in both tunnels at the same time. Tom was the only one who could act. He stood at the entrance of the two tunnels, near a crane and a heavy and voluminous box.*

This *flooded mine* dilemma (Figure 2) is largely inspired from the classical trolley problem (Thomson, 1985). The context has been augmented to allow a larger variety of alternative endings.

### Method, Participants and Materials

A total of 64 individuals (aged from 19 to 65 y.o., mean 26.11 (std. dev. 7.72), 26 females) participated to the test. The study was conducted online. Participants, mainly engineering students, were recruited via social networks and billposting.

They were asked to read the flooded mine story carefully. For each of the 4 phases of the test, several alternative endings were proposed, in which actions, causal links and consequences were varied. Alternatives were presented in the same order to all participants. Using the numbering defined later in this paper, the original orders for phases 1 to 4 were 1-2-3, 3-1-4-2, 2-4-1-3 and 1-4-2-3.

For each alternative, participants were asked to answer the two following questions on a 10-point scale:

1. "According to you, will the readers of the story approve Tom's actions?" (-5: "Disapprove", 5: "Approve")
2. "According to you, will the readers of the story find the alternative interesting?" (-5: "Not Interesting", 5: "Interesting")

We omitted the zero from this scale to force participants to choose between approval or disapproval (resp. interesting or not interesting). The answering times (with standard deviation) for the 4 phases were 3'32"(1'12"), 3'12"(1'36"), 1'36"(1'17") and 2'17"(1'31"). We manually checked the answer files for individuals who provided random or uncomplete results.

The different phases of the test successively explore the role that Kolmogorov complexity plays both on interest and on moral judgment.

### Phase 1

Former studies have shown that harming actions are more likely to be judged moral if their consequences are more indirect (Cushman, Young, & Hauser, 2006). In phase 1 of the test, we tried to reproduce this result and explore how causal complexity also affects narrative interest. We also investigated the role of the complexity of the action.

#### Alternative endings of phase 1

1. Tom pushed the box in front of the entrance of the tunnel A in order to interrupt the current in this tunnel.
2. Tom got in the crane, grabbed the box with the crane's hook, brought the box above the entrance of the tunnel A and dropped it in the middle of the current to stop the current in the tunnel.
3. Tom broke the dam of tunnel B to flood this tunnel immediately.

It interrupted the current in the tunnel A, the tunnel B was flooded.

Five persons were saved, one person died by drowning

**Results** There is a main effect of intention (F-test:  $F(1, 190) = 60.87, p < 0.0001$ ) on morality but no significant effect on interest ( $F(1, 190) = 0.0045, p = 0.95$ ). A pairwise comparison of the two alternatives involving the box revealed no effect of the way the box is carried in the middle of the current on morality ( $p = 1$ ) and interest ( $p = 1$ ) (see Figure 3). In this phase, we could replicate a classical result of the trolley problem, in which people approve actions that lead to harming a victim as a side-effect but not as a means.

The main result of this first phase is that situations which are less approved by participants are not necessarily more interesting. Elements such as harming someone as a side effect or as a means only affect moral judgment. In this test, the emotional intensity of consequences is not manipulated. In alternatives 1 and 2, the causal chain between Tom's action and its harming consequence is more complex than in alternative 3; our model predicts that alternative 3 will be less approved than alternatives 1 and 2. Since all consequences are equally (un)expected, our model predicts no effect on interest.

More generally, our model predicts that actions are more likely to be approved if their positive effects are more direct and if their negative effects are more indirect.

Figure 3: Results of phase 1: mean approval (left panel) and interest (right panel) ratings for three alternatives in which the proposed harmful actions vary in their intentional status (more or less direct action on the victim). Error bars indicate the 95% confidence interval.

## Phase 2

Phase 2 explores how the *length* of the causal chain of events between a causal action and its consequences affects moral judgments and narrative interest.

### Alternative endings of phase 2

Tom pulled the box in front of tunnel A.

1. As he expected, it stayed across the current because of its weight.
2. It was carried by the current and, as Tom expected, it was stopped by the struts in the tunnel.
3. It was carried by the current, hit the struts in the tunnel and, as Tom expected, some struts got broken and part of the ceiling at the entrance of the tunnel collapsed.
4. It was carried by the current and hit the struts in the tunnel; beams fell down from the ceiling; they were also carried by the current and were stopped by other struts. As Tom expected, it formed a new dam.

It interrupted the current in tunnel A. The five persons were saved, but the tunnel B got flooded and one person died by drowning

**Results** There is a main effect of the length of the causal chain of events on both morality ( $F(3, 252) = 3.01, p = 0.03$ ) and interest ( $F(3, 252) = 3.29, p = 0.02$ ) (see Figure 4)

In this phase, only causal generation complexity is manipulated. Since unexpectedness  $U$  in  $I$  is an increasing function of this complexity, longer deterministic chain of events make the outcomes more unexpected.  $\Delta E_a$  is a decreasing function of generation complexity for desired consequences. Our model correctly predicts that the outcomes will appear more interesting and that the actions will be less approved.

Jones (1991) used the expression *probability of effect* to refer to the probability that a harming event will occur. We suggest that the term of probability is not adapted, because in

Figure 4: Results of phase 2: mean approval (left panel) and interest (right panel) ratings for four alternatives in which the proposed causal chain of events vary in their length ( $L1 < L2 < L3 < L4$ ). Error bars indicate the 95% confidence interval.

many cases, the length of the chain of events is what is relevant, even if it is deterministic. The notion of unexpectedness correctly captures this phenomenon.

## Phase 3

Previous studies on morality (Bleske-Rechek et al., 2010) have shown that the identity of victims may affect our moral judgment. This phase explores how the identity of the single victim in tunnel B influences both moral judgment and narrative interest.

### Alternative endings of phase 3

Tom knew that [#1] was in tunnel B. Tom pushed the box in front of the entrance of tunnel A. It interrupted the current in tunnel A, tunnel B was flooded. Five persons were saved, [#2] died.

[#1]/[#2] were :

1. someone / one person
2. one of his friends / Tom's friend
3. his own cousin / Tom's cousin
4. a 10-years old child / the child

**Results** There is a main effect of the identity of the victim (undefined person, cousin, friend and 10-year old child) on morality ( $F(3, 252) = 11.79, p < 0.05$ ) and interest ( $F(3, 252) = 14.26, p < 0.05$ ) ratings. A series of pairwise contrasts clarifies the nature of this interaction. The presence of an undefined person elicited significantly higher moral approval ratings (*undefined person* vs. *friend*, *cousin*, *child*, respectively:  $F(1, 126) = 11.32, 14.07$  and  $38.25$ ;  $p = 0.001, 0.0003$  and  $< 0.0001$ ) and significantly lower interest ratings (*undefined person* vs. *friend*, *cousin*, *child*, respectively:  $F(1, 126) = 34.37, 18.32$  and  $24.87$ ;  $p < 0.0001, < 0.0001$  and  $< 0.0001$ ) (see Figure 5).

Alternatives in which victims are less complex to describe (Tom's cousin and Tom's friend) are more interesting than the ones involving some undefined victim. As suggested by our

Figure 5: Results of phase 3: mean approval (left panel) and interest (right panel) ratings for four alternatives in which the victims vary in their identity. Error bars indicate the 95% confidence interval.

model, the unexpectedness increases and the emotional gain decreases when undesired consequences are simpler. The model correctly predicts that alternatives 2 and 3 will be less approved and appear more interesting than alternative 1.

The fact that the victim is a child increases the hypothetical emotional intensity. Our model correctly predicts that harming a child will be less approved but more interesting.

Our model agrees with results of Bleske-Rechek et al. (2010) and with some aspects of Jones' "components of moral intensity" such as proximity (defined as the feeling of nearness the moral agent has for the victim) and the social consensus (defined as a degree of social agreement that a proposed act is evil) (Jones, 1991).

#### Phase 4

Two elements are manipulated in phase 4: the more or less direct action of Tom and the presence or absence of unexpectedness in the course of events.

##### Alternatives

1. Tom broke the dam of tunnel B to flood this tunnel immediately. What happened was not expected. The fragments of the dam formed a new dam at the entrance of tunnel B. It was not enough to stop the current in tunnel A. Five persons died, one person was saved.
2. Tom broke the dam of tunnel B to flood this tunnel immediately. It interrupted the current in tunnel A, the tunnel B was flooded. Five persons were saved, one person died.
3. Tom pushed the box in front of the entrance of the tunnel A in order to interrupt the current in this tunnel. What happened was not expected: the box was not big enough to stop the current in tunnel A. Five persons died, one person was saved.
4. Tom pushed the box in front of the entrance of tunnel A in order to interrupt the current in this tunnel. It interrupted the current in tunnel A. Tunnel B was flooded. Five persons were saved, one person died.

**Results** There is a main effect of unexpectedness in the course of events for both morality ratings and interest rat-

ings (*non unexpectedness* vs. *unexpectedness*, respectively :  $F(1, 252) = 14.66$  and  $9.30$ ;  $p = 0.0002$  and  $0.003$ ). As in the phase 1, the action of Tom has significant effect on approval ratings (*push the box* vs. *break the dam*,  $F(1, 252) = 16.03$ ,  $p < 0.0001$ ) but no significant effect on interest ratings ( $F(1, 252) = 1.83$ ,  $p = 0.18$ ) (see Figure 6).

Figure 6: Results of phase 4: mean approval (left panel) and interest (right panel) ratings for four alternatives in which in which the proposed harmful actions vary in their intentional status and the courses of events vary in the presence or non presence of unexpectedness. Error bars indicate the 95% confidence interval.

These results are consistent with the observations of the previous phases. They show that variations of Tom's action only affect moral judgment. They also show that a combined increase of unexpectedness and of hypothetical emotional intensity positively influences interest but negatively affects our moral judgment about Tom's action.

This test does not only confirm previous results. It also confirms the prediction that the combination *breaking the dam + unexpected outcome* will be the least approved alternative (and the most interesting one), whereas the combination *pushing the box + deterministic result* will be the most approved alternative (and the least interesting one). However, the model is not accurate enough to predict which one among the alternatives 2 and 3 will be more approved or more interesting. Such ranking would require precise estimates of complexity values, which depend on observers' knowledge and personal history.

## Discussion

The aim of this study was to present and test a complexity-based model for narrative interest and moral judgment in moral dilemma stories. The point was to explore the role played by Kolmogorov complexity. The model, based on Simplicity Theory, intends to offer a purely cognitive account of some judgements about morality and interest in moral dilemma stories, without using *ad hoc* hypothesis about moral or immoral classes of actions. This preliminary and exploratory study has shown that the model makes correct predictions and may explain classical results about moral judgements in terms of complexity. It intends to point out the dif-

ferent but complementary roles of complexity and emotional intensity in moral judgment and narrative interest.

Our moral judgments depend on the estimated emotional gain of the dilemma, which depends not only on the emotion attached to outcomes, but also on the complexity of the causal links that lead to them. A positive gain, for example an action which saves five but kills one, may be less morally approved if it appears that this positive consequences are more complex to produce than negative ones. The gain would also be considered as uncertain or unexpected. This contributes to explain why humans are highly sensitive to actions that would jeopardize the lives of relatives, friends, or family members.

Emotional intensity also plays an important role. This may be related to Haidt's work (Haidt & Hersh, 2001) that point out the role of automatic emotional processes. Due to cultural or societal consensus, some situations appears more emotionally intense than others.

Our model makes good qualitative predictions. In future work, we will explore how quantitative parameters that influence complexity (e.g. distance in space or time) affect the emotional intensity attached to outcomes. The identification and control of these quantitative parameters open the way to a variety of potential applications, for example in the domain of decision-making. Several factors that are spontaneously attributed to the emotional component of decision-making may be reinterpreted as complexity-based computations. Such an account, if valid, would not only be relevant from a scientific perspective. It would also be potentially useful to help decision-makers evaluate or anticipate certain decisions in which emotions are supposed to play a major role.

## Abstract

We defined learning while searching and browsing on the Web as "learning by searching." We used concept map to evaluate how users' knowledge structure changed as a result of their learning by searching. The influence of different topics and different scenarios was also investigated. In the experiment, participants were divided into divergent and convergent scenario groups. They were asked to assume the role of a journal editor and search for information to be presented at an editorial meeting. They performed two tasks within the topics of environment and travel. We compared the two concept maps drawn by the participants before and after the search and analyzed the web pages browsed by the participants during the tasks. The results showed that the participants' knowledge representation dynamically changed through learning as a result of searching, and the topics and scenarios influenced their processes and changed their conceptual structures before and after searching.

**Keywords:** Concept Map; Knowledge Structure; Information Seeking on the Web; Learning by Searching

## Introduction

Searching on the Web is more than just a tool for information retrieval; it has used a tool for investigating, learning, and decision making. For instance, when people buy a new digital camera, they often search and browse many digital camera sites. During these activities, they learn and acquire knowledge about digital cameras (i.e., function, structure, price, design, and size). We define this learning through searching and browsing on the Web as "Learning by Searching."

Learning by searching is considered a type of discovery learning. Discovery learning is inquiry-based, constructivist learning. The learner discover facts and relationships and new truths on their own (Bruner, 1967). Discovery learning facilitates the learner's spontaneous motivation and encourages discovery, as compared with learning by teacher instruction only. However, discovery learning is difficult for learners and research suggests that the effects of discovery learning are influenced by learning processes and the learner's skill or motivation. Learning by searching is considered to have the same benefits and problems as the discovery learning, but the factors that affect learning by searching have not been investigated. In this study, we focus on search topics and problem

contexts, and investigate how people acquire knowledge during their search and what influence search topics and situations have on their knowledge.

We used concept maps to evaluate the knowledge acquired by the users and how their knowledge structure changed as a result of their searching for information on the Web. The concept map is a graphical representation that allows people to explicitly represent their knowledge (Novak & Gowin, 1984). The concept map consists of concept words, arrows that connect the concept words, and linking words (link labels on the arrows.)

Concept maps have been used as measures to assess learners' knowledge and understanding. Meagher (2009) reported that the graph structures of concept maps became more complex from the first class in a course through the final exam. Rebich and Gautier (2005) also showed that the total number of useful items on post-course maps increased, while the total number of weak items and misconceptions decreased. Concept maps are also used to compare expert knowledge structures with novice knowledge structures. Chi, Feltovich, and Glaser (1981) compared the categories used by experts and novices and their explanations about the problems to examine the relationship between categorization and representation of physics problems. They drew concept maps to compare expert explanations with novice explanations.

Some research on information seeking behaviors has used concept maps as a means of measuring the change in a learner's knowledge. Vakkari and Pennanen (2003) explored how a student's conceptual structure is related to search tactics and search success. They reported that, between the beginning and end of the overall task, different features of the student's conceptual structures were connected to search success in terms of the useful documents they found. Cole, Lin, Leide, Large, and Beheshti (2007) focused on how students' mental model diagrams for a topic were represented in an early exploration stage of the information-seeking process and they suggested a 12-category classification schema of the mental models. Our previous researches also have studied

Figure 1: Concept map drawn by a participant for the environment topic in the divergent scenario.

how a user's concept map differs before and after a search (Egusa et al., 2010). A comparative analysis of the pre- and post-search concept maps indicated that users significantly changed their knowledge structures on a topic through learning by searching. However, there has been little research using concept maps as a measurement of how the user's knowledge has changed through the search process. Our final goal is to explore what and how people learn through searching and how their search processes influenced their learning.

## Methods

### Experimental Design

In the experiment, we focused on the influences of the topics (environment and travel) and scenarios (divergent and convergent). The participants were assigned to a factorial experiment that included two topics as within-subjects factors and two scenarios as between-subjects factors. The two within-subjects factors were counter-balanced.

### Participants

Thirty-two undergraduate students aged 20 to 23 years participated in this study (sixteen male and sixteen female). Participants

were recruited from various departments and universities in the Tokyo area. We selected participants who didn't have much experience and knowledge on the topics based on their responses to a pretest questionnaire. They were divided into two scenarios equivalent as to age, sex and major.

### Topics

The participants were instructed to assume the role of a magazine editor and to gather information on the Web in preparation for a regular magazine series on environmental and travel topics. The environment topic required the participants to introduce various environmental issues, while the travel topic asked them to present various destinations for one-day trips from Tokyo.

### Scenarios

There were two scenarios, divergent and convergent. In the divergent scenario, the participants were required to gather web pages for a series of articles to be a regular feature of the magazine. In the convergent scenario, they were required to gather pages for a single article of the regular feature. We prepared tasks for each scenario of the two topics.

Figure 2: The average number of common, lost, and new nodes in each task.

The instruction sets for the environment topic using the divergent scenario and the travel topic using the convergent scenario are shown in Appendix A and Appendix B, respectively.

## Procedures

The participants answered questions about their experience using web search engines and the Internet on a search-experience questionnaire. They were instructed on how to create the concept maps and were given time to practice. They then received their task instructions and drew a concept map for the assigned topic with a 10-minute time limit. A blank sheet of paper with a single node of the topic, either environmental issues or one-day trips from Tokyo, was provided for drawing the concept map.

After drawing the concept map, the participants conducted a 15-minute search task. While performing the search task, the log data were recorded using a plug-in software developed by our group. After completing each search task, the participants were required to again draw a concept map about the assigned topic and to answer questions about their prior knowledge of the task, their interest in the topic, the difficulty of the task, and the difficulty gathering information. They were also asked to provide comments on the task. They then repeated the task for the other topic, from the instruction stage to answering the questionnaire.

After the two main tasks were completed, the participants answered questions comparing the two tasks and the changes in their knowledge after completing the task, and then were asked to comment on how they felt about the changes between the two concept maps, i.e., before and after the web search.

In the final session, the participants were asked to check whether the same concept could be found on both concept maps and, if such corresponding concepts were found, they were assigned the same number.

## Results

We analyzed the two (before and after search) concept maps drawn by the participants to examine whether their knowledge representation of the topic changed. We also analyzed the web pages browsed by the participants during the tasks to

investigate the relationship between the participants' conceptual changes and their search behaviors.

## Numbers of Common, Lost, and New Nodes

Figure 1 shows the concept map drawn by a participant for the environment topic in the divergent scenario. The node enclosed in a double line show the center node. The nodes enclosed in a dotted line with the same number show that the participant checked these nodes as having the same meaning in the final session.

We defined three types of change between the participants' pre and post-search concept maps. The nodes that participants identified as having the same meaning in the pre and post-search maps were defined as common nodes, nodes existing only in the pre-search map were defined as lost nodes, and nodes first appearing in the post-search map were defined as new nodes. We then analyzed the number of common nodes, new nodes, and lost nodes. For instance, Figure 1(a) has four common nodes, 13 lost nodes, and 22 new nodes.

Figure 2 shows the average number of common, lost, and new nodes in each scenario of the two tasks. A 3-way mixed ANOVA (analysis of variance) with scenario as a between-subjects factor and topic and type of change as within-subjects factors revealed that there is significant interaction between topic and type of change ( $F(2,60)=6.56, p < .01$ ). The number of lost and new nodes in the travel topic were more than those in the environment topic (lost:  $F(2,60)=21.98, p < .01$ ; new:  $F(2,60)=8.81, p < .01$ ). There also were differences among the three types of change. In the environment topic, the number of new nodes was more than the other two types of nodes and the number of common nodes was less than the other two types of nodes ( $F(2,60)=41.21, p < .01$ ). In the travel topic, the number of common nodes was less than the other two types of nodes ( $F(2,60)=49.93, p < .01$ ).

In total, there were few common nodes and a relatively large number of lost and new nodes. These results suggest that the concept maps changed greatly after the web searches were conducted.

Figure 3: The differences from pre to post-search in the number of nodes at each distance.

Figure 4: The percentage of phrases with a frequency of 1 or more than 2 for each topic.

### Number of Nodes at Each Distance from the Center Node

Regardless of the scenarios and topics, the participants' maps changed dynamically before and after searching. Next, we examined whether or not there were any differences in the position of each node in the map between scenarios and topics.

To analyze differences in the position of each node, we defined distance in each node. Distance in each node is measured by the number of arrows following the center. Nodes that were linked to more than two nodes and had more than two distances were counted at each distance. We counted the number of nodes at each distance from the center node, that is, the node placed at the center of the concept map. Nodes at distance 4 or higher were counted as in the same category. Moreover, to clear the differences between scenarios and topics, we calculated the amount of change for each distance from the pre to post-search maps by subtracting the number of nodes at each distance in the post-search map from those in the pre-search map. If the number of nodes in the post-search map at distance  $n$  was more than that in the pre-search map, the amount of change at distance  $n$  was considered a positive value.

Figure 3 shows the amount of change at distances 1, 2, 3, and 4 or more for the two topics in each scenario. A 3-way mixed ANOVA with topic and distance as within-subjects factors and the scenario as a between-subjects fac-

tor revealed significant interaction between scenario and distance ( $F(3,90)=14.40, p < .01$ ). The amount of change at distances 1 and 2 in the divergent scenario occurred more than those in the convergent scenario (distance 1:  $F(3,90)=27.90, p < .01$ ; distance 2:  $F(3,90)=14.23, p < .01$ ). Differences were also found for each distance in the convergent scenario. The amount of change at distance 4 or more was more than the other distances ( $F(3,90)=16.80, p < .01$ ).

### Frequency of Phrases Used in Nodes

The position of the nodes in the map were different for the two scenarios. However, it is unclear whether or not these differences were also found in the phrasing used by the participants. We therefore compared the changes in the phrases used in the maps between the two scenarios and the two topics.

Before making our analysis, we extracted phrases included in nodes from the participants' concept map. These were phrases in both the pre and post-search maps put together with respect to each scenario and topic. Because these phrases were spelled in several different ways, we adjusted the differences based on the rules listed below. Finally, we counted the frequency of the phrases.

- phrases expressed in different forms, such as "東京", "とうきょう", and "トウキョウ" (These phrases all mean "Tokyo.").

Figure 5: The number of SERP and nonSERP in each topic.

- phrases expressed with or without a particle, as in “海面上昇” and “海面上昇”.
- phrases expressed in abbreviated form or not, such as “eco” and “ecology.”
- phrases with typographical errors.

Figure 4 shows the percentage of phrases used once and more than twice in each task. On the whole, 80 % of phrases were used only once. The results of the  $\chi^2$  test revealed significant differences between the two scenarios in the post-search map (Environment:  $\chi^2(1)=6.810$ ,  $p < .01$ ; Travel:  $\chi^2(1)=13.181$ ,  $p < .01$ ). The number of phrases occurring once in the convergent scenario was greater than those in the divergent scenario for the two topics and the number of phrases with a frequency of more than two in the convergent scenario was less than those in the divergent scenario for the two topics. There were no differences in the pre-search map.

### Number of Web Pages Browsed

Finally, we examined the relationship between the participants' conceptual changes and their search behaviors. We focused on the web pages browsed by the participants during the task because their conceptual changes would be most likely influenced by them. We extracted the web page URLs from the browser logs. These URLs were classified by a logging tool as a search engine result page (SERP) or some other page (nonSERP).

Figure 5 shows the average number of SERPs and nonSERPs for each topic. A 3-way mixed ANOVA with topic and page type as within-subjects factors and scenario as a between-subjects factor revealed a significant interaction between topic and scenario ( $F(1,30)=7.08$ ,  $p < .05$ ). In the environment topic, participants in the divergent scenario browsed more SERPs and nonSERPs than participants in the convergent scenario ( $F(1,30)=10.27$ ,  $p < .01$ ). In the convergent scenario, participants browsed more SERPs and nonSERPs for the travel topic than the environment topic ( $F(1,30)=9.39$ ,  $p < .01$ ). A significant interaction was also found between topic and page type ( $F(1,30)=15.13$ ,  $p < .01$ ). The participants browsed more nonSERPs for the travel topic than the environment topic ( $F(1,30)=12.55$ ,  $p < .01$ ). The number of SERPs

was more than those of nonSERPs for the two topics (Environment:  $F(1,30)=18.16$ ,  $p < .01$ ; Travel:  $F(1,30)=42.20$ ,  $p < .01$ ).

### Discussion

We defined learning during searching and browsing on the Web as “learning by searching.” We investigated how searchers' conceptual knowledge of topics changed by comparing their before search and after search concept maps. The influence of different topics and different scenarios was also investigated. In the experiment, participants were divided into divergent and convergent scenario groups. They were asked to assume the role of a journal editor and search for information to be presented at an editorial meeting. They also performed two tasks under the topics of environment and travel.

We analyzed the before and after search concept maps drawn by the participants to examine whether their knowledge representation of the topic changed during the search. The results show that their concept maps dynamically changed after the search regardless of the topics or scenarios. Egusa et al. (2010) also reported the same results. These results indicate that searching and browsing web pages strongly influences a searcher's knowledge structure of a topic. Why did their conceptual structure change so dramatically? One likely reason is that the participants searched and browsed web pages that suited their interests, which allows them to easily build new knowledge onto their existing knowledge base. An alternate reason is that they had this knowledge already and they reconstructed their knowledge through learning by searching. However, these changes might be temporary and forgotten with the passage of time. We need to further examine the continuousness of learning by searching.

Results also demonstrated the influence of topics and scenarios. The number of lost and new nodes in the travel topic was greater than those in the environment topic. These results indicate that there are differences in the knowledge structures for the topics and that the concept map can represent these differences. Cole et al. (2007) also found the differences between the concept map drawn by history students and those by psychology students.

Differences between the scenarios were found in the node distances and phrase frequencies. In the divergent scenario, nodes placed near the center increased and nodes placed far from the center decreased. On the other hand, nodes placed far from the center increased in the convergent scenario. As can be seen from the examples in Figure 1, the node concepts changed from general to specific as distance from the center node increased. Therefore, the participants in the convergent scenario acquire specific knowledge while the participants in the divergent scenario acquire general knowledge. A similar tendency was seen in the analysis of the frequency of phrases used in the nodes. In the convergent scenario, the phrases used once increased and the phrases used more than twice decreased.

We also analyzed the web pages browsed by the participants during the tasks to investigate the relationship between the participants' conceptual changes and their search behaviors. Differences between the scenarios were only seen in the environment topic. The number of SERPs and nonSERPs in the divergent scenario was greater than those in the convergent scenario. This indicates that the participants in the divergent scenario searched and browsed quickly to gather a wide scope of information about the environment topic, while the participants in the convergent scenario browsed web pages more minutely to gather detailed information about the specific theme of the environment topic. We presume that these web page results relate to the above concept map results. However, with the travel topic, we could not find differences between the scenarios. We must analyze other process data to explicitly capture the relationship between the searchers' search processes and the changes in their knowledge representation.

Finally, we discuss on the significance of our study. In this study, we compared different scenarios about the same topic. We found that these differences of scenario influenced breadth and depth of searching and quality of knowledge acquisition. In the discovery learning, it is also important to explicit relationship between how students explored and what they learned for helping students learn and discover effectively.

## Appendix

### A. Instructions for environment in divergent scenario

Please carry out this task as if you were in the following situation: You are working as an editor for a news magazine published by a national newspaper. Your chief has asked you to gather information to introduce various environmental issues for a regular series that will begin with the next issue. The chief will hold a meeting with other managers from several departments to discuss this regular series.

In the meeting, the chief would like to present an overall picture of each article for the series. For that purpose, you must gather various pieces of information that are sufficient for discussing which topic should be selected for each article of the series, rather than gathering detailed information for just a single article in the series.

Please choose the most interesting topics for the readers. You have just 15 minutes to search the Web and find the needed information. If you find a useful web page for the topic, add it to the bookmarks.

### B. Instructions for travel in convergent scenario

You are working as an editor for a travel magazine published by a major publishing company. Your chief has asked you to gather information to introduce various one-day trips for a regular series that will begin with the next issue. The chief will hold a meeting with other managers from several departments to discuss this regular series.

In the meeting, the chief would like to present the specific contents for one article of the series. For that purpose, you must gather detailed information for a single article of the series rather than information for several trips.

Please choose the most interesting topics for the readers. You have just 15 minutes to search the Web and find the needed information. If you find a useful web page for the topic, add it to the bookmarks.

# Towards a Cognitive Science of Literary Style: Perspective-Taking in Processing Omniscient versus Objective Voice

## Abstract

What are the consequences of narrative style for the cognitive operations that comprehenders perform? Third person narratives can adopt different voices. Omniscient voice has access to the mental states of characters, while objective voice only describes how characters would appear to an observer. It's currently unknown what cognitive consequences different voices have for people processing third person language. We hypothesize that in building representations of described scenes, omniscient voice may make comprehenders more likely to adopt the internal perspectives of characters than objective voice. We tested this prediction in a narrative-image matching study. Participants read short passages describing a third person character in either omniscient or objective voice. They then saw an image that either depicted the described scene or not, and which depicted the event from the perspective of the character or not. Their task was to decide as quickly as possible whether the image matched the narrative. In cases where the narrative and image matched, participants were significantly faster to indicate the correct decision when the narrative voice and the image perspective matched—that is, an image from the character's perspective after an omniscient narration or an image from a different perspective after an objective narration. This finding provides the first evidence that narrative voice affects the perspective from which comprehenders represent described scenes.

**Keywords:** language processing; perspective; narrative voice; literary style; grammatical person; mental simulation

## Introduction

Understanding the processes that underlie language comprehension is among the primary concerns of cognitive science, and justifiably so. Language is pervasively, and uniquely, human. The study of the cognitive processes underlying language comprehension has, also justifiably, begun by focusing on how people process words or sentences in isolation. Yet this is not language's natural state in the wild. We mostly interact with words and sentences embedded in context—social, physical, and linguistic. And one—though not the only—context in which words and sentences appear is in narrative. Across cultures, humans recount and process accounts of sequences of events, whether purportedly fictive or factive. We're all

story-tellers, from marketing directors to kindergarteners to shamans. The outstanding question for cognitive science is how we go about understanding narratives, with all their stylistic peculiarities. What cognitive operations do we perform to go from a story to understanding?

## Narrative Voice

A key feature of every narrative is that it is told using a particular (though possibly variable) narrative voice. Here, by way of illustration, is an example of two different narrative voices that appear in the same text. Ernest Hemingway's *The Old Man and the Sea* features an eponymous old man. Throughout the narrative, we read different kinds of descriptions of him. Early on, we read:

*The old man was thin and gaunt with deep wrinkles in the back of his neck. The brown blotches of the benevolent skin cancer the sun brings from its reflection on the tropic sea were on his cheeks. The blotches ran well down the sides of his face and his hands had the deep-creased scars from handling heavy fish on the cords. But none of these scars were fresh. They were as old as erosions in a fishless desert.*

Compare this with a passage that follows, as we're getting to know the old man a little better:

*He was asleep in a short time and he dreamed of Africa when he was a boy and the long golden beaches and the white beaches, so white they hurt your eyes, and the high capes and the great brown mountains. He lived along that coast now every night and in his dreams he heard the surf roar and saw the native boats come riding through it. He smelled the tar and oakum of the deck as he slept and he smelled the smell of Africa that the land breeze brought at morning.*

Although these two passages both describe the old man in the third person, they differ in terms of their narrative voice. While the first describes properties of the old man that can be viewed by an outside observer, the second omnisciently enters the old man's mind, so that the narrator is able to

recount aspects of the old man's mental life that would only be known to him.

For cognitive scientists, the first question is what the consequences of narrative voice choices are for comprehenders. Do we process omniscient voice differently from objective voice? And if so, in what way? Yet, to date, we know of no work addressing narrative voice and how it affects language processing.

## Perspective in Language Processing

One thing that's quite clear from recent work on language processing is that comprehenders construct detailed mental representations of scenes that they read or hear about. These are variously described in different literatures as *situation models* (Zwaan & Radvansky, 1998) or *mental simulations* (Barsalou, 1999). It also seems clear that these mental representations are often constructed from a particular perspective within the described scene. Different features seem to affect the perspective a comprehender will adopt (D'Argembeau, Comblain, & Van der Linden, 2002; Frank & Gilovich, 1989; Nigro & Neisser, 1983; Robinson & Swanson, 1993), but these at the very least include the types of actions the narrative describes (Borghi, Glenberg, & Kaschak, 2004) and the grammatical person of the narrative (for instance, 2<sup>nd</sup> versus 3<sup>rd</sup> person; Brunyé et al., 2009).

The effects of grammatical person on mental representations are particularly relevant to voice—in fact, deciding whether a narrative should use 1<sup>st</sup> person (*I*) or 3<sup>rd</sup> person (*he*), is a dimension of voice. There's been some work (Brunyé et al., 2009) showing that when people process 3<sup>rd</sup> person language, they are more likely to mentally represent the described scenario from the viewpoint of an outside observer (they adopt an *external* perspective) than from that of a character (an *internal* perspective). By way of comparison, 2<sup>nd</sup> person language (about *you*) is more likely to induce an *internal* perspective.

And yet, not all third person narratives are alike, as the Hemingway passages illustrate. There's evidence that the more a comprehender identifies with a character, the more likely he or she is to adopt that character's perspective when mentally reconstructing the described scene (Libby & Eibach, 2002; Libby, Eibach, & Gilovich, 2005).

So voice might make a difference. In cases where the narrator omnisciently describes a character's mental states, it could well be that this draws the comprehender into adopting that character's perspective in mental representations of the described scene. By contrast, objective voice, which describes characters as they would be viewed externally, might be more likely to induce external perspectives in mental representations of described scenes.

This reasoning leads to two key questions. First of all, is it ever the case that third person language can systematically lead comprehenders to adopt an internal perspective, rather than the external perspective that has previously been shown to predominate with third person language? And second, if it is, what is it about certain third person narratives that leads comprehenders to adopt an internal perspective?

We pursued both of these questions through an experiment looking at one property of narratives—narrative voice—that presents itself as a viable candidate for engaging internal perspectives in comprehenders. This is a first step in applying tools used to address comprehension processes to the stylistic details of narrative—a step in the direction of a cognitive science of literary style.

## Method

In order to investigate whether third person language using different narrative modes—objective or omniscient—induces mental representations of events from different perspectives in comprehenders, we adapted a method first used by Brunyé et al. (2009). We began by creating pairs of four-sentence narratives in English; one member of each pair used omniscient voice and the other used objective voice. Each pair of narratives concluded with the same fourth sentence. Native speakers of English read one narrative from each pair, and then saw a picture that either depicted the scene described in the narrative or not. The participant's task was to decide whether the depicted event could be part of the preceding story. We were only interested in those trials in which the image did depict the scene. These images depicted the scene from either an internal perspective (as if the reader were the character described in the narrative) or an external perspective (as if the reader were an outside observer of the action performed by the character). We predicted that if readers were more likely to adopt an internal perspective when reading omniscient voice narratives, this should make them faster to indicate their judgments about the internal perspective images following omniscient voice narratives, and conversely, if they were more likely to adopt an external perspective while processing objective voice narratives, then objective voice should make them faster when confirming matching external perspective images.

## Participants

Fifty-eight native speakers of English who were undergraduate students at the University of California, San Diego participated in this study in exchange for course credit. All participants reported normal or corrected-to-normal hearing and vision.

## Language Materials

We created twenty-four pairs of narratives. Within each pair, the two narratives were made up of three sentences that differed, but they both ended with a fourth sentence that was the same. Each narrative was entirely in the third person, and used one of the two narrative modes: omniscient or objective. Omniscient narratives included information about the mental states of the protagonist, while objective narratives only described externally visible features of the protagonist. The final sentence in both conditions described an event where the protagonist manipulated the given object with her hand (e.g., she threw away, grabbed, peeled off, or picked up the object). In addition to these twenty-four

critical narratives, which were paired with matching pictures, as described below, we also created twenty-four filler stories, half in the omniscient and half in the objective mode. These were paired with non-matching pictures. Here is a sample pair of critical narratives:

(1a) Third person omniscient narrative

She was very uncomfortable because her hands felt sticky and there was still clay under her nails from her ceramics class.

She desperately wanted to wash her hands, but could not see a sink anywhere.

She could feel the clay drying even more and eyed the small towel on the table.

She picked up the hand towel.

(1b) Third person objective narrative

She appeared out of breath when she rushed into the room.

She looked down at the table, where there was a hand towel.

Her hands were covered with clay, and she glanced back and forth between her clay-covered hands and the towel.

She picked up the hand towel.

In both narrative modes, the number of third person pronouns *she* was matched (mean: 4.8 for omniscient, 4.4 for objective), and the total number of words used for each set of items was similar (mean: 52.5 for omniscient and 56.3 for objective).

## Image Materials

The experiment used forty-eight critical pictures (twenty-four internal and twenty-four external perspectives) and twenty-four filler pictures (twelve internal and twelve external perspectives). For each set of critical sentences, corresponding pictures were taken to create a set that depicted the event from the internal perspective (i.e., a protagonist's or performer's viewpoint) as shown in Figure 1(a), and from the external perspective (i.e., an outside observer's viewpoint) as shown in Figure 1(b). Images were photographs taken using a tripod to ensure that all internal and all external images were taken from the same angle.

(a) Internal perspective

(b) External perspective

Figure 1: Internal versus external perspective images

## Procedure

Participants were tested individually. The experiment began with a set of four practice trials, followed by the experimental session, which was composed of twenty-four criticals (requiring “yes” responses) randomly mixed with twenty-four fillers (requiring “no” responses). In the experimental session, each participant viewed twelve critical and twelve filler item-sets in the omniscient narrative mode, and twelve criticals and twelve fillers in the objective narrative mode.

Each trial began with a fixation cross for 500 ms, followed by the first sentence in the middle of the screen. Participants pressed the spacebar as soon as they finished reading the sentence, at which point it was replaced on the screen by the next sentence. After the fourth and final sentence, participants saw another fixation cross for 500 ms, followed by a picture depicting, from either an internal or external perspective, an image that either was or was not part of the scene described in the story that they had just read. Participants then indicated if the pictured event was mentioned in the prior set of sentences, as quickly and accurately as possible, by pressing a button (“1” for “yes” or “a” for “no”).

Participants were asked to answer “yes” when the depicted scene was part of the prior story. No instructions were given regarding the different perspectives that images used or the different narrative voices, so as not to draw attention to these dimensions of the manipulation.

To ensure that participants paid equal attention to each of the four sentences in the narratives, every trial was followed by a comprehension question (after picture verification) that addressed one of the four sentences in the set, in equal proportions. We recorded the responses (i.e., “yes” or “no”) and measured the reaction times for picture verification and responses to comprehension questions.

The two independent variables, Narrative Mode (Omniscient, Objective) and Picture Perspective (Internal, External) were fully crossed and manipulated within participants. The four experimental conditions produced by crossing these two variables were equally assigned to four lists in a Latin-square design, resulting in six experimental items in each condition for each participant. Likewise, the twelve omniscient and twelve objective filler stories were followed by half internal, half external perspective pictures that depicted objects unrelated to the preceding scene.

## Predictions

We predicted that if third person omniscient narratives lead participants to project themselves into the protagonist and accept an internal perspective, participants should respond faster to internal perspective pictures, whose perspective matched that evoked by the preceding story, than to external ones, which mismatched. Conversely, if third person objective narratives drive participants to adopt an outside observer's perspective that has clear mental distance from the protagonist, it should facilitate responses to external perspective pictures.

## Results

Three participants were excluded for being left-handed, and an additional three participants were excluded due to low accuracy (below 80%) to picture verification or question comprehension. One item was excluded for its low accuracy rate (below 80%). The image, of sushi, may have been problematic because it depicted a type of sushi not typically available in the United States, which might have confused participants. Extremely slow responses (those over 4000 ms), incorrect responses to picture verifications and/or to comprehension questions, and responses that were more than 2.5*sd* above or below the mean response time for each participant were removed. This resulted in eliminating 11.8% of the data (3.0% exclusion due to incorrect picture verification, 4.8% due to inaccurate response to comprehension questions, and 4.0% due to the outliers).

Two-way Repeated-Measures ANOVAs revealed no significant main effect of Narrative Mode ( $F_1(1,51) = 1.0$ ,  $p = 0.3$ ,  $\eta^2_p = 0.02$ ;  $F_2(1,22) = 1.4$ ,  $p = 0.3$ ,  $\eta^2_p = 0.06$ ). Picture Perspective produced a non-significant main effect in the subject analysis ( $F_1(1,51) = 1.3$ ,  $p = 0.3$ ,  $\eta^2_p = 0.03$ ) but reached a significant effect in the item analysis ( $F_2(1,22) = 6.9$ ,  $p = 0.02$ ,  $\eta^2_p = 0.24$ ). However, as we predicted, Narrative Mode and Picture Perspective produced significant interaction effects ( $F_1(1,51) = 6.6$ ,  $p = 0.01$ ,  $\eta^2_p = 0.12$ ;  $F_2(1,22) = 5.5$ ,  $p = 0.03$ ,  $\eta^2_p = 0.2$ ) (Figure 2).

Planned pairwise *t*-tests showed that external-perspective pictures were verified significantly faster after participants read the third person sentences framed in the objective mode than after their counterparts in the omniscient mode (mean RTs for external-perspective pictures: 1510 ms after omniscient narratives, 1385 ms after objective narratives;  $t_1 = 2.3$ ,  $p = 0.03$ ;  $t_2 = 2.1$ ,  $p = 0.049$ ). The converse was true as well: internal perspectives were verified numerically faster after reading sentences formulated in the omniscient mode than after reading sentences in the objective mode. However, the differences did not reach significance (mean RTs for internal-perspective pictures: 1392 ms after omniscient narratives, 1432 ms after objective narratives;  $t_1 = 0.8$ ,  $p = 0.4$ ;  $t_2 = 0.4$ ,  $p = 0.7$ ). The most robust difference was found in the picture verification time after participants read the omniscient narratives (mean RTs after reading omniscient narratives: 1510 ms for external-perspective pictures, 1392 ms for internal-perspective pictures;  $t_1 = 2.6$ ,  $p = 0.01$ ;  $t_2 = 3.8$ ,  $p = 0.001$ ), while only a numerical difference was found after participants read the objective narratives (mean RTs after reading objective narratives: 1385 ms for external-perspective pictures, 1432 ms for internal-perspective pictures;  $t_1 = 1.1$ ,  $p = 0.28$ ;  $t_2 = 0.1$ ,  $p = 0.9$ ).

Figure 1: Mean RTs for picture verification, demonstrating an interaction effect between Narrative Mode (Omniscient vs. Objective) and Picture Perspective (Internal vs. External). Error bars indicate standard error.

In order to assess whether there could be a speed-accuracy tradeoff present in these data, we conducted an error analysis. We ran Repeated-Measures ANOVAs with Accuracy as the dependent measure and Narrative Mode and Picture Perspective as the independent measures. These revealed no significant main effects of Narrative Mode ( $F_s < 1$ ) or Picture Perspective ( $F_s < 1$ ), nor any interaction effect ( $F_s < 1$ ).

We also conducted post-hoc analyses to determine whether perspective adoption effects differed according to participants' sex; as the narratives all described a female protagonist, it's possible that female participants were more likely to adopt an internal perspective on the described scenes. We had unbalanced numbers of male and female participants (male = 15, female = 37). Three-way Repeated-Measures ANOVAs with Reaction Time as the dependent measure and Narrative Mode, Picture Perspective, and Participant's Sex as the independent variables did not show a significant three-way interaction of Gender by Narrative Mode by Picture Perspective ( $F_1(1,50) = 2.4$ ,  $p = 0.1$ ,  $\eta^2_p = 0.05$ ). This might indicate that perspective adoption is not significantly affected by participants' gender.

## Discussion

We investigated the notion that language comprehenders construct mental representations of described scenes by adopting particular perspectives, perspectives that, by hypothesis, might be affected by the narrative voice used. Previous work (Brunyé et al., 2009) has shown that third person language tends to elicit an external perspective on described events, but we found that it did not do so across the board. Rather, as predicted, the adopted perspective was modulated by the type of narrative voice. Omniscient voice made comprehenders significantly more likely to adopt an internal perspective, while objective voice made them quantitatively more likely to adopt an external perspective.

The asymmetry between the strong effect of omniscient voice and the relatively weaker one of objective voice may relate to the fact that all narratives and images in the experiment described or depicted to the same female protagonist. It's possible that there was a cumulative effect over the course of the experiment whereby participants came to identify with the protagonist. This might have resulted in third person objective language, which according to previous results should have facilitated external images, instead driving internal mental representations of described events.

In general, these results we observed are compatible with previous work showing that language comprehenders not only construct detailed mental representations of described scenes, but do so from a particular perspective. Critically, this study adds to the existing literature on perspective by showing that person is not the only linguistic factor that can push the comprehender's adopted perspective around—narrative voice appears to have a similar effect. The perspective a comprehender adopts in constructing mental representations of described scenes is the flexible product of stylistic aspects of the narration itself. It is already known that the same person does not always lead to the same perspective in comprehension. Previous research conducted by Brunyé et al. (2009) shows that first person *I* in an isolated sentence is more likely to induce an internal perspective, but when it's embedded in a richer discourse context, it tends to evoke an external perspective. Our findings show a similar flexibility for third person language, but whereas it is the presence or absence of a back-story that has been shown to modulate perspective during first person language processing, we found that the style of the narrative context itself modulates perspective in third person language processing.

Our specific finding is that when the protagonist's internal states are described, as in a third person omniscient narrative, readers are more likely to adopt the visual perspective of the relevant character. This may be related to empathetic projection in which a reader engages with that character (Carr et al., 2003; Decety & Sommerville, 2003; Lamm, Batson, & Decety, 2007; Perrine & Decety, 2004). Reading descriptions of the mental and emotional states of a character might lead comprehenders to identify with and imagine themselves as that character. As a result, omniscient narration might not only lead to measurable differences in the visual perspective comprehenders adopt, but also influence the extent to which they adopt the affective perspective of a character—the extent to which they recreate, while reading, the emotions that a character might experience (Havas, Glenberg, & Rinck, 2007).

Our results may also be related to resonant projection—observers are more likely to find a situation resonant when they share action-relevant characteristics with the actor, such as a viewpoint in hand-object interacting events (Bruzzo, Borghi, & Ghirlanda, 2008), similar motor competence (Calvo-Merino et al., 2006), or relevant motor knowledge or expertise (Calvo-Merino et al., 2010).

Readers do not adopt a fixed perspective that is evoked by language, and it might be that the modulation of perspective by narrative voice works similarly to these other factors that influence projection.

## Conclusion

In sum, the results we've reported here add to the existing literature on perspective adoption in language comprehension by showing that narrative style has an impact on whether comprehenders view a described scene from an internal or an external perspective. In some circumstances, third person language can be just as effective at transporting the comprehender into the described experience of a character as second person language can. Research like this shows the promise of using empirical cognitive science methods to explore the effects of literary style. Readers are, after all, humans, and reading is, after all, a cognitive behavior. Understanding the effects of cognitive style is well within our reach.

## Abstract

The study investigated whether the facilitating effect of high text comprehensibility on lay recipients' inclination to rely on their own decision about scientific claims is mitigated if the presented information is controversial. Moreover, it was assessed whether the impact of both information features is mediated by perceptions of topic complexity. Lay readers read medical text information varying in comprehensibility and controversiality and indicated their agreement strength and confidence with contained claims. Results revealed that participants' reliance on their own agreement decision was stronger after reading comprehensible than incomprehensible texts, but this difference was larger in case of uncontroversial than controversial information. However, these effects were not mediated by perceptions of topic complexity.

**Keywords:** knowledge evaluation; expertise; text comprehensibility; controversiality

## Introduction

Laypeople often find themselves in situations where they have to come to a judgment about the veracity of science-based knowledge claims, e.g. when they need to decide whether to undergo a certain medical treatment. The ease of accessing information on the Web has eliminated problems regarding the availability of science knowledge that might act as a basis for such decisions. The great challenge lies instead in the evaluation of accessed information and the knowledge claims they contain regarding their acceptability (Mason, Ariasi & Boldrin, 2011). The reason why this evaluation presents such a challenge is that we all are laypeople with regards to most science domains and lack the background knowledge and specialized training usually required for making well-founded decisions about knowledge claims. Consequently, laypeople are generally not in a position to evaluate claims by themselves but rather depend on experts for decision support (Bromme, Kienhues & Porsch, 2010; Keil, 2008). Hence, when confronted with

the necessity to decide about a science-based claim, laypeople can choose between two major courses of action: They can either rely on their own judgment despite their lay status or they can outsource the decision to an expert. However, given their own epistemic limitations, relying on experts is most often the appropriate and sensible strategy.

If laypeople nevertheless rely on their own claim decision, this should be reflected in their inclination to be easily persuaded by provided claim-related information that contains apparently sound arguments. Only if they see themselves in a position to decide about information quality should recipients make strong judgments in favor of a claim. Conversely, they should be more hesitant to strongly agree if they do not feel ready to decide. In addition, laypeople's willingness to rely on their own judgments should be reflected in high confidence in their claim decision, i.e. strong trust in their own judgment and a weak desire to hand over the decision to an expert (Scharrer, Bromme, Britt & Stadtler, 2012).

## Text Features influence Laypeople's Reliance on their own Decisions

Previous research indicates that laypeople's readiness to rely on their own decision about the veracity of science-based claims can be influenced by features of the text information they read about the topic.

**Information Comprehensibility** One such text feature is the comprehensibility of contained information. In popular scientific reports addressed to the lay public, information is frequently simplified in order to make it understandable for the audience (Wagner, Elejabarrieta & Lahnsteiner, 1995). Such simplification can be achieved through enhancement of comprehensibility, e.g. by translating technical terms. But while an increase in comprehensibility facilitates laypeople's ability to follow what is being said, it may also

raise their inclination to rely on their own decisions. A layperson's experience of easily understanding information about a scientific topic may induce the impression that they are not in need of expert support to reach a decision about related information. Previous findings support this assumption by showing that science-based information simplified by means of increased comprehensibility leads laypeople to more strongly and confidently agree with claims than incomprehensible information (Eagly, 1974; Scharrer et al., 2012).

Hence, while it may be worthwhile to simplify information for the sake of allowing the lay public to gain insight into topics important for their daily lives, such simplification also comprises the risk of making readers underestimate their own dependence on experts for decision advice. The question arises whether and how it is possible to inform laypeople about scientific topics without tempting them to overconfidently rely on their own derived decisions, i.e. whether there are further information characteristics that can prevent the observed comprehensibility effect.

**Information Controversiality** A textual feature that might counteract the influence of comprehensibility on laypeople's reliance on their own decisions is information controversiality. Due to the evolving and discursive nature of scientific knowledge production, views on a particular phenomenon held by different scientists are frequently conflicting. Confronting lay recipients with the controversiality of a particular topic might alert them that judging related claims is generally a highly demanding task, independently from whether related text information is easy or difficult to comprehend. The notion that encountering controversies might decrease recipients' persuasion is in accordance with previous findings showing readers to be more hesitant to agree with consistently supported than with controversial claims (Kienhues, Stadtler & Bromme, 2011; Yaniv, Choshen-Hillel & Milyavsky, 2009).

However, as of yet it has not been investigated whether the impact of information controversiality on recipients' persuasion interacts with the influence of information comprehensibility and thus can prevent the persuasive effect of high comprehensibility. Furthermore, it is still unclear which cognitive processes underlie the impact of comprehensibility and controversiality on recipients' reliance on their own decisions.

### **Possible Mechanism underlying the Influence of Comprehensibility and Controversiality**

On a theoretical level it is conceivable that the effects of both comprehensibility and controversiality on laypeople's decision readiness are mediated by recipient's assessment of the epistemic complexity of the topic. If laypeople encounter simplified texts tailored for them to comprehend, their understanding of the *text* may mislead them to consider the *subject matter* itself as less complicated than it really is (cf. Goldman & Bisanz, 2002; Scharrer et al., 2012). Consequently, they may overestimate their actual insight

into the topic and their ability to appropriately evaluate the provided information (cf. Keehner & Fischer, 2011). Likewise, laypeople may explain information controversiality with high epistemic complexity of the topic. As a result of encountering a conflict, laypeople might become attentive to the possibility that scientists can have opposing views on the same phenomena, and hence that a given claim might be valid only under specific circumstances. Laypeople may then become aware that reading the provided information does not equip them with sufficient knowledge to confidently decide about related claims.

However, the described mediating role of perceived topic complexity would require that laypeople elaborate on the epistemic demands of the problem at hand relative to their own epistemic capabilities to determine whether or not they can decide. Conversely, it is also possible that lay recipients do not engage in such elaborate reflections but rather base their judgment on intuitive or affective reactions. In light of such alternative possibilities it remains an open empirical question whether the influence of comprehensibility and controversiality on laypeople's decision behavior are indeed mediated by perceived epistemic topic complexity.

### **The Present Study**

The present study set out to pursue two goals. Firstly, we aimed to assess whether laypeople's increased reliance on their own decision after reading comprehensible compared to incomprehensible information is reduced if this information contains conflicting rather than consistent positions. Secondly, given the above considerations about the possible mediating role of perceived topic complexity, we aimed to gain insight into the processes by which comprehensibility and controversiality exert their influence on laypeople's decision behavior. For this purpose, we presented lay readers with argumentative text information that varied in comprehensibility and controversiality.

With regards to the first goal, we expected that comprehensible information would lead laypeople to rely more on their own decision than incomprehensible information if information is uncontroversial. However, we assumed that this comprehensibility effect is mitigated or even prevented if the received information is controversial. Specifically, we hypothesized that laypeople agree more strongly with a claim when reading comprehensible than incomprehensible information but that this difference is greater in case of uncontroversial than controversial information (H1). Furthermore, we expected laypeople's decision confidence to be analogously influenced by comprehensibility and controversiality. Decision confidence should be reflected in laypeople's respective preferences of three decision strategies: Strategy A to decide by oneself based on one's knowledge after reading the information should indicate high decision confidence, Strategy B to decide by oneself but only after obtaining further content information should indicate intermediate confidence, and Strategy C to leave the decision to an expert should indicate

low decision confidence. Hence, we hypothesized that laypeople find Strategy A more preferable after reading comprehensible than incomprehensible texts, but that this effect should be more pronounced in case of uncontroversial than controversial information (H2a). Similarly, Strategy B should be more popular after reading comprehensible than incomprehensible texts, but this difference should be greater in case of uncontroversial than controversial information (H2b). Finally, incomprehensible texts should lead to a greater preference of Strategy C than comprehensible texts but this effect should be stronger if the information is uncontroversial than controversial (H2c).

As to the second goal, we considered it possible that laypeople's impression of epistemic topic complexity mediates the influence of comprehensibility and controversiality on laypeople's persuasion strength and confidence. Comprehensible and uncontroversial information might facilitate the impression of the subject matter being simple and straightforward, i.e. decrease perceptions of epistemic complexity. As a result, laypeople may regard themselves able to appropriately understand the topic and may thus be inclined to rely on their own claim decisions. However, we would assume no mediation effect of topic complexity if laypeople's determination of their own decision readiness does not depend on elaborations of epistemic demands. Since both possibilities are conceivable, we formulated the following exploratory research question: Is the influence of comprehensibility and controversiality on claim agreement and agreement confidence mediated by perceived epistemic topic complexity?

## Method

The experiment was conducted using a 2x2 mixed design with the within-participant factor information comprehensibility (comprehensible vs. incomprehensible) and the between-participant factor controversiality (controversial vs. uncontroversial). In each condition, participants were presented with texts about a medical issue that were either comprehensible or incomprehensible and controversial or uncontroversial, respectively. Eighty-eight undergraduates of various majors at a German university participated in the experiment (54 female; mean age = 22.81 years,  $SD = 4.39$ ). To ensure participants' lay status, students of medicine, biology or related subjects were excluded from participation. Moreover, the medical issues addressed in the texts were fictitious in nature to ensure that participants were unable to make informed decisions about the contents based on their everyday knowledge and had no strong prior attitudes about the topics.

## Materials

Participants read a document (Document 1) containing a particular medical knowledge claim (e.g. "Bouchard arthrosis is caused by a deficiency of purinerase") followed by an explanation that described the mechanisms underlying the proposed claim and supporting empirical evidence. In addition, a second document (Document 2) was presented

consisting of a claim supported by empirical evidence. Depending on the controversiality condition, Document 2 either contained a claim that was in conflict with Document 1 (e.g. "A lack of purinerase is not among the causes of Bouchard arthrosis") or a claim that did not render the Document 1 information controversial (e.g. "A persistent lack of folic acid is not among the causes of Bouchard arthrosis"). The information contained in the documents was furthermore comprehensible or incomprehensible. In the incomprehensible conditions, both texts contained a large number of unexplained technical terms, whereas in the comprehensible conditions, technical jargon was translated into words that should be understandable for laypeople (e.g. "articulations" was translated to "joints"). All documents were comparable in length ( $M = 142.67$  words,  $SD = 44.66$ ).

Before reading a document pair, participants were confronted with a framing scenario in which a fictitious friend was described as having a medical problem and, due to their insecurity about the correctness of a particular problem-related claim, asked the participant for advice. The claim in question was the same that was later on stated and supported in Document 1. Participants were then presented with both text documents which they had allegedly found during an Internet search and which were described as being authored by different sources.

## Dependent Measures<sup>1</sup>

**Manipulation Check** In order to verify that comprehensibility had been manipulated as intended, participants rated each document for perceived comprehensibility on a Likert-scale from 1 ("very incomprehensible") to 7 ("very comprehensible"). Before providing their ratings, participants were given a definition of what we meant by comprehensibility. This definition described information as comprehensible when readers perceive the contents as clear and feel able to discriminate essential from less important parts and to evaluate information consistency.

**Claim Agreement** We assessed the extent to which participants were persuaded by measuring their agreement with the Document 1 claim after reading both documents. For this purpose, participants indicated their agreement on a 1 ("I don't agree at all") to 7 ("I totally agree") Likert-scale.

**Confidence in the Agreement Decision** Participants' confidence in their ability to decide about the claim was indicated by their agreement with three statements. Each statement reflects a strategy which individuals might use to come to a claim decision. Participants provided their agreement with these strategies on three separate 1 to 7 Likert-scales (1: "don't agree", 7: "strongly agree"):

<sup>1</sup> In addition to the above variables, further measures were collected. However, due to space constraints we only report the analysis of the presently listed measures.

(A) Trust in own agreement decision based on present knowledge: Following this strategy means participants felt ready to decide based on their knowledge after reading the documents. Preference for this strategy was measured by strength of agreement with the statement: “Based on my present knowledge about the topic, I am confident to decide whether it is correct that [Document 1 claim inserted]”.

(B) Trust in own decision based on further information: This strategy indicates that participants felt principally able to decide, but only after obtaining further topic information. Preference for this strategy was measured through agreement with the statement: “I want to obtain further information about [topic] which I then use to decide myself whether it is correct that [Document 1 claim inserted]”.

(C) Desire to consult an expert: Following this strategy means that participants wished to leave the decision to an expert. Preference for this strategy was measured by agreement with the statement: “I want to obtain information about experts in the field in order to identify a particular competent and credible expert. I would then consult this expert and rely on their judgment as to whether it is correct that [Document 1 claim inserted]”.

**Perceived Epistemic Complexity** Participants’ perception of epistemic topic complexity was assessed with six adjective pairs in a 7-point scale semantic differential format (very uncomplex—very complex, very multifaceted—very single-faceted, very unscientific—very scientific, very easy—very difficult, very uncomplicated—very complicated, very difficult to comprehend—very easy to comprehend). Two additional distracter pairs were presented to decrease transparency of the measurement intent (very unimportant—very important, very boring—very entertaining). Exploratory factor analyses (ML-extraction, oblimin rotation) showed the target items to load on one common factor in both comprehensibility conditions (comprehensible:  $KMO = .88$ ;  $\chi^2(15) = 350.71$ ,  $p < .001$ ; 70.43% explained variance; incomprehensible:  $KMO = .86$ ;  $\chi^2(15) = 230.52$ ,  $p < .001$ ; 58.88% explained variance). To determine a score of perceived topic complexity, the arithmetic mean of the target items was calculated. Internal consistency of the items was satisfactory in both comprehensibility conditions (comprehensible: Cronbach’s  $\alpha = .91$ , incomprehensible: Cronbach’s  $\alpha = .86$ ).

## Procedure

Participants received a paper booklet containing the text materials and scales for collecting the dependent measures. The booklet first presented a scenario describing the fictitious friend’s problem. Participants then read the document pair and provided their measures of claim agreement and confidence in their agreement decision. This was repeated four times, so that each participant read four document pairs in total, two in each condition. Afterwards, readers were asked to provide their ratings of comprehensibility for each document they had read and to evaluate the complexity of each addressed topic. Finally,

participants completed a demographic questionnaire before being debriefed about the fictitious nature of the text contents.

## Results

The means and standard deviations of the collected measures per experimental condition are shown in Table 1.

### Manipulation Check

A mixed ANOVA on comprehensibility ratings with document (Document 1 vs. Document 2) and comprehensibility (comprehensible vs. incomprehensible) as within-participant factors and controversiality (controversial vs. uncontroversial) as between-participant factor verified that texts designed as comprehensible were perceived as more comprehensible than texts designed as incomprehensible,  $F(1,85) = 648.11$ ,  $p < .001$ , part.  $\eta^2 = .88$ . Moreover, Document 2 was overall rated more comprehensible than Document 1  $F(1,85) = 22.54$ ,  $p < .001$ , part.  $\eta^2 = .21$ . The other main and interaction effects did not reach significance, all  $F(1,85) < 2.91$ , *ns*.

### Claim Agreement

Claim agreement scores were analyzed using a mixed ANOVA with the within-participant factor comprehensibility and the between-participant factor controversiality. Results showed that laypeople agreed more strongly with the Document 1 claim when the supporting information was comprehensible than when it was incomprehensible,  $F(1,86) = 9.34$ ,  $p < .05$ , part.  $\eta^2 = .10$ . Moreover, agreement was higher in the uncontroversial than the controversial condition, although this difference was only marginally significant,  $F(1,86) = 3.41$ ,  $p = .07$ , part.  $\eta^2 = .04$ . In line with H1 a significant interaction of comprehensibility and controversiality ( $F(1,86) = 4.89$ ,  $p < .05$ , part.  $\eta^2 = .05$ ) indicated that only in the uncontroversial condition did participants agree more strongly with claims from comprehensible than incomprehensible texts,  $t(43) = 3.52$ ,  $p < .01$ . In contrast, there was no difference in agreement between comprehensible and incomprehensible texts in the controversial condition,  $t(43) = .64$ , *ns*.

### Confidence in the Agreement Decision

To test H2a-c, we conducted separate mixed ANOVAs for each decision strategy using comprehensibility as within- and controversiality as between-participant factor.

**(1) Trust in own agreement decision based on present knowledge** This strategy was more popular in the comprehensible than in the incomprehensible conditions,  $F(1,86) = 51.08$ ,  $p < .001$ , part.  $\eta^2 = .37$ , as well as in the uncontroversial compared to the controversial conditions,  $F(1,86) = 23.74$ ,  $p < .001$ , part.  $\eta^2 = .22$ . Furthermore, and in line with H2a, there was a significant comprehensibility\*controversiality interaction,  $F(1,86) = 6.43$ ,  $p < .05$ , part.  $\eta^2 = .07$ . This was due to the difference

Table 1: Means and standard deviations (in brackets) of the collected measures as a function of comprehensibility and controversiality.

Condition	Comprehen- sibility		Claim- agreement	Decision based on present knowledge	Decision based on further info.	Decision through expert advice	Epistemic complexity
	Doc.1	Doc.2					
Compr./ uncontr.	5.80 (1.13)	5.93 (1.08)	4.53 (1.05)	3.30 (1.66)	5.16 (1.57)	5.16 (1.87)	4.38 (1.03)
Incompr./ uncontr.	2.05 (1.17)	2.38 (1.34)	3.90 (1.04)	2.10 (1.31)	5.25 (1.64)	5.41 (1.65)	5.46 (.86)
Compr./ contr.	5.57 (1.00)	5.97 (1.05)	3.98 (.94)	1.90 (.94)	4.99 (1.70)	5.47 (1.80)	4.22 (.92)
Incompr./ contr.	1.78 (.80)	2.37 (1.30)	3.88 (.621)	1.33 (.61)	4.82 (1.91)	5.73 (1.73)	5.47 (.78)

between both comprehensibility conditions being larger when the documents were uncontroversial than when they were controversial.

### (2) Trust in own decision based on further information

With regards to the popularity of this strategy results revealed no significant main or interaction effects (all  $F(1,86) < 1.26$ , *ns*), hence providing no support for H2b.

**(3) Desire to consult an expert** This strategy was shown to be more popular in the incomprehensible than in the comprehensible conditions,  $F(1,86) = 5.24$ ,  $p < .05$ , part.  $\eta^2 = .06$ . However, contrary to H2c, controversiality had no influence on participants' willingness to ask an expert, all further  $F(1,86) < .97$ , *ns*.

### Perceived Epistemic Complexity

To answer the research question whether the influence of comprehensibility and controversiality on claim agreement and agreement confidence was mediated by perceived epistemic topic complexity, we conducted separate mediator analyses for each combination of independent variable, mediator variable and dependent variable following the approach suggested by Baron and Kenny (1986) and Judd, Kenny, and McClelland (2001). Results showed that of the three preconditions necessary for a variable to act as a mediator (1. the independent variable affects the assumed mediator 2. the independent variable affects the dependent variable, 3. the mediator affects the dependent variable) the first two were fulfilled for most combinations, but the third precondition was fulfilled in no case (all  $F(2,41) < 3.23$ , *ns*). Hence, complexity perceptions do not appear to mediate the observed comprehensibility and controversiality effects.

## Discussion

By presenting medical laypeople with texts varying in comprehensibility and controversiality, the present experiment assessed whether the facilitating influence of high comprehensibility on recipients' reliance on their own decision about scientific claims is mitigated by information

controversiality. Moreover, the study was aimed to gain insight into the possible process through which both text features affect laypeople's decision behavior by examining the role of perceived epistemic topic complexity as a potential mediator.

The results revealed that in line with our expectations and previous research (Eagly, 1974; Scharrer et al., 2012), lay recipients agreed more strongly with claims from comprehensible than incomprehensible texts; however, this difference occurred only when the information was uncontroversial. In case of controversial information, laypeople's claim agreement was not affected by text comprehensibility. It seems that encountering controversial information makes laypeople more cautious to agree with a claim even if the information is easy to comprehend.

Moreover, both comprehensibility and controversiality affected laypeople's decision confidence; however this impact was manifested differently on the three decision strategies. Similar to the state of affairs regarding claim agreement, the strategy to decide based only on one's present knowledge was more popular after reading comprehensible than incomprehensible texts, but this influence of comprehensibility was diminished when information was controversial. In contrast, none of the text features had an effect on the strategy to decide based on further information and only comprehensibility had an impact on the strategy to ask an expert, with high comprehensibility decreasing the desire for expert advice. We assume that if information is incomprehensible, laypeople are generally willing to consult an expert regardless of controversiality. In case of comprehensible controversial texts, laypeople feel possibly more encouraged to determine which of both conflicting position is correct due to their comprehension success, for instance by seeking out further information. This might explain why their willingness to ask an expert in this condition is not higher than in case of comprehensible uncontroversial texts.

It is noteworthy that even when participants received comprehensible and uncontroversial texts, ratings of their willingness to ask an expert did not average below 5 on a scale from 1 to 7 (7 indicating a strong willingness).

However, the observed influence of comprehensibility on desire for expert advice suggests that a too strong simplification of scientific contents may mislead lay recipients to underestimate their dependence on experts.

As to our second goal, to get an insight into the possible process through which comprehensibility and controversiality affect laypeople's reliance on their own decisions, we found that the influence of neither information feature is mediated by perceived topic complexity. It seems that laypeople do not base their judgment of whether or not to rely on their own decisions on reflections about epistemic complexity. Perhaps the experience of fluently comprehending information simply triggers positive affective reactions, which then translate to more favorable evaluations in general (Schwarz, 2004). However, this can so far only be assumed, and the exact mechanisms that underlie the influences of comprehensibility and controversiality remain subject to further empirical clarification.

In sum, the present findings largely confirm our assumption of a combined influence of comprehensibility and controversiality on laypeople's reliance on their own decisions. The results indicate that the facilitating influence of comprehensibility on claim agreement found in previous research is more pronounced if the information is uncontroversial but seems to be reduced or even prevented in case of controversial information. As to laypeople's confidence in their claim decision, the results are less conclusive. While it appears that controversiality has a moderating effect on the influence of comprehensibility regarding laypeople's trust in their own decision based on current knowledge, this influence does not translate to their preference of the decision strategy to consult an expert. Finally, we found that perceived epistemic topic complexity does not appear to act as a mediating factor of either the observed comprehensibility or controversiality influence.

The results have practical implications by informing about how scientific information can be optimally communicated to the lay public. Although simplified science reports have the advantage to provide lay recipients insight into scientific issues, it is possible that based on such easy-to-comprehend information laypeople become overly ready to make own decisions, in spite of their lack of background knowledge and training. The present results suggest that when scientific findings are communicated to laypeople, the inclusion of information about related controversies can serve to weaken the comprehensibility effect. As a result, laypeople are more likely to be prevented from readily relying on their own claim evaluations and might rather turn to a pertinent expert for support.

### Acknowledgments

We are grateful to Jasmin Hettinger, Stephanie Sievers and Nikolai Wystrychowski for their help with data collection. This research was supported by the Deutsche Forschungsgemeinschaft (DFG), grant BR 1126/6-1.

## Abstract

Although many speech perception studies have suggested that long-term memory representations of phonemes induce categorical perception along an acoustic continuum (e.g., voice-onset time; VOT) when identifying speech sounds, other studies have suggested that acoustic information is preserved and that graded responses can be observed in within-category comparisons. Using subjective confidence reports, we present findings that support the use of both acoustic and phonemic cues during speech perception. Replicating earlier findings, we observed evidence for two well-defined phoneme categories along the voice-onset time continuum. Additionally, we also observed overconfidence in responses suggesting that the explicit representation of phonemes differs from the representations used to make identification and discrimination responses. Taken together with results from other studies, our findings support the claim that listeners can access both phonemic and acoustic representations, with explicit knowledge of the former but not the latter.

**Keywords:** speech perception, category boundaries, confidence processing

## Introduction

Listeners presented stimuli from a continuum of sounds varying in an acoustic cue such as voice-onset time respond as though they perceive sharp discontinuities or category boundaries when tested in identification and discrimination tasks. On their own, however, measures of identification (ID) and discrimination (e.g., AX) do not indicate the extent to which participants are aware of these categories or their boundaries. In order to examine subjective awareness of categories and category boundaries, we used post-decisional confidence reports after the ID and discrimination responses to examine how response certainty varies across the continuum.

## Categorical Perception of Speech Sounds

Results from speech perception studies were originally interpreted as indicating speech sounds are perceived as members of discrete phonemic categories (e.g., Liberman, Harris, Hoffman, Griffith, 1957). In such studies an acoustic cue such as VOT is varied to generate a continuum of stimuli (e.g., Pisoni, 1973; for a review, see Raphael, 2005). Participants then identify items using two categories such as /ba/ and /pa/. Importantly, the resulting ID functions show a well-defined category boundary that partitions the continuum into two phonemic categories. Moreover, in the accompanying discrimination task, participants exhibit greater accuracy when discriminating between speech

sounds from two phonemic categories relative to those from the same phonemic category even when the absolute acoustic differences are equivalent. Collectively, these ID and discrimination results constitute the phenomenon of categorical perception.

Categorical perception is a robust phenomenon. However listeners also retain some within-category acoustic information (Pisoni & Tash, 1974) and can show graded responses within a phonemic category (e.g., McMurray, Tanenhaus, Aslin, & Spivey, 2003; Miller, J. L., & Volaitis, 1989). Using an AX task, Pisoni (1973) found that when two speech sounds were presented with a long inter-stimulus interval (ISI), participants perceived could not discriminate between stimuli. When stimuli were presented with shorter ISIs, however, participants' accuracy at making within-category comparisons improved (cf. Werker & Logan, 1985). Pisoni (1973) used these findings to suggest a two-stage model for speech perception with an initial stage that processes acoustic information and a second stage that retrieves categorical cues from long-term memory (see also Pisoni & Tash, 1974). Further support for multiple representations also comes from studies of so-called sine-wave speech wherein a participant will identify the stimuli as either noise or speech depending on their prior expectations (e.g., Remez, Rubin, Pisoni, & Carrell, 1981; Davis & Johnsruide, 2007; for other top-down effects, see also Davis, Johnsruide, Hervais-Adelman, Taylor, & McGettigan, 2005).

One possible account of these findings is that participants only have explicit access to phonemic information and are insensitive to acoustic properties of the stimuli that could be used to parse the continuum in an alternative manner. If an effective measure of explicit knowledge about category structure can be obtained that can be contrasted with performance on perceptual tasks, we should be capable of determining the extent to which listeners are aware of stimulus properties beyond explicit phonemic categories.

## Subjective Awareness and Confidence Reports

Whether participants can maintain a representation and yet have little or no awareness of it is a controversial issue. For instance, in a typical experiment assessing such awareness, participants perform a task and indicate how certain they are in their response on a subjective probability scale (e.g., with 50% representing a guess and 100% representing complete certainty). In these tasks participants'

confidence reports typically deviate from their actual performance, i.e., they are miscalibrated. *Calibration* assesses the difference between the subjective probability of an event (confidence level) and the observed probability of a correct response (proportion correct; for formulae, see Baranski & Petrusic, 1994). In this way, calibration represents the extent to which participants are aware of their primary decision on a trial-to-trial basis. When assessing average confidence and accuracy in a given condition, participants are typically either *overconfident* [confidence > p(cor)] or *underconfident* [confidence < p(cor)]. These systematic deviations have been argued to be evidence for both implicit and explicit representations of knowledge (e.g., Dienes & Berry, 1997). For instance, if overconfidence is observed, this suggests an explicit representation that is less accurate than the implicit representation used to classify stimuli. Confirming this, recent studies do find overconfidence bias in perceptual tasks and no overconfidence bias in conceptual tasks thought to involve information stored in long-term memory (e.g., Kvidera, & Koustaal, 2008). Such effects suggest two representations, with moderate calibration suggesting at least some explicit awareness but with overconfidence suggesting a well-defined explicit representation that does not reflect the actual representation used to discriminate and classify stimuli. If a multiple-representation account of speech perception is correct (e.g., Pisoni, 1973) then a confidence report methodology might be capable of assessing these different representations.

An important concern related to the existence of multiple sources of information is how confidence reports are generated. Traditional approaches to confidence processing have been agnostic about the nature of the representations used to make the primary decision and report confidence. Early models of confidence assumed a decisional-locus (e.g., Ferrel & McGooney, 1980; Gigerenzer, Hoffrage, & Kleinbolting, 1991; Pleskac & Busemeyer, 2010) wherein confidence reports are based solely on information used by the primary decision process thereby requiring no additional processing, a post-decisional locus wherein confidence is computed following the primary decision (e.g., Audley, 1960; Vickers & Packer, 1980), or an alterable locus wherein confidence processing can occur during or after the primary decision depending on speed or accuracy stress (Baranski & Petrusic, 1998). For instance, in a study conducted by Baranski and Petrusic (2001) participants were given blocks of trials wherein they were required to simply make a decision or make a decision followed by a post-decisional confidence report. They found that response latencies for the primary decision were significantly longer when confidence was required relative to a no confidence condition indicating an additional set of operations was required to compute confidence. More recently, Schoenherr, Leth-Steensen, and Petrusic (2010) found that information that is nondiagnostic of the primary decision can create variations in confidence reports independently of accuracy. Applied to phonemic

categorization, if acoustic information is available from a perceptual process and phonemic representations are available from the activation of long-term memory representations, then both sources of information should influence confidence reports. Substantial differences in the patterns observed between accuracy and confidence would suggest the existence of acoustic and phonemic representations.

### Present Study

In order to assess whether participants have explicit knowledge of acoustic information and phonemic category boundaries, the present study compares confidence reports to performance in ID and discrimination (AX) tasks. In the ID task, awareness of acoustic cues would be evidenced if certainty increases as a function of the distance from the category boundary. This would suggest that the ID function is merely an artifact of the requirement that participants use only two labels to categorize stimuli when they have in fact encoded and stored (temporarily) acoustic information. If, on the other hand, there is no systematic deviation of confidence and ID performance, then it seems reasonable to conclude that participants are only using phonemic information to identify stimuli. Alone, however, ID performance might not be capable of differentiating.

In order to determine whether participants have access to both acoustic and phonemic representations, we replicated Pisoni and Tash's (1974) paradigm wherein response times in the AX task were used to suggest different levels of processing. In addition, the present study also used postdecisional confidence reports. Again, deviations between performance and confidence reports would suggest that two representations are used to classify and discriminate speech sounds. If participants only perceive speech sounds as exemplars of discrete phonemic categories, then they should be reasonably well-calibrated on a trial-to-trial basis and exhibit little or no over-/underconfidence bias. If participants exhibit poor calibration and overconfidence in the AX task, then this suggests that despite the availability of acoustic properties within the implicit system the explicit representation is phonemic. More specifically, such a finding suggests that participants have an explicit representation of the phonemic category but also maintain graded acoustic information from stimuli along a continuum. Given the intuitive saliency of the phoneme, we assume that category boundaries are an explicit representation but that some acoustic information must remain available (e.g., Pisoni, 1973).

### Experiment

The goals of this experiment were threefold. First, we sought to validate the use of subjective confidence reports in a speech perception task by comparing a confidence and no confidence condition. Second, using subjective calibration measures, we examined whether participants had explicit awareness of the phonemic category boundary. Third, we examined whether this awareness was task-dependent by using both ID and AX tasks.

## Participants

Listeners were 15 Carleton University students who received course credit for their participation. All participants reported normal hearing and no speech pathologies.

## Materials

Using the paradigm developed by Pisoni and Tash (1974) participants were presented with /b/ and /p/ stimuli that varied along the VOT continuum. Seven speech stimuli corresponding to 0 to 60 ms VOT, originally synthesized by Lisker and Abramson (1967), were obtained from the Haskins Laboratories website (HL, 2011). The sounds were originally recorded on reel-to-reel tape and later converted into AIFF format. Stimuli were pre-processed using a DC offset correction to eliminate high frequency noises present in the AIFF versions and converted into WAV files. These stimuli were used in both the ID and AX tasks.

## Procedure

Trials in the ID task had one or two components depending upon block. In both blocks of trials participants reported whether the stimulus was a /b/ or /p/ using the 'V' or 'N' key, respectively. For one block participants also rated the confidence they had in their ID responses using a 6-point scale, with 50% representing a guess and 100% representing certainty. Participants completed a total of 180 trials in each block of the ID task.

Trials in the AX task also had one or two components depending on block. In both blocks of trials participants decided whether two stimuli separated by a 250 ms ISI were the same or different, using the 'D' and 'K' key, respectively. Replicating Pisoni and Tash (1974), stimulus pairs differed in either 0-, 2-, 4- or 6-steps and were either selected from the same phonemic category or different phonemic categories. Three replications of the eight within-category comparisons and four replications of the six between-category comparisons were presented in a block of 48 trials. For one block of AX trials participants also provided a confidence rating of their AX decision using the same scale described above.

Half of the participants performed the ID task first whereas the other half performed the AX task first. Half of the blocks of trials required participants to provide confidence reports whereas the other half only required participants to complete the ID and AX tasks alone. Presentation of confidence and no confidence blocks was counterbalanced as were the responses keys for the AX task. The experiment required approximately 30 minutes to complete. Stimuli were presented via headphones using PsychoPy software (Peirce, 2007).

## Results

In the following analyses we use two sets of assumptions. Following Pisoni and Tash (1974), we assume that stimuli 1-3 are assigned to the /ba/ category whereas stimuli 4-7 are assigned to the /pa/ category. From this we derive measures of accuracy. In the AX task we additionally assume that accuracy is determined by acoustic properties when making paired comparisons.

Calibration was computed by obtaining the average differences between proportion correct for each confidence category with calibration scores range from 0.0 (perfect calibration) and 1.0 (perfect miscalibration). Notably, calibration scores above 0.10 are rare. Under-/Overconfidence was computed by taking the difference between mean confidence and mean accuracy for each condition, with positive values representing overconfidence and negative values representing underconfidence (for further details see, Baranski & Petrusic, 1994).

For all ID and AX analyses, repeated measures ANOVAs were conducted using dependent variables for the primary decision and confidence reports. Greenhouse Geisser adjusted values are reported with unadjusted degrees of freedom. Bonferroni pairwise comparisons were also performed as a post-hoc test.

## Identification Task

**Proportion Identification.** Figure 1 shows the mean response frequency for each category label in the ID task in the confidence report condition. Participants clearly identified two discrete categories for /ba/ and /pa/, respectively, with a category boundary situated between +20 and +30 ms VOT. This pattern replicates the findings obtained by Pisoni and Tash (1974) as well as other studies (e.g., Experiment 1 in McMurray et al., 2003).

The proportion of correct ID responses was analyzed for each VOT stimulus and whether a confidence report was provided or not. The only significant finding observed was the location of the stimuli along the VOT continuum,  $F(6,84) = 6.394$ ,  $MSE = .019$ ,  $p = .02$ ,  $\eta^2 = .314$ . The absence of a main effect or interaction of confidence reports is important as it suggests that the addition of confidence reports did not significantly affect ID performance thereby permitting a straightforward interpretation of the remaining results.

Figure 1. Mean identification functions, response times for confidence (unfilled circles) and no confidence (filled circles) conditions and mean confidence across VOT continuum. Identification function uses performance in confidence condition to allow comparison with mean confidence.

**Mean Confidence.** Figure 1 also demonstrates the effect of confidence measures. Like ID accuracy, we found that subjective confidence varied along the VOT continuum,  $F(1,14) = 6.55$ ,  $MSE = 44.11$ ,  $p = .008$ ,  $\eta^2 = .319$ . Pairwise comparisons revealed that this effect arose from the difference in confidence between stimuli located at 20 and 30 ms VOT ( $p = .035$ ), which corresponds to the stimuli adjacent to the category boundary.

**Calibration Indices.** An analysis of subjective calibration revealed only a marginally significant difference across the VOT continuum,  $F(6,84) = 3.401$ ,  $MSE = .013$ ,  $p = .085$ ,  $\eta^2 = .195$ . This suggests that the greatest difference between subjective awareness and performance occurs for the 20 ms VOT stimulus. Our comparison of over/underconfidence bias did not reveal any significant effects,  $F(6,84) = 1.948$ ,  $MSE = .035$ ,  $p = .183$ ,  $\eta^2 = .122$ . Together, these findings suggest that participants are only explicitly aware of the phonemic representation.

Table 1. Mean dependent measures for “Same” responses to Within-Category Paired Comparisons

	/ba/		/pa/	
	A-A	A-a	A-A	A-a
Mean RT	756 ms	818 ms	693 ms	737 ms
% Error	4.4	11.1	1.1	1.1
Conf	97.44	98.67	99.67	99.56

**Identification Response Time.** Analysis of our RT data also replicated Pisoni and Tash’s (1974) findings (see Figure 1). Specifically, we observed significant changes in RT across the VOT continuum,  $F(6,84) = 8.323$ ,  $MSE = .030$ ,  $p < .001$ ,  $\eta^2 = .373$ . We found that responses to the stimulus located at 20 ms VOT were longer than those for stimuli at 0, 10, 50, and 60 ms VOT. Moreover, replicating Baranski and Petrusic (2001), we also observed a significant main effect of confidence condition,  $F(6,66) = 4.701$ ,  $MSE = .041$ ,  $p = .021$ ,  $\eta^2 = .572$ . Participants took longer to identify stimuli when confidence reports were required ( $M = 871$  ms) relative to the no confidence condition ( $M = 698$  ms).

#### Discrimination Task

**Proportion “Same” Responses.** AX responses were assessed based on a category criterion such that ‘same’ responses were considered correct for within category comparisons and incorrect for between category comparisons. Table 1 provides a point of comparison with Pisoni and Tash (1974), wherein AA and Aa represent, acoustically and phonemically identical stimuli, respectively. Table 2 provides mean dependent measures for within (AA, Aa) and between (AB through AB”) for 2-step through 6-step, respectively) category comparisons.

Using a category criterion, we observed an interaction between phoneme category (/ba/ v. /pa/) and the comparison type (within v. between),  $F(1,13) = 13.421$ ,  $MSE = .004$ ,  $p = .003$ ,  $\eta^2 = .508$ . Participants were far more accurate in making within-category comparisons from the /pa/ category relative to all others (see Table 2).

Table 2. Mean dependent measures for correct and incorrect responses for within- and between-category comparisons collapsed across confidence condition.

	/ba/		/pa/	
	AA/Aa	All AB	AA/Aa	All AB
Mean RT	753 ms	809 ms	693 ms	734 ms
% Error	7.6	5.6	1.1	7.2
% Conf	96.6	96.4	99.6	97.3

**Mean Confidence.** Our analysis of mean confidence revealed a pattern similar to that of the accuracy analysis. We found an a marginally significant interaction of phoneme category and comparison type,  $F(1,13) = 4.589$ ,  $MSE = 3.8393$ ,  $p = .052$ ,  $\eta^2 = .261$ . The only significant effect was for phonemic category,  $F(1,13) = 5.895$ ,  $MSE = 9.627$ ,  $p = .030$ ,  $\eta^2 = .312$ . Participants expressed more confidence when responding to stimuli from the /pa/ category ( $M = 98.456$ ) relative to those from the /ba/ category ( $M = 96.507$ ). Taken together with the results of the ID task, this suggests that the representation of the /pa/ category is more well-defined than the /ba/ category for these VOT stimuli.

**Calibration Indices.** As with the mean confidence analysis, the interaction of phoneme category and comparison type was only marginally significant when using category coding,  $F(1,13) = 3.613$ ,  $MSE = .0004$ ,  $p = .080$ ,  $\eta^2 = .217$ . However, when responses are scored with acoustic coding we find significant miscalibration,  $F(4,52) = 776.8$ ,  $MSE = .019$ ,  $p < .001$ ,  $\eta^2 = .984$ . Like the ID task, we did not observe any overconfidence bias in the AX task when category coding of accuracy was used, all  $F$ s  $< 2.5$ . Again this suggests that participants access a phonemic representation to make their confidence decision. Confirming this, significant overconfidence was observed when acoustic coding of accuracy was used to compute overconfidence,  $F(4,52) = 1709$ ,  $MSE = .007$ ,  $p < .001$ ,  $\eta^2 = .992$ . Post-hoc paired comparisons on these means (see Table 3) revealed that AA pairs differed from all other pairs ( $p < .001$ ) but no other differences were observed.

Table 3. Mean calibration and overconfidence for comparison type using acoustic coding for response accuracy.

	Comparison Type				
	AA	Aa	AB	AB’	AB”
OU	.013	.976	.950	.962	.994
CAL	.008	.959	.913	.936	.988

**Discrimination Response Time.** Following Pisoni and Tash (1974), response latencies across comparison pairs were also analyzed. Only correct response latencies were analyzed (i.e., “Same” responses for within-category comparisons and “Different” responses for between-category comparisons). Replicating their findings, the type of comparison affected response latencies,  $F(4,52) = 5.976$ ,  $MSE = .088$ ,  $p = .007$ ,  $\eta^2 = .315$ . Importantly, an interaction was also observed between the confidence condition and comparison type,  $F(1,13) = 9.072$ ,  $MSE = .029$ ,  $p = .01$ ,  $\eta^2$

= .315. As Figure 2 indicates, participants were fastest when responding to acoustically similar stimuli and slowest to compare stimuli between categories separated by small steps along the VOT continuum. The additional requirement of confidence increased response latencies for acoustically dissimilar pairs.

Figure 2. Discrimination response time for paired-comparisons within and between phonemic categories for no confidence (bars) and confidence (points) responses. Error bars represent standard error of the mean.

As in the ID task, we also observed a main effect of confidence condition,  $F(1,13) = 4.92$ ,  $MSE = .352$ ,  $p = .045$ ,  $\eta^2 = .275$ . More time was required to discriminate stimuli when confidence was required ( $M = 861$  ms) relative to the no confidence condition ( $M = 696$  ms)<sup>1</sup>.

### Discussion

Results generally replicated those observed by Pisoni and Tash (1974): participants perceived two distinct phonemic categories along the VOT continuum. In addition, we also found that stimuli could be discriminated with greater speed and accuracy when they were selected from two contrasting phoneme categories rather than within a category. However, although our results suggest participants represented stimuli as phonemic categories, the /ba/ category was not as well defined as the /pa/ category. This was evidenced in a shallower portion of slope between stimuli at 10 and 20 ms VOT in the ID function and the reduced accuracy and confidence when comparing acoustically dissimilar stimuli within that category.

Of equal importance, the experiment also replicated findings in the confidence processing literature: participants were faster when they made ID and AX decisions alone compared to when they were additionally required to report confidence post-decisionally (e.g., Baranski & Petrusic, 2001). Such a finding suggests that confidence processing requires a secondary set of operations to generate a confidence report. Importantly, however, the requirement of

a confidence report did not appear to adversely affect ID or AX performance.

Confidence performance complimented ID and AX performance: participants expressed the most uncertainty in the /ba/ category, and more specifically in the stimulus at the category boundary (20 ms VOT). An absence of overconfidence bias and excellent calibration in the category analysis of both ID and AX tasks suggests that participants' explicit knowledge of phoneme categories guides their classification. Supporting this interpretation, when we reanalyze discrimination accuracy in terms of acoustic properties we found that mean indices of overconfidence and miscalibration were at ceiling for all stimuli other than AA pairs, indicating an inability to discriminate acoustically dissimilar pairs within the same phonemic category.

### Conclusions

The present study replicated findings in both the speech perception and confidence processing literatures. Participants' responses indicated categorical perception of acoustically dissimilar stimuli along a voicing continuum and confidence reports required additional time to process. Moreover, confidence reports revealed that participants do not appear to be aware of acoustic information used to activate phoneme representations under the presentation conditions. Although the present study used only one ISI, follow-up studies will vary ISI in an AX task to further differentiate subjective awareness from performance. Moreover, phoneme categories that participants might have less familiarity with (e.g., Pisoni et al., 1982) should demonstrate larger differences in overconfidence and calibration. In short, our findings suggest that confidence reports can be used along with other measures (see also McMurray et al., 2003; Miller & Volaitis, 1989) to assess metalinguistic awareness in the context of speech perception.

Several caveats remain. First, VOT represents one among many physical cues that have been implicated in speech perception. In as much as the processing of speech in a natural environment requires multiple cues, the findings of the present study might be limited to this continuum. One possibility is that with a greater number of cues subjective certainty might increase. This concern about the limits of using synthesized speech has been a recurrent theme in speech perception research (Raphael, 2005). Second, space limits prevent inclusion of an analysis of individual differences, such as working memory capacity and individual ID functions. Finally, studies will need to assess whether these findings generalize to non-speech sounds that share similar properties such as the relative onset of two tones (Pisoni, 1977) or whether overconfidence is limited to only speech sounds. Despite these caveats, the results of the current work suggest that the application of a confidence report methodology holds considerable promise in clarifying the nature of the representations used for speech perception and how these representations are accessed. Calibration can be used to assess whether one or multiple acoustic cues are

<sup>1</sup> An analysis of all (correct and incorrect) responses also revealed the effect of comparison type,  $F(4,52) = 7.729$ ,  $MSE = .037$ ,  $p < .001$ ,  $\eta^2 = .373$ , and the requirement of confidence,  $F(1,13) = 5.07$ ,  $MSE = .247$ ,  $p = .042$ ,  $\eta^2 = .281$ . Post hoc paired comparisons revealed that AA differed from both Aa and AB (all  $ps < .035$ ).

used whereas under-/overconfidence suggests the extent to which phonemic and acoustic information is available to listeners.

## Abstract

Much of what we learn, we learn from others. What guides learners' choice of informants? Research suggests that learners resist informants who provide incorrect information or insufficient information for accurate inference. Here we propose that learners' choices of informants are rationally guided by the extent to which evidence supports accurate inference, rather than the sheer amount of evidence provided. Extending recent research formalizing pedagogical reasoning, we propose a computational model of efficient teaching. We present an experiment on adults testing three different hypotheses about learners' preferred level of the amount of data. The results suggest that learners care about the inductive sufficiency of evidence, rather than the amount of evidence provided. We conclude by discussing the implications of these findings for cognition and cognitive development.

**Keywords:** Trust; Pedagogical reasoning; Bayesian model.

People face a seemingly intractable problem in learning about the world. There is an endless amount of information to learn, but relatively limited time to acquire information. Fortunately, learners are surrounded by other agents who can help them learn. However, although some people may be valuable sources of information, not all are, and learners must decide whom to ask for information. What governs learners' choices of informants?

Most prior research about learners' sensitivity to the reliability of informants has been conducted with children. Koenig and Harris (2005) found that by four years of age, children track whether informants have been correct or incorrect in the past and use this to guide their future choices of informants. Moreover, children are sensitive to parametric variations in informants' accuracy (Pasquini, Corriveau, Koenig, & Harris, 2007). Additionally, children use information about group consensus to select informants (Corriveau, Fusaro, & Harris, 2009). These results suggest that by four years of age, children can use diverse cues to establish the reliability of informants.

However, there is good reason to believe that reliability is not the only factor that influences children's epistemic trust. A recent study by Gweon, Pelton, and Schulz (2011) suggests that children not only expect teachers to provide accurate data, but also expect teachers to provide inductively sufficient data. Children gave lower ratings to a teacher who showed one function of a toy that actually had multiple functions, than to a teacher who gave the same demonstration on a toy that actually had just the one function.

Indeed, one advantage of social learning is that it reduces the amount of data required for accurate inference by allowing the learner to make inductive inferences from small amounts of data. How much evidence is enough?

We hypothesize that people do not simply use the sheer quantity of data to decide how helpful a teacher is, but instead consider the extent to which the data provided supports accurate inductive inferences. If a learner's goal is simply to acquire as much data as possible, people should always prefer a teacher who offers more data. However, if the learner's goal is specifically to acquire as much data as necessary for accurate inference, then two teachers can be considered equally helpful, even if one of them provides much less data overall. Consider the toys in Figure 1a; the toys have a number of knobs, which when pressed may or may not cause exciting effects. As a learner, you may be curious to know how many of the knobs cause an effect. You may also have past experience with toys like this, and this experience might generate expectations about how many knobs are likely to work. For instance, you may know that just a few knobs (e.g., two on average) cause effects and the rest do not (independent of the total number of knobs). If you were to learn about one of the toys, would you choose a demonstrator who exhaustively pressed all of the knobs, or one who pressed a few working knobs and stopped? (See Figure 1b.)

Figure 1: Figure illustrating the toys used in the experiment, and possible demonstrations. (a) Toys could have 6 or 20 knobs, which when pressed may (or may not) lead the toy to create a sound and the button to change color. (b) Two possible sets of demonstrations. In the first case, only three knobs are pressed, all of which elicit effects. In the second case, all of the knobs are pressed, only three of which elicit effects.

Clearly, the exhaustive demonstration would provide the most data; indeed, such a demonstration would be deductively sufficient to infer the number of working knobs. If the only goal is to maximize the overall amount of data, the learner should always prefer more demonstrations to fewer demonstrations.

By contrast, if the learner is sensitive to the cost of providing data and cares most about minimizing this cost, then the learner should penalize teachers who provide data beyond what is necessary to make a reasonable guess. Rather than thinking that a teacher who provides exhaustive evidence is being helpful (e.g., by demonstrating that the remaining knobs are in fact inert and thereby marginally reducing the uncertainty), a learner who has a strong bias against incurring the cost of additional demonstrations should resist demonstrations that are consistent with the learner's beliefs. In this case, learners should prefer informants who provide fewer demonstrations.

However, if as we hypothesize, learners value data that leads to accurate inferences, learners may be satisfied with seeing just a few working knobs (since the learner can infer that informant omitted superfluous demonstrations of the inert knobs), but also may be happy to see additional demonstrations that provide maximal certainty about the toy. Such a flexible trade-off between efficiency and certainty would lead to a preference for inductively sufficient demonstrations.

Building off of recent research formalizing data selection in teaching situations, we introduce a computational model of efficient teaching. The model captures these three hypotheses about learners' choices of informants: that learners strongly prefer informants who offer as much data as possible; that learners are very sensitive to the cost of data and thus prefer teachers who offer as little data as possible, or finally, that learners care that the data supports accurate induction but are happy to acquire additional data as well. In our experiment, we ask adult participants to choose between informants who provide data that is always true but varies in quantity and informativeness. We conclude by contrasting our research with previous findings

and discussing the implications for cognition, cognitive development and education.

### A computational model of efficient teaching

To formalize what constitutes sufficient data, we must consider which data should be chosen and the degree to which the data increase the learners' certainty relative to the added cost of the demonstration. To do so, we adopt a Bayesian learning perspective, building off Shafto and Goodman's (2008) research formalizing teaching and learning in pedagogical settings.

In Bayesian learning, the goal for the learner is to infer the probabilities of different hypotheses,  $h$ , given data,  $d$ . The degree to which the learner believes a hypothesis after observing the data---the learner's posterior beliefs---are denoted  $P(h|d)$ . According to Bayes' theorem, posterior beliefs are determined by the product of the learner's prior beliefs in the hypothesis,  $P(h)$ , and the probability of sampling the data assuming the hypothesis is true,  $P(d|h)$ .

Standard approaches to learning typically assume that data are sampled randomly. However, in pedagogical contexts in which the informant is knowledgeable and the informant's goal is to help the learner infer the true hypothesis, the data are not randomly sampled, but purposefully selected. Shafto and Goodman (2008) formalized teaching and learning in such pedagogical situations. The key differences between pedagogical and random sampling are that the teacher is assumed to be knowledgeable and helpful in her choice of data, and the learner believes that the teacher is knowledgeable and helpful. Teaching is formalized as choosing data that tend to maximize the learner's probability of inferring the correct hypothesis,  $P_T(d|h) \propto P_L(h|d)$ , where the subscripts T and L indicate teacher and learner, respectively. Learners update their beliefs using the knowledge that teachers are choosing data purposefully,

$$P_L(h|d) \propto P_T(d|h)P_L(h). \quad (1)$$

That is, the key difference between Equation 1 and standard approaches to learning is that in Equation 1 the learner

updates her beliefs based on the assumption that the teacher chooses data to help the learner infer the correct hypothesis.

Here we propose that teachers, in addition to choosing data that is helpful, may also consider the *degree* to which additional data increase the learner's certainty. Similarly, learners may vary in how much data they expect the teacher to provide. To capture this difference, we introduce prior probabilities of choosing data. The pedagogical model can be extended to reflect this fact by introducing a term,  $P(d)$ , in the teacher's choice of data,

$$P_T(d|h) \propto P_L(h|d)P(d). \quad (2)$$

Data are assumed to have a cost, and differences in the cost of data capture the three hypotheses of interest.

The probability of data  $P(d)$  depends on two factors: the number of total demonstrations,  $n$ , and the cost of an individual demonstration,  $c$ . Intuitively, an informant may be biased toward presenting more data, less data, or may be unbiased; the learner may accordingly have different expectations of the informant. These three possibilities correspond to three qualitatively different cost parameters in our model. If the learner expects the teacher to demonstrate as much data as possible then providing fewer demonstrations incurs a higher cost. If the learner prefers to minimize the number of demonstrations, then given a choice between more data and less data, less data is more probable; the total cost of a set of demonstrations increases with the number of demonstrations. If the learner is willing to accept any evidence that it is inductively sufficient, then any amount of data is equiprobable; the total costs are constant, independent of the quantity of data. To capture these possibilities, we formalize the prior probability of the data as

$$P(d) \propto e^{-cn}. \quad (3)$$

A negative value of  $c$  corresponds to an expectation of more data; a positive value of  $c$  corresponds to an expectation of less data;  $c=0$  corresponds to equiprobable data.

These hypotheses generate different predictions about learners' choices of informants. In the following experiment, we investigate how learners evaluate informants. Participants are asked to make a choice between two informants, which we model using a log-likelihood ratio. To test the hypotheses, we treat the cost as a free parameter and fit it to the behavioral data. If the best-fitting cost parameter is less than 0, then this would support the hypothesis that learners prefer as much data as possible; if the best-fitting parameter is greater than 0, this would support the hypothesis that learners prefer to minimize data; if the best-fitting parameter is approximately 0, then this supports inductive sufficiency, the hypothesis that learners want enough data to make a confident inference but are happy to accept additional data.

### Experiment: Who is the better teacher?

To investigate learners' choices of informants, we conducted an experiment in which two informants provided demonstrations on different toys (as in Figure 1). The

experiment included two conditions. In one condition, either one, two or three knobs worked on the toys (Consistent condition); in the other condition, between 1/6 and 1/2 of the knobs worked on the toys (Proportional condition). These two conditions allowed us to generate cases in which the model makes different predictions about identical sets of evidence. (See Model predictions below.)

Each demonstration consisted of informants pressing knobs that either elicited effects or were inert. Trials varied in the number of demonstrations, as well as their composition. Additionally, toys varied in the number of total knobs (either 6 or 20). Participants used a sliding scale to indicate which informant was relatively more helpful.

This design allows us to assess the correlation between the model predictions and people's choices. In addition, we can investigate specific cases where the three accounts generate contrasting predictions.

## Method

**Participants.** Forty-four University of Louisville undergraduates (22 per condition) participated in exchange for partial or extra credit.

**Materials.** Participants saw a series of novel toys, described as wugs or daxes on a computer screen. The toys had either 6 or 20 knobs extending from a central sphere (see Figure 1). Clicking on a knob caused a change in its color and size. Only some knobs elicited the effect when clicked; the rest were inert.

**Design.** Participants were randomly assigned to one of two conditions: Consistent or Proportional. In both conditions, participants first interacted with three six-knob-toys and then with three twenty-knob toys to learn how many knobs worked on average. In the Consistent condition, the six-knob toys had one, two or three working knobs, as did the twenty-knob toys. In the Proportional condition, the six-knob toys again had one, two, and three working knobs but the twenty-knob toys had 3, 7, and 10 working knobs.

**Procedure.** Participants were seated at Mac Pro Desktop computers. The experiment proceeded in two phases: training and testing. In the training phase, participants learned how many knobs tended to work by interacting with the toys, as described in the Design section. At the end of the training phase, participants indicated how many knobs worked on average for the six-knob and twenty-knob toys. These questions were checks to ensure that the training phase was successful in inducing appropriate prior beliefs about the toys. Participants were then given feedback about the actual average number of working knobs.

During the testing phase, participants were presented with a series of pairs of unique informants each performing demonstrations on a unique toy. The screen was split in half; in each half of the screen there was an informant with a toy. In the Consistent condition, the pairs were generated by

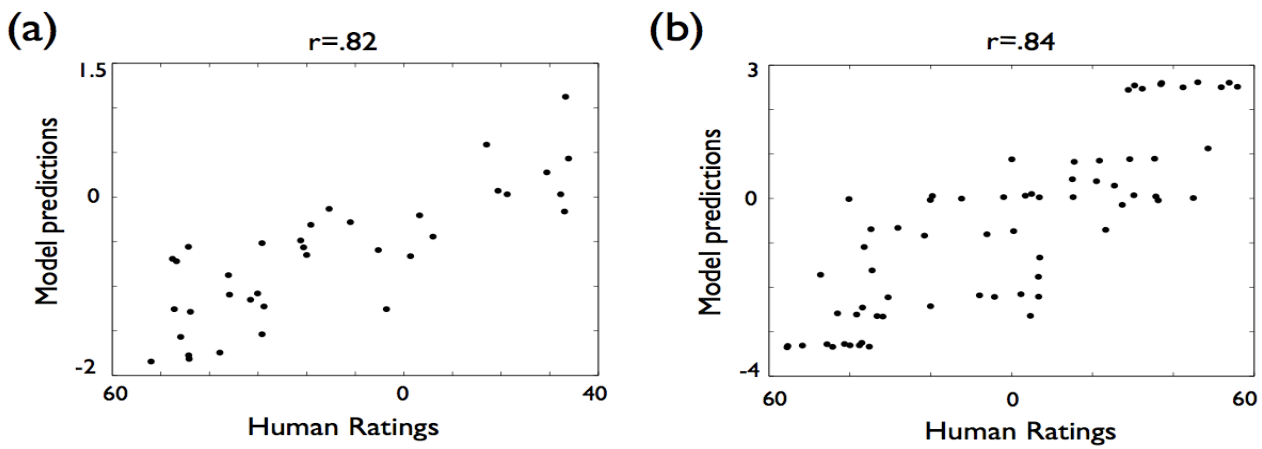

Figure 2: Correlations between human judgments in the (a) Consistent and (b) Proportional conditions. Overall, there is a strong correlation between the model predictions and people's judgments.

comparing all possible pairs of the following demonstrations. For the six-knob-toys, there were four kinds of demonstrations: 3+ 3- (show 3 working knobs and 3 inert knobs), 3+ (show 3 working knobs), 3- (show 3 inert knobs), 2+ 2- (show two working knobs and two inert knobs). For twenty-knob toys, there were five kinds of demonstrations: 3+3-, 3+, 3-, 2+2-, 10-, resulting in 36 questions total. In the Proportional condition, the pairs were generated from the following demonstrations 3+3-, 3+, 3-, 2+2-, 10+, 10-, 7+7- and 10+10- for the twenty-knob toys, resulting in 66 total questions. To ensure that participants remembered the prior knowledge established during training, they were reminded of the average number of working knobs every ten questions.

The start of each demonstration was indicated by the appearance of a hand symbol pointing to a knob, which proceeded around the toy clockwise. The order of positive and negative examples and the locations of working knobs on the toy were determined randomly. After observing the demonstrations by the informant on the left, participants watched the informant on the right. After both sets of demonstrations, participants indicated which informant they judged as 'more helpful' using a slider that appeared in the middle, below the two toys. The order of pairs was randomized, as were the sides on which each informant appeared. After completing all of the questions for their condition, participants were debriefed and thanked.

**Modeling.** The prior knowledge,  $P(h)$ , was set based on the demonstrations that participants observed. For simplicity, trials were assumed to be independent. For each condition, the number of working knobs (out of total number of knobs on the toy) were entered to a Beta-Binomial model with uniform parameters and the resulting distribution was the prior for the experimental judgments. This was performed separately for the six- and twenty-knob toys for each condition.

To find the parameter that best fits people's judgments, we performed a grid search over the values from -2 to 2 in increments of .02.

## Results & Discussion

As an initial test of the model, we assessed the correlation between people's judgments and the model predictions for

the 36 questions in the Consistent condition and the 66 questions in the Proportional condition. To do so, we fit the cost parameter separately to each of the two sets of data. The best-fitting value for the consistent condition was .02 and for the proportional condition was 0. These resulted in robust correlations between the model predictions and human judgments; they were  $r=.82$  and  $r=.84$  for the Consistent and Proportional conditions, respectively.

We can compare our model to a number of alternative proposals in which people's judgments might be explained by attention to more superficial aspects of the stimuli. Specifically, we investigated whether people's judgments were consistent with choosing based on the number of knobs on the toy, the number of positive examples demonstrated, the number of negative examples demonstrated, the number of knobs pressed, the percent of positive examples (out of the total knobs), and the percent of negative examples (out of the total number of knobs).

Our model provided significantly better fits to people's judgments than (a) number of knobs (Consistent:  $r=-.47$ ,  $z=6.77$ ,  $p<.0001$ ; Proportional:  $r=-.47$ ,  $z=9.72$ ,  $p<.0001$ ), (b) the number of knobs pressed (Consistent:  $r=.27$ ,  $z=3.57$ ,  $p<.001$ ; Proportional:  $r=.58$ ,  $z=3.14$ ,  $p<.01$ ), and (c) the number of negative examples demonstrated (Consistent:  $r=-.14$ ,  $z=5.27$ ,  $p<.0001$ ; Proportional:  $r=.01$ ,  $z=6.80$ ,  $p<.0001$ ), (d) the percent of negative examples (Consistent:  $r=.13$ ,  $z=4.17$ ,  $p<.0001$ ; Proportional:  $r=.14$ ,  $z=6.06$ ,  $p<.0001$ ).

However, the correlation between people's judgments and (e) the number of positive examples demonstrated were not significantly different from our model (Consistent:  $r=.66$ ,  $z=1.48$ ,  $p=.14$ ; Proportional:  $r=.75$ ,  $z=1.39$ ,  $p=.16$ ) and (f) the percent of positive examples (Consistent:  $r=.77$ ,  $z=-.55$ ,  $p=.58$ ; Proportional:  $r=.88$ ,  $z=-.87$ ,  $p=.38$ ).

To further investigate the degree to which our model and the remaining alternatives (number of positive examples and percent of positive examples) fit the data, we turn to analyses of individuals' judgments. For our model, we fit the parameter to each individual's judgments as described above. We correlated the predictions of our model, the number of positive examples, and the percent of positive examples with individual participants' judgments. Our model (Consistent:  $M=.52$ ; Proportional:  $M=.57$ ) predicted people's judgments better than the number of positive examples (Consistent:  $M=.29$ ,  $t(42)=2.7$ ,  $p<.01$ ; Proportional:  $M=.38$ ,  $t(42)=2.84$ ,  $p<.01$ , by one-tailed t-test)

and the percent of positive examples (Consistent:  $M=.33$ ,  $t(42)=2.27$ ,  $p<.05$ ; Proportional:  $M=.46$ ,  $t(42)=1.67$ ,  $p=.05$ , by one-tailed t-test). These results suggest that our model provides a better explanation of people's behavior than these alternatives.

Next, we turn to the amount of data learners expect. Recall that expecting the informant to provide as much data as possible is indicated by parameter values much greater than 0, expecting the informant to provide as little data as possible is indicated by parameter values much less than 0, and expecting inductively sufficient data is indicated by parameter values near 0. For the group data, the best fitting parameters were 0 for the Consistent condition, and .02 for the Proportional condition. These parameters are most consistent with the hypothesis that learners expect data that suffices for accurate inference but exact no penalty for additional data.

The three different accounts make opposite qualitative predictions for subsets of the questions. To explore these differences we contrast the three hypotheses using parameter values of 2, -2, and 0 respectively.

The hypothesis that learners expect as much evidence as possible and the hypothesis that learners expect inductively sufficient evidence but are happy with more evidence make opposite predictions for five questions in both the Consistent and Proportional conditions. For example, in the Consistent condition, the preference for maximal evidence predicts that 2+2- should be preferred to 3+ (because there's a total of four demonstrations versus only three); whereas inductive sufficiency predicts the opposite preference.

With so few questions, it is not surprising that, although people's judgments tended toward a preference for inductive sufficiency, there were not statistically significant differences in participants' responses to these questions (Consistent:  $M=11.36$ ,  $t(4)=1.81$ ,  $p=.14$ ; Proportional:  $M=4.66$ ,  $t(4)=-.38$ ,  $p=.72$ ).

To separate the predictions of a preference for maximal data and inductive sufficiency, we identified the ten questions on which the predictions differed the most in each condition. We standardized the predictions of each model and chose the questions that had the largest absolute difference in predictions.

In the Consistent condition, the question with the largest difference compared a six-knob-toy with 3- and a twenty-knob-toy with 3+. Inductive sufficiency predicts a strong preference for the 3+ demonstration on the twenty-knob toy (because the learner is certain that three knobs work on the twenty-knob toy but uncertain whether 1, 2, or 3 knobs work the six-knob-toy) whereas a preference for maximal data predicts a strong preference for the 3- demonstration on the six-knob-toy (because the learner has evidence for half of the knobs on the six-knob-toy but only 3 of 20 for the twenty-knob-toy). That is, the learner might prefer the greater confidence afforded by the demonstration of the working knobs or might prefer a greater relative number of demonstrations (3- out of 6). Over the ten questions, there was a stronger correlation between inductive sufficiency and

people's judgments,  $r=.85$ , than between the preference for maximal evidence and people's judgments,  $r=-.20$ ,  $z=2.73$ ,  $p<.01$ .

In the Proportional condition, the question with the largest difference compared 10+ versus 10- on twenty-knob-toys. Inductive sufficiency predicts a strong preference for 10+, whereas the preference for maximizing demonstrations predicts a slight preference for 10+. Over the 10 questions, there was a stronger correlation between inductive sufficiency and people's judgments,  $r=.90$ , than between maximizing demonstrations and people's judgments,  $r=.29$ ,  $z=2.2$ ,  $p<.05$ .

The hypothesis that learners expect as little evidence as possible and the hypothesis that learners expect inductively sufficient evidence make opposite predictions for 13 questions in the Consistent condition and 18 questions in the Proportional condition. For example, in the Consistent condition, a preference for minimal demonstrations predicts that 2+2- is preferred to 3+3- whereas inductive sufficiency predicts the opposite.

People's responses on these questions were coded as positive if consistent with the predictions of inductive sufficiency and negative if they were consistent with a preference for less data. People's judgments in the Consistent condition were in agreement with the predictions of inductive sufficiency both on average,  $M=32.6$ ,  $t(12)=8.91$ ,  $p<.0001$ , and in every individual case. Similarly, people's judgments in the Proportional condition were overwhelmingly in accord with the predictions of inductive sufficiency,  $M=34.63$ ,  $t(17)=10.27$ ,  $p<.0001$ .

## General Discussion

We have proposed that learners' choice of informants is guided primarily by the degree to which evidence supports accurate inference. We presented a computational model that differentiates among the hypotheses that learners choose informants who provide as much data as possible, informants who minimize the amount of data provided, and informants who provide at least enough data to support accurate induction. The results show that people's behavior is best explained by inductive sufficiency.

Note that providing maximal data can, in simple cases, lead to deductive certainty. For finite, well-defined sets of possibilities (like those tested here), exhaustive demonstrations eliminate uncertainty. However, our results show that even on relatively small, well-defined learning problems, learners do not simply prefer informants who provide maximal amounts of data. In fact, people are just as likely to endorse much smaller sets of data, as long as the data provided suffices for accurate inductive inference. This suggests that learners are sensitive to the trade-off between the benefit of increased certainty from acquiring more data and the cost of acquiring more data; this sensitivity enables learners to decide how much data is 'enough'.

We did not find evidence for a simple preference for less data. A particularly interesting example is that people did not prefer someone who provides three working knobs over

someone who provides exhaustive evidence, despite that the amount of data were twice as much in the latter. This may be due to features of our experimental design. There was relatively little reason to avoid additional demonstrations (among other things, each additional knob only took a second to press). Furthermore, our dependent measure asked learners to rate the helpfulness of the informant and learners have little reason to consider an exhaustive informant unhelpful. Finally, the additional demonstrations genuinely reduced some uncertainty: each toy was unique and the training only provided a few examples to establish the base rate of the effective knobs. Had the learners been more certain about the number of working knobs, they might have shown a stronger bias against exhaustive evidence.

We have presented evidence that learners' choice of informants is not solely guided the sheer amount of information; learners do not merely maximize the amount of data they can observe, nor do they minimize it. Learners use their inductive certainty to decide when enough is enough.

## Abstract

The present study aims to isolate the locus of the frequency effect within the spoken word recognition architecture. By applying the additive factors logic (Sternberg, 1969) to an auditory lexical decision task where both word frequency and stimulus quality were factorially manipulated, the reaction time data can be analyzed to study processing stages along the time course of spoken word recognition, and determine if frequency has an early or late locus. A significant underadditive interaction of frequency and stimulus quality was obtained. Surprisingly, the typically robust frequency effect was not reliable for words of low stimulus quality. This finding suggests that word frequency influences a relatively late stage in the spoken word recognition process. Implications for extant models of spoken word recognition are discussed.

**Keywords:** Spoken word recognition; word frequency effects; stimulus quality effects; additive factors logic; auditory lexical decision.

## Introduction

Determining whether word frequency has an early or late locus has profound theoretical implications for models of spoken word recognition (SWR). While it is well established that frequently occurring words are recognized faster than less frequently occurring words (Goldinger, 1996), what is less obvious is where the *locus* of the frequency effect lies within the word recognition process. Specifically, does frequency influence word recognition at an early stage, as the speech signal begins to unfold, or does frequency influence word recognition at a later stage in the form of a bias? Models of SWR can easily account for the frequency effect, but they do not necessarily agree on the locus of the frequency effect due to varying assumptions and architectures. Hence one way to test the validity of these models is to isolate the locus of the frequency effect.

Several researchers have investigated this issue by employing a variety of experimental techniques and methodologies. Generally, studies which used traditional behavioral experiments (e.g., lexical decision and word identification) have demonstrated that word frequency has a late locus that occurs after lexical processes are complete (Broadbent, 1967; Connine, Mullennix, Shernoff & Yelen, 1990; Luce & Pisoni, 1998). On the other hand, recent studies employing eyetracking technology (e.g., Dahan, Magnuson & Tanenhaus, 2001) and novel behavioral applications of the parallel refractory period paradigm (Cleland, Gaskell, Quinlan & Tamminen, 2006) concluded that word frequency exerts early and facilitatory effects on

word recognition. With overwhelming evidence supporting both sides of the debate, the question as to whether word frequency affects spoken word recognition at an early or late stage continues.

The present study aims to isolate the locus of the frequency effect in spoken word recognition by making use of the additive factors logic to investigate this particular research question. The additive factors logic (Sternberg, 1969) is widely used by cognitive psychologists to interpret RT data in factorial experiments and study the stages of processing in a number of research topics (e.g., Stanovich & Pachella, 1977), as the logic can be easily applied in the study a wide array of research topics, including psycholinguistics (e.g., Yap & Balota, 2007).

## Additive Factors Logic

According to the additive factors logic (Sternberg, 1969), when two factors affect theoretically determined independent stages in the information processing stream, it should result in *additivity* in mean RTs (i.e., two main effects for each factor, but no interaction). This is represented in the top part of Figure 1, where Factor A affects processing at only Stage 1 and Factor B affects processing at only Stage 2. On the other hand, if the two factors affect the same stage in the information processing stream, this results in a statistical interaction (more precisely, an *overadditive* interaction where the effect of one factor is larger on the “slower” level of the second factor). This is depicted in the bottom part of Figure 1, where both Factor A and Factor B affect processing at a common Stage X.

How can the incorporation of an additional variable, stimulus quality within the auditory lexical decision task, allow us to isolate the locus of the word frequency effect? How can the additive factors logic be used to help us make specific hypotheses about the pattern of results for RT data? In contrast to the lack of consensus with regards to the locus of the frequency effect, few would question the notion that stimulus quality has an early locus of influence in the word recognition process. In fact, a major assumption of most SWR models (e.g., TRACE) involves a process which converts physical, acoustic input into phonemic information (McClelland & Elman, 1986). This necessarily implies that degraded input must be normalized at a relatively early point in the word recognition process.

Hence, if we assume that stimulus quality affects an early stage in the word recognition process, then Factor A corresponds to stimulus quality and Factor B corresponds to

frequency, as shown in Figure 2. Hence, additivity (i.e., main effects of frequency and stimulus quality, but no interaction) indicates that stimulus quality and frequency have independent loci of influence, and this further implies that frequency affects a later stage (one that occurs after stimulus quality; as shown in the upper section of Figure 2). An overadditive interaction where the frequency effect is greater for words of low stimulus quality as compared to high stimulus quality would indicate that these two variables influence at least one stage in common, and it follows that frequency has an early locus of influence (as shown in the bottom of Figure 2).

Figure 1. Sternberg's (1969) Additive Factors Logic

In fact, within the area of visual word recognition, some studies have employed the additive factors logic to investigate the joint effects of stimulus quality and frequency in lexical decision (Borowsky & Besner, 1993; Yap & Balota, 2007). Researchers have consistently found that frequency and stimulus quality have *additive* effects in visual lexical decision. This finding is best accommodated within a two-stage model where stimulus quality influences an early stage and frequency influences the second stage (Borowsky & Besner, 1993), which implies that processing at earlier stages is not necessarily frequency-sensitive.

It is also interesting to note that, despite extensive research involving perceptual identification and auditory lexical decision paradigms, researchers almost universally study the effect of stimulus quality on identification accuracy, but not on response latencies. The study of the effects of stimulus quality on spoken word recognition has been largely limited to perceptual and tone identification experiments (Broadbent, 1967; Hawkins & Stevens, 1950; Luce & Pisoni, 1998; Savin, 1963). To our knowledge, stimulus quality has never been directly manipulated as an independent variable in auditory lexical decision, and the joint effects of frequency and stimulus quality have not been previously studied in any auditory word recognition task. Hence, another objective of the present study is to address these gaps in the literature.

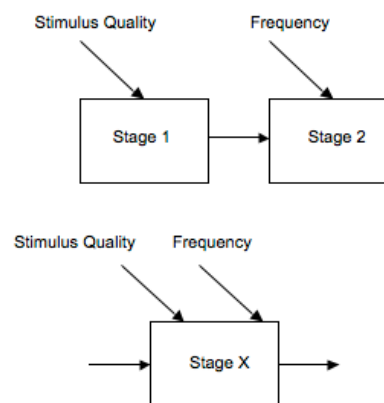

Figure 2. Hypothetical diagrammatic representation of the loci of stimulus quality and frequency effects

## Method

### Participants

Eighty National University of Singapore undergraduates participated in this study for course credit. Participants' first language was English, and they had no previous reported history of speech or hearing disorders.

### Design

A 2 (word frequency: high, low)  $\times$  2 (stimulus quality: clear, degraded) mixed-design was used. The within-participants independent variable was word frequency and the between-participants independent variable was stimulus quality. Stimulus quality was manipulated as a between-participants variable to minimize possible carry-over effects that may occur in a fully within-participants design (Poulton, 1982). The dependent variables were reaction time (RT) and accuracy.

### Stimuli

Table 1 shows a summary of the descriptive statistics for word and nonword stimuli. 58 high frequency and 58 low frequency English words were selected as stimuli. Using LogFreqHal values generated from the English Lexicon Project (ELP; Balota *et al.*, 2007), the difference between the high and low frequency conditions was reliable,  $F(1,114) = 329.72$ ,  $MSe = 273.29$ ,  $p < .001$ . High and low frequency words were also matched on number of phonemes, number of syllables, phonological neighborhood density, familiarity rating, uniqueness point, and word duration. A one-way between-items ANOVA showed that for all lexical characteristics,  $F_s < 1$ .

116 nonwords were constructed and matched with words on number of phonemes, number of syllables, duration and baseword phonological neighborhood density (an estimation of the nonword density based on the neighborhood density of its closest sounding word). The difference between words and nonwords on each of those variables was not significant, all  $F_s < 1$ . All stimuli were spoken by a linguistically trained female speaker and digitally recorded in 16-bit mono, 44.1kHz, .wav format.

Table 1: Descriptive statistics of word and nonword stimuli.

Lexical Characteristics	Word Stimuli				Nonword Stimuli	
	High Frequency		Low Frequency		<i>M</i>	<i>SD</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>		
Number of phonemes	3.95	0.98	4.12	1.04	4.03	1.01
Number of syllables	1.48	0.60	1.43	0.53	1.46	0.57
Phonological neighbourhood density (Baseword phonological density for nonwords)	6.98	6.80	7.31	7.69	7.15	7.23
Duration	582	91	590	81	586	86
Familiarity rating	6.99	0.07	6.98	0.06		
LogFreqHal	11.37	0.75	8.30	1.05		
Uniqueness Point	4.33	0.87	4.26	0.79		

**Degrading auditory stimuli.** White noise was used to degrade the spoken stimuli, in accordance with past perceptual identification experiments (Broadbent, 1967; Savin, 1963). All degraded trials were presented at SNR +10dB, with white noise at 70dB and target stimuli at 80dB.

**Phonemic distributions.** Various studies have shown that white noise has differential masking effects on different phonemes (Horii, House & Hughes, 1970; Pisoni, 1996). Following Chan and Vitevitch (2007), chi-square analyses were conducted on the onset consonants, vowels and fricatives of all word stimuli to ensure that no single phoneme was overrepresented among them. The phonetic transcriptions of each word were obtained from the ELP, and subsequent chi-square analyses were not significant.

## Procedure

Participants were tested on individual PCs in groups no larger than five. Forty subjects were assigned to the clear condition (without noise) and forty participants were assigned to the degraded condition (with noise). Stimuli were binaurally played through BeyerDynamic DT150 headphones, and E-prime 1.2 software and the PST serial response box (Schneider, Eschman & Zuccolotto, 2002) were used for stimuli presentation and data collection. Participants were instructed to listen to the stimuli carefully and decide, as quickly and accurately as possible, whether the token was a word or a nonword, using the right- and left-most buttons respectively on the response box. Prior to the actual experiment, participants were given 20 practice trials which were not included in the subsequent analyses. For degraded trials, white noise was played for 100ms before the stimulus was presented and continued until 100ms after stimulus offset. Once a response was made, 500ms elapsed before the initiation of another trial. Latencies were measured from the onset of the stimulus until button press. There were a total of 232 experimental trials and participants were allowed a short break after every 58 trials.

## Results

For the reaction time data, only correct word trials with RTs more than 200ms and less than 3000ms were included in

the analyses. Trials with RTs less than 200ms were excluded, and trials with RTs more than 3000ms were substituted with 3000ms and included in the analysis. This reduces the amount of data excluded and ensures that extreme scores are preserved while reducing their impact (e.g., Marian, Blumenfeld & Boukrina, 2008). Following which, the overall mean and *SD* of each participant's RT was calculated and trials with latencies that were 3 *SD*s above or below each participant's mean RT were removed. These trimming criteria resulted in the removal of 10.2% of all word trials.

The average RTs and Accuracy across the 4 conditions are summarized in Table 2. A two-way mixed-design ANOVA was conducted on the RT and accuracy data, by participants and items.

Table 2: Mean RTs (ms) and accuracy (proportion)

	RT		Accuracy	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Clear trials				
High frequency	890	64	0.96	0.03
Low frequency	908	65	0.92	0.04
Frequency effect	18		0.04	
Degraded trials				
High frequency	997	130	0.90	0.05
Low frequency	1002	129	0.87	0.07
Frequency effect	5		0.03	
Interaction	13		0.01	
Nonwords	1237	260	0.76	0.15

## Reaction Time

A reliable main effect of stimulus quality,  $F_p(1,78) = 19.56$ ,  $MSe = 400656.27$ ,  $p < .001$ ;  $F_i(1,114) = 263.64$ ,  $MSe = 617419.13$ ,  $p < .001$ , was found for both participant and item analyses. Across high and low frequency words, participants were slower at recognizing words presented with noise ( $M = 999$ ,  $SD = 129$ ) than for words presented in the clear ( $M = 899$ ,  $SD = 64$ ). The main effect of frequency was significant by participants,  $F_p(1,78) = 13.91$ ,  $MSe = 5029.26$ ,  $p < .001$ , but not by items,  $F_i < 1$ . Across both conditions of stimulus quality, response latencies for high frequency words ( $M = 944$ ,  $SD = 115$ ) were significantly

faster than response latencies for low frequency words ( $M = 955$ ,  $SD = 112$ ).

The Frequency  $\times$  Stimulus Quality interaction was significant by participants,  $F_p(1,78) = 4.20$ ,  $MSe = 1517.33$ ,  $p < .05$ , but not by item analyses,  $F_i(1,114) = 2.14$ ,  $MSe = 5019.49$ ,  $ns$ .

Tests of the simple main effect of frequency was significant in the clear condition,  $F(1,78) = 16.69$ ,  $MSe = 6035.73$ ,  $p < .001$ , but not in the degraded condition,  $F(1,78) = 1.41$ ,  $MSe = 510.86$ ,  $ns$ . Participants recognized clear high frequency words ( $M = 890$ ,  $SD = 64$ ) more quickly than clear low frequency words ( $M = 908$ ,  $SD = 65$ ). However, for degraded words, participants did not differ on their response latencies for high ( $M = 997$ ,  $SD = 130$ ) and low frequency words ( $M = 1002$ ,  $SD = 129$ ). There was an 18 ms frequency effect at the clear condition, but this was abolished at the degraded level. Tests of the simple main effect of stimulus quality was significant for both high frequency,  $F(1,78) = 21.57$ ,  $MSe = 225743.00$ ,  $p < .001$ , and low frequency conditions,  $F(1,78) = 16.99$ ,  $MSe = 176430.60$ ,  $p < .001$ . Among high frequency words, participants were slower to recognize degraded words ( $M = 997$ ,  $SD = 130$ ) than clear words ( $M = 890$ ,  $SD = 64$ ). Among low frequency words, participants were also slower to recognize degraded words ( $M = 1002$ ,  $SD = 129$ ) than clear words ( $M = 907$ ,  $SD = 65$ ).

## Accuracy

A reliable main effect of stimulus quality was also found for both participants and items,  $F_p(1,78) = 37.52$ ,  $MSe = .14$ ,  $p < .001$ ;  $F_i(1,114) = 34.68$ ,  $MSe = .20$ ,  $p < .001$ . Participants were more accurate at recognizing high and low frequency words presented in the clear ( $M = 0.94$ ,  $SD = 0.04$ ) than in the degraded condition ( $M = 0.88$ ,  $SD = 0.06$ ). The frequency effect was reliable by participants,  $F_p(1,78) = 30.38$ ,  $MSe = .04$ ,  $p < .001$ , and by items,  $F_i(1,114) = 4.09$ ,  $MSe = .06$ ,  $p < .05$ . Across both levels of stimulus quality, accuracy rates for high frequency words were higher ( $M = 0.93$ ,  $SD = 0.05$ ) than for low frequency words ( $M = 0.90$ ,  $SD = 0.06$ ). No interaction was observed for frequency and stimulus quality in both analyses by participants and by items,  $F_p(1,78) = 2.18$ ,  $MSe = .003$ ,  $ns$ ;  $F_i < 1$ .

## Discussion

In the present study, the joint effects of stimulus quality and word frequency are characterized by an underadditive interaction, as the frequency effect for words of high stimulus quality was reliable but not for words of low stimulus quality. This finding may be considered counterintuitive because additive factors logic does not *a priori* predict underadditivity between two factors. According to additive factors, a statistical interaction is indicative of both variables influencing at least one stage in common in the processing architecture. This interpretation was based on an *overadditive* interaction (Sternberg, 1969),

where the effect of one factor is larger at the “slower” level of the second factor. However, the interaction observed here was an *underadditive* one, where the effect of one factor is smaller, instead of larger, at the “slower” level of the second factor.

Consider Figure 3 below, where stimulus quality influences Stage 1 and frequency influences Stage 2. For clear words, word recognition proceeds from Stage 1 to Stage 2. For degraded words, degradation could have slowed processing to the extent that the optional Stage 2 is not initiated. Note that if we assume Stage 2 to be optional and is presumably not necessary for word recognition, then word recognition can still take place without engaging this frequency-sensitive stage. This is consistent with the hypothesis that stimulus quality and frequency influence *separate* processing stages. According to this interpretation, word frequency has a *late* locus of influence that occurs after that of stimulus quality.

It is interesting to note that the underadditive interaction between frequency and stimulus quality parallels the findings of previous studies which have studied the joint effects of frequency and neighborhood density in auditory lexical decision (Goh, Suarez, Yap, & Tan, 2009; Luce & Pisoni, 1998; Metsala, 1997). These studies found that frequency and neighborhood density interact underadditively, and frequency effects are attenuated for words belonging to dense neighborhoods. This appears to correspond with our present finding that the frequency effect was not reliable for degraded words, as both results indicate that frequency effects are *smaller* when word processing is *slowed* down, either via degradation or neighborhood density effects.

Figure 3. Diagrammatic representation of the underadditive effects of frequency and stimulus in a two-stage model

To some extent, degraded words are analogous to words belonging to dense neighborhoods. Words in dense

neighborhoods have several phonological neighbors, which are defined as words differing from the target word on at least one phoneme in any position (Yates, 2005). The acoustic-phonetic patterns of these words are likely to be more confusable because there are several words sharing similar patterns (Luce & Large, 2001). Hence, words with several neighbors tend to activate many more word units than words with fewer neighbors. This results in more competition among word units which inhibits word recognition performance for high density words (Luce & Pisoni, 1998).

Therefore, it is possible that introducing degradation to word stimuli similarly increases the level of competition among word units. Due to increased acoustic ambiguity, a degraded stimulus can be potentially matched to a large number of words in the lexicon and this leads to a large number of potential word candidates being activated and subsequently competing for recognition. In general, it appears that the ambiguity of the acoustic input (due to either exogenous noise or the perception of the acoustic input as possibly corresponding to several word units) ultimately leads to an increase in competition among activated word units, slowing processing to the point that any biasing effects of word frequency are not observed.

### Implications for Models of SWR

The present study is of theoretical importance because the results can impose additional constraints on speech recognition models. In this section the implications of the underadditive interaction for extant models of SWR are briefly reviewed.

To account for the finding that frequency effects are attenuated in certain tasks (e.g., Connine *et al.* 1990), NAM posits that frequency effects are non-obligatory and that it is possible for word recognition to occur *without* involving the later, frequency-sensitive stage (Luce & Pisoni, 1998). NAM conceptualizes the frequency effect as a decision bias that occurs later in the word recognition process, and it appears that this bias can be “turned off” depending on the task demands and conditions. Therefore, NAM is able to accommodate the present finding because in this model word recognition can still occur with limited or no processing at Stage 2 (see Figure 3), and this explains why a reliable frequency effect was not obtained for degraded words.

Other models of SWR are unable to accommodate the present finding as easily. In the TRACE model of speech perception, (McClelland & Elman, 1986), since frequency and stimulus quality both influence an architecture that allows bidirectional flow of information between processing levels, it should predict an overadditive interaction as this is analogous to two variables influencing a common stage (the influences of word frequency or stimulus quality are not independent of each other). In order to accommodate the underadditive interaction, we speculate that the model needs to allow for a flexible word processing

system that can reduce the influence of frequency when the acoustic input is compromised such that bottom-up flow of perceptual evidence is considerably slowed down.

The results are also inconsistent with the predictions of another major model of SWR - Shortlist B. According to this model, optimal listeners rely more on prior probabilities to compute conditional probabilities (using Bayes Theorem) when ambiguity of the speech input is high (Norris & McQueen, 2008). Since prior probabilities of words are approximated to word frequency and adding white noise to spoken stimuli increases the perceptual uncertainty of the speech input, the model predicts that the frequency effect should be larger for degraded words compared to clear words (Norris & McQueen, 2008). However, in this study, the frequency effect was abolished for degraded words, which seems to imply that listeners actually rely *less* on prior probabilities under increased perceptual uncertainty.

In summary, to account for the non-reliable frequency effect in the degraded condition, we proposed that this was due to degradation inducing a high level of competition among word candidates, such that the frequency-sensitive stage is not invoked over the course of spoken word recognition. Therefore, the finding of an underadditive, rather than overadditive, interaction between stimulus quality and frequency can be accommodated by a two-stage model where the second, frequency-sensitive stage is not mandatory for word recognition. This further suggests that these variables influence *separate* stages in the word recognition process, and by extension, that word frequency has a late locus of influence occurring after that of stimulus quality.

### Notes

As suggested by a reviewer, we conducted mix-effects modelling on our data using R (R Development Core Team, 2011). A linear mixed effects model was fitted to the RT data from the experiment, using the lme4 package (Bates *et al.*, 2012); *p*-values for fixed effects were computed using the languageR package (Baayen, 2012). The main effects of stimulus quality and frequency, and the interaction between the two factors were treated as fixed effects, while participants and items were treated as random variables. Our results revealed a significant main effect of stimulus quality ( $p < .001$ ) and no effect of frequency. These were qualified by a marginally significant stimulus quality by frequency interaction,  $p = .070$ .

# Zero anaphora and object reference in Japanese child-directed speech

## Abstract

To learn the meanings of words, children must connect referents in the world around them with the sounds they hear. One proposed mechanism for this process is cross-situational word learning: tracking associations between words and objects across time. We consider the problem of anaphora for a cross-situational word learner: after an object has been introduced it is unlikely to be named in every succeeding reference to it. This problem is particularly pronounced in Japanese, which uses “zero anaphora,” where pronouns can be omitted from utterances. We analyze a corpus of Japanese mothers talking to children about sets of objects, originally recorded by Fernald and Morikawa (1993). Overall rates of anaphora were much higher for Japanese mothers compared with English mothers. Zero anaphora was primarily used when the discourse topic was already established, suggesting that a discourse-finding strategy may be important for word learning in Japanese. In addition, unexpectedly, due to the existence of zero anaphora as a common referential strategy, pronouns were more likely to be used when the topic was new than when it was given (reversing common results for English).

**Keywords:** Child-directed speech; Japanese; zero anaphora; discourse analysis; language acquisition.

## Introduction

From the perspective of a scientist, early word learning seems a difficult problem. Although infants quickly learn to pair sound sequences in their caregivers’ speech with concepts and entities in their environment, it is still uncertain how they associate words and concepts. One proposed mechanism for this process is cross-situational word learning: tracking associations between words and objects across time (Siskind, 1996; Yu & Smith, 2007). Though possible for even very young children in simple contexts (Smith & Yu, 2008) and in principle feasible for large lexicons (Blythe, Smith, & Smith, 2010), the effectiveness of pure cross-situational learning in natural contexts is still unknown.

One issue for cross-situational learning in the natural learning environment is *anaphora*: the use of shortened—or even absent—expressions that refer back to a previously-named entity. If learners are keeping track of associations between words and objects, the tendency towards anaphoric reference should cut down considerably on these associations. Although anaphora is pervasive in language use, object names are typically repeated frequently in the speech of English-speaking mothers to their children (Fernald & Morikawa, 1993). This repetition has allowed models of cross-situational word learning to succeed in establishing word-object mappings even in small natural datasets (Yu & Ballard, 2007; Frank, Goodman, & Tenenbaum, 2009).

Repetition of object labels is not nearly as prevalent in some other languages, however. In the same study that established the presence of repetition in English mothers’ speech,

Fernald and Morikawa (1993) noted that Japanese mothers used far fewer noun labels and the labels they used were generally more diverse, including onomatopoeia and diminutive forms as well as the prototypical labels used by American mothers. In addition, Japanese, unlike English, is a pro-drop language, meaning that the subject and object of verbs may be omitted. This omission is known as “zero anaphora.” For example, when an English speaker might say “the dog barks,” a Japanese speaker might say only “barks.” One study suggests that zero anaphora in Japanese may lead to increased difficulty in early verb learning (Rispoli, 1995), but to our knowledge, no work has examined the direct relationship between zero anaphora and object reference, in Japanese or any other language.

What effect does the varied use of noun-labels and anaphora (especially zero anaphora) have for Japanese word learners? Under a pure cross-situational analysis, the sparse mappings between words and objects in this language might be very difficult to overcome. If objects that are being talked about often go unnamed in Japanese, a pure cross-situational learner might be more likely to learn, for example, “bark” rather than “dog” for the concept of a dog. If, however, word learners do not treat utterances as independent entities, but instead resolve reference within a *topical discourse*—a set of utterances about a particular topic—the problems posed by changing object labels and zero anaphora might be mitigated. A learner could figure out what topic was being talked about and then assume that future utterances refer to this topic, even if it was not named.

Recent work has taken up the suggestion that children could potentially aggregate information about word meanings—as well as other knowledge about a particular object referent—not just across sentences but also across these topical discourse units (Rohde & Frank, under review; Frank, Tenenbaum, & Fernald, in press). On this kind of view, a first utterance establishes the topic (in the cases we examine, often a simple object referent), and then future utterances contribute new information (Clark, 1996). For such a learner, zero anaphora might not be as problematic if the discourse topic were already known.

The current study examined zero anaphora in Japanese from this perspective. We conducted a reanalysis and annotation of Japanese infant- and child-directed speech from the Fernald and Morikawa (1993) study, focusing on anaphora. We asked when zero anaphora was used within topical discourses, in comparison with object naming and the use of other pronouns. We found that although overall rates of anaphora were much higher for Japanese mothers compared

with English mothers, zero anaphora was primarily used when the discourse topic is already established. Also, we found a trade-off between zero anaphora and pronominal anaphora that caused pronouns to be more likely when the discourse topic was newly established. This sensitivity of zero and pronominal anaphora to the discourse topic suggests that a discourse-finding strategy may be even more important for Japanese-learning children than it is for English learners.

## Methods

### Corpus Materials

Our data consisted of a set of transcribed videos of object-centered play between mothers and children in their homes, from a study by Fernald and Morikawa (1993). While the original corpus contained both American and Japanese mother-child pairs, the current analysis focuses primarily on the Japanese mothers (American data was analyzed in Frank et al., in press). Discourse from 29 Japanese mother-child pairs with audio and video data was analyzed. The infants were divided into three age groups: 5-6 months (N=9, 5 males), 11-14 months (N=10, 5 males), and 18-21 months (N=10, 5 males).

Prior to recording, mother and child played comfortably together with the child's toys. Next, the child's own toys were removed and the video recording began. During the video the mothers were asked to play with the child using three standardized pairs of toys: dog and pig, car and truck, and brush and box. The mother was asked to play with the toys "as she normally would." The toys were introduced one pair at a time and removed before introduction of the following pair. The ordering of whether the dog and pig were introduced first or the car and truck were introduced first was counterbalanced across trials, but the brush and box were always introduced last (and only for the older two groups).

Towards the end of the play session, mothers of children from the two older age groups were asked to hide the toys and get the child to retrieve them using words alone. Because this scenario might affect how the mother referred to the objects (indeed it was inserted in order to elicit object names), we only considered utterances prior to this "hiding game." We also excluded utterances with sound and audio issues (167), and those spoken by the mother to the experimenter. In total, 8852 utterances taken from 6 hours and 51 minutes of video were analyzed in the current study.

### Conventions for Annotating Object Reference

A native Japanese speaker first divided the mothers' speech into "utterances," or segments of speech separated by pauses, on the basis of prosodic and syntactic cues. Most utterances ranged from a single word to a complete sentence; complete sentences were usually not counted as multiple utterances unless there was a pause or interruption of the speaker's turn.

Next, using the video and transcript data, a native Japanese speaker annotated, for each utterance spoken by the mother

Table 1: Descriptive statistics for each file in the FM Corpus. Utts = utterances, Length = length in minutes and seconds.

to the infant, what object or objects (if any) were being referred to. An object was considered to be referred to if A) the mother said the name of the object or B) the mother used a pronoun that the annotator judged to refer to the object. Although other toys and objects were occasionally referred to in the corpus, in the following analysis we will only examine references made to the six toys that were standardized across participating dyads (dog, pig, car, truck, brush, and box).

In Japanese, baby words for toys are often derived from onomatopoeia. We counted misnomers and onomatopoeia as references to the toy under clearly referential circumstances. For misnomers, this was when e.g. "moomoo" ("moo-moo," meaning "cow") was used in reference to the pig. We also counted alternative labels, such as "omocha" ("toy") and "nuigurumi" ("stuffed animal"), as references. However, we did not count misnomers and alternative labels as cases of "object naming," which we defined in a more restricted sense, described below. We counted onomatopoeia-derived noun phrases as references to objects, but not onomatopoeia that was used to describe sounds or actions. Our annotator made judgments about when the mother was using phrases such as "wanwan" as a noun and when she was using them to indicate sounds or actions that the toy was making. Thus, "wan-chan" ("Mr. woof") and, in some cases, "wanwan" ("woof-woof"), were coded as referring to nouns.

In Japanese, objects are frequently referred to without use of an explicit noun or pronoun. As noted above, grammat-

Figure 1: Proportion of total references that used pronominal or zero anaphora for American (Am) and Japanese (Jp) dyads. Error bars show standard error of the mean across dyads.

ical subjects and objects are frequently omitted in Japanese, where in English they would be marked using a pronoun. We included implicit subjects and objects as intended referents, but gave them a special marking. Whenever the subject or object of a verb or the noun modified by an adjectival phrase was omitted, we counted it as a case of implicit reference to the omitted noun, or “zero anaphora.” We did not count objects as being referred to if they were a missing instrument of action, the possessor of an object that was explicitly mentioned, or if they had a spatial or some other relationship to the objects that were mentioned. While each of these might sometimes qualify as zero anaphora, our annotation scheme treated them conservatively (hence, zero anaphora counts would if anything be higher under a revised scheme).

We further categorized non-zero references to objects into two types: those that used a referential pronoun and those that named the object. We counted a reference as “naming” the object when: 1. the utterance was marked as referring to the object by our annotator and not marked as being a case of zero anaphora, 2. the utterance contained one of a list of character strings found in words for the referred object (including common misspellings), and 3. the English gloss (created by a second native speaker for the original Fernald & Morikawa, 1993 study) contained one of a list of possible glosses for words for the referred object. We counted a pronoun as being used referentially when: 1. the utterance was marked as referring to the object by our annotator and not marked as being a case of zero anaphora, 2. the utterance contained one of a list of pronouns, and 3. the reference had not already been marked as object naming.

## Results

Mothers talked about each toy in alternating bouts of utterances. They frequently used onomatopoeia, and engaged in “social routines” (Fernald & Morikawa, 1993), such as re-

questing objects from the child and saying thank you. A plot of references to the six toys over a single video is presented in Figure 2, as a representative discourse structure.

We report three main sets of analyses. First, simple univariate counts of pronominal and zero anaphora. Second, analyses of transitions between different kinds of reference. Third, changes in use of zero anaphora across the corpus.

## Anaphora Use Across Languages

Our first analysis counted pronominal and zero anaphora proportions in the corpus at each age. We normalized these counts by the total number of object references that were identified (including all anaphoric references)<sup>1</sup>. These data are shown in Figure 1, along with English data on pronoun use in object references from Rohde and Frank (under review).

Several trends are apparent in these data. First, pronoun use is approximately equivalent between English and Japanese speakers. Speakers of both languages use pronouns approximately one-third of the time. Second, Japanese use of zero anaphora constitutes an additional third of *all* object references. Unlike the English-speaking mothers, Japanese-speaking mothers were using anaphora more often than not to refer to the toys that they were playing with. Finally, pronoun use declined with the age of the children in our sample. This trend was somewhat modest compared with the large cross-linguistic differences, but was nevertheless significant in a simple linear regression predicting pronoun use by age in months ( $\beta = -.005$ ,  $p < .001$ ). However, this age difference likely reflects the fact that videos were shorter for the 6 month old group than the other two groups. As will be discussed below, pronoun use declined substantially over the discourse for all three age groups, and so proportion of pronoun use in the 6 month old group might have been inflated by the shorter video—and hence shorter discourse—length.

## Discourse Continuity in Japanese

We next examined how likely each mother was to refer to the same object in two consecutive utterances. This analysis was used by Frank et al. (in press) as a first-pass indicator that discourse references to objects were relatively continuous. A high probability of repeated reference to an object suggests that a learner who “smoothed” their guesses about reference across time would be relatively successful. If they didn’t know what a particular utterance was referring to, they could just guess that the referent was the same as in the previous utterances in the discourse.

**Continuity of Reference** We calculated transition probabilities between referential and non-referential utterances of

<sup>1</sup>In the Japanese data, 281 out of 3642 references (7.7%) were marked as “ambiguous” as to whether the toy was referred to or not. Only non-ambiguous cases were used in the first analysis.

Figure 2: References to the six main toys in a sample video. Toys are plotted on the Y axis and blue lines signal that the toy was referred to in a particular utterance. name = object naming, zero = zero anaphora.

Table 2: Transition probabilities between referential and non-referential utterances of various types.  $P(Y|X)$  refers to the probability that in the current utterance an object is referred to using Y given that in the previous utterance it was referred to using X. zero = zero anaphora, name = object naming, nonref = nonreferential utterance.

X	P(name X)	P(zero X)	P(pronoun X)	P(other X)	P(nonref X)
name	.25	.12	.06	.02	.55
zero	.04	.28	.05	.01	.62
pronoun	.10	.15	.19	.03	.53
other	.05	.06	.11	.08	.70

various types.<sup>2</sup> As in our previous work, transition probabilities were first calculated for each of the six toys, then averaged together, weighted by the number of times each toy was referred to in the video (or referred to using a particular reference type, as appropriate).

Mothers varied considerably in how likely they were to refer to an object in two consecutive utterances. The probability of referring to an object in the next utterance given it was referred to in the current utterance ranged between .20 and .57 for each mother (mean = .43). Probability of repeated reference remained relatively stable when calculated for the utterances in each age group, although it tended to rise with the age of the child, from .39 at 6 mos, to .44 at 12 mos, and .47 at 18 mos. Overall these levels were somewhat lower than those for English-speaking dyads.

When we removed utterances that consisted of backchanneling—checking for a response from the child—such as “nn,” “n?,” “a,” and “hai hai hai” (“yes, yes, yes”), this slightly increased the probability of consecutive reference (mean = .49), and decreased variance between mothers. This analysis suggests that the higher tendency of Japanese mothers to use backchanneling, combined with the lower overall frequency of object reference, may account for the difference between Japanese and English-speaking dyads.

**Transitions Between Reference Types** We next examined transitions between referential and non-referential utterances of various types, including zero anaphora, pronouns, and object naming. The goal of this analysis was to understand the directionality of zero anaphora use in discourse. If zero

anaphora is used more after naming, then transition probabilities should be asymmetric:  $p(\text{zero}|\text{name})$  should be higher than  $p(\text{name}|\text{zero})$ .

Results are summarized in Table 2. The largest trend was for referential utterances to be followed by non-referential utterances, indicating (as above) that Japanese discourses contained more non-referential speech overall than in English. Nevertheless, there were still distinct trends in which referential strategies were used earlier in discourses. Zero anaphora after object naming was three times as likely as object naming after zero anaphora. Zero anaphora after pronominal anaphora was three times as likely as pronominal anaphora after zero anaphora. Surprisingly, pronouns were more likely to be used before object naming than after it, unlike in English (Ariel, 1990; Gundel, Hedberg, & Zacharski, 1993).

## Changes in Anaphora Use Across the Discourse

**Zero Anaphora Over Time** In our third analysis, we examined how often mothers used zero anaphora at different points in the discourse. For each utterance that referred to one of the six main toys, we calculated the number of times the object had been mentioned prior to that utterance. We call this the “number of previous references” (NPR) for the utterance. If an utterance refers to the dog for the fifth time in a video, that utterance has an NPR of 4. Next, we collapsed all references with a particular NPR across mothers and toy referents, and calculated the proportion of the time the references used zero anaphora.

The proportion of time that mothers referred to an object using zero anaphora increased with the log of the NPR at all ages (Figure 3). We created a mixed effects model of zero anaphora usage, with age group and NPR as fixed effects and mother as a random effect with random intercept and slope with respect to NPR. Because of the very large number of observations, we used the  $z$  approximation to esti-

<sup>2</sup>We calculated transition probabilities between utterances both counting and discounting cases where the referent was ambiguous. However, none of the transition probabilities besides those for the “other” category changed by more than .02 when the ambiguous cases were counted as non-reference, and so we count them as non-reference in the current analysis.

Figure 3: Proportion of total references that use zero anaphora as a function of the number of previous references to the object (NPR), plotted separately by age group. NPR depicted on a logarithmic scale, NPRs with fewer than 10 data points were dropped. A loess curve was fitted to each plot.

mate significance for individual coefficients. We found that zero anaphora use increased significantly with NPR ( $\beta = .049, p < .001$ ), while age group had no effect ( $\beta = -.001, ns$ ). We modified the model to include the interaction term of age group and NPR as a fixed effect, and found that the resulting coefficient was nonsignificant ( $\beta = -.002, ns$ ).

We also examined whether mothers were more likely to use zero anaphora when referring to some toys than others. We created a mixed effects model with age group, NPR and toy as fixed effects and mother as a random effect with random slope and intercept with respect to NPR. There was no significant effect of any of the toys with the exception of the box, which had significantly higher zero anaphora use compared to all other toys ( $\beta$  values ranged between  $-.79$  and  $-1.08, p < .001$  for each of the other toy coefficients when box was used as the referent). This is likely due to the fact that mothers would repeatedly ask their children to “open” and “close” the box without specifying a direct object. We find this an intriguing hint that some objects may be referred to via associated verbs, especially when they provide salient action affordances.

**Zero Anaphora vs. Other Reference** Our final analyses examined the proportion of zero anaphora use as compared to the proportion of pronominal anaphora and object naming (Figure 4). As the log of the number of previous references increases, zero anaphora use increases substantially

and pronominal anaphora decreases substantially. However, object naming only decreased slightly at higher NPRs. For the first 20 times the mother referred to an object, the proportion of the time that she named the object stayed relatively flat. In other words, zero anaphora increases over time at the expense of pronominal anaphora, rather than object naming.

We also extracted discourses of consecutive references to the same object, and examined zero anaphora, pronominal anaphora and object naming at each “utterance position” in the discourse. The first utterance of a discourse has an utterance position of 1, the second has an utterance position of 2, etc. We examined a total of 791 discourses of three or more consecutive references to an object. Once again, the proportion of zero anaphora use increased with the log of the utterance position, and the proportion of pronominal anaphora decreased. For the first six utterance positions, the sum of the proportion of zero anaphora use and pronominal anaphora use was flat. (Over 90% percent of the discourses we examined were six or fewer utterances long). This analysis again indicates that the proportion of zero anaphora rises at the expense of pronominal anaphora before having any effect on the proportion of references that name the object.

## General Discussion

We examined patterns of anaphora use in child-directed speech by Japanese mothers of infants aged 6, 12 and 18 months. We found that Japanese mothers used far more total anaphora than English-speaking mothers, although pronominal reference was about equally likely in Japanese and English. We examined the transition probabilities between zero anaphora, referential pronouns, and object naming, finding that pronouns are more likely to occur earlier in the discourse, while zero anaphora is more likely to follow both pronouns and object naming. Finally, we assessed how object naming and anaphora use evolve over the discourse, using two measures: the number of previous references to an object and the utterance position in discourses of consecutive reference. Zero anaphora use rapidly accelerated over the discourse at the expense of pronouns, while object naming persisted at a steady rate that only gradually declined later on.

These findings give insight into how object reference varies between languages like English, which have a two-tiered system of nominal and pronominal reference, and those like Japanese that have a third possibility: zero anaphora. In English, both pronoun use and elision are more likely when the referent is given information (MacWhinney & Bates, 1978). From this one might expect that both pronominal and zero anaphora use would increase with the givenness of the referent in Japanese.

However, the distribution of pronoun types differs drastically between these languages: both personal and demonstrative pronouns are frequent in English, while in Japanese, most pronouns are demonstrative, and zero anaphora is used in place of personal pronouns most of the time. According to Gundel’s hierarchy of givenness (Gundel et al., 1993), per-

Figure 4: Proportion of total references that involve object naming, zero anaphora, or referential pronouns, as a function of the number of previous references to the object (NPR) and utterance position. NPR and utterance position depicted on a logarithmic scale, NPRs and utterance positions with fewer than 10 data points were dropped. Utterance position calculated using all discourses of three or more consecutive references to an object.

sonal pronouns and zero anaphora are used only when the referent is in focus, but demonstratives can also be used when it is out of focus but in working memory. By Grice's maxims, this leads to demonstrative pronouns being used more frequently when there is a topic shift, or when the referent has been introduced non-linguistically (Gundel et al., 1993; Gundel, Hedberg, & Zacharski, 2004). In our data, Japanese pronouns were more likely to be used in reference to an object the first time it was referred to than at any other point in the discourse. This suggests that in Japanese child directed speech pronoun use may signal topic change (e.g. "look at this!"), rather than topic continuity.

As suggested originally by Fernald and Morikawa (1993), pure word-object mapping in Japanese might be a very hard problem: Only about a third of references name the object, while the other two-thirds make use of pronouns and zero anaphora. Moreover, references to objects in Japanese (as in English) are not evenly distributed in discourse. But if children have some sense of what the current topic of discourse is—what is given, and what is new—this problem might be somewhat alleviated. A Japanese-learning infant could infer the topic of conversation and then assume that future comments, whether using names or anaphora, referred to that topic. Thus, this study underscores the importance of topical discourse in early word learning, suggesting that tracking the topic of conversation across utterances may be even more crucial to word learning success in pro-drop languages.

## Abstract

Recent work suggests that people predict how objects interact in a manner consistent with Newtonian physics, but with additional uncertainty. However, the sources of uncertainty have not been examined. Here we measure perceptual noise in initial conditions and stochasticity in the physical model used to make predictions. Participants predicted the trajectory of a moving object through occluded motion and bounces, and we compared their behavior to an ideal observer model. We found that human judgments cannot be captured by simple heuristics, and must incorporate noisy dynamics. Moreover, these judgments are biased in a way consistent with a prior expectation on object destinations, suggesting that people use simple expectations about outcomes to compensate for uncertainty about their physical models.

**Keywords:** intuitive physics, stochastic simulation, uncertainty, probabilistic inference

## Introduction

Predicting how the world will unfold is key to our survival and ability to function on a daily basis. When we throw a ball, cross a busy street, or catch a pen about to fall off of a desk, we must foresee the future physical state of the world to plan our actions. The cognitive mechanisms that help us make these predictions have been termed ‘intuitive physics’ models.

Although human performance in physical prediction tasks tends to approximate real-world (Newtonian) physics, it does not match exactly: people make systematic prediction errors. While this has been taken as evidence that human models of intuitive physics are non-Newtonian (e.g., McCloskey, 1983), more recently human behavior has been explained by intuitive Newtonian physics models under uncertainty. On this account, human predictions deviate from Newtonian mechanics because of stochastic error – uncertainty about the initial positions or velocity of objects propagates through the non-linear physical model and causes variability and bias in final judgments. For instance, human predictions about the stability of a tower of blocks or the most likely direction for that tower to fall are consistent with a purely Newtonian model of physics with a small amount of uncertainty in the initial positions of the constituent blocks (Hamrick, Battaglia, & Tenenbaum, 2011). Similar models of physics with perceptual noise have been used to explain relative mass judgments in collisions (Sanborn, Mansinghka, & Griffiths, 2009) and infants’ expectations for object movement (Téglás et al., 2011).

There are numerous ways in which uncertainty can be introduced into intuitive physical reasoning. We broadly classify these into two categories: perceptual uncertainty and uncertainty about dynamics. Perceptual uncertainty

arises because initial measurements of the location and velocity of objects is imperfect; this initial noise propagates through the model. Uncertainty about dynamics reflects noise in the physical model itself. Real object movement and collisions are perfectly deterministic only in an idealized system; in the world, objects can deviate from their ideal path because of multiple, unknowable interactions with the environment (e.g., a ball rolling across gravel will not move in a straight line). Stochastic dynamics could thus reflect such environmental uncertainty.

Our goal is to disentangle the influence of initial noisy percepts and noisy physics on human predictions of object dynamics. We compared human behavior in a simple physical prediction task to a stochastic physics model with parameters reflecting the different types of uncertainty.

## Stochastic Physics Model

We designed a model to replicate stochastic physics in a simple environment: a ball bouncing around a two-dimensional box. We based this model on idealized mechanics, but also incorporated the two sources of uncertainty: we added noise to the initial position and velocity to capture perceptual uncertainty, while dynamic uncertainty was captured by jitter in object movement over time, and variability in bounce angles.

## Uncertainty Parameters

The model was based on a simple two-dimensional physics engine customized to add our sources of uncertainty. As physical uncertainty goes to zero, this model reduces to laws from idealized mechanics: the ball would continue to move in a straight line at a constant velocity until it hit a wall, at which point it would bounce elastically and with angle of incidence equal to the angle of exit. Uncertainty was captured using four parameters, two for the perceptual error, and two for the stochastic error:

**Perceptual Uncertainty** At the start of the simulation, the ball’s position and velocity were based on where the ball would be in a perfectly deterministic simulation, but with noise added. Position was perturbed by isotropic two-dimensional Gaussian noise parameterized by standard deviation,  $\sigma_p$ . Noise in velocity direction was captured in a von Mises (circular normal) distribution on direction of motion, parameterized by concentration (inverse variance)  $\kappa_v$ . We did not consider uncertainty in the speed of the ball, as this would only affect the timing of the ball’s movement but not its destination, which is the prediction we aim to capture.

**Dynamic Uncertainty** Noise was added during the simulation in two ways. First, at each time step (1000/sec), the direction of the ball was ‘jittered’ by adjusting its direction using a von Mises distribution with the concentration parameter  $\kappa_m$ . In addition, noise was added during each bounce by assuming that the angle the ball bounced off of the wall was defined by a von Mises distribution centered on the angle of incidence with a concentration parameter  $\kappa_b$ .

Figure 1: Sources of uncertainty in the stochastic physics model

## Experiment

We aimed to test model predictions against human data and to estimate uncertainty parameters in intuitive dynamics. In this experiment, subjects predicted the trajectory of a ball in a two-dimensional environment on a computer screen. This was done in a ‘Pong’ game where participants tried to catch the ball with a paddle. Crucially, we occluded the latter part of the ball’s movement, so that successful prediction of the final position required the mental simulation of the object trajectory. We could estimate the final position predicted by our stochastic physics model with different parameters, and thus compare human behavior to model predictions under varying types and degrees of uncertainty.

In this experiment we parametrically varied both the distance the ball would travel<sup>1</sup> and the number of bounces off of walls while occluded. If intuitive dynamics models are deterministic, then the number of bounces will have no effect on human predictions. The distance manipulation was designed to tease apart the contributions of perceptual uncertainty about velocity and dynamic velocity noise.

## Methods

52 UCSD undergraduates (with normal or corrected vision) participated in the experiment for course credit.

Subjects used a computer mouse to control the vertical position of an on-screen ‘paddle’ to catch a moving ball. The ball moved according to the deterministic physics underlying the stochastic physics model. Both the paddle and the ball were confined to a 1200 by 900 pixel area in the center of the screen. Each trial began with a display of only the paddle, which subjects could move up and down. The

paddle was 100 pixels in height and was centered on the vertical position of the mouse before each trial. A mouse click triggered the start of a trial. A ball would then appear on the screen, moving at a constant velocity of 600 pixels/second. After the ball moved 400 pixels, a grey rectangle would occlude the portion of the screen containing the ball (Figure 2). During this period, the ball would continue to move, bouncing perfectly elastically off of the edges of the field, but would not be visible. Once the subjects caught the ball with the paddle, or the ball broke the plane of the paddle, the trial would end and the occluder would be removed, showing whether (and by how far) the subject missed the ball. Upon clicking the mouse, the screen would clear and reset for the next trial. The number of balls caught by the subject was always displayed in the upper right corner as a motivation to perform well.

Figure 2: Diagram of a trial. (A) The ball moves unoccluded in a straight line. (B) Once the field is occluded, the ball continues to move until caught or it passes the paddle plane.

Subjects were given 648 trials throughout the experiment. These 648 trials were identical for all subjects, but presented in a randomized order. Each trial had a particular ball trajectory, generated by one of nine conditions. The nine trajectory conditions crossed the distance the ball travelled while occluded (600, 800, or 1000 pixels) with the number of bounces (0, 1, or 2); there were 72 trials of each condition. The specific path for each trial was generated prior to the experiment subject to the constraints of the condition and the constraint that the final position was not in the top 20% or bottom 20% of the enclosed area to avoid bias due to positioning the paddle at the ends of the screen.

Before starting the experiment, subjects were given seven trials without the occluder to demonstrate how the ball would move, then six practice trials with the occluder.

For each trial, we recorded the position of the midpoint of the paddle once the ball was caught or moved past the paddle. From this measure we could calculate, for each trial, (a) the average expected position of the ball, and (b) the variance of predictions around that expectation.

## Subject Performance

**Accuracy** Subjects caught the ball on 43.8% of all trials. Individual subject accuracies varied between 25.6% and 63.7% (chance was 11%). Accuracy also varied by trial condition: subjects were most accurate in the shortest, no

<sup>1</sup> Because the ball always moved at a constant velocity, distance was proportional to duration of occlusion.

bounce condition (69%) and least accurate in the longest, two-bounce condition (32%).

Accuracy improved slightly over time, increasing from 42.7% in the first half of trials to 44.9% on the second half ( $\chi^2(1) = 15.9$ ,  $p < 0.001$ ). However, because this was a small effect, and because in a logistic model predicting accuracy, trial order did not interact with either distance ( $\chi^2(2) = 0.72$ ,  $p = 0.70$ ) or number of bounces ( $\chi^2(2) = 4.18$ ,  $p = 0.12$ ), we do not try to account for this change.

Figure 3: Mean predicted paddle position versus path endpoint using deterministic physics as a function of trial condition. Each point represents a separate trial.

**Expected Positions** In addition to decreasing accuracy, subjects also showed increasing bias in average predictions as the distance or number of bounces increased. The mean final position of the paddle for each trial shifted towards the center as compared to the final ball position (see Figure 3).<sup>2</sup> The magnitude of this bias toward the center of the screen increased as either distance or number of bounces increased.

Table 1: Percent of distance ‘shifted’ from actual end ball position towards center by trial condition

		Distance		
		600	800	1000
Bounce	0	24%	44%	53%
	1	23%	60%	70%
	2	41%	63%	84%

<sup>2</sup> There was low lag-one autocorrelation between the position of responses and prior responses (0.11) that did not vary by condition, suggesting that this mean shifting was not driven by subjects leaving the paddle in the same position as their prior trial.

**Variance of Responses** The variability of subjects’ responses around the mean also increased with distance and bounces, but only up to a ceiling - well below the maximum possible spread - once subjects had to take into account even one bounce.

Table 2: Average standard deviation (in pixels) of responses within a trial by condition

		Distance		
		600	800	1000
Bounce	0	65	76	94
	1	111	115	114
	2	115	111	121

## Model Application

The coarse results suggest that prediction error and variability increases with distance or number of bounces. But they do not indicate which sources of uncertainty contribute to intuitive physics predictions, nor do they explain why some trials within the same condition produce greater bias and variability than others.

We aimed to tease these factors via our model of stochastic physics. By finding the set of uncertainty parameters that best fits the empirical data, we can compare the relative contribution of the perceptual uncertainty parameters to the dynamic uncertainty parameters. A good model should capture trial-level differences in subjects’ performance, and explain trial difficulty based on the interplay of different sources of uncertainty.

## Simulation

We replicated the experimental task in the stochastic physics model, simulating the same 648 trials. To mirror this task, each simulation started at the point of occlusion (when subjects could no longer visually track the ball and must predict its path) and ended when the simulated ball crossed the plane of the paddle. On each simulation, we measured the position of the simulated ball along that plane. Because there is no analytic form of the probability distribution over possible trajectories, we simulated each trial 500 times, thus estimating the predictive distribution for each trial via sampling.

No set of uncertainty parameters produced mean estimates of the final position of the ball that were systematically shifted toward the center like the empirical data; as long as Newtonian physics underlies the model, it will in general simulate trajectories that are centered around the actual endpoint, regardless of the uncertainty parameters chosen. Since the magnitude of the center bias scaled with distance and number of bounces, we suspected that subjects were incorporating a prior on final position, producing a center bias proportional to the uncertainty in their physics-

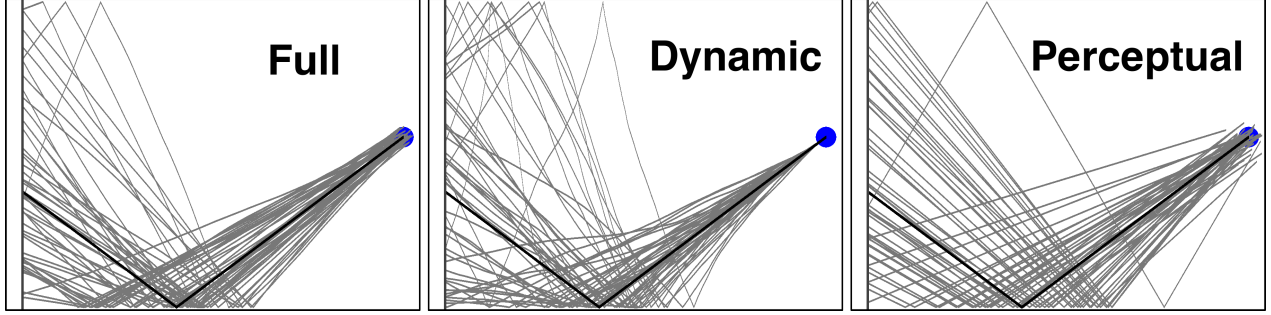

Figure 4: Sample simulation paths for one trial with each model. The grey lines represent individual simulations, the black line represents deterministic simulation. There is no initial uncertainty in the dynamic model, but it builds quickly over time, resulting in wavy paths. The initial position and velocity vary significantly in the perceptual model, but once started, the simulation unfolds deterministically. The full model uses both types of uncertainty and so has more certainty in starting positions than the perceptual model and straighter paths than the dynamic model.

based predictions.<sup>3</sup> People therefore appear to incorporate prior expectations with their intuitive physics models.

We treated this bias as a simple Gaussian prior on the final ball position centered on the middle of the screen, with standard deviation as a free parameter ( $\sigma_{\text{prior}}$ ). One value of this parameter was used for all trials and conditions.

The final distribution of predictions for each trial was calculated by combining the center-prior with the distribution of predicted positions simulated by the stochastic physics engine. We treated the distribution of predicted positions as a Gaussian and calculated their mean and standard deviation. We could then calculate the mean and standard deviation of the posterior distribution using Bayesian cue combination (e.g., Ernst & Banks, 2002):

$$\sigma_{\text{post}}^2 = \left( \frac{1}{\sigma_{\text{prior}}^2} + \frac{1}{\sigma_{\text{sim}}^2} \right)^{-1}, \mu_{\text{post}} = \left( \frac{x_{\text{center}}}{\sigma_{\text{prior}}^2} + \frac{\mu_{\text{sim}}}{\sigma_{\text{sim}}^2} \right) * \sigma_{\text{post}}^2$$

Using these equations, trials with greater simulation variance will be more affected by the prior, and will shift further towards the screen center. Thus, the model can account for the center-bias in a manner sensitive to prediction uncertainty.

We found the maximum likelihood parameters to fit three quarters of the data (with an equal number of trials from each of the distance by bounce conditions).<sup>4</sup> We also fit two other models: one with only perceptual uncertainty and prior parameters, and one with only dynamic uncertainty and prior parameters. We compared these models based on the likelihood of the 25% of the remaining (cross-validation) data.

## Model Results

**Model Comparison** The stochastic physics model was designed to tease apart how various sources of uncertainty

contribute to intuitive physics. Thus we compared the model with both dynamic and perceptual uncertainty to the two nested models with either dynamic or perceptual uncertainty parameters alone to determine which sets of parameters were necessary to best explain the data.

In addition, we tested how well any of the stochastic models captures human behavior by comparing them to a simple regression model with different parameters for each condition. The regression model assumes that people will provide the correct answer, plus some error that varies by condition without regard to individual trial details. We assume that the average reported position will have some variance (estimated independently for each condition), and some bias towards the center (estimated by regressing the average reported position against the deterministic end positions within each condition) – in other words, the regression model is a non-physical error model. This model can capture the gross ‘shift’ in expected position that was observed in the data in each condition (see Figure 3), but does not treat the shift as an inference done independently on each trial. The spread in responses was assumed to be constant within each condition, and was set at the average empirical standard deviation from that condition. Like the stochastic models, this model was fit on three-quarters of the trials and tested on the remaining data.

Table 3: Model prediction of left-out data

Model	$\Delta\text{LLH}$
Full	2,588
Dynamic	2,568
Perceptual	2,197
Regression	2,326
Oracle	3,259

Table 3 shows cross-validation likelihood for the four models. All log-likelihoods are shown as improvement over a baseline assuming that all data came from a single Gaussian. In addition, we included an ‘oracle’ model that knows the mean and standard deviation of responses for each trial – this serves as the plausible upper limit on how well different models might do. The full stochastic model

<sup>3</sup> The actual endpoint of the ball was uniformly distributed within the space of allowable endpoints. Therefore, this prior is unlikely to have been learned from the experiment.

<sup>4</sup> Numerical optimization techniques can find local minima, so we used multiple starting points and grid search across 1,600 sets of parameters to ensure we were finding the global minimum.

does best, followed closely by a model including only dynamic noise. Both the perceptual noise model and the non-physical model perform worse by many orders of magnitude.

The dynamic model performed nearly as well as the full model for two reasons. First, the parameter representing error in the initial position ( $\sigma_p$ ) was set to a small value in the full model and explained very little of the variance in simulations. Second, much of the noise in initial velocity direction can be captured by increasing dynamic velocity noise, and so we cannot say whether any initial velocity noise is required. The model with only perceptual noise did quite poorly because subjects' performance changed with each additional bounce, and thus human performance cannot be captured without dynamic uncertainty.

**Trial-Level Simulations** Human predictions about individual trials within the same distance-by-bounce condition varied significantly: some had much larger variations in responses or greater shifts toward the center than others. These differences arose from trajectory characteristics other than total distance traveled or number of bounces. For instance, it is harder to predict the end position of a ball that bounces in a corner or balls that approach the paddle at a steep angle. If the stochastic physics model is capturing characteristics of intuitive physics, then it should capture this within-condition variability as well.

Figure 5: Full model vs. empirical mean position by condition. Each point is a separate trial.

The full stochastic model fit the variation in mean paddle position across trials well ( $r=0.93$ ), and slightly better than the predictions of the regression model ( $r=0.90$ ). However, the difference between models is highlighted when

considering individual conditions: although both models account for the mean position in the no-bounce conditions, only the full model continues to perform well as bounces and distance are added (see Table 4).

Table 4: Correlation between model and empirical by-trial means within condition

		Full			Regression		
		Distance			Distance		
		600	800	1000	600	800	1000
Bounce	0	.99	.99	.99	.99	.99	.99
	1	.86	.88	.85	.88	.77	.68
	2	.89	.87	.82	.82	.68	.45

The standard deviation of predictions from the full stochastic model was well correlated with the standard deviation of subjects' responses across trials ( $r=0.79$ , see Figure 6), albeit with a tendency to overestimate. Moreover, the stochastic physical model also captures the variability across trials within each distance-by-bounce condition (Table 5). Together, these results indicate that human uncertainty about final outcomes accumulates in a manner qualitatively similar to that predicted by a stochastic physical model.

Figure 6: Full model vs. empirical standard deviation by trial

Table 5: Correlation between full model and empirical by-trial standard deviations within condition

		Distance		
		600	800	1000
Bounce	0	.54	.43	.17
	1	.53	.44	.30
	2	.14	.16	.17

In the experimental data, the amount of mean-shifting for each trial is related to the variance of the observations from that trial (Spearman's  $\rho = 0.30$ ), suggesting that people hedge their guesses towards the middle more as the amount

of uncertainty increases. A center-prior captures this behavior by causing more reliance on the prior when there is a wider distribution of model simulations. This has the effect of shifting guesses more towards the center when physical simulations are more uncertain. The stochastic physics model captures this phenomenon by predicting trial-level differences in uncertainty, and is thus better able to describe variation in human responses across trials than a constant mean-shift for each condition (see Figure 5).

## General Discussion

We found that human performance on a physical prediction task is captured by a model of stochastic physics with a prior expectation about the final position of objects. Furthermore, we found that bias and variability of human predictions are driven by uncertainty about the dynamics: people use stochastic, rather than deterministic, physics to make predictions. This result supports recent findings that people predict object dynamics using unbiased intuitive physics models (e.g., Hamrick, et al., 2011), and suggests two refinements to this view. First, the internal physics models themselves must be stochastic rather than rely solely on perceptual uncertainty to demonstrate non-determinism. Second, people do not directly use predictions from their physical models, but combine them with simple priors to produce rich behaviors.

Though we found that dynamic uncertainty contributes substantially to predictions in this task, we do not know how people might adjust this uncertainty based on task demands. In this experiment, the ball was easy to see (low perceptual uncertainty) and the background was uniform (suggesting less perturbation during movement). Lower contrast between object and background might cause greater perceptual uncertainty; likewise, backgrounds suggesting a rough surface might cause people to introduce more stochastic movement error into their simulations. An interesting direction for future work is to explore how people adjust the uncertainty within their intuitive physics models to account for different expectations about the world.

We also found that people modulate their physical predictions via prior expectations about the outcomes. Although these expectations could arise in many ways, here we were able to capture human behavior well by using a simple expectation about the final position: despite there being no evidence for it within the experiment, people believed that the ball was more likely to end up in the center of the screen. We made a simplifying assumption that this was a prior expectation about final location; it is possible that this is an approximation of other sorts of priors (e.g., objects tend to travel in a more horizontal direction). More research is required to understand exactly what these prior expectations are, how they develop, and under what conditions they become integrated into models of intuitive physics. Regardless of the prior used, we think that this might reflect a more general strategy that people may adopt to account for their uncertainty in their internal physical

model itself: by adjusting model predictions via a simple prior on outcomes, behavior will be more robust to errors in the simulation model. A similar process may suggest a means for combining model-based and model-free predictions (Gläscher, Daw, Dayan, & O'Doherty, 2010): learning simple expectations about the world is a good hedge against model error.

Our models predicted systematically larger variances than those we observed. This may be due to our simplistic choice of the shape of the prior. Gaussian cue combination of the prior and simulated distributions produces dependence between variance and mean-shift: a greater mean-shift arises only from greater variance. Thus to best fit the predicted means, using a Gaussian prior required a biased variance estimate. Further work is required to understand the priors people actually hold (e.g., Stocker & Simoncelli, 2006) to refine the models that people use to simulate the world.

This work supports the hypothesis that intuitive physics models can be built upon a Newtonian framework. Moreover, these models are not deterministic, but incorporate sources of dynamic uncertainty. Furthermore, people do not trust these models entirely, but combine their predictions with simple expectations about the outcome itself. Though just a first step, this provides a framework for disentangling and understanding the various components of intuitive physics models.

## Abstract

Judgmental detection of changes in time series is an ubiquitous task. Previous research has shown that human observers are often relatively poor at detecting change, especially when the series are serially dependent (autocorrelated). We present two experiments in which participants were asked to judge the occurrence of changes in time series with varying levels of autocorrelation. Results show that autocorrelation increases the difficulty of discriminating change from no change, and that observers respond to this increased difficulty by biasing their decisions towards change. This results in increased false alarm rates, while leaving hit rates relatively intact. We present a rational (Bayesian) model of change detection and compare it to two heuristic models that ignore autocorrelation in the series. Participants appeared to rely on a simple heuristic, where they first visually match a change function to a series, and then determine whether the putative change exceeds the variability in the data.

**Keywords:** change detection; judgment; forecasting

## Introduction

Detecting changes in time series is a surprisingly ubiquitous task. Doctors and therapists monitor diagnostic indicators for signs of disease onset and for evidence that a prescribed treatment is effective; farmers monitor soil conditions to decide whether additional irrigation is necessary; local authorities monitor river levels for increased likelihood of flooding; probation officers monitor probationers' behaviour for evidence of return to crime; financiers monitor data, such as exchange rates, for signs of trend reversal. Many other examples could be given. As with forecasting and control tasks, monitoring tasks may be tackled by formal statistical methods, by using judgment alone, or by using some combination of these two approaches. The method most favoured depends to a large extent on the domain. Typically, implementation of and training in formal methods consume more resources (time, money, effort) but the investment may be worthwhile if those methods have considerable benefits over judgment in terms of accuracy. Thus, it would be useful to know just how good human judgment is relative to formal methods.

There are many formal statistical methods for detecting change in time series (e.g., Albert & Chib, 1993; Carlin, Gelfand, & Smith, 1992; Hamilton, 1990). This variety is partly because some approaches represent the event producing the regime change as deterministic whereas others represent it as a random variable and partly because, whichever of these approaches is adopted, there is still some debate about how best to estimate the likelihood that a change has occurred.

In contrast, there has been very little research into judgmental assessment of regime change. Originally, behavioural

psychologists working within the Skinnerian tradition used judgment (visual inference) to assess whether a manipulation changed some aspect of an animal's behaviour represented as a time series. They argued that this is a conservative approach because only large effects can be detected (e.g., Baer, 1977). Their claims were not directly tested. However, when behaviour analysts later used the same approach to assess human patients, there was concern that the shorter pre-treatment baselines in the series impaired visual inference. As a result, some experiments were carried out to investigate how accurately people can detect change.

## Judgmental change detection and autocorrelation

Jones, Weinrott, and Vaught (1978) found that people were poor at detecting change in real series: inter-rater reliability of judgments was low at .39 and average miss and false alarm rates were 48% and 33%, respectively. Sequential dependence (autocorrelation) in series increased false alarm rates. This study used interrupted time series analysis as the gold standard for establishing whether there was a real change in the series. However, series were so short that this statistical approach would have lacked power. People may have been able to detect changes that the statistical analysis could not: if so, their performance may not have been as bad as it appeared to be. To circumvent this problem, Matyas and Greenwood (1990) simulated series with known levels of random noise and first-order autocorrelation. However, they still found that false alarm rates (typically over 40%) were much higher than miss rates (typically about 10%), especially when data were autocorrelated. They concluded that judgment is not as conservative as behaviour analysts assumed.

The increase in false alarm rates under positive autocorrelation is problematic. In single-subject research, where visual assessment of change is still the dominant method (Brossart, Parker, Olson, & Mahadevan, 2006), there is positive autocorrelation in the large majority of series (Busk & Marascuilo, 1988). Why does autocorrelation impair change detection? Consider a time series  $y_{1:T} = (y_1, \dots, y_T)$  which follows an  $r$ -th order autoregressive process

$$y_t = \mu_t + \sum_{k=1}^r \alpha_k (y_{t-k} - \mu_{t-k}) + \varepsilon_t \quad \varepsilon_t \sim N(0, \sigma_\varepsilon^2) \quad (1)$$

This process implies a serial dependence between successive time points such that when a previous value  $y_{t-k}$  is above the mean  $\mu_{t-k}$ , a later value  $y_t$  is more likely to also be above the mean (for  $\alpha_k > 0$ , positive autocorrelation), or more likely to be below the mean ( $\alpha_k < 0$ , i.e., negative autocorrelation).

Figure 1: Examples of time series with a change and no change, under different levels of autocorrelation.

We allow for the possibility of an abrupt change in baseline value

$$\mu_t = \mu_0 + \delta \mathbb{I}_{t \geq t^*} \quad \delta \sim N(\mu_\delta, \sigma_\delta^2) \quad (2)$$

where  $t^*$  is the change point and  $\mathbb{I}_{t \geq t^*}$  is an indicator function with value 1 when  $t \geq t^*$  and value 0 otherwise. This is the process used in the experiments reported below. Figure 1 shows examples of time series produced by a first-order ( $r = 1$ ) autoregressive process. Note that each series is created from identical noise values  $\varepsilon_t$ ; the only difference is in the value of the autocorrelation, and whether there is a change in the baseline (after time point 25 in the series on the left) or not. As can be seen in these examples, positive autocorrelation ( $\alpha_1 = 0.8$ ) tends to make series “smoother”, which can make abrupt changes less apparent. Also, when there is no change, positive autocorrelation can increase false alarms, because a sudden large noise perturbation will tend to persist, giving the appearance of a change in mean. In contrast, negative autocorrelation ( $\alpha_1 = -0.5$ ) tends to make series more “jagged”, which can impair change detection by increasing the apparent noisiness of the series, even though the actual error variance is unaffected.

### Cognitive processes underlying change detection

Research on judgmental change detection has been mainly empirical. Little attention has been given to the cognitive processes underlying performance in the task. An exception is the work of Wampold and Furlong (1981), who argued that people may use one of two types of heuristic.

First, people may assess a putative change in the data relative to the overall variability that is present. A putative change is judged to be real if its magnitude exceeds the natural variability in the data by some criterial amount. This is a global assessment: all the presented data are taken into account. According to this model, positive autocorrelation increases false alarms because it is ignored when the natural variability in the data is estimated. This results in an underestimation of the

variability and, hence, over-estimation of the likelihood of a change. In contrast, negative autocorrelation would result in an over-estimation of the variability, and hence an underestimation of the likelihood of a change.

Alternatively, people may monitor the data for large absolute changes and ignore the natural point-to-point variability. This approach assumes that they access internal prototypes of possible changes and classify series into those with and without a change by matching them against these prototypes. In other words, they make local assessments: candidate changes are judged in isolation from the rest of the series.

Steyvers and Brown (2005) proposed that people may rely on a heuristic similar to the latter<sup>1</sup> when detecting changes in times series while making sequential predictions about the next datum in the series. They showed that this heuristic closely followed an optimal Bayesian model, which also fitted participants responses well. In later work, Brown and Steyvers (2009) proposed that people generally use Bayesian inference in these problems, although they may work from incorrect assumptions and use limited samples to approximate the full Bayesian analysis.

### Present study

Previous research suggests that human detection of change in time series is impaired by the presence of autocorrelation. In the two experiments presented here, we sought to replicate this finding with a range of (positive) autocorrelations (Experiment 1) and a second-order autoregressive process (Experiment 2). By formulating different models and fitting these to participants’ judgments, we sought to uncover the cognitive processes underlying change detection in graphically

<sup>1</sup>But not exactly the same. According to Steyvers and Brown (2005), a change will be detected whenever the distance between a prediction and the actual value exceeds a criterial amount. However, the distance was not measured on the scale of the outcome, but rather as the log likelihood ratio of the outcome given a change vs no change.

presented time series. Uncovering the strategies people use when monitoring series for regime change is a first step in determining how to improve judgmental change detection.

## Experiment 1

The objective of Experiment 1 was to assess the accuracy of judgmental change detection under levels of no ( $\alpha_1 = 0$ ), medium ( $\alpha_1 = .4$ ), and high ( $\alpha_1 = .8$ ) autocorrelation.

### Method

**Participants** Fifty participants (23 male) were recruited from the UCL subject pool and paid £5 for their time. The mean age was 26.06.

**Task** The change detection task consisted of 60 trials. On each trial, participants were presented a graph depicting a time series and asked to indicate whether the series contained a change or not. After this, they indicated their confidence in their response.

In Experiment 1, the time series were created by a first-order autoregressive process (i.e., setting  $r = 1$  in Equation 1). The autocorrelation was varied within participants. For each level of autocorrelation,  $\alpha_1 = \{0, .4, .8\}$ , there were 10 series with, and 10 series without a change. Each change  $\delta$  was randomly drawn from a Gaussian distribution with mean  $\mu_\delta = 8$  and variance  $\sigma_\delta^2 = 9$ . The initial baseline value was set at  $\mu_0 = 50$  and the variance of the noise was set at  $\sigma_\epsilon^2 = 5$ .

**Procedure** Participants took the role of a trainee flood engineer with the task of monitoring water levels for risk of flooding. Participants were told a risk of flooding consisted of a persistent increase in water level, but that the level would fluctuate regardless of whether there was a risk of flooding or not. For 60 different locations, they would monitor the water level over a 50 hour period, and participants were informed that a flood risk could occur anywhere between hour 11 and hour 40 (i.e.,  $t^* \in \{11, \dots, 40\}$ ). Finally, participants were instructed that there was a flood risk for half of the locations.

### Results

The main detection results are given in Table 1. Autocorrelation did not affect hit rates,  $F(2, 98) = 1.278$ ,  $p = .283$ , but increased false alarms,  $F(2, 98) = 27.913$ ,  $p < .001$ . This indicates that, as autocorrelation increased, participants adjusted their criterion to detect changes. This was confirmed in a signal detection analysis. Increased levels of autocorrelation reduced the discrimination ( $d'$ ),  $F(2, 98) = 11.915$ ,  $p < .001$ . Contrast analysis showed that this effect was mainly due to a linear trend,  $F(1, 49) = 22.79$ ,  $p < .001$ ; the quadratic trend was not significant,  $F(1, 49) = 1.37$ ,  $p = .25$ . In addition, increased autocorrelation reduced the centered decision criteria ( $C$ ),  $F(2, 98) = 20.56$ ,  $p < .001$ . Contrast analysis showed that this effect was mainly due to a linear trend,  $F(1, 49) = 32.58$ ,  $p < .001$ ; the quadratic trend was not significant,  $F(1, 49) = 0.79$ ,  $p = .38$ . This indicates that autocorrelation increased the difficulty of the task and participants

Table 1: Mean hit (H) and false alarm (FA) rates, discrimination ( $d'$ ) and (centered) criterion ( $C$ ) parameters. Values in parentheses are standard deviations.

$\alpha_1$	$\alpha_2$	H	FA	$d'$	$C$
Experiment 1					
0		.72 (.18)	.06 (.15)	2.06 (.69)	-0.40 (.12)
0.4		.76 (.14)	.11 (.19)	1.90 (.65)	-0.44 (.12)
0.8		.77 (.15)	.24 (.20)	1.48 (.77)	-0.50 (.11)
Experiment 2					
0.5	0.3	.68 (.24)	.14 (.15)	1.65 (.86)	-0.42 (.14)
0.5	0.0	.74 (.22)	.10 (.15)	2.01 (.85)	-0.43 (.12)
0.5	-0.3	.70 (.23)	.07 (.16)	2.00 (.81)	-0.40 (.14)
-0.5	0.3	.72 (.22)	.07 (.14)	2.07 (.89)	-0.41 (.12)
-0.5	0.0	.72 (.23)	.03 (.07)	2.18 (.67)	-0.39 (.12)
-0.5	-0.3	.68 (.24)	.03 (.09)	2.09 (.80)	-0.37 (.12)

responded by lowering the criterion to detect a change (biasing decisions towards changes), resulting in increased false alarms.

Average confidence levels for the different trial types and autocorrelation levels are depicted in Figure 2. We analysed the confidence ratings with a linear mixed effects model, including random intercepts for each participant, as well as random slopes for the autocorrelation and contrast codes for whether a decision was correct and whether it was a “change” (vs a “no change”) decision. This showed that confidence was higher for correct (hits and correct rejections) than incorrect decisions (misses and false alarms),  $F(1, 2946) = 216.4$ ,  $p < .001$ . In addition, confidence was generally lower when participants responded change (hits and false alarms) compared to no change (correct rejections and misses),  $F(1, 2946) = 11.19$ ,  $p < .001$ . A significant interaction between these two factors shows that confidence was more strongly related to correctness when people judged there was a change than when people judged there was no change,  $F(1, 2946) = 4.68$ ,  $p = .031$ . Finally, confidence decreased as the level of autocorrelation increased,  $F(1, 2946) = 16.83$ ,  $p < .001$ .

To summarize the results, increasing autocorrelation resulted in poorer discrimination between series with and those without a change. This increased difficulty was also reflected in participants’ confidence in their judgments. Participants appeared to respond to the increased difficulty by relaxing their decision criteria in favour of detecting change, resulting in increased false alarm rates.

## Experiment 2

The objective of Experiment 2 was to investigate change detection in a second-order autoregressive process. Depending on the autocorrelation values, second-order autoregressive processes can show complex periodic patterns (e.g., Gottman, 1981). In particular, when  $\alpha_1^2 + 4\alpha_2 < 0$ , the spectral density functions show broad peaks across a band of mid-range

Figure 2: Mean confidence levels by autoregression level and trial type (H = hit, FA = false alarm, M = miss, CR = correct rejection). Error bars represent 95% confidence intervals.

frequencies, and the time series is nondeterministically periodic. Such periodic behaviour may appear as a change in mean, increasing false alarms. To investigate this possibility, Experiment 2 included series with and without such periodic behaviour.

## Method

**Participants** 70 students (18 male) participated in the experiment for course credit. The mean age was 18.97 ( $SD = 1.12$ ).

**Task** The task was identical to that in Experiment 1. However, the time-series were now produced by a second-order autoregressive process (setting  $r = 2$  in Equation 1), with autocorrelation parameters  $\alpha_1 = \{-0.5, 0.5\}$  and  $\alpha_2 = \{-0.3, 0, 0.3\}$ . There were 10 series for each combination of the autocorrelation parameters, of which five did and five did not contain a change. Series were presented in random order. Series with  $\alpha_1 = .5$  and  $\alpha_2 = -.3$ , or  $\alpha_1 = -.5$  and  $\alpha_2 = -.3$ , were likely to show periodic trends. If this impairs detection ability, we would expect to find a difference between these series and those generated with other combinations of autocorrelation parameters.

## Results

The main detection results can be found in Table 1. As in Experiment 1, autocorrelation affected false alarm rates,  $F(1, 68) = 56.67$ ,  $p < .001$  and  $F(2, 136) = 24.99$ ,  $p < .001$ , for  $\alpha_1$  and  $\alpha_2$  respectively, but not hit rates,  $F(1, 68) = 0.03$ ,  $p = .87$  and  $F(2, 136) = 1.42$ ,  $p = .25$ . Signal detection analysis showed that both autocorrelation parameters affected

discrimination ability ( $d'$ ),  $F(1, 69) = 9.81$ ,  $p = .003$ , and  $F(2, 138) = 3.50$ ,  $p = .033$ , for  $\alpha_1$  and  $\alpha_2$  respectively; the interaction was not significant,  $F(2, 138) = 1.79$ ,  $p = .17$ . Discrimination was generally better for  $\alpha_1 = -.5$  than  $\alpha_1 = 0.5$ . Discrimination was worse for  $\alpha_2 = 0.3$  compared to the other two values,  $F(1, 69) = 5.77$ ,  $p = .019$ , while there was no difference between  $\alpha_2 = 0$  and  $\alpha_2 = -0.3$ ,  $F(1, 69) = 0.52$ ,  $p = .47$ . Both autocorrelation parameters also affected the centered decision criteria ( $C$ ),  $F(1, 69) = 7.52$ ,  $p = .008$ , and  $F(2, 138) = 3.17$ ,  $p = .045$ . Decision criteria were more biased towards change for positive compared to negative autocorrelations (for  $\alpha_2$ , there was a linear trend,  $F(1, 69) = 5.78$ ,  $p = .019$ , but no quadratic trend,  $F(1, 69) = 0.81$ ,  $p = .37$ ).

Average confidence levels for the different trial types and autocorrelation levels are depicted in Figure 2. Analysis with a linear mixed effects model replicated the results of Experiment 1. Confidence was higher for correct (hits and correct rejections) than incorrect decisions (misses and false alarms),  $F(1, 4124) = 226.14$ ,  $p < .001$ , and lower when participants responded change (hits and false alarms) compared to no change (correct rejections and misses),  $F(1, 4124) = 44.80$ ,  $p < .001$ . Confidence was more strongly related to correctness when people judged there was a change than when people judged there was no change,  $F(1, 4124) = 8.1$ ,  $p = .005$ . Confidence was higher for negative than positive first-order autocorrelation ( $\alpha_1$ ),  $F(1, 4124) = 5.69$ ,  $p = .017$ , and this difference was larger when the second-order autocorrelation was negative rather than positive,  $F(1, 4124) = 5.62$ ,  $p = .018$ .

The results of this experiment replicate those of Experiment 1 with a second-order autoregressive process. Positive (first- and second-order) autocorrelation resulted in poorer discrimination between series with and series without a change and this increased difficulty was reflected in participants' confidence in their judgments. Participants responded to the increased difficulty by relaxing their decision criteria, increasing false alarm rates. As the interaction between the autocorrelations was not significant, we found no evidence that periodic trends in the time series affected detection ability.

## A Bayesian change detection model

To compare participants' judgments against a gold standard, we used a Bayesian model to detect changes in time series as defined by Equations 1 and 2. By taking the autocorrelation into account, this model is expected to perform well, although the relatively short length of the series may limit its performance.

In our analysis, change detection is based on the relative evidence for a model  $M_1$ , which incorporates the possibility of a change, over a model  $M_2$ , which does not allow for change. The measure of relative evidence is the Bayes Factor

$$BF = \frac{p(y_{1:T}|M_1)}{p(y_{1:T}|M_2)} \quad (3)$$

where  $p(y_{1:T}|M_j)$  the marginal likelihood

$$p(y_{1:T}|M_j) = \int p(y_{1:T}, \theta_j | M_j) d\theta_j \quad (4)$$

integrating over the parameters  $\theta_j$  of model  $j$ . For  $M_1$ , the parameters are  $\theta_1 = \{\mu_0, \delta, \alpha_1, \alpha_2, \sigma_\epsilon, t^*\}$ . The parameters of model  $M_2$  exclude  $\delta$  and  $t^*$ . Recall that participants were informed there could be only one change point in each series, and that possible change points could be anywhere between time points 11 and 40. In model 1, the posterior distribution of the change point  $t^* \in \{11, \dots, 40\}$ , conditional on the other parameters, can then be expressed relatively simply as

$$p(t^* | y_{1:T}, \theta_{1,-t^*}, M_1) \propto p(y_{1:T} | t^*, \theta_{1,-t^*}, M_1) p(t^* | M_1) \quad (5)$$

where  $\theta_{1,-t^*}$  denotes the parameter vector excluding  $t^*$ , and  $p(t^* | M_1)$  the prior distribution over the change points  $t^*$ , which we took to be uniform. For  $\mu_0$  and  $\delta$ , we used truncated Normal distributions with means of 50 and 0 respectively, and variance  $10^5$ . Both distributions were restricted to the range between 0 and 100. For  $\mu_0$ , this reflects the range of the time series on the graphs. For  $\delta$ , this reflects that changes can only be positive. For  $\sigma_\epsilon$ , an inverse Gamma distribution was used. For  $\alpha_1$  and  $\alpha_2$ , we used truncated Normal distributions (centered on 0) restricting the range such that the process is stationary<sup>2</sup>. Posterior distributions for the parameters can be efficiently estimated by Gibbs sampling (for computational details, see Albert & Chib, 1993). Bayes Factors were estimated from the Gibbs sampler using the technique of Chib (1995).

We computed the Bayes Factor for each of the time series in the two experiments. Using the simple criterion of  $BF > 1$  to detect a change, the hit rate of the model was 92.3%, but the false alarm rate was rather high at 15.8%. Inspection of the parameter estimates showed that false alarms were generally associated with relatively small changes (50% of the posterior means of  $\delta$  were smaller than 2.31) occurring relatively late in the series (50% of the posterior modes of  $p(t^*)$  were larger than  $t = 33$ ). False alarm rates increased with positive autocorrelation. This suggests that even while explicitly accounting for autocorrelation, the Bayesian model is not immune to illusory changes produced by autocorrelation.

## Modelling human change detection

To link the Bayesian and heuristic models to participants' responses  $R_{ik}$ , we assume that, for a time-series  $k$ , each method of change detection  $j$  provides a signal  $v_{jk}$ , which is corrupted by noise  $e_{ijk} \sim N(0, \sigma_{ij})$ , and that participants judge there to be a change when the noisy signal exceeds a criterion  $c_{ij}$ . As a result, the probability of a change judgment, for participant  $i$  judging series  $k$  with model  $j$ , can be written as

$$P(R_{ik} = \text{change} | j) = 1 - \Phi\left(\frac{v_{jk} - c_{ij}}{\sigma_{ij}}\right) \quad (6)$$

<sup>2</sup>For a first-order autoregressive process, that means that  $|\alpha_1| < 1$ . For a second-order autoregressive process, the requirements are that  $\alpha_1 + \alpha_2 < 1$ ,  $\alpha_2 - \alpha_1 < 1$ ,  $|\alpha_2| < 1$ .

Table 2: Model fits (AIC) and numbers of participants best fitted according to the AIC ( $n_{\text{best}}$ ).

	Experiment 1		Experiment 2	
	AIC	$n_{\text{best}}$	AIC	$n_{\text{best}}$
Bayes	2891	3	3728	9
CRV	2280	47	2846	61
LAC	3512	0	5314	0

where  $\Phi$  denotes the cumulative Normal distribution. For the Bayesian model, we assume that

$$v_{\text{Bayes},k} = \log BF \quad (7)$$

i.e., that decisions depend on the logarithm of the Bayes Factor (Equation 3).

In addition to the Bayesian model, we formalised the heuristics of Wampold and Furlong (1981) described in the introduction. We'll refer to these as the Change-Relative-to-Variability (CRV) and the Largest-Absolute-Change (LAC) heuristic. The CRV heuristic compares a putative change to the overall variation in the series. In doing so, we assume people first visually fit a step function to the series, in such a way as to minimize the noise. The step function represents the mean water level before and after the change-point, and with that the timing and size of the putative change in water level. This putative change is compared to the deviations of the series around the step function. More formally, we assume the (increasing) step function, defined by the initial level  $m_0$ , change point  $t'$ , and the increase  $d$  after the change, is determined by minimizing the sum of squared error (SSE):

$$t', m_0, d = \arg \min_{t', m_0, d} \sum_{t=1}^T (Y_t - m_0 - d \mathbb{I}_{t \geq t'})^2 \quad (8)$$

The putative change  $d$  is then compared to an estimate  $s$  of the standard deviation (derived from the sum of squared errors). The value used for decisions, according to this heuristic, is then simply

$$v_{\text{CRV},k} = d - s \quad (9)$$

According to the second heuristic, a change is determined solely by comparing deviations between time points to a pre-existing "prototype". For this heuristic, we therefore assume the signal consists of the maximum deviation between consecutive time points

$$v_{\text{LAC},k} = \max_t |y_t - y_{t-1}| \quad (10)$$

We fitted the models in two ways. First, we fitted each model to the whole group of participants using a generalized linear mixed effects model, including random decision criteria  $c_{ij}$  and dispersion parameters  $\sigma_{ij}$ . In addition, we fitted each model to each participant separately. The results of both analyses (Table 2) were in agreement: the model that best described participants' responses was the Change-Relative-to-Variability (CRV) heuristic, followed by the Bayesian model.

The Largest-Absolute-Change (LAC) heuristic fitted none of the participants best.

## Discussion

We presented two experiments on human change detection in autocorrelated time series. In agreement with Matyas and Greenwood (1990), we found little evidence of conservatism. As the level of autocorrelation increased, participants maintained a similar hit rate, but increased their false alarm rate, indicating a relaxing of decision criteria such that more changes are (erroneously) detected. For second-order autoregressive processes, detection was most impaired when both autocorrelations were positive. There was no evidence that periodic trends resulting from particular autocorrelation levels affected detection performance.

Most participants responded in accordance with a simple change detection heuristic, where an underlying change-in-mean function is (visually) fitted to a noisy series and it is determined whether the putative change exceeds the natural variability in the series.<sup>3</sup> For the graphically presented time series used here, this strategy seems plausible. And as this strategy closely matches the performance of the Bayesian analysis which accounts for autocorrelation in the series, it is not a bad strategy either – at least not for the types of series studied here. Participants were explicitly told the range of time points over which a change could occur, as well as that there could only be one change in each series. For more complex problems with multiple change points or changes in other parameters than the baseline, the Bayesian and heuristic analyses are more likely to diverge.

We found no evidence that people relied on (absolute) differences between values on successive time points, a heuristic suggested by e.g. Steyvers and Brown (2005). An important difference between the present study and the latter one is that our participants were presented with complete time series, while Steyvers and Brown used an online prediction task in which participants viewed each datum sequentially and thus had to rely on memory. It is likely that change detection strategies will differ between online and offline detection tasks. In online tasks, the information available for detection is constrained by (working) memory capacity, as well as by the fact that only previous data can be used to judge a change at the current datum. In this case, strategies that rely on small samples, such as an absolute change heuristic, seem more plausible than strategies which use all the data, such as the Bayesian model and Change-Relative-to-Variability heuristic as implemented here.

Autocorrelation clearly impeded detection performance. Further research is required to assess the extent to which people can learn to “see through” autocorrelation. In the present experiments, participants did not receive feedback about their detection performance. It is possible that, after extensive

training, people can learn to distinguish between real changes and those that are merely apparent due to autocorrelation. In domains such as risk assessment, the finding that autocorrelation increases false alarms, but does not decrease hit rates, may provide some comfort. However, when assessing treatment effectiveness, a more cautious approach may be called for.

## Abstract

Listeners tend to gaze at objects to which they resolve referring expressions. We show that this remains true even when these objects are presented in a virtual 3D environment in which listeners can move freely. We further show that an automated speech generation system that uses eyetracking information to monitor listener's understanding of referring expressions outperforms comparable systems that do not draw on listener gaze.

## Introduction

In situated spoken interaction, there is evidence that the gaze of interlocutors can augment both language comprehension and production processes. For example, speaker gaze to objects that are about to be mentioned (Griffin & Bock, 2000) has been shown to benefit listener comprehension by directing listener gaze to the intended visual referents (Hanna & Brennan, 2007; Staudte & Crocker, 2011; Kreysa & Knoeferle, 2011). Even when speaker gaze is not visible to the listener, however, listeners are known to rapidly attend to mentioned objects (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). This gaze behavior on the part of listeners potentially provides speakers with useful feedback regarding the communicative success of their utterances: By monitoring listener gaze to objects in the environment, the speaker can determine whether or not a referring expression (RE) they have just produced was correctly understood or not, and potentially use this information to adjust subsequent production.

In this paper we investigate the hypothesis that speaker use of listener gaze can potentially enhance interaction, even when situated in complex and dynamic scenes that simulate physical environments. In order to examine this hypothesis in a controlled and consistent manner, we monitor listener performance in the context of a computer system that generates spoken instructions to direct the listener through a 3D virtual environment with the goal of finding a trophy. Successful completion of the task requires listeners to press specific buttons. Our experiment manipulated whether or not the computer system could follow up its original RE with feedback based on the listener's gaze or movement behavior, with the aim of shedding light on the following two questions:

- Do listener eye movements provide a consistent and useful indication of referential understanding, on a per-utterance basis, and when embedded in a dynamic and complex, goal-driven scenario?
- What effect does gaze-based feedback have on listeners' (gaze-)behavior and does it increase the more general effectiveness of an interaction?

We show that the listeners' eye movements are a reliable predictor of referential understanding in our virtual environ-

ments. A natural language generation (NLG) system, that exploited this information to provide direct feedback, communicated its intended referent to the listener more effectively than similar systems that did not draw on listener gaze. Gaze-based feedback was further shown to increase listener attention to potential target objects in a scene, indicating a generally more focused and task-oriented listener behavior. This system is, to our knowledge, the first NLG system that adjusts its referring expressions to listener gaze.

## Related work

Previous research has shown that listeners align with speakers by visually attending to mentioned objects (Tanenhaus et al., 1995) and, if possible, to what the speaker attends to (Richardson & Dale, 2005; Hanna & Brennan, 2007; Staudte & Crocker, 2011). Little is known, however, about speaker adaptation to the listener's (gaze) behavior, in particular when this occurs in dynamic and goal-oriented situations. Typically, Visual World experiments have used simple and static visual scenes and disembodied utterances and have analyzed the recorded listener gaze off-line (e.g., Altmann & Kamide, 1999; Knoeferle, Crocker, Pickering, & Scheepers, 2005). Although studies involving an embodied speaker inherently include some dynamics in their stimuli, this is normally constrained to speaker head and eye movements (Hanna & Brennan, 2007; Staudte & Crocker, 2011). Besides simplifying the physical environment to a static visual scene, none of these approaches can capture the reciprocal nature of interaction. That is, they do not take into account that the listeners' eye movements may, as a signal of referential understanding to the speaker, change the speaker's behavior and utterances on-line and, as such, affect the listener again.

One study that emphasized interactive communication in a dynamic environment was conducted by Clark and Krych (2004). In this experiment, two partners assembled Lego models: The directing participant advised the building participant on how to achieve that goal. It was manipulated whether or not the director could see the builder's workspace and, thus, use the builder's visual attention as feedback for directions. Clark and Krych found, for instance, that the visibility of the listener's workspace led to significantly more deictic expressions by the speaker and to shorter task completion times. However, the experimental setting introduced large variability in the dependent and independent variables, making controlled manipulation and fine-grained observations difficult. In fact, we are not aware of any previous work that has successfully integrated features of natural environments—realistic, complex and dynamic scenes in which the visual salience of objects can change as a result of the listener's moves in the environment—with the reciprocal

nature of listener-speaker-adaptation while also being able to carefully control and measure relevant behavioral data.

Recently, researchers have examined eye gaze of speakers and listeners in the scenes of Tangram puzzle simulations on computer screens (Kuriyama et al., 2011; Iida, Yasuhara, & Tokunaga, 2011). In these experiments, eye gaze features are found to be useful for a machine learning model of reference resolution. However, this setting is restricted in its dynamics, as it does not embed the objects into physical scenes or involve any updates to the spatial and visual context of the objects in the scenes. In contrast, by *generating* REs and asking the subjects to resolve them, rather than resolving human-produced REs itself, the system we propose here can provide more control over the language that is used in the interaction.

Computational models of gaze behavior are frequently implemented in embodied conversational agents as part of non-verbal behavior that aims at improving the human-computer interaction (see e.g. Foster, 2007). Such agents do not typically employ listener gaze tracking for the generation of appropriate REs, though. One work that focuses on situated RE generation is Denis (2010), which takes the visual focus of objects into account for the gradual discrimination of referents from distractors in a series of utterances. However, visual focus in Denis’ work is modeled by visibility of objects on screen rather than eye gaze. To our knowledge, there exists no prior RE generation algorithm that is informed directly by listener gaze.

Finally, gaze as a modality of interaction has been investigated in virtual reality games before, e.g. by Hülsmann, Dankert, and Pfeiffer (2011). However, most such settings do not use language as a further modality. One virtual game-like setting which focuses on language is the recent Challenge on Generating Instructions in Virtual Environments (GIVE; Koller et al., 2010), which evaluates NLG systems that produce natural-language instructions in virtual environments. In this work we use the freely available open-source software infrastructure provided by GIVE<sup>1</sup> to set up our experiment.

## Methods

In the GIVE setting (Koller et al., 2010; Striegnitz et al., 2011), a human user can move about freely in a virtual indoor environment featuring several interconnected corridors and rooms. A 3D view of the environment is displayed on a computer screen as in Fig. 1, and the user can walk forward and backward, and turn left and right, using the cursor keys. They can also navigate to buttons and, once they have approached them closely enough, click on them with the mouse to press them. In Fig. 1 the object currently under inspection by the user is the rightmost button on the wall, marked with a large white circle. The trace of the fixation’s coordinates is rendered by smaller white circles. These gaze markings do not appear on the user’s screen during the experiment.

The user interacts with an NLG system in the context of a treasure-hunt game, where the user’s task is to find a trophy

Figure 1: A screenshot of one of the virtual 3D environments.

hidden in a wall safe. They must press certain buttons in the correct sequence in order to open the safe; since they do not have prior knowledge of which buttons to press, they rely on instructions and REs generated by the NLG system in order to carry out the task. A room may contain several buttons other than the *target*, which is the button that the user must press next. These other buttons are called *distractors* and are there to make the RE resolution task more challenging. Rooms also contain a number of landmark objects, such as chairs and plants, which cannot be interacted with, but may be used in REs to nearby targets. For our experiment we use three different virtual environments designed by Gargett, Garoufi, Koller, and Striegnitz (2010), which differ in what objects they contain and where they are located.

## Generation systems

We implemented three different NLG systems for generating instructions in these virtual environments. All systems generate navigation instructions, which guide the user to a specific location, as well as object manipulation instructions such as “press the blue button” containing REs such as “the blue button”. The generated instructions are converted to speech by the MARY text-to-speech system (Schöder & Trouvain, 2003) and presented via loudspeaker. At any point, the user may press the ‘H’ key on their keyboard to indicate that they are confused. This will cause the NLG system to generate a clarified instruction. All three systems operate on the same codebase for the generation of simple yet effective navigation instructions (e.g. “go through the doorway”), but differ in their RE generation strategies.

Our baseline system generates REs that are optimized for being easy for the listener to understand, according to a corpus-based model of understandability (Garoufi & Koller, 2011). Crucially, this system does not monitor whether the listener understood an RE. It never gives any (positive or negative) feedback, and will only generate a follow-up RE if the user either asks for help (‘H’ key) or presses the wrong button. Therefore we call this system the *no-feedback* system.

The *movement* system extends the no-feedback system by

<sup>1</sup><http://www.give-challenge.org/research>

monitoring the user's movements in the game after it has uttered an RE, and attempting to predict whether they will press the button it described or not. This system does nothing until only a single button in the current room is visible to the user; then it tracks the user's distance from this button, where "distance" is a weighted sum of walking distance to the button and the angle the user must turn to face the button. If, after hearing the RE, the user has decreased the distance by more than a given threshold, the system concludes that the hearer has resolved the RE as this button. If it is the button the system intended to refer to, it utters the positive feedback "yes, that one!" For incorrect buttons, it utters the negative feedback "no, not that one."

Finally, the *eyetracking* generation system attempts to predict whether the user will press the correct button or not by monitoring their gaze. At intervals of approximately 15 ms, the system samples the (x,y) position on the screen that the user is looking at. It then resolves this (x,y) screen position to an object in the 3D scene. If the user fixates the same object for more than 300 ms, the system counts this as an inspection of that object; interruptions of the inspection of less than 150 ms are ignored. Once it has detected an inspection to a button in the room, the eyetracking system generates positive or negative feedback utterances in exactly the same way as the movement system does.

The system maps the screen positions reported by the eyetracker to 3D objects as follows: When the 3D engine renders the 3D scene onto the 2D screen, it assumes a certain position of the "camera" in the 3D environment; this roughly corresponds to the position of the user's eyes. For each object that is currently visible, the system computes its bounding box, i.e. the smallest box that completely contains the object. It determines the minimum angle  $\alpha$  between the ray from the camera position to some corner of the bounding box and the ray from the camera position to the center of the bounding box. Intuitively,  $\alpha$  represents the size of the object on the screen. The system also determines the angle  $\beta$  between the ray from the camera position to the (x,y) position in the screen plane reported by the eyetracker and the center of the bounding box. Small values of  $\beta$  represent situations in which the user looks directly at the center of an object. An object is a candidate for being fixated if one of  $\beta/\alpha$  or  $\beta - \alpha$  is below a certain threshold. Among all candidates (if there are any), the system then finally chooses the object with the smallest  $\beta$ .

Both the movement-based and the eyetracking-based model withhold their feedback until a first full description of the referent (a *first-mention RE*) was spoken. Additionally, they only provide feedback on newly approached or inspected buttons and will not repeat this feedback unless the listener has approached or inspected another button in the meantime. We call the time between the onset of the first-mention RE and the next button press in a scene, the *critical time region*.

## Participants

Thirty-one students, enrolled at Saarland University, were paid to take part in this study (12 females). All reported

their English skills as fluent, and all were able to complete the tasks. Their mean age was 27.6.

## Task and procedure

A faceLAB eyetracking system<sup>2</sup> remotely monitored participants' eye movements on a 24-inch monitor. Before the experiment, participants received written instructions that described the task and explained that they would be given instructions by an NLG system. They were encouraged to request additional help anytime they felt that the instructions were not sufficient (by pressing the 'H' key).

The eye-tracker was calibrated using a nine-point fixation stimulus. We disguised the importance of gaze from the participants by telling them that we videotaped them and that the camera needed calibration. Participants then started with a short practice session to familiarize themselves with the game controls and to clarify remaining questions, before playing three full games (each with a different virtual environment and generation system). The order of games was alternated according to the Latin square design. Finally, each participant received a questionnaire which aimed to assess whether participants noticed that they were eye-tracked and that one of the generation systems made use of that. The entire experiment lasted approximately 30 minutes.

## Analysis

Firstly, we determined whether the participant pressed the correct button (without having to ask for help by pressing the 'H'-key) by comparing each button the participant pressed with the target referent of the most recent first-mention RE. REs that did not lead to a button press (e.g. because the participant navigated away to another room, causing the system to switch to navigation instructions) were considered unsuccessful. This served as a dependent variable but also as a means for subdividing data according to un-/successful trial completion. Secondly, inspections recorded on a button in the player's room, i.e., on the target or a distractor, during the critical time region were registered in all conditions (not just the eyetracking NLG system) and analyzed as a main dependent variable. Further total trial time, i.e., the time taken from the onset of an RE to the button press, as well as the onset time of system feedback (when provided) were recorded. Finally, we considered the frequency with which participants asked for help by pressing the 'H' key as a measure of confusion.

To control for external factors, we discarded individual scenes in which the systems rephrased their first-mention REs (e.g. by adding further attributes), as well as a few scenes which the participants had to go through a second time due to technical glitches. To remove errors in eyetracker calibration, we included interactions with the eyetracking NLG system in the analysis only when we were able to record inspections (to the referent or any distractor) in at least 80% of all referential scenes. This filtered out 9 interactions out of the 93 we collected.

<sup>2</sup><http://www.seeingmachines.com/product/facelab>

Inferential statistics on this data were carried out using mixed-effect models from the lme4 package in R (Baayen, Davidson, & Bates, 2008). Specifically, we used logistic regression for modeling binary data such as referential success rates, Poisson regression for count variables (e.g., ‘H’-key strokes) and linear regression for inspection durations. Further, main effects and interactions were determined through model reduction, which assesses the contribution of a predictor or interaction to a fitting model by running a  $\chi^2$ -comparison between models with and without the particular predictor(s).

## Results

The post-task questionnaires, revealed no differences in participants’ preferences for any particular NLG system. Similar numbers of participants chose each of the systems on questions such as “which system did you prefer”. When asked for differences between the systems in free-form questions, no subject mentioned eye gaze. We take this to mean that the participants did not realize they were being eyetracked.

### Eye movements

We recorded and analyzed inspections to target and distractor buttons in all conditions. Mean inspection durations during the critical time region (reference onset until button press) were correlated with the success in pressing the correct button and are provided in Table 1.

To investigate our first hypothesis, namely that listener eye movements provide a consistent and useful indication of referential understanding even when embedded in a dynamic, complex and goal-driven scenario, we first consider our baseline condition, the no-feedback system, separately: Model reduction revealed that both inspection duration on the target and inspection duration on the distractors indeed predict success ( $\chi^2(1) = 28.87, p < .001$  and  $\chi^2(1) = 96.24, p < .001$ , respectively). While target inspection duration positively predicts success (Coeff. = 0.00110, SE = 0.00024, Wald’s  $Z = 4.53, p < .001$ ), distractor inspections negatively predict success (Coeff. =  $-0.00178$ , SE = 0.00027, Wald’s  $Z = -6.71, p < .001$ ).

Further, to assess the influence of gaze-based feedback back on listeners’ gaze behavior, we investigated whether the type of system used for generating REs did in fact influence inspection durations (as given in Table 1). We fitted models to target inspection duration and distractor inspection duration using system as predictor, for successful and unsuccessful scenes separately. Model reductions revealed a main effect of system (target:  $\chi^2(2) = 12.79, p < .01$ , distractor:  $\chi^2(2) = 47.10, p < .001$ ) on both inspection variables, but only in successful scenes. That is, with the eyetracking-based feedback system, participants inspected both the target and distractor buttons longer than with the other two systems. An average trial also lasted longer with this system than with the no-feedback system. In unsuccessful scenes no significant differences between inspection durations were observed.

Table 1: Mean inspection durations for target and distractor buttons and the total trial time in milliseconds, for successful and unsuccessful button presses separately. (ET = eyetracking-based system, MOV = movement-based system, NO = no-feedback system.) Differences to ET are significant at: \*\*\*  $p < 0.001$ , \*\*  $p < 0.01$ , \*  $p < 0.05$ , #  $p < 0.1$ .

System (# Trials)	Target	Distractor	Trial Total
Successful:			
<b>ET</b> (182)	2111.6	720.5	8096
<b>MOV</b> (258)	1493.8**	260.5***	7418
<b>NO</b> (237)	1492.0***	185.7***	6877**
Unsuccessful:			
<b>ET</b> (16)	752.1	3378.9	10892
<b>MOV</b> (37)	602.6	2113.1	10343
<b>NO</b> (47)	619.5	1891.7	9130

However, this is most likely due to the low amount of unsuccessful scenes.

Finally, we considered only cases in which feedback was indeed given in order to more precisely assess the influence of effective feedback (types) on participant inspections during reference resolution. Table 2 shows this data further subdivided into scenes with initially positive feedback and scenes with initially negative feedback (the eyetracking system is used as intercept for comparisons between both systems). This is to explore the effect of positive and confirming feedback given by each system and the possibly different effect of negative feedback which unspecifically re-directs the participant to other buttons. We observed that positive feedback of both systems leads to a similar increase of target and decrease of distractor inspections (cf. before and after columns in Table 2). However, eyetracking-based feedback was given earlier (Coeff. = 573.6, SE = 240.2,  $t = 2.39, p(\text{MCMC}) < 0.05$ ) and led to overall longer inspections of the target *and* distractor buttons relative to the trial duration. That is, participants spent significantly more time of a trial (34.1%) looking at potential target buttons than with movement-based feedback (25.5%, Coeff. =  $-0.0552$ , SE = 0.0178,  $t = -3.11, p(\text{mcmc}) < 0.01$ ). This effect was even larger with negative feedback where the difference in feedback onset was even greater (Coeff. = 1237.8, SE = 378.1,  $t = 3.27, p(\text{MCMC}) < 0.01$ ) and the relative button inspection time was also longer (Coeff. =  $-0.1818$ , SE = 0.0283,  $t = -6.43, p(\text{MCMC}) < 0.001$ ). Possibly because of this large difference in feedback onset, we also found (marginally) longer inspections to the buttons after feedback onset.

### Interaction Effectiveness

To evaluate our second hypothesis, namely that gaze-based feedback potentially sustains a more effective interaction than other or no feedback, we considered several indicators for in-

Table 2: Mean values for initial positive and negative feedback separately: inspection durations for target and distractor buttons (before and after feedback onset), feedback onset times, total trial durations, proportion of time spent fixating buttons during trials, and referential success rates. Differences to ET are significant at: \*\*\*  $p < 0.001$ , \*\*  $p < 0.01$ , \*  $p < 0.05$ , #  $p < 0.1$ .

	Target		Distractor		Feedback Onset	Trial Total	Button Fix. Proportion	Success
	Before	After	Before	After				
Positive Feedback:								
ET	513	1389	111	67	4115	6511	34.1	97.6
MOV	465	1123	196	30	4688*	7051*	25.5**	97.0
Negative Feedback:								
ET	109	2155	733	1596	3987	11888	39.5	84.0
MOV	120	926***	484#	802#	5225**	11319	20.1***	68.0*

teraction effectiveness. As a first measure, we looked at the frequency with which participants pressed the ‘H’ key to indicate their confusion. The overall average of ‘H’ keystrokes per game was 1.14 for the eyetracking generation system, 1.77 for the movement system was employed, and 2.26 for the no-feedback system. A model fitted to the key stroke distribution per system shows significant differences both between the eyetracking and the no-feedback system (Coeff. = 0.703, SE = 0.233, Wald’s  $Z = 3.012$ ,  $p < .01$ ) and between the eyetracking and the movement-based system (Coeff. = 0.475, SE = 0.241, Wald’s  $Z = 1.967$ ,  $p = .05$ ).

A second measure of interaction quality is the ratio of all REs that the participants resolved correctly. Mean success rates for trials with feedback only are further reported in the final column of Table 2. Logistic mixed-effects models revealed a significant difference in success rates (Coeff. =  $-0.918$ , SE = 0.461, Wald’s  $Z = -1.990$ ,  $p < .05$ ) for negative feedback while the success rates were similar for positive feedback. Additionally, total trial time is significantly shortened by positive (but not negative) eyetracking-based feedback (Coeff. = 713.7, SE = 311.4,  $t = 2.29$ ,  $p < .05$ ). Thus, when positive feedback was given, the eyetracking system had shorter trial times (along with earlier feedback), while having similar success rates as the movement system. Conversely, negative feedback led to similar trial times but with higher success rates by the eyetracking system.

## Discussion

Concerning our first hypothesis—that gaze reflects online referential understanding even in dynamic 3D environments—we find that participants indeed tend to rapidly fixate the object described by the system. Appropriate feedback by the eyetracking system, in turn, elicits longer inspection durations on potential targets, showing more focused, task-oriented listener attention.

This positive finding is further supported by the perfor-

mance of the eyetracking NLG system, which outperforms the no-feedback baseline on listener confusion and on RE success rate. If gaze was not a reliable indicator of RE interpretation, this system would frequently give misleading feedback and therefore perform worse. Together with the finding that positive gaze-based feedback leads to shorter trial times than positive movement-based feedback, while negative gaze-based feedback leads to better success rates than negative movement-based feedback, this confirms our second hypothesis. That is, the eyetracking system (positively) influences interaction effectiveness.

One observation from the games in the experiment is that listeners tend to rapidly look back and forth between different buttons when they are confused. However, it needs to be still worked out, how to interpret such signals more generally. A further issue is that all objects in the 3D world shift on the screen when the user turns or moves in the virtual environment. The user’s eyes will typically follow the object they are currently inspecting, but lag behind until the screen comes to a stop again. One topic for future work would be to remove such noise from the eyetracking signal.

Finally, the negative feedback our systems gave was very unspecific (“no, not that one”, even when there were other distractors) and given earlier and numerically also more frequently by the eyetracking system. This could explain the different effects of positive and negative feedback on inspection behavior and the time-accuracy trade-off for each system: Longer trial times but better success rates for negative gaze-based (compared to movement-based) feedback. We used negative feedback to keep the experimental situation more controlled but the performance of the feedback systems could possibly be improved by giving more specific feedback (“no, the BLUE button”). Another avenue for future research is to examine whether listener gaze could also be useful for other NLG or dialog tasks apart from RE generation.

## Conclusion

We reported on an experiment in which an NLG system used listener gaze to track the listener's understanding of REs and provide positive or negative feedback when needed. This shows that listener gaze provides consistent and useful feedback about the listener's interpretation process, and that NLG systems can be improved by tracking this interpretation process in real time.

These findings have consequences both for psycholinguistics and for computational linguistics. On the psycholinguistic side, they open the way for eyetracking experiments that are set in a more natural and dynamic, and importantly, truly interactive, environment than traditional Visual World experiments. On the computational side, they offer a testbed for interactive NLG and dialogue systems; even though eyetracking devices are not yet commonplace as computer peripherals they can still allow us to implement and test theories of how to effectively track the comprehension process of the user.

## Acknowledgments

The research reported of in this paper was partly supported by the "Multimodal Computing and Interaction" Cluster of Excellence at Saarland University. We thank Irena Dotcheva for help with data collection as well as Alexandre Denis and Christoph Clodo for software support.

## Abstract

We investigated whether concurrent exercise would affect statistical learning (SL). During familiarization, participants were exposed to pictures that appeared sequentially, in a seemingly random fashion. In fact, the pictures were grouped into triplets. In the surprise test phase, participants identified triplets they had seen during familiarization. There were three groups: a group that performed familiarization seated on an exercise bike (CON), a group that performed familiarization while engaged in resistance free cycling (RF), and a group that performed familiarization while cycling at 60% of maximum effort (EX). The CON group correctly identified 72% of triplets in the test phase. The RF and EX groups correctly identified 61% and 55%, respectively. Only the CON group demonstrated performance that was significantly greater than chance. The RF group only just failed to demonstrate significant SL. Thus, concurrent exercise can suppress SL. Work is underway to determine the mechanism by which such suppression occurs.

**Keywords:** Statistical learning; exercise; metabolic loading.

## Introduction

Statistical learning (SL) refers to the ability to detect statistical regularities implicitly and use this information to guide related behavior. Since the seminal research conducted by Saffran, Aslin and Newport (1996) demonstrating that 8-month old infants are capable of learning syllables embedded in an auditorily presented sequence, this area of research has increased rapidly. SL has now been shown to operate on sequential auditorily presented stimuli (Aslin, Saffran & Newport, 1998; Saffran et al., 1996; Saffran et al., 1997) and sequential visually presented stimuli (Arciuli & Simpson, 2011; Fiser & Aslin, 2001; Turk-Browne & Scholl, 2009). It has been shown to operate on adjacent dependencies (Lany & Gómez, 2008; Newport & Aslin, 2004) and non-adjacent dependencies (Creel, Newport & Aslin, 2004; Gebhart, Newport & Aslin, 2009). SL operates on spatial as well as temporal regularities (Turk-Browne & Scholl, 2009). Recently,

researchers have linked a capacity for SL with key cognitive activities such as spoken language proficiency (Conway, Karpicke & Pisoni, 2007; Evans, Saffran & Robe-Torres, 2009) and reading (Arciuli & Simpson, in press).

In short, SL is a robust process that develops early in life and is linked with a wide range of cognitive and perceptual activities. As such, it is important to understand whether SL can be enhanced or suppressed. While there have been a handful of studies investigating brain activity during SL (Turk-Browne, Scholl, Chun & Johnson, 2009; Turk-Browne, Scholl, Johnson & Chun, 2010), little is known about the physiological processes that underpin the capacity for SL. In this study, we sought to learn more about these physiological underpinnings by examining the effects of metabolic loading (i.e., exercise) on SL.

It is well known that exercise can affect brain activity and cognitive function; however, these effects can operate in different ways. Cognition appears to be enhanced over the longer term as a result of *ongoing* exercise (Hill, Storandt & Malley, 1993; Ratey & Loehr, 2011). Researchers studying the behaviors of animals have demonstrated exercise-related increases in brain-derived neurotrophic factors as well as increasing levels of neural plasticity of brain tissue (for a comprehensive review, see Hertzog, Kramer, Wilson & Lindenberger, 2009).

There is conflicting evidence related to cognition during *acute* exercise, with several researchers finding an enhancement (Chmura, Nazar, Kaciuba-Uscilko, 1994; Yagi, Coburn, Estes & Arruda, 1999), others finding suppression (Audiffren, Brisswalter, Brandet & Bosquet, 1998; Dietrich & Sparling, 2004), and some finding no difference (Davranche et al., 2006; Dietrich & Sparling, 2004; McMorris et al, 2003;). Yagi et al. (2006) suggested that neural activation in the brain is enhanced by exercise, whereas Dietrich and Sparling (2004) suggested that exercise causes function in the prefrontal lobe to become depressed during exercise; hence, they found suppression in some cognitive tests, but no effect in others.

Importantly, existing research has used tasks of explicit cognitive processing to assess performance. The task that has been most commonly utilized is the choice reaction time task (e.g. Audiffren et al., 1998; McMorris et al., 2003). However, a range of cognitive tasks have been used. For example, Dietrich and Sparling (2004) used a mathematics test (to test pre-frontal function) and a vocabulary test (which they suggested was a test of non pre-frontal function). We are not aware of research on the effects of exercise on implicit cognitive processing. Specifically, to date, no researchers have examined the impact of exercise on the brain's capacity to learn statistical regularities.

The primary aim of this experiment was to examine how metabolic loading affects concomitant SL. The exploratory nature of this research meant that directional hypotheses could not be easily formulated. It seemed likely that concomitant exercise might suppress SL in comparison with a non-exercising control group; however, it was important to control for the possibility that some kind of dual-task loading, rather than the exercise itself, might also affect SL. Thus, we included an additional condition where participants performed the SL task while engaging in resistance-free cycling.

## Methods

### Subjects

A total of 24 participants (age  $24 \pm 3.3$ ; 14 females,  $\dot{V}O_{2\max} = 47.8 (\pm 4.9) \text{ ml.kg}^{-1}.\text{min}^{-1}$ , no known neurological or physical problems) were recruited from the University of Sydney population. Ethics approval was granted by the institution.

### Statistical learning task

Participants undertook the embedded triplet learning task created by Arciuli and Simpson (2011; 2012). The task is comprised of a *familiarization* and then a surprise *test* phase, controlled by Eprime presentation software (v2.0, Psychology Software Tools, PA, U.S.A.). Stimuli were eighteen cartoon-like figures sourced from the website <http://www.clipartconnection.com/en/>. Six were used exclusively for instruction and practice. The remaining twelve appeared only in the familiarization and test phases. None resembled real-world animals, people or popular cartoon characters. The twelve stimuli used for the familiarization and test phases can be found in the Appendix sections of Arciuli and Simpson (2011; 2012). These twelve experimental stimuli were divided into four groups of three (four base triplets), hereafter referred to as *ABC*, *DEF*, *GHI* and *JKL* (see Appendix 1).

The familiarization phase consisted of a continuous stream of stimuli, with each cartoon character shown in isolation in the centre of the display against a white background. Each was visible for 800msec with an inter-stimulus-interval (ISI) of 200msec. Each base triplet was

selected for inclusion 24 times each (resulting in a total of 96 triplets). For six of these 24 instances, one of the cartoon characters was presented twice in a row in order to provide a cover task (detection of repeated characters). Detection of these repeated characters was the cover task during familiarization. This cover task ensured that participants paid attention to the familiarization stream because participants were required to watch the screen and press a button whenever they saw a repeated character. Repetitions were counterbalanced among and within each triplet. So, for example, the repetitions for base triplet *ABC* meant there were two occurrences of the sequence *AABC*, two occurrences of the sequence *ABBC*, and two occurrences of *ABCC* (along with 18 occurrences of the sequence *ABC*). This procedure meant that for each base triplet the strict triplet structure was violated (e.g., *ABBC*) on two of twenty-four occasions. The repetition was done in this way (all three items in a triplet used for repetition) to ensure that the repetitions did not inadvertently cue the participants to the existence of the triplet boundaries. The familiarization phase consisted of 312 individual characters, with each of the 12 characters appearing 26 times each. The order of the triplets within the familiarization phase was randomized. The sole restriction was that the same base triplet could not appear consecutively (e.g., *ABCABC*).

In both of the previous studies reported by Arciuli and Simpson the familiarization phase was followed immediately by the surprise test phase. However, in the present study, the surprise test phase was given to participants after a time delay of 5 minutes. This was necessary because participants required time to move from the bike to a desk where they performed the surprise test phase.

The surprise test phase consisted of 64 trials with each trial containing two triplets: one of the four base triplets and one of four impossible triplets. These impossible triplets never appeared in the familiarization stream and each was created by taking one character from three different base triplets (e.g., *AEI*, *DHL*, *GKC* and *JBF*). The stimuli in the test trials were presented individually with the same duration and ISI as was used in the familiarization stream. A 1,000 msec gap separated the two triplets in each test trial. After all six characters had been presented participants were prompted to identify which of the two triplets had appeared previously (during familiarization). This procedure constituted a 2-alternative forced-choice task (2AFC). The presentation order of base triplets and impossible triplets was counterbalanced. Across the 64 test trials each base triplet and each impossible triplet was seen 16 times, and each individual character was seen 32 times. Participants received a different random order for the test trials.

### Procedure

Participants performed a  $\dot{V}O_{2\max}$  test on a Lode Cycle ergometer. The  $\dot{V}O_{2\max}$  test required participants to cycle until fatigued. They started at a low intensity and it was

increased every minute until either the participant chose to stop or the investigator ended the test (for safety or diagnostic reasons). Heart rate was collected with a heart rate monitor (Polar) and  $\dot{V}O_2$  were collected throughout the test using an electronic metabolic cart (MedGraphics) (Thompson, Gordon & Pescatello, 2009).

Participants were randomly allocated into 3 groups, with 8 participants in each; a control group (CON) who performed *familiarization* while seated, a resistance free group (RF) who performed familiarization while free pedaling on the cycle, and the exercise group (EX), who performed the familiarization whilst cycling at their own 60%  $\dot{V}O_{2\max}$  to ensure participants in this group were exercising at equivalent levels of intensity (i.e., relative to their personal  $\dot{V}O_{2\max}$ ). This power output was chosen because it is a commonly used power output in studies of exercise and conscious cognition (Arcelin & Brisswalter, 1999; Pesce, Capranica, Tessitore & Figura, 2002; Pontifex & Hillman, 2006).

All participants underwent the familiarization phase while seated on the cycle so that all had the same level of postural discomfort. The Lode Cycle ergometer had the function of allowing a power output to be set which would be automatically maintained even when cadence changed. This was particularly important for the EX as it ensured participants could maintain attention on the SL task without having to focus on maintaining a certain cadence. For the cover task during familiarization, participants were asked to respond by pressing a button that was placed on the handlebars. This button was connected to an E-prime response box which was not fixed to the handle bar, so the participant could choose their preferred hand and move the button into a position for comfort. Each participant in the EX group cycled at their respective 60%  $\dot{V}O_{2\max}$  values for the duration of the familiarization phase only. These participants cycled for 5 minutes prior to the commencement of the familiarization, during which time metabolic data was collected. Metabolic recording equipment was removed before beginning the familiarization phase so as to not discomfort the participants. Instead, continuous heart rate monitoring was used during familiarization. Upon completion of the familiarization phase, all groups were given a 5 minute rest period before the testing phase. For all participants the surprise *test* phase was performed at a desk while seated on a chair.

### Data Analysis

A participant was considered to have learnt about the embedded regularities in the familiarization phase if they identified more than 50% of the triplets (above chance level). Thus, one-sample t-tests were used to determine whether there was significant SL for each group. This was the same data analysis technique used by Arciuli and Simpson (2011; 2012). Overall averages were then compared across the three groups using a one-way ANOVA

and follow-up t-tests. An  $\alpha$  level of .05 was set for the experiment.

## Results

First, detection of repeated aliens during familiarization (the cover task) was examined. These data are reported in Table 1. Participants appeared to be paying similar, high levels of attention during familiarization across each of the three experimental conditions. A one-way ANOVA was conducted on the accuracy of detecting repeated characters during the *familiarization phase*. No significant difference was found ( $F_{(2,21)} < 1$ ), across the three groups.

Table 1: Accuracy of responding during *Familiarization* ( $\pm$ SD).

Group	Number of repeated characters identified
CON	97.4% ( $\pm$ 2.2%)
RF	98.4% ( $\pm$ 3.1%)
EX	99.5% ( $\pm$ 1.5%)

The overall degree of SL for each group during the surprise test phase is displayed in Table 2. One-sample t-tests revealed that only the CON group showed significant SL by demonstrating a level of performance that was significantly greater than chance (i.e., greater than 50%),  $t_{(7)} = 4.175$ ,  $p < .05$ . The RF group just failed to demonstrate statistical learning,  $t_{(7)} = 2.311$ ,  $p = .054$  whereas the EX group did not demonstrate statistical learning,  $t_{(7)} = 1.050$ ,  $p = .329$ .

Table 2: Degree of SL during *Test* phase ( $\pm$ SD).

Group	Percentage triplets identified
CON	72% ( $\pm$ 14%)
RF	61% ( $\pm$ 14%)
EX	55% ( $\pm$ 13%)

A one-way ANOVA demonstrated that there was no significant difference amongst these means  $F_{(2,21)} = 3.011$ ,  $p = .071$ ; however, given the marginal significance, post-hoc t-tests were conducted. Results demonstrated that the only significant difference was between the CON and EX groups,  $t_{(14)} = 2.337$  ( $p = .035$ ).

## Discussion

The results reported here provide several insights into statistical learning (SL). First, significant SL was observed in the CON group. This finding adds to a growing body of evidence indicating that humans can implicitly learn regularities embedded in input, even while undertaking a cover task. A novel finding was that metabolic loading appears to impact upon participants' ability to detect these statistical regularities. This effect occurs even during a relatively short bout of exercise. The RF group showed a higher degree of SL compared with the EX group but less

learning compared with the CON group. SL in the RF group just failed to reach significance, potentially due to low statistical power. The latter finding may suggest a graded pattern of performance whereby the mental effort associated with dual-task requirements (cycling resistance-free while also performing the SL task) affects SL. We interpret this data to demonstrate that even without any metabolic interference on the brain, the task of simply moving the legs, which in itself is a seemingly automatic task, appears to reduce the level of SL. This reduction appears to be amplified when metabolic loading is introduced.

Given the uncertainty surrounding the mechanisms underpinning explicit cognitive function during acute exercise, and given the possible differences between explicit and implicit cognition, it is difficult to know what caused the reduction in SL we observed in our EX group.

As exercise only lasted for around 15 minutes, at what is classed 'moderate intensity', and given that all participants had eaten and were hydrated, it is highly unlikely that metabolic factors such as dehydration or low blood glucose would have contributed to the results. It seems more likely that some form of psychological or neurological interference induced by exercise may have suppressed SL.

From a psychological standpoint, a similar phenomenon was demonstrated by Audiffren et al. (2008) where reaction time significantly increased during exercise compared to rest. This phenomenon has since been referred to as resource allocation competition. Pontifex and Hillman (2007) demonstrated that EEG activation is reduced when cycling, reflecting an 'inefficiency' of resource allocation. Specifically, they demonstrated reduced N1 amplitude, which has been shown to be part of the visual discrimination resource component (Vogel & Luck, 2000). Turk-Browne et al. (2009) conducted an fMRI study where participants performed a similar statistical visual learning task to the one presented here and found that activation in the occipital regions was increased (along with significant SL). If cycling suppresses some function in the visual cortex, sensitivity to visually presented statistical regularities may be affected. We aim to conduct the same experiment using an auditorily presented version of this SL task to further investigate this hypothesis.

There is another possibility, related to a more general effect of acute exercise on the brain. A review by Williamson, Fadel and Mitchell (2006) highlighted that there is a high neuroelectrical resource demand on the brain to maintain central control over metabolic reactions, such as vascular control for blood pressure, despite these processes being autonomic. Pontifex and Hillman (2007) suggested that additional neuroelectric demands further increase the load associated with dual tasking within the brain. Given that the RF group had the added demand of the resistance free cycling, and the EX group had the even greater demand of cycling plus central metabolic control, this may help to explain why there appeared to a graded pattern of results.

These findings open up many avenues for further research and as such we are currently undertaking several additional studies. To investigate whether exercise causes changes in both implicit and explicit tasks measures of cognitive performance, we will use the same exercise paradigm whilst participants undertake an explicit working memory task, such as digit span. We are also planning to compare the effects of exercise on implicit versus explicit versions of the embedded triplet task. In addition, we are exploring the effect of different exercise intensities so that we can determine at what metabolic level impairments in begin to SL occur. As mentioned, we will also examine whether exercise affects SL similarly regardless of whether stimuli are presented visually or auditorily. It is also interesting to ponder what would happen if we were to reverse the timing of the exercise in order to study how metabolic loading during the *test* phase affects answers after completing the familiarization phase at rest.

## Abstract

We present a large-scale cognitive neural model called Spaun (Semantic Pointer Architecture: Unified Network), and show simulation results on 6 tasks (digit recognition, tracing from memory, serial working memory, question answering, addition by counting, and symbolic pattern completion). The model consists of 2.3 million spiking neurons whose neural properties, organization, and connectivity match that of the mammalian brain. Input consists of images of handwritten and typed numbers and symbols, and output is the motion of a 2 degree-of-freedom arm that writes the model's responses. Tasks can be presented in any order, with no "rewiring" of the brain for each task. Instead, the model is capable of internal cognitive control (via the basal ganglia), selectively routing information throughout the brain and recruiting different cortical components as needed for each task.

**Keywords:** Neural engineering; cognitive architecture; spiking neurons; cognitive control; whole-brain systems

## Introduction

In a forthcoming book, Eliasmith (2012) details a neural architecture for biological cognition called the *semantic pointer architecture* (SPA). This architecture, based on the Neural Engineering Framework (Eliasmith & Anderson, 2003), uses groups of spiking neurons to form distributed representations of high-dimensional vectors, which can in turn encode symbol-like tree structures. Synaptic connections between groups of neurons compute particular functions on those vectors, allowing high-level cognitive algorithms to be implemented in detailed spiking neuron models.

In this paper, we present an overview of the Semantic Pointer Architecture: Unified Network (Spaun) model and discuss its behaviour on six different tasks. We demonstrate that this biologically plausible spiking neuron model has the following features:

**Task Flexibility:** No changes are made to the model between tasks. Visual input indicates which task to do next.

**Motor Plans:** Model output provides a motor plan for a simple 2-joint arm, giving hand-written digits as responses.

**Visual Memory:** Even after an input has been recognized and classified as a particular symbol, details of the original image can still be recovered and used.

**Compositionality:** Multiple items can be represented and reliably bound together, allowing for the creation and manipulation of symbol-tree-like structures.

**Symbolic Induction:** Language-like patterns in visual input can be discovered after only a few presentations, and used to guide subsequent responses.

Input to the model consists of idealized and hand-written digits and symbols (Figure 1a). These images are given as a 28x28 grid of pixels. This input domain has the advantage of including significantly variable, real-world input, while also providing a reasonably limited semantics that the model must reason about. Output from the model consists of the motion of a 2-degree-of-freedom arm. The neural model generates a sequence of target locations which directly drive the controller for the arm. This provides the model with its own handwriting output (Figure 1b).

### a) Input

### b) Output

Figure 1: Example visual input and arm-movement output from Spaun. Input digits are from the MNIST database, and input symbols are used to inform the model of details of the current task. The model produces output by controlling a 2-joint arm, and variation in the internal representations produces the variation in its output hand-writing.

We can think of Spaun as having a single, fixed eye and a single 2-joint arm. The eye does not move, but instead the experimenter changes the image falling on it by showing different inputs over time, with each input shown for 150ms, followed by 150ms of blank background. To begin a specific task, Spaun is shown the letter "A" followed by a number between zero and seven. The subsequent input is then interpreted by the model in the context of the specified task and processed accordingly, resulting in arm movements that provide Spaun's response. All internal processing is performed using spiking neurons, with neural properties and connectivity consistent with the mammalian brain.

## Neural Engineering Framework

While complete details on the construction of Spaun are available elsewhere (Eliasmith, 2012; <<http://nengo.ca>>), it is based on our continuing work on the Neural Engineering Framework (NEF; Eliasmith & Anderson, 2003). The NEF is a generic method for converting high-level algorithms into realistic spiking neuron models.

Two basic principles of the NEF are that a) groups of neurons form distributed representations of vectors, and b) connections between groups of neurons specify a computation to be performed on those vectors. Importantly, the NEF provides a method for analytically solving for the synaptic connection weights that will efficiently compute any given function.

While the NEF supports any type of neural model, for Spaun we use Leaky Integrate-and-Fire (LIF) neurons. The various properties of the LIF model (refractory period, capacitance, resistance, post-synaptic time constant, etc.) are set to be consistent with known neurophysiological results for the various brain regions modelled.

To represent a vector using a group of neurons, the NEF generalizes the idea of preferred direction vectors. Each neuron in a group has a randomly chosen vector  $\mathbf{e}$  for which it will fire most strongly. In particular, the amount of current  $J$  flowing into the neuron is the dot product of the preferred vector  $\mathbf{e}$  with the represented value  $\mathbf{x}$ , times the neuron's gain  $\alpha$ , plus the background current  $J_{bias}$  (Eq. 1).

While Eq. 1 lets us convert  $\mathbf{x}$  into neural activity, we can also do the opposite by computing  $\mathbf{d}$  via Eq. 2. This produces a set of linear decoding weights that can be multiplied by the activity of each neuron in the group. The result is the optimal least-squares linear estimate of  $\mathbf{x}$ . Thus, given a spiking pattern we can estimate what value is currently represented by those neurons.

Most crucially, we can use  $\mathbf{d}$  to calculate the synaptic connection weights that will compute particular operations. To compute a linear operation where one group of neurons represents  $\mathbf{x}$  and a second group should represent  $\mathbf{M}\mathbf{x}$ , where  $\mathbf{M}$  is an arbitrary matrix, we set the connection weights between neuron  $i$  in the first group and neuron  $j$  in the second group to  $\omega_{ij}$  as per Eq. 3. For non-linear operations, we need to compute a new set of  $\mathbf{d}$  values via Eq. 4.

$$J = \alpha \mathbf{e} \cdot \mathbf{x} + J_{bias} \quad (1)$$

$$\mathbf{d} = \Gamma^{-1} \mathbf{Y} \quad \Gamma_{ij} = \int a_i a_j dx \quad \mathbf{Y}_j = \int a_j \mathbf{x} dx \quad (2)$$

$$\omega_{ij} = \alpha_j \mathbf{e}_j \cdot \mathbf{M} \mathbf{d}_i \quad (3)$$

$$\mathbf{d}^{f(\mathbf{x})} = \Gamma^{-1} \mathbf{Y} \quad \Gamma_{ij} = \int a_i a_j dx \quad \mathbf{Y}_j = \int a_j f(\mathbf{x}) dx \quad (4)$$

This approach allows us to convert a high-level algorithm written in terms of vectors and computations on those vectors into a detailed spiking neuron model. Importantly, this approach works for recurrent connections as well. For example, we can implement memory by connecting a group of neurons back to itself with connections weights determined by Eq. 3 where  $\mathbf{M}$  is the identity matrix. If that group of neurons is currently representing  $\mathbf{x}$ , then given no external input it will drive itself to keep representing  $\mathbf{x}$ , thus storing information over time.

## Spaun

The Semantic Pointer Architecture: Unified Network model consists of multiple modules, depicted in Figure 2. These modules are considered to be cortical and subcortical areas that implement different operations. All components consist of LIF neurons connected via synaptic weights (Eq. 3), but each area computes a different set of functions.

To perform a particular task, information must be selectively routed between cortical areas, as each task uses a different subset of the components. This is achieved through an action selection system modelled after the mammalian basal ganglia and thalamus. We have previously shown that this model matches the anatomy and timing behaviour of the basal ganglia (Stewart, Choo, & Eliasmith, 2010) and provides enough flexibility to perform planning and problem solving in our model of the Tower of Hanoi task (Stewart & Eliasmith, 2011).

The model presented here is the first use of this neural action selection system with multiple tasks and detailed perceptual-motor systems. The action selection system is a neural production system, allowing us to write rules of the form “if cortical area  $X_1$  matches the vector  $\mathbf{a}$  and cortical area  $X_2$  matches the vector  $\mathbf{b}$ , then send vector  $\mathbf{c}$  to area  $X_3$  and route the vector from area  $X_4$  to area  $X_5$ ”. These rules are implemented by converting the rules into functions, applying Eq. 3, and using the resulting synaptic connection weights between the cortex, basal ganglia, and thalamus.

Importantly, the set of rules is fixed across all the tasks, giving a single, unified model. All input to Spaun is through its perceptual system, and all behavioral output from its motor system. The representational repertoire, background knowledge, cognitive mechanisms, neural mechanisms, etc. remain untouched while the system performs any of the tasks in any order.

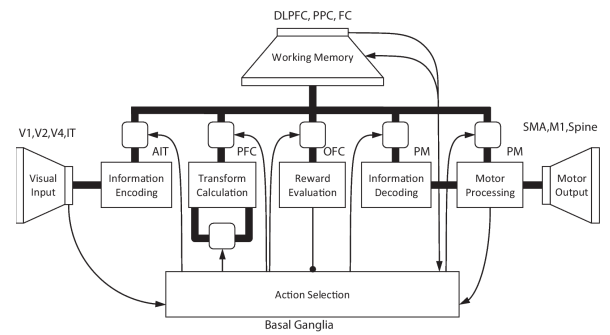

Figure 2: The Spaun architecture

The Spaun model (Figure 2) consists of three hierarchies, an action selection mechanism, and five subsystems. The first hierarchy is the visual system, which compresses an input image into a high-level abstract representation of that input. We adapt Hinton's (2010) Deep Belief Network to use LIF spiking neurons (via the NEF) and use it to compress a 28x28 image into a 50-dimensional vector we refer to as a *semantic pointer*: it is semantic because the high-level representation maintains similarity relationships from the image space; and it is a pointer because, as we will

see, the system can recover the original information from the compressed form. Similarly, Spaun includes a motor hierarchy which dereferences an output semantic pointer representing a number into a motor plan to drive a two degree-of-freedom arm (DeWolf, 2010). A third internal hierarchy (discussed in more detail below in the *serial working memory* section) forms a working memory capable of binding and unbinding arbitrary semantic pointers, providing the compositionality that is crucial for complex cognition. The working memory component also provides stable representations of intermediate task states, task subgoals, and context. Anatomically, these functions cover large portions of prefrontal and parietal cortex.

The five subsystems, from left to right in Figure 2, are used to: 1) map the visual hierarchy output to a conceptual representation as needed (**information encoding**); 2) extract relations between input elements (**transformation calculation**); 3) evaluate the reward associated with the input (**reward evaluation**); 4) map output items to a motor semantic pointer (**information decoding**); and 5) control motor timing (**motor processing**). Several of the subsystems and hierarchies consist of multiple components needed to perform the identified functions. For instance, the working memory subsystem includes eight distinct memory systems, each of which can store semantic pointers. Overall, the model uses 2,341,212 spiking leaky integrate-and-fire (LIF) neurons. Additional details necessary to fully reimplement the model, and a downloadable version of the model can be found at <<http://nengo.ca>>.

## Digit recognition

The simplest task for Spaun is digit recognition. We present the input sequence **A1[X?**, where **X** is a randomly chosen hand-written digit from the MNIST database. Each symbol is shown for 150ms, with 150ms between symbols. To perform this task, Spaun includes synaptic connections in the action selection system to implement the following algorithm:

- If visual input matches **A**, store **?** in the *state* area of the working memory. (This tells the system it is about to start a new task.)
- If **?** matches *state*, route the output of the visual encoding system to the state area of working memory. (This identifies and remembers which task is to be performed.)
- If the visual input is **1**, activate the routing between the information encoding system and the general-purpose working memory. (This tells Spaun to store whatever digits appear next.)
- If the visual input is **?** and *state* is 1, route the pattern in working memory to the motor system.

Responses from this model for different inputs **X** are shown in Figure 3. Recognition accuracy is 94%, which compares well to humans on this task (~98%; Chaaban and Scheessele, 2007). The model is thus capable of correctly categorizing over a wide range of input variability.

Figure 3: Input-output pairs for 20 different inputs. Each input (on the left) is correctly recognized by the model, which produces the output (on the right) via motor control.

## Tracing from memory

While the previous task showed that the model can treat very different stimuli as tokens of the same type, we also want the model to be able to be sensitive to the variations within a type. To demonstrate this ability, we ask the model to do digit recognition, but to draw its response *in the same style as the original input*.

This is implemented by defining, for each digit, five different motor control sequences that draw five visually distinct versions of that digit. If the input pattern is **X** and the motor sequence is **Y**, then we can define the tracing function  $f(X)=Y$ . We build a neural connection between the vision system and the motor system via Eq. 3, and allow it to be selectively controlled via the action selection in the basal ganglia. If we now present new input  $X_{\text{new}}$  that was not among the 5 original inputs, the resulting  $Y_{\text{new}}$  value will be the model's linear extrapolation of what motor sequence would be appropriate for that novel input pattern.

To use this system, we use the sequence **A0[X?** and add a single rule to the basal ganglia action selection system:

- If the visual input is **?** and *state* is 0, route the pattern in working memory to the motor system via the tracing function.

This rule, combined with the previous ones for digit recognition, result in the behaviour shown in Figure 4. Note that it is capable of drawing 2's both with and without loops, 6's where the loops join in different locations, and generally following the slanting of the digits. It is not a perfect reconstruction of the original input, but it does demonstrate that while the internal neural representation of all 2's are very similar (as shown by Spaun's success in the previous task), there are still variations in the representation due to different visual features, and those variations can be used to successfully drive behaviour.

Figure 4: Input-output pairs for tracing from memory. The inputs (on the left) are recognized by the model, and then recreated from memory based on representational similarity to five previously known example pairs for each digit.

## Serial Working Memory

For this task, Spaun is given a list of numbers and must repeat them back, in order. The algorithm used here is based on our previous work (Choo & Eliasmith, 2010) on a special-purpose serial memory model.

The NEF gives us a method for representing vectors via spiking neurons. The Semantic Pointer Architecture approach maps symbols onto particular vectors, so one vector might represent ONE while another vector represents TWO. Each vector, when represented, would produce a distinct firing pattern in that population of neurons.

To represent an ordered sequence, we cannot simply add the vectors together, since we could not distinguish ONE+TWO from TWO+ONE. Instead, we can perform *binding* by creating a new vector from two different vectors. We start by introducing new vectors for different positions: P1, P2, P3, etc. We then store the sequence ONE, TWO by representing the vector  $\text{ONE} \otimes \text{P1} + \text{TWO} \otimes \text{P2}$ . Many mathematical operations can be used for  $\otimes$ ; we choose circular convolution since it is easy to accurately implement in spiking neurons using the NEF. This approach to representation using vectors is generally known as a Vector Symbolic Architecture (Gayler, 2003), and has been shown to scale well to adult-level vocabulary and grammar.

The action selection rules for this task are based on the previous one, with the addition of the **]** marker to indicate the end of a sequence. Figure 5 shows not only the input and output of the model, but also the ongoing spiking behaviour in various areas during the execution of the task.

Figure 5 also shows a method for interpreting what is currently being represented in a particular cortical area. The second working memory line shows how similar the current pattern in the working memory is to various different ideal patterns<sup>1</sup>. In particular, after the presentation of the final digit ( $t=2$  seconds), the value being represented is similar to  $\text{FOUR} \otimes \text{P1}$ ,  $\text{THREE} \otimes \text{P2}$ ,  $\text{TWO} \otimes \text{P3}$ , and  $\text{SIX} \otimes \text{P4}$ . In other words, this one group of neurons is capable of storing any arbitrary sequence of digits. As the sequence gets longer, accuracy decreases, and both primacy and recency effects are seen (Choo & Eliasmith, 2010).

## Question Answering

In addition to simply repeating a sequence, Spaun is capable of answering questions about the sequence. In particular, it can identify which digit is at a given location, and it can identify the location of a given digit.

This is accomplished by adjusting the transformation which takes the contents of working memory and routes it to the motor area. Given the vector  $S = \text{FIVE} \otimes \text{P1} + \text{SIX} \otimes \text{P2}$ , we can find the digit in position 1 by computing  $S \otimes \text{P1}$ , where  $\otimes$  is circular correlation, since  $S \otimes \text{P1} \approx \text{FIVE}$ . The accuracy of this approximation is dependent on the length of the sequence, the number of neurons used, and the dimensionality of the vectors.

<sup>1</sup> Formally, this is the dot product between the ideal vector for that symbol and the decoded value found using Eq. 2.

To implement this task, the sequence is presented in the same manner as the serial working memory task. We then present the symbol P for a query based on position, or the symbol K for a query based on the kind of digit to look for in the list. The action selection rules route the appropriate transformation vector to the working memory area, providing the required information to the motor system.

Figure 5: Serial recall of the sequence 4,3,2,6. Infero-temporal cortex (IT) holds the compressed representation of the visual input. Striatum (Str) activity determines how good a match each rule is to the current state. Globus pallidus internus (GPi) performs action selection, inhibiting all but the current best-matching rule. Frontal cortex (FCtx) holds task information, and working memory (WM) stores the list as a single vector:

$$\text{FOUR} \otimes \text{P1} + \text{THREE} \otimes \text{P2} + \text{TWO} \otimes \text{P3} + \text{SIX} \otimes \text{P4}.$$

Figure 6: Answering questions about a list. The first case presents the list 9,4,7,3,0 and asks what is position 5. The model correctly answers 0. The second case presents the list 8,6,9,4,7 asks where the 6 can be found. The model correctly answers that it is in location 2.

## Addition by Counting

For the fifth task, we show that Spaun is capable of performing sequences of internal actions, where there are a multiple steps to go through before producing a final output. This is demonstrated here by performing mental addition via counting. That is, to compute  $4+3$ , the model must go through the steps of counting 4, 5, 6, and 7, entirely internally, and then finally producing the output 7.

Spaun achieves this by having multiple, general-purpose working memories. We use the first of these (WM1; the same neurons that stored the list and the recognized numbers in the previous task) to store the current value. A second group of neurons (WM2) stores the number of counting steps that are needed, and a third group (WM3) stores how many steps have been made.

Figure 7 shows Spaun performing this task over time for the specific case of  $4+3$ . Importantly, the model produces accurate results for any single-digit addition. Furthermore, Spaun exhibits the expected linear relationship between subvocal counting and response times, as seen in human subjects (Cordes et al., 2001). That is, each counting step requires  $419 \pm 10$ ms, which is within the empirical range of  $344 \pm 135$ ms for subvocal counting (Landauer, 1962).

Successful counting demonstrates that flexible action selection is effectively incorporated into Spaun. It also shows that the model has an understanding of order relations over numbers, and can exploit that knowledge to produce appropriate responses.

Figure 7: Adding  $4+3$  by mentally counting 4, 5, 6, 7 (WM1). WM2 keeps track of the fact that it should stop counting when it reaches the third step, and WM3 keeps track of what step it is at (0, 1, 2, 3).

## Pattern Completion

Finally, we show that Spaun is capable of quickly identifying and responding to patterns in its input via inductive learning. This specifically targets a type of task that has long been held to be problematic for connectionist approaches: the ability to rapidly create and bind symbolic variables (e.g. Marcus, 2001; Jackendoff, 2002). The following example (from Hadley, 2009) shows a pattern completion task that humans are readily able to solve given only a few items. They are told that if they hear “biffle biffle rose zarple”, the correct response is “rose zarple”.

After a three such examples, they must generalize to a new case:

### Training Set

- Input: *Biffle biffle rose zarple*. Output: *rose zarple*.
- Input: *Biffle biffle frog zarple*. Output: *frog zarple*.
- Input: *Biffle biffle dog zarple*. Output: *dog zarple*.

### Test Case

- Input: *Biffle biffle quoggie zarple*. Output: ?

Hadley suggests that this task requires rapid variable creation because the second last item in the list can take on any form, but human cognizers can nevertheless identify the overall syntactic structure and identify “quoggie zarple” as the appropriate response. So it seems that a variable has been created, which can receive any particular content, and that will not disrupt generalization performance.

Figure 8 shows Spaun’s behavior on a stimulus sequence with the same structure as that proposed by Hadley. Importantly, this is done extremely quickly ( $\sim 2$  seconds, consistent with human performance), and *without changing neural connection weights*. In other words, there is no learning rule; Spaun is able to learn to complete this pattern without any neural rewiring.

To achieve this result, we use a simplification of our earlier work with a neural model capable of performing Raven’s Matrices (Rasmussen & Eliasmith, 2011). We store the representation of the first list in one area of working memory (WM1) and a representation of the second list in another area (WM2). Since we are using the semantic pointer method of representing lists, these lists are encoded as two high-dimensional vectors ( $V1$  and  $V2$ ). We can then compute the transformation  $T$  which takes the first vector ( $V2=V1 \otimes T$ , so  $T=V2 \oslash V1$ ). We implement this in Spaun by adding a cortical area which computes the transformation between two working memory components, and adding rules to the basal ganglia to route this information appropriately when performing this task. As more examples are given, the value  $T$  is built up as the average over all the examples, improving accuracy.

Figure 8: Pattern completion solving Hadley’ rapid variable creation problem. The input consists of pairs of lists. After seeing  $0094 \rightarrow 94$ ,  $0014 \rightarrow 14$ , and  $0024 \rightarrow 24$ , it correctly concludes that given  $0074$ , it can complete the pattern by outputting  $74$ .

## Discussion

The basic components of the model presented here are not new; we have previously published spiking neuron models capable of exhibiting list memory (Choo & Eliasmith, 2010), pattern completion (Rasmussen & Eliasmith, 2011), action selection (Stewart, Choo, & Eliasmith, 2010), and sequential reasoning (Stewart & Eliasmith, 2011). However, the work presented here is the first demonstration of these capabilities in a single, unified model. There are no adjustments made to the model between tasks, and indeed the model can seamlessly go from one task to the next.

Furthermore, we feel that an important feature of this cognitive model is that it includes the entire system: visual perception, cognition, and motor action. The neural representations used throughout the model are the same, as are the underlying computational principles, and methods of mapping to neural spikes. As a result, this single model has neuron responses in visual areas that match known visual responses, as well as neuron responses and circuitry in basal ganglia that match known responses and anatomical properties of basal ganglia, as well as behaviorally accurate working memory limitations, as well as the ability to perform human like induction, and so on. Spaun is thus both physically and conceptually unified.

It should be noted that the current set of tasks Spaun can perform are in a constrained semantic space – that of lists of numbers. However, the basic principle of using high-dimensional vectors that can be bound together (i.e. semantic pointers) generalizes to more complex domains.

Furthermore, the model's architecture is not tightly tied to the set of tasks being implemented. That is, rather than having particular components to perform each task, the components presented here provide generic cognitive capacities, and any given task can recruit these components as needed. For example, the Pattern Completion task requires use of a component that can find the transformation that relates the information in two different areas of working memory. This cortical component would also be useful for performing other tasks, such as a Raven's Matrix task (Rasmussen & Eliasmith, 2011).

For the model presented here, all synaptic connection weights between neurons are analytically derived, rather than having them be learned, as in traditional neural network models. While this demonstrates that our model is capable of learning without connection weight changes (as in the pattern completion task), it leaves open the question of how these connections are learned in the real brain. While we do not have a complete developmental story for the various cortical components, we have developed a dopamine-based reinforcement learning system (Stewart, Bekolay, & Eliasmith, 2012) that has been integrated with Spaun in an n-arm bandit task, but the results are not presented here due to space limitations. This system allows Spaun to learn the connections between the cortical components and the basal ganglia, allowing the model to learn to recruit different components for different tasks.

Spaun presents a detailed spiking neural model capable of visual recognition, cognitive control, working memory, symbolic manipulation, and producing hand-written motor outputs. This sort of model is required for connecting high-level cognitive theory and behavioural data to the biological constraints available from neuroscience.

# Perception of Randomness: Subjective Probability of Alternation

Yanlong Sun (Yanlong.Sun@uth.tmc.edu)

## Abstract

We present a statistical account for the subjective probability of alternation in people's perception of randomness. By examining the *spatio-temporal distances* between pattern events, specifically, the *frequency* and *delay* of binary patterns in a Markov chain, we obtain some normative measures to calibrate people's expectation of randomness. We suggest that it can be fruitful to study subjective randomness in the context of human object representation and perception of time and space.

**Keywords:** subjective randomness; probability of alternation; waiting time; perception of time and space.

## Introduction

Much is known that subjective randomness—people's intuitive judgment on how an event or a series of events appears random—systematically deviates from the stochastic randomness described by normative probability theories. Among many statistics describing such discrepancy, the *probability of alternation* ( $p_A$ ) has been the most extensively studied in psychology literature (e.g., Budescu, 1987; Falk & Konold, 1997; Kahneman & Tversky, 1972; Kareev, 1992; Lopes & Oden, 1987; Nickerson, 2002; Sanderson, 2011). In a binary sequence generated by independent and stationary Bernoulli trials (for example, repeatedly tossing a fair coin),  $p_A$  can be defined as the probability that the outcome of any single event is different from the preceding one. If the process is truly random (e.g., the same fair coin is being tossed independently), the probability of alternation has the expected value  $p_A = .5$ . However, reviewed by Falk and Konold (1997, Table 1, p.304), in almost all of the studies with the tasks of recognizing or generating randomness, the modal *subjective probability of alternation* was approximately .60. That is, people tend to perceive sequences with  $p_A \approx .60$  as the most random and generate random sequences with  $p_A \approx .60$ .

One particular reason that the probability of alternation  $p_A$  receives a great deal of attention in the studies on subjective randomness is that it is highly correlated with many other sequential statistics, such as the runs test and serial correlation. Together, these statistics cover a variety of empirical phenomena, for example, the perception of streaks in basketball shooting (Burns, 2004; Gilovich, Vallone, & Tversky, 1985; Sun & Wang, 2010b), the recency effect (Ayton & Fischer, 2004), the working memory capacity and detection of covariances in short sequences (Kareev, 1992), and the encoding of subjective complexity (Falk & Konold, 1997; Falk, Falk, & Ayton, 2009). (For a recent review, see Oskarsson, Van Boven, McClelland, & Hastie, 2009).

To explain the biased probability of alternation in subjective randomness, Falk and Konold (1997) developed a “difficulty predictor” (DP) as a measure of “subjective complexity”.

Based on the concept that random sequences are irreducibly complex (i.e., algorithmic complexity, Kolmogorov, 1965), Falk and Konold propose that people's sense of randomness is not based on the deviations from the equiprobability of patterns of the same length (i.e., “ $n$ -grams”), rather, it may be based on the difficulty level when people attempt to memorize or copy a sequence by its minimal description. Given any binary sequence, the difficulty predictor is defined by adding twice the number of alternating runs to the number of pure runs. For example, the following sequence is partitioned into 5 segments, where pure runs (streaks) are underlined and alternating runs are double underlined:

H H T H T H T H T H T T T H H T H T H T H

Thus, the DP score for this particular sequence is  $1 + 2 + 1 + 1 + 2 = 7$ . By this measure, a perfect streak would be perceived as the most nonrandom because of its lowest DP score (i.e., the easiest to remember). In contrast, sequences with more alternating runs—hence greater  $p_A$ —are more difficult to encode therefore tend to be perceived as more random.

Overall, it has been demonstrated that DP correlates remarkably well with participants' ratings of randomness, memorization time, assessed difficulty of memorization, and copying difficulty. And, the mean ratings of randomness show the classic preference for over-alternating sequences (Falk et al., 2009; Falk & Konold, 1997). However, Griffiths and Tenenbaum (2003) point out that DP remains a subjective measure since its objective counterpart, algorithmic complexity, is not computable. Instead, Griffiths and colleagues propose to use Bayesian inferences to account for subjective randomness (Griffiths & Tenenbaum, 2001, 2003; Hsu, Griffiths, & Schreiber, 2010). By this account, the subjective randomness of a particular sequence  $X$  is defined as

$$\text{random}(X) = \log \frac{p(X|\text{random})}{p(X|\text{regular})} \quad (1)$$

Then, the problem of judging randomness can be reduced to comparing two probabilities—whether the sequence is produced by a random process (e.g., independent and stationary Bernoulli trials), or, by a process with some regularities. To specify  $p(X|\text{regular})$ , Griffiths and Tenenbaum (2003) develop a hidden Markov model that makes transitions between hidden states depending on whether a motif is to be repeated or altered, where a motif is a short pattern such as H, T, HT, or, TH. By maximizing  $p(X|\text{regular})$ , they obtain a set of parameters that provide a better fit to the mean randomness ratings reported by Falk and Konold (1997).

The difficulty predictor and the Bayesian account have the

advantage to test against specific encoding strategies. However, DP has some counterintuitive properties. For example, in Figure 1, sequence (a) may appear to be more random than sequence (b), but the former actually has a lower DP score ( $DP = 5$ ) than the latter ( $DP = 6$ ). The Bayesian approach can fix this problem by adding more motifs of various length, but at the cost of computational complexity—to include all motifs of length 4, the hidden Markov model will have 22 motifs and 72 states (Griffiths & Tenenbaum, 2003).

Figure 1: “Fast detection” of regularities. Without exactly counting alternating runs or calculating probabilities, it would be easily discernible that sequence (a) appears more “random” than sequence (b). The regularity in sequence (b) can be detected by the equal distances between patterns (for example, between the filled squares or the interruptions of unfilled squares). In addition, this example shows some of the counterintuitive properties of the difficulty predictor in that sequence (a) has a lower DP score than sequence (b).

Perhaps more interestingly, Figure 1 also prompts a speculation: whether the judgment of randomness can be reached at *before* any effort of encoding or estimating the probabilities of the observed sequences. For example, the regularity in Figure 1(b) might be quickly spotted by the equal distances between patterns. Such a speculation has actually led us to consider the recent advances in the investigations on *perception of time and space*. For instance, it has been posited that complex achievements such as mathematics and geometry, which are uniquely human in their full linguistic and symbolic realization, rest nevertheless on a set of core knowledge systems driven by the representations of object, space, time, and number, and these representations may have an early developmental origin shared by human infants as well as animals (e.g., Dehaene & Brannon, 2010; Spelke & Kinzler, 2007; Spelke, Lee, & Izard, 2010). Applied to the research on subjective randomness, it would be plausible to hypothesize that when people attempt to judge randomness (or detect regularities), the processing of spatio-temporal distances between observations and patterns is the primitive driving force, *before* any encoding effort of memorizing, copying the observed sequences or comparing the probabilities of specific processes.

### Spatio-Temporal Distances between Patterns

In the present paper, we propose to utilize the spatio-temporal principles in object representation and human perception of time and space (e.g., Spelke & Kinzler, 2007) to study subjective randomness. Our approach is to first examine the spatial and temporal distributions of pattern events produced by random processes then match them to the psychological

spatio-temporal distances in people’s perception of randomness. To study the spatio-temporal distances between events, we focus on two sets of statistics, namely, given a random or a regular process, *how often* or *how likely* an event or a series of events would occur; And, from the start of an observation, *when* or *where* the events of interest would be encountered.

Apparently, *how often*, *when*, and *where* are different statistical properties and may bear different psychological relevancies. To set ideas, consider a simple case of coin tossing. If we tossed a coin three times and got three heads in a row as HHH (H = heads and T = tails), many of us might start getting suspicious about the fairness of the coin. But we would think it not at all noteworthy if the three tosses resulted in the pattern THH. The apparent randomness (or nonrandomness) cannot be explained by the frequency of encounters since the probability of obtaining either pattern in their exact orders is precisely the same,  $(\frac{1}{2})^3 = \frac{1}{8}$  (i.e., the equiprobability of the “*n*-grams”, Falk & Konold, 1997). However, less is known that there is a set of statistical properties that may very well explain why people consider a streak pattern rare and remarkable. When a fair coin is tossed repeatedly, it takes on average 8 tosses to observe the first occurrence of THH, but it takes on average 14 tosses to observe the first occurrence of HHH. Moreover, when both patterns are monitored simultaneously in one global sequence, the odds are 7 to 1 that one is more likely to first encounter THH than to first encounter HHH. That is, despite equal probabilities of occurrences, the time it takes to first encounter HHH is significantly “delayed” than that of THH.

Figure 2: Spatio-temporal intervals between encounters of random events. An observation starts *from scratch* at Time = 0.  $T_1$  is the first arrival time and its expected value  $E[T^*]$  is called *waiting time*.  $T_2, T_3, \dots$ , are the interarrival times between successive occurrences of the events, and their expected value  $E[T]$  is called *mean time*.

For formal definitions, we record the time (or location) when an event occurs at  $S_1, S_2, S_3, \dots$ , counting from the very beginning of the process (Figure 2). Then,  $T_1 = S_1$  is the first arrival time with an expected value  $E[T_1] = E[T^*]$  called *waiting time*.  $T_2 = S_2 - S_1, T_3 = S_3 - S_2, \dots$ , are the interarrival times between successive occurrences of the events, and their expected value  $E[T]$  is called *mean time*.<sup>1</sup> It can be shown that the mean time of a pattern is in effect a measure of *frequency* as the inverse of probability of occurrence, and the waiting time is a measure of *delay* in that a pattern’s expected first arrival time may be longer but not shorter than

<sup>1</sup>Note that since the first arrival time may have a different distribution than later interarrival times, we use  $T^*$  to denote the first arrival time and  $T$  to denote interarrival times.

its mean time (Ross, 2007).

Consider an irreducible Markov chain  $\{X_n, n \geq 0\}$  with transition probabilities  $P_{i,j}$  and stationary probabilities  $\pi_i$ ,  $i \geq 0$ . Then, for pattern  $(i_1, i_2, \dots, i_k)$ , its mean time (i.e., inverse of the pattern's frequency) is the mean number of transitions between successive visits to the pattern,

$$E[T_k] = \frac{1}{\pi_{i_1} P_{i_1, i_2} \dots P_{i_{k-1}, i_k}} \quad (2)$$

For the pattern's waiting time, we first consider whether a successive arrival of the pattern can "reuse" any of the elements from its previous arrival. For example, in sequence THHH, pattern HH has occurred twice and its second arrival has reused the last element from the first arrival. An overlap index  $s$  is defined as the maximum number of elements at the end of the pattern that can be used as the beginning part of the next arrival,

$$s = \max \{j < k : (i_{k-j+1}, \dots, i_k) = (i_1, \dots, i_j)\} \quad (3)$$

For example,  $s_{HT} = 0$  and  $s_{HH} = 1$ . Let  $\mu(a, b)$  denote the mean number of transitions for the Markov chain to enter state  $b$  from state  $a$ . If the pattern has no overlap,  $s = 0$ , its waiting time is,

$$E[T_k^*] = \mu(a, i_1) - \mu(i_k, i_1) + E[T_k] \quad (4)$$

If the pattern has an overlap  $s > 0$ , we first consider  $E[T_s^*]$ , the waiting time for a shorter sub-pattern  $(i_1, i_2, \dots, i_s)$ , which is consisted of the first or the last  $s$  elements in pattern  $(i_1, i_2, \dots, i_k)$ . Then,

$$E[T_k^*] = E[T_s^*] + E[T_k] \quad (5)$$

By recursively applying Equation (5) until we reach the shortest sub-pattern with no overlap, we can obtain the waiting time for the original pattern. Comparing Equations (4) and (5), we can see that when looking for the first arrival of a pattern, if the pattern has an overlap  $s > 0$ , anything that goes wrong after the first  $s$  elements will make the counting process start from scratch. In other words, a pattern's *waiting time* can be *delayed* by the pattern's overlapping property. In contrast, Equation (2) shows that a pattern's *mean time* or *frequency* is not affected by the overlapping property.

### Frequency and Delay by $p_A$

To generate binary patterns, we can use a Markov chain with two states H and T, where  $P_{H,T} = P_{T,H} = p_A$ , and  $P_{H,H} = P_{T,T} = 1 - p_A$ . This Markov chain is equivalent to the models used by Lopes and Oden (1987), where  $p_A < .5$  represents the tendency of repetition, and  $p_A > .5$  represents the tendency of alternation.

Assuming that the initial state is equally likely to be in either H or T, from equation (2), we have

$$E[T_{HT}] = E[T_{TH}] = \frac{2}{p_A} \quad (6)$$

$$E[T_{HH}] = E[T_{TT}] = \frac{2}{1 - p_A} \quad (7)$$

From Equations (4) and (5), we have

$$E[T_{HT}^*] = E[T_{TH}^*] = 1 + \frac{3}{2p_A} \quad (8)$$

$$E[T_{HH}^*] = E[T_{TT}^*] = \frac{-2p_A^2 + 5p_A + 1}{2p_A(1 - p_A)} \quad (9)$$

Figure 3 plots the mean time and waiting time for patterns of length 2 as the functions of probability of alternation  $p_A$ . When  $p_A = .5$ , we have a case of independent and stationary Bernoulli trials. We first note that the mean time is the same for all patterns of the same length. For example,  $E[T_{HT}] = E[T_{HH}] = 4$ . However, the waiting time can be different depending on the pattern's overlapping property. For example,  $s_{HT} = 0$ ,  $E[T_{HT}^*] = 4$ , and,  $s_{HH} = 1$ ,  $E[T_{HH}^*] = 6$ . That is, the waiting time is longer for the shortest streak patterns HH or TT than for the shortest alternating pattern HT or TH. Solving the equality between Equations (8) and (9), we obtain  $p_A = \frac{1}{3}$ . Thus, as long as  $p_A > \frac{1}{3}$ , we have  $E[T_{HH}^*] > E[T_{TH}^*]$ .

Moreover, let  $\text{Var}(T)$  denote the variance of the interarrival times, it can be shown that patterns may differ substantially in how evenly they are distributed over time (or space), for

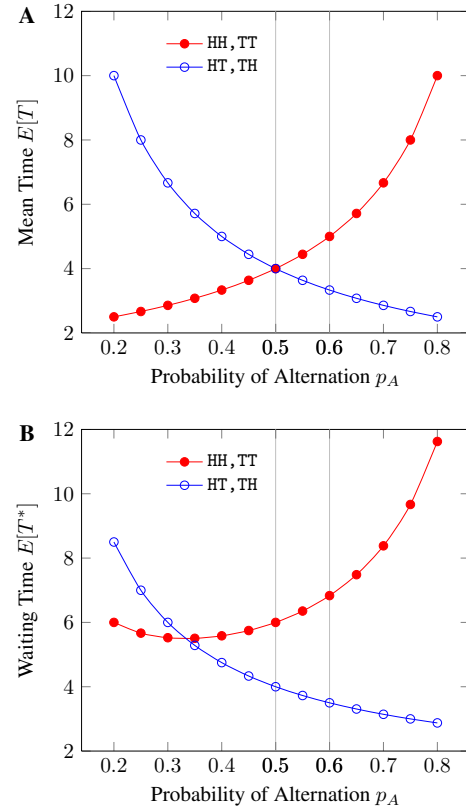

Figure 3: Mean time (A) and waiting time (B) as the functions of probability of alternation  $p_A$ . When  $p_A = .5$ , the process is equivalent to independent and stationary Bernoulli trials.

example,  $\text{Var}(T_{\text{TH}}) = 4$ , and  $\text{Var}(T_{\text{HH}}) = 20$ . In addition, the waiting time is highly correlated with the variance of interarrival times since both values are extended by a pattern's overlap tendency (see Table 1). (For the calculation of variances, see Sun & Wang, 2010a.)

Table 1: Mean and variance of the first arrival time ( $T^*$ ) and interarrival times ( $T$ ) for binary patterns in independent Bernoulli trials ( $p_A = 0.5$ ) when tossing a fair coin. Reciprocal patterns are listed only once, for example, HH is equivalent to TT, and, HT is equivalent to TH.

Patterns	$s$	$E[T]$	$\text{Var}(T)$	$E[T^*]$	$\text{Var}(T^*)$
H	0	2	2	2	2
HT	0	4	4	4	4
HH	1	4	20	6	22
HHT	0	8	24	8	24
HTT	0	8	24	8	24
HTH	1	8	56	10	58
HHH	2	8	120	14	142

## Psychological Implications

The Markov model described above may provide quantitative measures to calibrate subjective randomness, particularly regarding the seemingly miscalibrated subjective probability of alternation  $p_A$ . Different from previous studies that focus on the frequency of patterns, here we examine the spatio-temporal distances between pattern events that cover both frequency and delay (including variances), either from the very beginning of the process (waiting time), or between successive occurrences of the pattern given that the pattern has occurred before (mean time).

It should be noted that so far our analyses are limited to short patterns. This consideration is based on the empirical findings that people are sensitive to even the shortest patterns of length 2. For example, it has been reported that participants would report “a streak is occurring” beginning at the third repeating event (Carlson & Shu, 2007). In an fMRI study, Huettel, Mack, and McCarthy (2002) show that a distributed set of regions in prefrontal cortex are exquisitely sensitive to the presence and the termination of streak patterns even when pattern length was only 2, despite the fact that participants were informed of the random order of the sequences.

It appears that the waiting time statistics fit well to one of the most influential accounts for subjective randomness, the “representativeness heuristic” (e.g., Gilovich et al., 1985; Kahneman & Tversky, 1972). By this account, people expect smaller sequences to resemble the balanced distributions in the long run, such that a streak of heads would seem to be rare and remarkable as it would not be representative of the process of random coin tossing. This would have explained the biased subjective probability of alternation in that people tend to expect fewer and shorter streaks than would be mathematically probable when observing sequences produced by a random

process, and, they avoid repetitions of the same elements when instructed to generate such sequences (e.g., Falk & Konold, 1997; Wagenaar, 1972).

Despite its plausibility, the representativeness account has been criticized for the lack of definition (Ayton & Fischer, 2004; Falk & Konold, 1997; Gigerenzer, 1996). Nevertheless, it has been proposed that the waiting time statistics may provide quantitative explanations to this account (Hahn & Warren, 2009; Sun, Tweney, & Wang, 2010a; Sun & Wang, 2010a, 2010b). Specifically, people judge the frequency of an event on the basis of how it is representative of the underlying population or process (representativeness), and how easily an example can be brought to mind (availability). When people think of a truly random process (by actually tossing a coin or conducting a mental experiment), a streak pattern—even at its shortest length of 2 (e.g., HH in tossing a coin)—may be perceived as the most nonrepresentative and the most unavailable. Compared with other patterns of the same length, a streak is the most delayed in its first arrival and has the largest variance of interarrival times thus the most uneven or clustered distribution over time (see Table 1). Note that these particular properties are not limited to independent Bernoulli trials where  $p_A = .5$ . For example, Figure 3B shows that as long as  $p_A > \frac{1}{3}$ , the waiting time for the streak pattern HH will be longer than that of non-streak pattern HT.

Moreover, there has been direct evidence suggesting that people may at least have an approximate sense of the waiting time, namely, the delayed occurrence of streak patterns. Oppenheimer and Monin (2009) report that when participants were asked to estimate the number of coin flips before the occurrence of a pattern of length 5, they believed that a sequence of coin flips was nearly twice as long before a streak (mean estimate = 16.2) than when there was no streak (mean estimate = 8.7). Applying Equations (4) and (5), we can show that for patterns of length 5, the waiting time for a streak is 62 tosses, and the average waiting time for non-streak patterns is approximately 34.3 tosses: the former is nearly twice as long as the latter.

In the light of the delayed first arrival for streak patterns, we speculate that people's expectation of the probability of alternation as  $p_A \approx 0.6$  might in effect have been driven by their experiences of pattern events as random patterns unfold in time and space. For example, we can reconstruct the task of generating randomness with the Markov chain described above. Since at any given moment, participants face the choice of either repeating or reversing the current outcome (an H or a T), the generation process is equivalent to the process of choosing patterns of length 2—either a streak pattern (HH or TT) or a non-streak pattern (HT or TH). Then,  $p_A = .6$  means that 60% of the time participants choose a non-streak pattern, indicating a false belief that in tossing a fair coin independently (i.e.,  $p_A = .5$ ), streak patterns should occur less frequently than non-streak patterns. Such belief can be formulated as a ratio of pattern mean times. From Equations (6) and (7), when

$$p_A = .6,$$

$$E [T_{HH,TT}] : E [T_{HT,TH}] = p_A : (1 - p_A) = 3 : 2$$

Then, comparing the waiting time in the process of independent coin tossing yields exactly the same ratio, where  $p_A = .5$ ,

$$E [T_{HH,TT}^*] : E [T_{HT,TH}^*] = 6 : 4 = 3 : 2$$

That is, measured by the mean time, participants have failed the task of producing randomness (i.e., the independence property where  $p_A = .5$ ) as if they have falsely believed that patterns HH and TT would occur less frequently than patterns HT and TH. Quantitatively, this comparison indicates that the observed bias might have stemmed from participants' expectation of waiting time from a truly random process, since the mean time does not distinguish any patterns when  $p_A = .5$  (e.g., see Figure 3A).

## Discussion

The development of waiting time statistics appears to be promising and may have potential significance in explaining a range of human cognitive functions (e.g., Oppenheimer & Monin, 2009; Sun et al., 2010a; Sun, Tweney, & Wang, 2010b; Sun & Wang, 2010b, 2010a, 2011). Specifically, we argue that it can be fruitful to study subjective randomness in the context of *human perception of time and space*. And, the *frequency* and *delay* of pattern events, rather than individual events (e.g., a single coin toss), may be the key statistics and theoretical constructs that underlie human perception of randomness.

It has been posited that by exposing to the various environmental statistics, human mind may have evolved an accurate sense of randomness but may fail to reveal it by the standard of a particular measuring device (e.g., Pinker, 1997). Given that the waiting time and the variance of interarrival times can be substantially different for patterns with the same mean time (e.g., Table 1 and Figure 3), one may logically assume that these statistics may play a critical role in shaping people's perception and judgment of randomness. Unfortunately, in the long lasting investigations on subjective randomness, the mean time of patterns serves as the sole normative measure of randomness. Despite various forms of experimental tasks (e.g., randomness generation or recognition, probabilistic predictions) and statistical methods (e.g., runs test, serial correlation, Bayesian inferences), existing studies have been focusing on the discrepancies between subjective responses and the probabilities of the occurrences of random patterns. Nevertheless, the absence of waiting time statistics in the investigations on subjective randomness may be due to its late and still ongoing development in statistical research (e.g., Pozdnyakov, 2008; Ross, 2007), and, remain fairly novel to the audience in psychology (c.f., Hahn & Warren, 2009; Konold, 1995; Nickerson, 2007; Sun et al., 2010a, 2010b).

More significantly, recent advances in the behavioral and neurological sciences on human cognitive achievements all point to the role of the perception of time and space. It has

been proposed that complex achievements such as mathematics and geometry, which are uniquely human in their full linguistic and symbolic realization, rest nevertheless on a set of core knowledge systems that are driven by the representations of object, space, time and number (Dehaene & Brannon, 2010; Spelke & Kinzler, 2007; Spelke et al., 2010). And, these representations may have a common perceptual metric in the form of a *mental number line* (Burr & Morrone, 2011; Dehaene, Piazza, Pinel, & Cohen, 2003) and have an early developmental origin shared by human infants as well as other animals (de Hevia & Spelke, 2010; Haun, Jordan, Vallortigara, & Clayton, 2010; Hubbard, Piazza, Pinel, & Dehaene, 2005). Applied to the research on subjective randomness, it would be plausible to hypothesize that when people attempt to judge randomness (or detect regularities), the processing of spatio-temporal distances between observations and patterns is the primitive driving force, *before* any encoding effort for memorizing, copying, or assessing the probability of pattern occurrences (e.g., see Figure 1).

Nonetheless, we need to collect more empirical evidence to investigate whether and how human cognition is sensitive to the statistics of random patterns, for example, via experiments that manipulate the overlapping and delay properties of pattern events then measure the psychological responses. Moreover, a theoretical breakthrough would also require us to firmly demonstrate the psychological relevance of the pattern time statistics and the spatio-temporal principles in object representation and human perception of time and space, in order to develop a mental calculus of how these constructs work together.

## Abstract

Inhibitory control is an important aspect of analogical reasoning critically dependent on prefrontal cortex. We used a novel visual analogy paradigm with scalp electroencephalography (EEG) to explore several ways the brain uses inhibitory control to perform analogy. Previous studies have suggested that inhibitory control helps to manage working memory, so we used a separate task to measure individual differences in working-memory span to help us interpret differences in inhibitory control during reasoning. We found evidence that low working-memory span individuals likely lacked the necessary inhibitory control to keep unattended relations from entering visuospatial working memory early in processing. We also found that a late frontal event-related potential sensitive to relational distraction was differentially modulated in high and low working memory span individuals. These findings provide additional evidence for the importance of inhibitory control during analogical processing.

**Keywords:** analogy, working memory, inhibitory control, EEG, ERP

## Introduction

Studies involving children (Richland, Chan, Morrison, & Au, 2010; Richland, Morrison, & Holyoak, 2006; Thibaut, French, & Vezneva, 2010a, 2010b), younger adults (Cho, Holyoak, & Cannon, 2007; Cho et al., 2010), older adults (Viskontas et al., 2004), and patients with damage to prefrontal cortex (Krawczyk et al., 2008; Morrison et al., 2004) have all provided evidence that inhibitory control in working memory (WM) is an important aspect of both visual and verbal analogical reasoning. Neuroimaging

studies of analogical reasoning have implicated areas in prefrontal cortex (PFC) as critical for semantic retrieval during analogy (Bunge, Wendelken, Badre, & Wagner, 2005), avoiding distraction from non-goal related relational information (Cho et al., 2010), and performing analogical mapping and similar types of relational integration (Bunge, Helskog, & Wendelken, 2009; Cho et al., 2010; Green et al., 2010; Morrison, Nikitin, Bharani, & Doumas 2012). Computational accounts of these data (Doumas, Morrison, & Richland, under review; Knowlton, Morrison, Hummel, & Holyoak, 2012; Morrison et al., 2004; Morrison, Doumas, & Richland, 2011; Viskontas et al., 2004) suggest that inhibitory control is central to the processes of semantic retrieval and analogical mapping; however, there is little direct experimental evidence for mechanisms by which inhibitory control is recruited during analogical reasoning.

WM has been thought to play a critical role during analogical reasoning (Halford, 1992; Morrison, 2005). Domain-specific as well as central-executive WM dual tasks interfere with analogical processing (Morrison, Truong, & Holyoak, 2001; Waltz, Lau, Grewal, & Holyoak, 2000). Likewise, individual differences in working-memory span (see Conway et al., 2005) are frequently related to matrix reasoning performance (e.g., Kane & Engle, 2002). In an effort to understand how inhibitory control may be involved in WM processing, Vogel, McCollough, and Machizawa (2005) asked participants with high and low WM span to perform a simple delayed match-to-sample WM task while their brain activity was observed using scalp electroencephalography (EEG). Vogel et al. identified a Continuous Negative Variation (CNV) event-related

potential (ERP) during the delay period in the task that correlated with the number of items the participants were required to hold in WM. Interestingly, when participants were asked to remember two items and ignore two others, the ERPs of high-WM span participants resembled those for two item trials, while those of low-WM span participants resembled those for four items. Thus, high-WM span individuals appear to be better at managing their WM using inhibitory control to suppress goal-irrelevant information. Shimamura (2000) has argued that his type of dynamic filtering appears to be a fundamental function of PFC.

Based on Learning and Inference with Schema and Analogy (LISA; Hummel & Holyoak, 1997, 2003), a neurally-plausible model of analogical reasoning, we have previously argued that inhibitory control is necessary throughout analogical processing (Morrison et al., 2004; Morrison, Dumas, & Richland, 2011; Viskontas et al., 2004). Specifically, inhibition plays a central role in (a) LISA's manipulation of relations in WM, (b) its ability to select items for placement into WM, (c) its ability to discover analogical mappings. Thus, we anticipate that inhibitory control will be evident in analogical reasoning, and may be modulated by the WM span of participants.

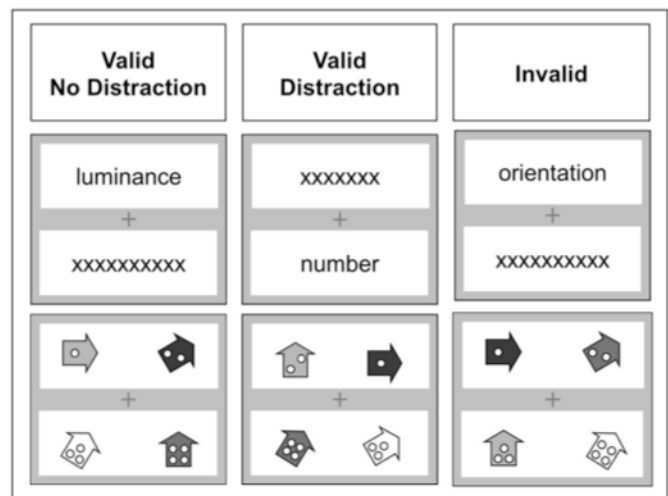

In an effort to explore two possible roles for inhibitory control during analogical processing, we developed an experimental paradigm for use with EEG (see Figure 1). On each trial, participants were cued to solve a visual analogy based on one of three abstract relations present in the stimuli. Critically, on some valid trials one of the unattended relations was not congruent. Participants need to ignore this relation to arrive at the correct solution. Thus, the task is similar to the version of the People Pieces analogy task we had developed for behavioral (Cho, Holyoak, & Cannon, 2007; Viskontas et al., 2004) and neuroimaging studies (Cho et al., 2010) except that participants were considering asymmetric relations as opposed to same-different relations. The task was also similar to Vogel et al. (2005), in that participants had a goal-relevant WM load (i.e., the to-be-attended-to relation) in the presence of potentially distracting information.

We had two central hypotheses. First, people lower in WM-span would be less efficient than higher WM-span individuals in keeping goal-irrelevant information out of visuospatial WM. Thus, we expected to see a more negative CNV (Vogel et al., 2005) in occipitoparietal regions in low WM-span individuals, indicating that they were storing more information in their WM than higher WM-span individuals who were efficiently filtering the goal-irrelevant information.

Second, we predicted that relationally distracting trials require the engagement of inhibitory control and thus should engage areas in inferior frontal cortex (e.g., Cho et al., 2010) to protect the analogical mapping process from goal-irrelevant information.

## Method

Participants verified visual analogies constructed from shapes that possessed three varying properties (luminance, orientation, and number; see Figure 1). On each trial, participants were cued to attend to *only one* of the relations formed by the three properties. Participants decided whether the relation in the top pair was the same or different than the relation in the bottom pair. There were three conditions in this experiment: *Valid–No Distraction*, *Valid–Distraction*, and *Invalid*. In the Valid–No Distraction condition, all three relations were congruent between the top and bottom pair, with the correct answer being “yes” to indicate that the problem as cued was a valid analogy. In the Valid–Distraction condition, the cued property had congruent relations as in the previous condition; however, one of the two unattended relations was incongruent, thus creating a response conflict between the attended and unattended relation. Invalid trials were just like Valid–Distraction stimuli, except that participants were asked to attend to the relation that did not map.

*Figure 1:* Participants saw analogy problems in one of three conditions. In “Valid–No Distraction” problems, participants mapped based on a single relation (e.g., luminance—the shapes get darker from left to right), while the other relations (e.g., orientation and number) could also be successfully mapped between pairs. In “Valid–Distraction” problems, participants once again were only required to map based on one relation (e.g., number—the number of dots in the shape decreased from left to right); however, one of the other relations present did not successfully map between pairs (e.g., luminosity in the source decreased from left to right, while it increased from left to right in the target). “Invalid” trials were like “Valid–Distraction” trials; however, participants were to map based on the invalid relation (e.g., orientation—the arrowhead of the shape rotated counterclockwise in the source, but clockwise in the target).

## Participants

Twenty-nine undergraduate students from Loyola University Chicago participated in the experiment. Of the 29 participants three were omitted from the analysis because of poor EEG recording quality. The remaining 26 participants were divided based on median WM-span into two equally sized groups. The low-WM span group ( $M = 33$ ,  $SEM = 2$ ) had a WM span smaller than the high WM-span group ( $M = 61$ ,  $SEM = 2$ ;  $t(24) = 7.5$ ,  $p < .001$ ).

Participants gave informed consent to take part in the study. The Loyola University Chicago Institutional Review Board approved all recruitment methods and procedures.

## Materials

Each analogy problem consisted of two pairs of geometric shapes (see Figure 1). Each shape had one of four levels of three parametrically manipulated properties: luminance, orientation, and number. Shapes were combined into pairs to create order relations with respect to the three properties. For instance, pairs of shapes could be increasingly bright or dark (luminance); rotate clockwise or counter clockwise (orientation); and increase or decrease in *number*. In any given problem a relation in the source (i.e., top pair) could either match or mismatch the corresponding relation in the target (i.e., bottom pair). A set of 144 unique stimuli was generated, 72 of which contained pairs of shapes with all congruent relations (used for Valid-No Distraction trials). The remaining 72 stimuli were divided into thirds, with each third having one mismatching relation in one of the three properties. For the problems containing a mismatching relation, if the participant was cued to attend to the mismatching relation the trial was Invalid, but if the participant was cued to attend to one of the matching relations the trial type was Valid-Distraction.

## EEG Recording

Scalp electroencephalography signal (EEG) was recorded from each participant using a 38-channel Biosemi Active2 EEG system. 32 electrodes were located at standard 10/20 locations in a nylon-elastic cap. Two electrodes were placed on the left and right mastoid bones for subsequent digital re-referencing. To expand the coverage of EEG monitoring, we placed four electrodes on the face on the inferior and lateral aspects of the eye orbit. These electrodes were used to expand PFC electrode coverage and for ocular artifact correction and rejection. Unfiltered EEG was re-referenced to an average of the two mastoid electrodes and a 0.01 Hz high-pass filter was applied after recording. A band-stop filter from 59 to 61 Hz was also applied to the raw EEG to remove any AC electrical contamination. EEG signal was corrected for ocular artifacts using a spatial PCA filter corrected for the average noise level in the signal according a method available in EMSE (Source Signal Imaging, San Diego CA). Signal was further cleaned via a  $\pm 100\mu V$

rejection criterion. Included participants have fewer than 15% of trials rejected due to EEG artifacts.

## Procedure

After a participant was fitted with the EEG cap and electrodes, he or she sat in a soundproof chamber equipped with a 21-inch CRT monitor and an electronic response box controlled by a program written in e-Prime 2.0. The participant was positioned so that their head was 100cm from the monitor. The stimulus was adjusted to 4 degrees of visual angle. The participant then received task instructions followed by 24 practice trials with feedback. After completing these trials, the participant was asked if they had any questions, and then was reminded to respond as quickly and as accurately as possible and to blink only after a response was made.

Each trial began with a randomly jittered fixation screen that lasted 500 to 1000 ms. Then, the name of one of the three properties appeared near the fixation point (see Figure 1), also for 500 to 1000 ms, before it disappeared (for 500 to 1000 ms) and was replaced by the stimulus shapes, which remained visible until a button press was made. There were no systematic difference in any of these jittered times between conditions. The entire experiment consisted of 216 trials, and accuracy and response times (RT) were measured. Participants completed four blocks of 54 trials, with conditions and stimuli randomized within and across blocks. One-minute breaks were given between blocks, during which cumulative mean accuracy and RT were reported to the participant.

## WM Span

After completing the visual analogy task, participants completed a 15-20 min operation span WM task (Conway et al., 2005). On each trial, participants were asked to verify a simple mental arithmetic problem and then were to remember a letter. Trials were from 2 to 7 problems/letters long. At the conclusion of a trial, participants were presented with an array of letters and were to click the letters in the sequence they were presented. WM span was defined as the total number of letters correctly remembered in the presented order. All participants performed the math problems at 85% correct or better.

## Results

### Behavioral Results

Because yes-valid/no-invalid responses were used, we report accuracy using  $d$ -prime<sup>1</sup>. Participants were less accurate in the Valid-Distraction ( $M=3.0$ ,  $SEM=.13$ ) than the Valid-No Distraction ( $M=3.2$ ,  $SEM=.16$ ) condition  $F(1,24) = 17$ ,  $p < .001$ ,  $\eta_p^2=.4$ ); however, there was no

<sup>1</sup> Hit rates of 1 were replaced with .99 and hit rates of 0 were replaced with .01 for purposes of calculating  $d$ -prime.

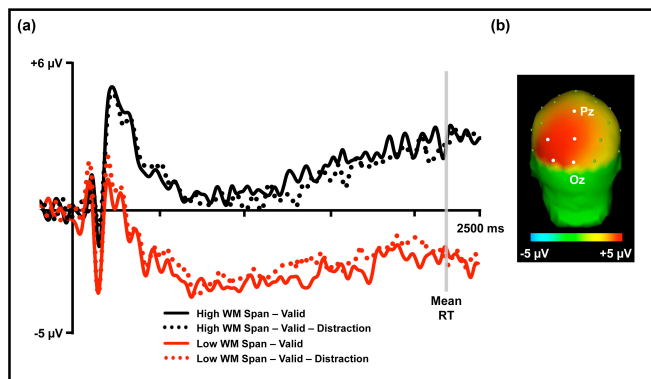

difference in RT between Valid-Distractor ( $M=2.2s$ ;  $SEM=.08$ ) and Valid-No Distractor ( $M=2.2s$ ;  $SEM=.09$ ;  $F(1,24) = .001$ ,  $ns$ ,  $\eta_p^2<.001$ ). Additionally, there was no interaction with WM-span group for either accuracy ( $F(1,24) = .46$ ,  $p = .5$ ,  $\eta_p^2=.02$ ) or RT ( $F(1,24) = 1.3$ ,  $p=.3$ ,  $\eta_p^2=.05$ ). Thus, we saw an effect of relational distraction even in these relational simple problems; however, this effect appeared not to be moderated by WM span.

## EEG Results

**Individual Differences in WM** Our first predication was that WM-span would be reflected in the CNV (Vogel et al., 2005) in occipitoparietal regions. We believed this would result from low WM-span individuals' inferior ability to ignore goal-irrelevant information during analogical processing, similar to the effect observed by Vogel et al. (2005) during a delay period in a delay match-to-sample task. Consistent with this prediction we found that participants in the low WM-span group showed a more negative CNV (see Figure 2) from just after the occipital N1 wave (180ms) all the way through the end of task processing (1700ms;  $F(1,24) = 7.1$ ,  $p = .01$ ,  $\eta_p^2=.2$ ). This effect was not modulated by relational distraction ( $F(1,24) = .2$ ,  $p = .7$ ,  $\eta_p^2 = .008$ ).

**Effect of Relational Distraction** Our second prediction involved the role of PFC in managing distraction during analogical mapping. Using a similar analogy task with fMRI, Cho and colleagues (2010) had previously shown areas in middle and inferior frontal gyri were sensitive to relational distraction. We further hypothesized that this effect would be late in processing, coincident with analogical mapping (Morrison et al., 2012). We did not find a main effect of relational distraction (see Figure 3;  $F(1,24) = .6$ ,  $p = .4$ ,  $\eta_p^2=.024$ ); however, we did find an area in right

**Figure 2:** Modulation of the neural correlates of visuospatial working memory during analogical reasoning by WM-span. (a) A CNV ERP was more negative for the low than the high WM-span group in occipitoparietal electrodes (indicated by white dots in Figure 2b). (b) Map showing high minus low WM-span subtraction topography from 180 to 1700ms post-stimulus.

**Figure 3:** Modulation of the neural correlates of relational distraction by WM-span. (a) The Valid-No-Distractor ERP for low WM-span participants was significantly less positive than either the Valid-Distractor ERP for the same group, or either condition ERP for the high WM-span group in right frontal electrodes (indicated by white dots in Figure 3b). (b) Map showing double subtraction topography from 1000 to 1700ms post-stimulus.

PFC consistent with Cho et al. (2010) which showed an interaction between WM-span and relational distraction ( $F(1,24) = 7.1$ ,  $p = .01$ ,  $\eta_p^2=.2$ ). While the high WM-span group did not show a difference between the Valid-Distractor and Valid-No Distractor conditions ( $F(1,12) = 5.1$ ,  $p = .3$ ,  $\eta_p^2=.07$ ), the low WM-span group did ( $F(1,24) = 1.0$ ,  $p = .01$ ,  $\eta_p^2=.2$ ). Specifically, both conditions for the high WM-span group showed similar levels to the Valid Distractor condition for the low WM-span group, while the Valid-No Distractor condition for the low WM-span group was reliably less positive.

## Discussion

In many real-world problem-solving situations, one may have to choose between multiple common relations for use as the source for an analogy. For instance, a molecular biologist may want to favor repeat sequences instead of common codons as the basis for an analogy between two genes. Attending to codons when one is looking for repeat sequences may be misleading, thus good attention to just the chosen relation (e.g., a repeat sequence) and inhibition of the irrelevant information (e.g., a specific codon) for the situation is most efficient. However, faced with a new situation, codons may now be the better relation to use, so the system must be flexible to solve the problem at hand. In the paradigm used in this study, reasoners were sometimes asked to favor the relation based on one stimulus characteristic over another as the basis for their analogy. However, their focus needed to be flexible because what was critical on one trial may be misleading on the next. Using this paradigm we demonstrated two ways in which inhibitory control can influence analogical processing.

First, as in Vogel and colleague's (2005) demonstration using EEG with a delayed match to sample task, we found

EEG evidence that low WM-span individuals allowed more information to enter visuospatial WM than high WM-span individuals. It is likely that this difference resulted from low-WM span individuals considering goal-irrelevant relations regardless of condition. This occurred early in the reasoning time course, beginning just after the first signals of spatial attention (i.e., the occipital N1), and continued throughout the trial time course. While, this did not result in a difference in behavioral performance on the task, one can imagine that in a more difficult task (e.g., at higher levels of relational complexity), this inefficient gating of WM may have behavioral consequences.

Secondly, we found sensitivity to relational distraction as measured by a subtraction between Valid-No Distraction and Valid-Distraction trials in a right frontal ERP was modulated also by WM-span. It appears that high WM-span individuals frequently engage this area of the brain during later stages of analogical mapping, while low WM-span individuals engage it more in the face of distraction. We believe this aspect of inhibitory control is likely distinct from the previous result. If high WM-span individuals are better at using early inhibitory control to gate WM from non-goal related information one might hypothesize that they would require the later PFC mechanisms less; however, it appears that high WM-span individuals use it consistently, and on average more than low WM-span individuals. In contrast, low WM-span individuals, could certainly make use of the PFC mechanism for Valid-No Distraction trials to focus on just the relevant relations; however, they don't, using it only when actual conflict is detected. Thus, the use of PFC seems to be more reactive in the case of low WM-span individuals, while it is more proactive with high WM-span individuals. Thus, this appears to be a second neural mechanism that favors high WM-span individuals.

This result is also consistent with the results from a previous fMRI study using a very similar task that identified areas in bilateral inferior frontal gyrus (IFG) as being more active during analogy in the presence of relational distraction (Cho et al., 2010). The EEG topography shown in Figure 3 is consistent with the activation reported by Cho and colleagues and also many other studies investigating the role of inhibitory control in WM (e.g., Goel et al., 2000; Goel & Dolan, 2003; Prado & Noveck, 2007; De Neys et al., 2008). Also, as in Cho and colleague's study the topography resulting from the distraction contrast appears to be at least partially distinct from the frontopolar area previously identified as being associated with analogical mapping via both EEG (Morrison et al., 2012) and fMRI (Green et al., 2010) methods. Future investigations will need to focus on how frontopolar PFC and IFG may interact in the service of analogical reasoning.

Several previous behavioral studies have shown evidence of the importance of inhibitory control during analogical reasoning in the face of distraction (e.g., Cho et al., 2007; Krawczyk et al., 2008; Morrison et al., 2004; Viskontas et al. 2004); however, these studies typically only found

reliable effects when distraction was present in more relationally complex problems.<sup>2</sup> In the present study we show the engagement of inhibitory control for even simple one-relation analogy problems. However, this effect was apparent only in the ERP results, and accuracy, not RT.

So what exactly does inhibitory control do during analogical reasoning? Given our results it is quite likely that the answer is not a unitary one. Likewise, in the LISA model of analogical reasoning (Hummel & Holyoak, 1997, 2003; Knowlton et al., 2012), the function of inhibitory control may be multifaceted, and may differ across the time course of processing analogies. Future neuroimaging studies will be driven by precise computational accounts of the neural mechanisms underlying analogical processing (e.g., Knowlton et al., 2012; Morrison et al., 2012) and will likely require EEG time-frequency analysis techniques to appreciate the temporal dynamics of the neural circuits responsible for analogical reasoning.

## Acknowledgments

The authors thank Keith Holyoak and Rebecca Silton for comments on an earlier draft of this paper. ## Abstract

Skilled, sequential movements can be acquired explicitly or implicitly. In the present study, we examined the effects of explicit knowledge obtained through instruction or spontaneous detection on transfer of visuomotor sequence learning. In the first session, participants learned a visuomotor sequence by trial and error. In subsequent sessions, the sequence was changed according to specific rules. Some participants received explicit instruction about which specific rules changed, while the others did not. Knowledge of changes via explicit instruction led to slower performance with fewer errors; the sluggishness persisted even in the last phase of transfer learning. On the other hand, knowledge discovered independently by the participants produced slower performance in the initial phase of learning with fewer errors, but their performance speed eventually reached the same level as that of the unaware participants. These results suggest that explicit knowledge may help to reduce errors in the initial phase of visuomotor sequence learning but may interfere with increasing speed, particularly when the knowledge is given rather than found.

**Keywords:** Sequence learning; Explicit knowledge; Transfer; Interference

## Introduction

Skilled sequential movements, such as typing on a keyboard, dialing a phone number, or playing the piano, have key roles in motor behavior in daily life. Many studies have examined how people acquire or improve such sequential behaviors. One of the most common ways to investigate the acquisition of sequential learning is called the Serial Reaction Time (SRT) task (Nissen & Bullemer, 1987). In this task, participants press one of four aligned buttons that are associated with visual stimuli at different positions. In several experimental blocks, a specific sequence was repeated or partly repeated, but participants were not informed of the repetition and did not notice the structure of the sequence (because the sequence was long enough; for example, see Reed & Johnson, 1994; Reber & Squire, 1988). Nevertheless, a reduction in response time occurs without awareness of the sequence structure. In another paradigm, participants first learn a sequence of finger movements and then performance is measured in terms of speed and accuracy (i.e., this paradigm focuses on improvement in performance rather than acquisition) (Karni et al., 1998; Walker et al., 2003).

Explicit knowledge (e.g., whether or not participants notice a repeated sequence and whether or not they were instructed about the sequence explicitly) likely leads to various changes in performance and learning processes in terms of speed and accuracy. In general, implicit learning in the SRT task facilitates response even when participants do not notice a specific sequence (Nissen & Bullemer, 1987). Curran and Keele (1993) assigned participants into three groups: the intentional, more aware, and less aware groups. In the intentional group, the participants were instructed about the repeated sequence before completing the task. The authors defined the participants who were aware of the repeated sequence as the more-aware group and those who were not aware of the sequence as the less-aware group. Participants in that study conducted a single task first, then a dual task. In the single-task blocks, participants were required to press certain buttons when an X appeared on the screen. In the dual-task blocks, a tone sounded several times within the 200-ms stimulus-response interval of the primary task, and the tones were composed of low and high pitches. The participants were instructed to count the number of high-pitched tones while ignoring the low-pitched tones. The results showed that all three groups differed in terms of performance time in the single task: explicit knowledge conveyed intentionally before starting the task led to faster performance during the task. However, in the dual task, the groups did not differ in terms of performance times. They interpreted the results as signifying that awareness affects sequence learning only when attention is fully available; when attention was divided, additional knowledge gained by the aware and intentional groups was not conveyed to the non-attentional mechanism. Similarly, in a previous study (Moisello et al., 2011), participants performed visuomotor sequence learning of a finger opposition task, and response time (i.e., the interval between stimulus presentation and the onset of the corresponding touch) and touch duration (i.e., the contact time between thumb and another finger) were measured for each finger opposition movement of the sequence. The results indicated that sequence learning induced a double-faced effect on motor performance: the participants who were instructed explicitly about a sequence decreased their reaction times, but increased their touch duration, which was regarded as the combination of a sensory phase and a motor preparation phase. Thus, whether

explicit knowledge enhances or interferes with performance in sequential learning is still under debate.

In the present study, we examined the effects of explicit knowledge on transfer of visuomotor sequence learning by using another sequential learning paradigm employing instruction or spontaneous detection. The task we employed was a sequential button press task that was originally devised for monkeys as participants (Hikosaka et al., 1995; Rand et al., 1998) and subsequently used on humans (Hikosaka et al., 1995, 1996, 2002; Sakai et al., 1998, 2003) and with which performance improvements in terms of speed and accuracy can be measured separately (Hikosaka et al., 1995, 1996, 2002; Sakai et al., 1998, 2003; Watanabe et al., 2006, 2010). In the first session, participants were required to complete a visuomotor sequence learning task without any instruction (i.e., by trial and error). In the subsequent sessions, the sequence was altered according to a specific rule; either the first and the third responses were switched (reversed) or the first and the second responses were switched (partially reversed). Some participants were explicitly instructed about the specific rule changes before performing the task, while the others did not receive explicit instructions. We also examined whether participants who spontaneously noticed the specific rules without instruction used their knowledge to change their performance.

## Method

### Participants

Thirty-seven right-handed participants (23 male, 14 female; mean age = 21.02 years, standard deviation = 2.39) participated in the experiment. They were divided into two groups: the explicit-instruction group (14 participants; 8 male, 6 female) and the no-instruction group (23 participants; 15 male, 8 female). All participants had normal or corrected-to-normal visual acuity, normal motor functioning, and were naïve to the purpose of the study. All participants gave written informed consent prior to participation. All procedures were conducted in accordance with the Declaration of Helsinki.

### Procedure

The participants performed a sequential button press task, which we call “3 × 7 task.” We used essentially the same experimental paradigm as previous studies (e.g., Sakai et al., 2003; Watanabe et al., 2006, 2010). Sixteen LED buttons (10 mm × 10 mm each) were mounted on a panel in a 4 × 4 matrix and were separated from each other by 8-mm spaces. At the bottom of the panel was another LED button, which was used as the “home” key. The participant used his/her right index finger to press the buttons. The home key was turned on at the beginning of each trial. When the participant pressed the home key for 500 ms, 3 out of the 16 target LEDs turned on simultaneously, which we called the “set.” The participant was required to press the illuminated buttons in the correct order, which he/she was required to

discover by trial and error. Upon success, the LEDs turned off one by one and a different triplet of LEDs was illuminated; the participant was again required to discover the correct order and press the buttons accordingly. When the participant pressed an incorrect button, all the LED buttons were briefly illuminated, a beep sounded, and then the trial was aborted. The participant then had to restart the trial by pressing the home key. A total of seven sets, which we call the “hyperset,” were presented in a fixed order for trial completion. A trial was considered successful when the participant completed an entire hyperset (seven sets). The same hyperset was repeated until the participant completed it successfully for 20 trials (called a “block”). Participants were asked to perform the task as quickly and as accurately as possible. We prepared three hypersets, called “original,” “reversed,” and “partially reversed.” The original hyperset was randomly generated for each participant. For each set, the triplet of buttons were defined [1][2][3] in the to-be-pressed order. In other hypersets, the spatial configurations of the sets were not changed, but the sequences of correct button presses were changed. In the reversed hypersets, the participants needed to press the buttons in the order [3][2][1] (i.e., the first and the third buttons were switched). In the partially reversed hypersets, they needed to press the buttons in the order [2][1][3] (i.e., the first and second buttons were switched).

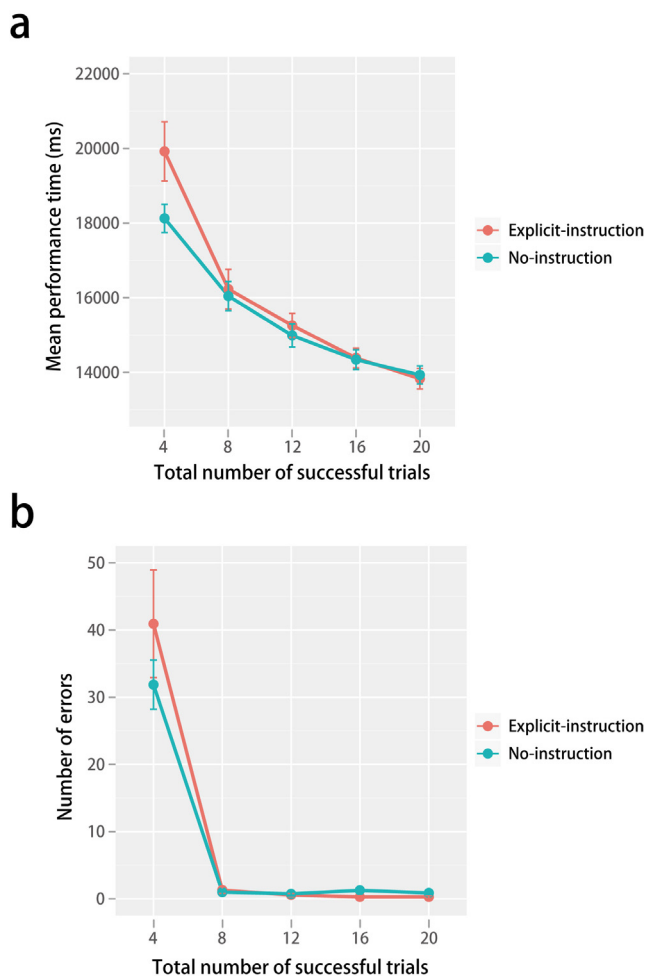

**Figure 1.** Schematic flow of the experiment. Participants were instructed to learn the correct order of button presses by trial and error. The LED buttons were square-shaped (10 mm × 10 mm) and 8 mm apart.

The participants conducted one session using the original hypersets, followed by two sessions using the reversed and the partially reversed hypersets. The order of the final two test sessions was counterbalanced across participants. The three sessions were separated by a 5-minute break. In the explicit-instruction group, the rules of the reversed and the partially reversed orderings were explicitly told to participants before the beginning of each session. In the no-instruction group, they were told that the sets were randomly assigned. For the no-instruction group, the participants were asked whether they had noticed anything peculiar after each session. If the answer was yes, then they were questioned further and asked if they had noticed the rules of changes in the hypersets. Then, participants who noticed the rules were defined as the aware group, and those who did not notice the rules were defined as the unaware group. Hence, we eventually had three groups: the explicit, aware, and unaware groups.

## Data Analysis

We used two measures to assess the accuracy and speed of performance in each block. As a measure of accuracy, we counted the number of errors before correctly completing each trial. To evaluate speed, we measured the time that elapsed from the moment the home key was pressed to the moment the third button of the final (7th) set was pressed for each successful trial. Similar parameters were employed in previous studies and proved to be useful (Hikosaka et al., 1999, 2002; Watanabe et al., 2006, 2010). We calculated average performance using each hyperset by assessing five sections of cumulative successes (i.e., 1st to 4th, 5th to 8th, 9th to 12th, 13th to 16th, and 17th to 20th). For the reversed and partially reversed hypersets, we normalized performance time by using each participant's performance in the last section (i.e., mean performance from the 17th to 20th trials) in which the original hypersets were used as the baseline. Mean performance times of the five sections using the reversed and partially reversed hypersets were subtracted from performance times at baseline.

**Figure 2.** Performance changes in the first block with the learning hyperset. Error bars show the standard error of the means. (a) Average performance time for successful trials.

(b) Average number of errors before the successful completion of each trial.

## Results

### Learning session with original hyperset

A significant decrease was found in both the accuracy (the number of completion failures) and speed measures (averaged completion time for successful trials) in the first session with the original hyperset irrespective of the group (Figure 2), indicating that learning did occur [ANOVA;  $F(4, 140) = 51.44$ ,  $p < 0.0001$ ; for both measures]. The accuracy measure decreased rapidly in the first few completed trials while the speed measure decreased more gradually. These results are in accordance with those of previous studies (Hikosaka et al., 1995, 1996, 2002; Sakai et al., 1998, 2003; Watanabe et al., 2006).

### Comparison between explicit-instruction and no-instruction groups

First, we examined the effects of explicit instruction on the  $3 \times 7$  task. Explicit instruction slowed down performance. The partially reversed hypersets also slowed performance. A three-way ANOVA revealed significant main effects of instruction ( $F(1, 35) = 13.84$ ,  $p < 0.001$ ; explicit > no-instruction), hyperset ( $F(1, 35) = 40.78$ ,  $p < 0.0001$ ; partially reversed > reversed), and trial section ( $F(4, 140) = 145.85$ ,  $p < 0.0001$ ; post hoc, Shaffer's method, 1st > 2nd > 3rd > 4th > 5th). A significant interaction was also found between instruction and trial section ( $F(4, 140) = 30.34$ ,  $p < 0.001$ ).

On the other hand, explicit instruction had a positive effect on the accuracy measure, but only for the first sections using the reversed and partially reversed hypersets. A three-way ANOVA revealed significant main effects of instruction ( $F(1, 35) = 8.35$ ,  $p < 0.01$ ; no-instruction > explicit), hyperset ( $F(1, 35) = 12.44$ ,  $p < 0.01$ ; partially reversed > reversed), and trial section ( $F(4, 140) = 29.15$ ,  $p < 0.001$ ; post hoc, Shaffer's method, 1st > all other sections). A significant interaction was also found between instruction and trial section ( $F(4, 140) = 12.33$ ,  $p < 0.001$ ).

### Comparison between aware and unaware groups

Among 23 participants in the no-instruction group, 8 participants spontaneously noticed the specific rules of both the reversed and the partially reversed hypersets during the experiment; hence, they were classified as the "aware" group. The other 15 participants did not notice either of the rules during the experiment and were classified as the "unaware" group.

**Figure 3.** Performance of the explicit and no-instruction groups in the second and third sessions using the reversed and partially reversed hypersets. Error bars show the standard error of the means. (a) Average normalized performance times. (b) Average number of errors before the successful completion of each trial.

Figure 4a shows the mean normalized performance times of the aware and unaware groups. The aware group exhibited slower normalized performance times when using both the reversed and partially reversed hypersets. A three-way ANOVA revealed significant main effects of instruction ( $F(1, 21) = 4.99, p < 0.05$ ; aware > unaware), hyperset ( $F(1, 21) = 16.83, p < 0.001$ ; partially reversed > reversed), and trial section ( $F(4, 84) = 116.51, p < 0.0001$ ; post hoc, Shaffer's method, 1st > 2nd > 3rd > 4th = 5th). A significant interaction between instruction and trial section was also revealed ( $F(4, 84) = 10.34, p < 0.0001$ ). The number of errors observed was higher in the aware group's first section compared to the unaware group's first section (Figure 4b). A three-way ANOVA revealed significant main effects of instruction ( $F(1, 21) = 8.43, p < 0.01$ ; unaware > aware), hyperset ( $F(1, 21) = 13.49, p < 0.01$ ; partially reversed > reversed), and trial section ( $F(4, 84) = 35.20, p <$

$0.001$ ; post hoc, Shaffer's method, 1st > all other sections). A significant interaction between instruction and trial section was also found ( $F(4, 84) = 8.87, p < 0.001$ ).

**Figure 4.** Performance of the aware and unaware groups in the second and third sessions using the reversed and partially reversed hypersets. Error bars show the standard error of the means. (a) Average normalized performance times. (b) Average number of errors before the successful completion of each trial.

## Discussion

In the present study, we examined the effects of the acquisition of explicit knowledge through instruction or spontaneous detection on transfer of visuomotor sequence learning. Knowledge of changes via explicit instruction led to slower performance with fewer errors, and this sluggishness persisted even in the last phase of learning. On the other hand, knowledge discovered spontaneously by participants produced slower performance in the initial phase of learning with fewer errors, but performance speed tended to peak at the same level as that of the unaware participants (using the partially reversed hyperset). These

results suggest that explicit knowledge may help to reduce errors in the initial phase but may interfere with increasing speed, particularly when the knowledge is given rather than found.

The participants who spontaneously noticed the presence of the rules showed slower performance than those who did not notice the rules in the initial phase of the session, which they performed with fewer errors. The lack of influence of explicit knowledge on the later stages of learning is consistent with the two-loop model of visuomotor sequence learning (Nakahara et al., 2001) and with previous studies (Watanabe et al., 2006). Watanabe et al. (2006) examined the influence of explicit knowledge of stimulus configuration (workspace) in visuomotor sequence learning, and their experimental paradigm was essentially the same as that of the present study. After the first session (i.e., learning a specific visuomotor sequence by trial and error), the workspace was rotated for the second session without notifying the participants. It is noteworthy that participants who noticed the rules of rotation did not improve in terms of performance time, though they were able to use their explicit knowledge of the rotation. In the task employed in the present study, explicit knowledge of the sequence is critical for performing and proceeding through the task (as in other learning paradigms that involve explicit instructions of sequences; Jueptner et al., 1997a, 1997b; Karni et al., 1995). For other types of procedural learning, including rotary movement pursuit and mirror tracing, explicit knowledge has little effect on the accuracy and/or speed of task performance (e.g., Heindel et al., 1989). Differences in the necessity of explicit knowledge may explain this discrepancy between results.

Slower performance by participants who received explicit instruction might appear contradictory with the results of previous studies. In the SRT task, explicit knowledge given before the task could lead to faster performance during the task (Curran & Keele, 1993). One possible interpretation is that the role of explicit knowledge may differ in different paradigms of sequential learning because spatial sequence is learned by trial and error in the  $3 \times 7$  task, whereas spatial sequence is defined in a stimulus-driven way in the SRT task (Curran & Keele, 1993; Nissen & Bullemer, 1987; Willingham et al., 1989). Another possible interpretation is that the effects of explicit knowledge may depend on the demands of the task. Curran and Keele (1993) showed that explicit knowledge of a to-be-learned sequence led to faster performance in a single task but not in a dual task, and they implied that explicit knowledge facilitated sequence learning only when attention was fully available. In the present study, the participants were required to complete a task without instruction first, and then the participants in the explicit-instruction group conducted the task with explicit knowledge of the rule changes. In other words, the participants were required to maintain the prior order and the instruction to reverse the original hyperset, whereas participants in the SRT task were required only to retain information about which button to press. This difference

also might be related to the capacity limit of working memory. Previous work showed that if an individual is asked to hold words in working memory and to judge whether a probe word was one of the retained words, response time increased with memory set size (e.g., McElree & Doshier, 1989; Sternberg, 1969). In the present study, the performance speed of the explicit-instruction group did not reach an equal level to that of the no-instruction group even in the final phase. Thus, explicit knowledge given by another person thoroughly hindered performance speed for the duration of the experiment. As for individual differences in hindrance, participants who have high working memory capacities might not be influenced, and vice versa. Clarification of this proposal would require further investigation.

The present findings can be exemplified by a more familiar hypothetical case. Assume that you are dialing a phone number that you know well. In this case, you can dial it quickly. If you are asked to dial a new phone number that is actually the reverse of the well-known phone number, and you do not notice this fact, you will become able to dial it fast. If you notice that the new phone number is the reverse of the well-known phone number on your own, it would slow your learning, but you will eventually be able to dial the new number quickly. However, if you are explicitly asked to dial the reverse of the well-known phone number, you will not be able to dial the reversed phone number as quickly as the original phone number. It is noteworthy that in the final phase, the performance speed in the explicit-instruction group did not reach the same level as that in the no-instruction group. This could be because attentional resources need to be partly devoted to holding explicit knowledge, which reduces the efficacy of learning. However, further investigation is warranted in order to elucidate how explicit knowledge interferes with learning.

## Abstract

People often perform spontaneous body movements during spatial tasks. How are these spontaneous gestures related to spatial problem-solving? We measured spontaneous movements during a perspective-taking task inspired by map reading. Analyzing the motion data to isolate its rotation and translation components in specific geometric relation to the task, we found out that most participants executed spontaneous miniature rotations of the head that were significantly related to the main task parameter. These head rotations were as if participants were trying to align themselves with the orientation on the map, but with tiny amplitudes, typically below 1% of the actual movements. Our results are consistent with a model of sensorimotor prediction driving spatial reasoning. The efference copy of planned movements triggers this prediction mechanism. The movements themselves may then be mostly inhibited; the spontaneous gestures that we measure are the visible traces of these planned but inhibited actions.

## Introduction

### Motor activity in spatial tasks

People often perform spontaneous body movements during spatial tasks such as giving complex directions or orienting themselves on maps. Spontaneous gestures in spatial tasks have been studied by Chu & Kita (2011), who showed that their participants spontaneously produced hand gestures while performing a mental rotation task. Motor activity can also trigger mechanisms that simulate the outcome of an action (see Wolpert & Flanagan, 2001, for a review of sensorimotor prediction) and thus infer otherwise unavailable information. For instance, Wexler, Kosslyn, & Berthoz (1998) and Wohlschläger & Wohlschläger (1998) showed that unseen manual rotations improved performance in mental rotation tasks when the mental and manual rotations were in the same direction, and interfered with mental rotation when the two were in opposite directions. The execution of at least some of the visuo-spatial tasks mentioned above includes a motor component that can either improve task performance or interfere with it. This conclusion is supported by the findings of neuroimaging studies (Kosslyn, Ganis, & Thompson, 2001).

### Spatial perspective-taking (SPT)

Spatial perspective-taking occurs when one adopts a viewpoint different from one's physical viewpoint. SPT is more difficult when the imagined perspective differs

from the actual (physical) one by a rotation than by a translation (Rieser, 1989). Performance after an imagined rotation depends on the absolute magnitude of the rotation angle between the actual and the imagined perspective and shows the typical and robust angular disparity effect: the bigger the angle of rotation to the imagined perspective, the lower the performance. More importantly, when people are allowed to move to the location of their imagined or novel perspective, even in absence of visual and auditory cues, performance after perspective rotations is greatly facilitated and may even attain the baseline level.

Spatial updating seems simple and automatic if a person were to perform the full rotations that he or she imagines. The updating is therefore driven by a sensorimotor prediction mechanism, and this mechanism is activated by motor plans or efference copies of the motor command (Wolpert & Flanagan, 2001). The planned action itself could be wholly or partly inhibited further downstream in the motor system. If spontaneous movements are a visible reflection of such simulated but inhibited actions, they should be correlated in some geometrically specific way with the mental task being performed. To determine if this is so was the major goal of our study.

## Methods

24 unpaid participants took part in the experiment. The motion tracking data of 5 participants did not attain our inclusion criterion (see below) and were discarded. We therefore performed all analyses on the data of the remaining 19 participants (8 women, mean age 33.8, standard deviation (SD) 7.1 years).

The participants were told to watch on a computer display a simple map depicting the crossing of two streets. (see Fig. 1). The participants' task was to answer as quickly and accurately as possible if, at the intersection, they needed to turn left or right in order to reach the (red) dot.

The stimuli were parametrized by two variables: the *deviation angle* (see Fig. 1), and the *corner angle* (not shown in Fig. 1). We take the upward orientation as our "zero" because pilot results showed that it is easiest to perform the task when one's initial imagined orientation is upwards. Deviation angles are taken as positive counterclockwise and negative clockwise. The second independent variable, the corner angle, is the angle between the two streets on the map. It was used to mask the similarity between the trials with the same value of the deviation angle.

Figure 1: Two examples of stimuli (the dashed lines, the angle arrow and text were not part of the stimuli). Every stimulus represents the crossing of two streets. Participants imagined being on the darker (green) street, at the position of the triangle, and facing the intersection. We call this orientation the *imagined orientation*. The task was to decide if at the intersection one should turn left or right in order to reach the (red) dot on the other street. We call the angle between the 6 o'clock (or upwards-facing) direction and the imagined orientation the *deviation angle*. (A) An example stimulus with deviation angle of  $-90$  deg. (B) An example stimulus with deviation angle of  $+135$  deg.

Participants were seated at about 60 cm from a computer display on which the stimulus was displayed. They used the left and right shift keys on a keyboard to answer respectively “left” and “right” with the corresponding hand. Each trial began with the display of a central fixation red cross. After 0.5 seconds, the stimulus was displayed until participant’s answer. We recorded both the response and the response time (RT). The experimental session lasted for about 40 minutes and included 10 practice trials and 500 experimental trials. Every one hundred trials were followed by a pause; its duration did not exceed 5 minutes.

Participants’ head and shoulder movements were recorded using a CODA cx1 scan unit of a Codamotion optical motion tracking system (Charnwood Dynamics Ltd., UK); we used three sensors for each body part. The system recorded the spatial coordinates of each of the six sensors at a sampling rate of 200 Hz.

We used a within-participant factorial design. The main independent variable, the deviation angle, had 8 levels ( $0^\circ$ ,  $\pm 45^\circ$ ,  $\pm 90^\circ$ ,  $\pm 135^\circ$ ,  $180^\circ$ ). The second independent variable, the corner angle, had 10 levels ( $\pm 30^\circ$ ,  $\pm 60^\circ$ ,  $\pm 90^\circ$ ,  $\pm 120^\circ$ ,  $\pm 150^\circ$ ). Five repetitions were set for each condition except for deviation angle angles of  $0^\circ$  and  $180^\circ$ , for which 10 repetitions were set. Trials were presented in random order.

A trial was considered valid if all sensor values were available for at least half of its duration and only subjects with at least 50% of valid trials were included in the motion analysis. Only data from correctly answered valid trials with a RT that did not exceed the mean RT plus 3 SD were included in the analyses. A rectangular moving average filter of 20 samples (0.1 s) was applied in order to smooth the motion data. The

trials with a deviation angle of  $180$  deg were excluded from the analysis of the geometrical properties of rotations and translations as the sign of the angle cannot be used to discriminate the direction of rotations or translations.

We used the distance travelled by a body part (by summing the absolute Euclidean distances between all successive samples of a sensor) as a first measure of motion. If participants did not move more for higher values of deviation angles, our hypothesis would be invalidated from the start. We selected the maximum path length among the three sensors for each body part as the representative value of its motion extent. Since the path length is always positive, we posited a simple regression model of the path length on the absolute values of deviation angle:  $P_i = a + |\theta_i| b$ , where  $P_i$  is the maximum path length of the three motion sensors on trial  $i$  (expressed in mm),  $\theta_i$  the deviation angle on that trial,  $b$  a regression coefficient, and  $a$  a constant term. If the slope is found to be positive, we can proceed to a more specific analysis, which consists in decomposing the motion in its translational and rotational components and analyzing their geometrical specificity in relation to the signed values of deviation angles.

For the sake of the detailed motion analysis, we assume that both the head and shoulders undergo rigid motion in space—a combination of rotation and translation. We extracted the rotation and translation, using an optimization algorithm. We first calculated the relative vectors between the three sensors, which isolates the rotation component of the rigid motion. Our algorithm then searched through the (three-dimensional) space of rotations, finding the rotation that most closely matched the final relative vectors. We calculated the translation separately by performing vector subtraction between centers of mass of the three sensors for the head and shoulders.

For each sample of sensor positions provided by the motion tracker, we computed participants’ head and shoulder rotations (axes and angles) and translations with respect to their initial orientation and position, respectively. We then selected the maximum values of rotation and translation reached during the trial. We could not predict the axis about which the spontaneous rotations take place. We therefore posited the following simple linear regression model, in terms of axis-angle rotation vectors (indicated in boldface) for the relation between spontaneous movements and task variables:  $\mathbf{R}_i = \theta_i \mathbf{r}$ , where  $\mathbf{R}_i$  is the maximum rotation—of either the head or the shoulders—on trial  $i$  (expressed in the axis-angle vector representation),  $\theta_i$  the deviation angle on that trial, and  $\mathbf{r}$  a triplet of regression coefficients. Thus, the vector  $\mathbf{r}$  represents the rotation (again, as a vector in axis-angle space) that the participant would perform for deviation angle  $\theta$  equal to 1 deg. We decomposed this vector into its axis-angle components:  $\mathbf{r} = z \hat{\mathbf{a}}$ , where its length or norm,  $z$ , is a regression coefficient that we will call the *spontaneous rotation coefficient*, and its direction,  $\hat{\mathbf{a}}$ , the unit vector that corresponds to the axis of rotation. Our regression therefore yields both the

spontaneous rotation coefficient and the axis of spontaneous rotation.

We posited a similar model for translations:  $\mathbf{T}_i = \theta_i w \hat{\mathbf{u}}$ , where  $\mathbf{T}_i$  is the maximum translation vector of the head or shoulders, and  $\hat{\mathbf{u}}$  is a unit vector indicating the direction of translation, and  $w$  the spontaneous translation coefficient.

To calculate statistical confidence intervals of these spontaneous motion coefficients, we performed a bootstrap. For each bootstrap resample  $j$ , we calculated the rotation vector  $\mathbf{r}^{(j)}$  [or the translation  $w^{(j)} \mathbf{t}^{(j)}$ ]. We then calculated a 95% confidence ellipsoid for these points. If the origin fell outside this ellipsoid, then the regression was said to yield a coefficient statistically different from zero. We used the geometric mean of the ellipsoid semi-axes as a measure of standard error of the spontaneous motion coefficients.

## Results

### Response times and error rates

Overall, the mean RT on raw unfiltered data was  $1.17 \pm 0.38$  s ( $\pm$  between-subject SD). Increasing the deviation angle lowers performance, increasing the RT, as shown in Fig. 2.

Figure 2: RT as a function of the deviation angle. Gray dots represent individual participants' data, the black curve the mean, and error bars between-subject standard errors. The data for deviation angles  $\pm 180^\circ$  is shown twice. Several outlying datapoints are not shown.

The mean reaction time was submitted to a repeated-measures ANOVA with the factors: sign of deviation angle (2 levels), absolute value of deviation angle (6 levels, excluding 0 and 180 deg), sign of corner angle (2 levels) and absolute value of corner angle (5 levels). The analysis revealed a significant main effect of absolute value of the deviation angle ( $F_{2,36} = 29.1$ ,  $p < 0.001$ , Huynh-Feldt corrected), a significant main effect

of the sign of corner angle ( $F_{1,18} = 16.9$ ,  $p < 0.001$ ), a significant main effect of the absolute value of corner angle ( $F_{3,4,60,6} = 8.3$ ,  $p < 0.001$ ) and a significant third-order interaction between the sign of deviation angle, the sign of the corner angle and the absolute value of corner angle ( $F_{2,8,50,9} = 4.3$ ,  $p < 0.01$ ). The main effect of the sign of the deviation angle was not statistically significant nor were the other interactions.

To quantify the relation between the deviation angle and the RT, we calculated the slopes of the linear regression of the RT on the absolute values of the deviation angle for every participant. (Since the sign of the deviation angle had no effect on the response times, we collapsed data for positive and negative deviation angles.) All individual slopes were positive and statistically significant (bootstrap with  $10^4$  resamples,  $p < 0.05$ ); the mean slope was  $3.09 \pm 2.30$  ms/deg ( $\pm$  between-subject SD). In other words, mean RT increased by 3.09 ms for every additional degree of deviation angle. The plot of RT versus deviation angle (Fig. 2) has a noticeably curvilinear shape, with the RT slope seemingly higher for deviation angles above 90 deg. The mean slope for deviation angles between 0 and 90 deg was  $1.20 \pm 0.89$  ms/deg, whereas between 90 and 180 degrees it was  $5.05 \pm 3.82$  ms/deg. This difference between slopes for small and large deviation angles was statistically significant (paired  $t_{18} = 5.41$ ,  $p < 0.0001$ ) and showed that RTs increased faster (more than 4 times faster, according to the means) as a function of deviation angle above 90 deg.

The median error rate was  $1.2 \pm 0.6\%$  ( $\pm$  between-subject median absolute deviations). Overall, the error rate was very low: the task was seemingly well understood by our participants and easy to perform. The analyses of the relation between error rates and deviation angles lead to similar findings as the ones of the RT and are not provided here.

### Spontaneous body movements and their relation to the task

**Analysis of Path Length** As a first analysis of the relation between task performance and body movements, we wanted to see if there was a relationship between the extent of spontaneous motion and the deviation angle. As a measure of motion extent, we used the length of the path traveled in space. Fig. 3 shows the mean path lengths as a function of the absolute deviation angle.

The mean path length across participants and deviation angles is  $13.1 \pm 10.2$  mm ( $\pm$  between-subject SD) for the head and  $10.3 \pm 6.9$  mm for the shoulders. The slope of the linear regression (including a constant term, see Methods) of path lengths on the absolute deviation angles provides an indication on the relation between the movements and the deviation angle: if positive, it would indicate that the participants move more in trials with higher deviation angles. For head movements, 17/19 (89%) regression slopes were positive and 13/19 (68%) were significantly so (bootstrap with  $10^4$  resamples,  $p < 0.05$ ); the mean slope

was  $0.038 \pm 0.058$  mm/deg ( $\pm$  between-subject SD). For the shoulders, 17/19 (89%) regression slopes were positive and 12/19 (63%) were significantly so (bootstrap with  $10^4$  resamples,  $p < 0.05$ ); the mean slope was  $0.026 \pm 0.041$  mm/deg.

Figure 3: Mean path length traveled by the head and shoulders as a function of deviation angle. Gray dots represent individual participants' data, the black curve the mean, and error bars between-subject standard errors. Several outlying datapoints are not shown.

This analysis of path lengths shows that for most participants there was a relationship between the *absolute extent* of spontaneous movements and the absolute value of the principal task parameter, the deviation angle. Because the movements of the head and shoulders were nearly rigid, for further analysis we decomposed them into the two components of rigid motion, rotations and translations.

**Analysis of Absolute Amplitude of Rotations** As stated in the Methods, for each trial we calculated the maximal rotation of the head and shoulders with respect to their initial orientations at the start of the trial. We represented these rotations as 3D vectors using the axis-angle representation, in which the length of the vector is the angle of rotation and its direction the axis.

To begin with, we analyzed only the angles of the maximal rotations. As in the preceding analysis, we wished to test whether this measure of absolute magnitude of rotation was correlated with task difficulty, i.e., the absolute value of deviation angle. Fig. 4 shows the mean maximal rotation magnitude as a function of the absolute deviation angle.

The overall mean rotation amplitude is  $1.57 \pm 0.5$  deg ( $\pm$  between-subject SD) for the head and  $0.78 \pm 0.17$  deg for the shoulders. Some of the spontaneous rotations were not specifically related to the main task parameter, as shown by the presence of rotations even when deviation angle is zero.

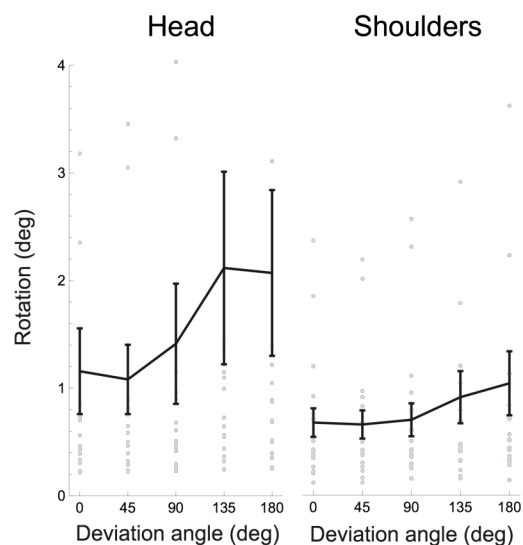

Figure 4: Absolute rotation amplitude, for the head and shoulders, as a function of the absolute deviation angle. Gray dots represent individual participants' data, the black curve the mean, and error bars between-subject standard errors. Several outlying datapoints are not shown.

We performed a linear regression (including a constant term) of the rotation amplitude versus absolute deviation angles to quantify the relation between the rotations and the deviation angles. We found out that 17/19 (89%) regression slopes were positive for both head and shoulder rotations and 10/19 (53%) for the head and 7/19 (37%) for the shoulders were significantly so (bootstrap with  $10^4$  resamples,  $p < 0.05$ ); the mean slope was  $0.006 \pm 0.013$  ( $\pm$  between-subject standard deviations) for the head and  $0.002 \pm 0.005$  for the shoulders.

The analysis of absolute rotation angles shows that there was a relationship between the *absolute amplitudes* of spontaneous rotations and the deviation angle. It doesn't tell us, however, if this relationship was geometrically specific. Did participants spontaneously move in one direction for the positive deviation angles and in the opposite direction for the negative ones?

**Directional Analysis of Rotations** To answer the question above, we performed a linear regression of the full axis-angle rotation vectors (i.e., including the direction of rotations in addition to their amplitudes) on the deviation angle—rather than just its absolute value—of the corresponding trial. We call the slopes of these linear regressions the spontaneous rotation coefficients (see Methods for details).

For head rotations, the mean spontaneous rotation coefficient is  $0.007 \pm 0.018$  ( $\pm$  between-subject SD); the median coefficient is  $0.001 \pm 0.0009$  ( $\pm$  between-subject median absolute deviations). For the shoulders, the mean coefficient is  $0.001 \pm 0.002$ ; the median coefficient is  $0.0005 \pm 0.0002$ . The interpretation of these parameters, for example for head spontaneous

rotations, is as follows: on the average, participants rotated their head by 0.7% (or 0.1%, if we use the medians) of the deviation angle. Contrary to the preceding analyses, we have extracted the directionally-specific component of the spontaneous rotations: rotations that are in opposite directions for clockwise and counterclockwise deviation angles. The axis of these rotations varies from one participant to the next; we will return to the question of axes below.

To test whether these correlations were statistically significant, we stepped back to our original regression model,  $\mathbf{R}_i = \theta_i \mathbf{r}$  (recall that the spontaneous rotation coefficients are the lengths of the regression vectors  $\mathbf{r}$ ), and used the regression vectors  $\mathbf{r}$  for significance analysis. We performed a bootstrap resampling ( $10^5$  resamples) of the vectors  $\mathbf{r}$  and calculated the 95% confidence ellipsoid of these vectors (see Methods).

First of all, an omnibus regression analysis, including all data sets of all participants at once, shows a statistically significant spontaneous rotation coefficient of 0.0068 for the head and of 0.0006 for the shoulders. Second, although the individual spontaneous rotation coefficients were small (all but two were smaller than 1%), in case of head rotations 15/19 (79%) participants had a statistically significant linear relationship between maximum rotation and deviation angle. In case of shoulder rotations, on the other hand, only 4/19 (21%) participants had significant fits to the model. Given that only a few participants executed significant shoulder rotations, we carried out the rest of rotation analyses only for head movements.

**Analysis of Rotation Axes** Along with the spontaneous rotation coefficients, our analysis also yielded an axis of rotation for each subject, separately for the head and the shoulders. Fig. 5 shows these axes, as unit vectors (the vector  $\hat{\mathbf{a}}$  in our regression model), for the head rotations of the 15 participants whose regression analyses yielded significant results. The meaning of each of these vectors is as follows: it is the axis that maximizes the correlation between a participant's rotations and the corresponding values of the deviation angle.

Fig. 5 also shows the mean head rotation axis over all of these participants, equal to  $(+0.13, -0.65, +0.75)$ . The axes of the fifteen participants are rather tightly clustered around this mean; the mean difference between the individual axes and the mean axis is only 24 deg. The largest contributions to this mean rotation axis come from the Z and Y axes. The signs of the components in this vector mean that for *positive* values of the deviation angle, participants tended to carry out rotations about the *positive* Z axis (head turned to the left, as seen from above, see Fig. 6 B) and the *negative* Y axis (head inclined to the left, as seen from behind, see Fig. 6 D); for trials in which the deviation angle was negative, on the other hand, the rotations tended to be in the opposite direction. We will return to the significance of these axes of rotation in the Discussion.

Figure 5: Individual head rotation axes represented in the space of rotations, shown in gray, as well as their mean, shown in red. The individual axes are shown in shades of gray that correspond to the value of the spontaneous rotation coefficient (the darker the arrow, the higher the corresponding coefficient). The three euclidean coordinates represent the mean axis. Given our regression model, the axes change to opposite directions for negative deviation angles.

**Analysis of Translations** The statistical analysis here is the same as for rotations. The mean spontaneous translation coefficients for the head and shoulders are respectively  $0.012 \pm 0.017$  ( $\pm$  between-subject SD) and  $0.008 \pm 0.016$ . The translations of 7 (37%) and 6 (32%) out of 19 participants, for respectively the head and shoulders, were significantly correlated to deviation angle (bootstrap with  $10^4$  resampled datasets,  $p < 0.05$ ).

## Discussion

When asked for directions some people execute spontaneous incipient body movements. If a geometrical relation were found between represented spatial self-displacements and co-occurring incipient spontaneous body movements, it would be indicative of the implication of motor processes (motor plans or efference copies) in our spatial task and consistent with the activation of a sensorimotor prediction mechanism in solving spatial updating problems. Based on findings of the studies on spatial perspective-taking, we focused on the study of the imagined rotations and the angular disparity effect.

We devised a spatial updating task (see Methods and Fig. 1). In addition to behavioral data, we measured the spontaneous movements of our participants. To our knowledge, spontaneous movements have not been quantified so far in a spatial updating task.

Our behavioral results replicate the studied angular disparity effect on task performance (see Introduction).

We found that 15 out of 19 (79%) participants executed spontaneous head rotations related to the task parameters (if we include translations, 17 out of 19 participants (89%) executed a statistically significant motion)—in spite of the ease of the task, as shown by low error rates. These rotations were very small in

amplitude (typically below 2 deg). In most of the participants, the movements were too small to be seen, but could nevertheless be measured with the motion tracker, and their relationship to the task parameters shown using our analysis. Indeed, these miniature head rotations were reliably correlated to the deviation angle, but much smaller (typically less than 1% of the deviation angle).

The geometrically specific correlation between spontaneous head rotations and the deviation angle has two aspects. First, larger deviation angles (corresponding to more difficult trials) led to larger rotations. Second, opposite deviation angles led to head rotations in opposite directions about a specific rotation axis, that we calculated using our linear model in rotation space.

The mean axis of rotation, averaged across participants, has a main vertical Z-axis component (i.e. a head turn, see Fig. 6 A, B) and a strong but lesser front-back Y-axis component (Fig. 6 C, D): the resulting head movement is thus a horizontal rotation of the head with an important tilt component. These head rotations are as if participants were trying to align themselves with the imagined orientation on the map. In the case of the front-back Y-axis, this alignment is in the image plane; in the case of the vertical Z-axis, it is as if the participants back-projected the vertical image onto the ground plane, and then tried to align themselves with the imagined orientation in this projection.

Fig. 6: The main component axes of average spontaneous head rotations. (A, B) Head turn about vertical Z axis. (C, D) Head tilt about naso-occipital Y axis.

Our findings on spontaneous head rotations are consistent with a motor contribution to spatial-updating task performance and with our action inhibition

hypothesis as the characteristics of the spontaneous movements are geometrically consistent with those of actual rotations in the ground plane or image plane that would be required to bring the participant into alignment with the required initial orientation. We may speculate on several types of contribution. The premotor cortex could prepare an actual movement, which would lead to two separate processes: an anticipation process that predicts the outcome of the action (i.e., the map with the you-are-here street aligned with the participant's vertical axis) from an efference copy of the motor command, and the execution of the overt motor action, which would be inhibited at early stages (earlier for some participants than for others).

Alternatively, the implication of the motor system may be *epiphenomenal*, related to concurrent cognitive processes but not causally so.

We cannot at this stage answer the question of causality of the spontaneous movements. To settle this argument, we need a new experimental setting contrasting a condition in which movement is allowed or facilitated with another one where movement is restrained. It will allow us to measure the impact of each condition on the task performance and shed more light on the causality of the motor processes in mental spatial updating tasks.

## Abstract

In contrast to the wealth of saliency models in the vision literature, there is a relative paucity of models exploring auditory saliency. In this work, we integrate the approaches of (Kayser, Petkov, Lippert, & Logothetis, 2005) and (Zhang, Tong, Marks, Shan, & Cottrell, 2008) and propose a model of auditory saliency. The model combines the statistics of natural soundscapes and the recent past of the input signal to predict the saliency of an auditory stimulus in the frequency domain. To evaluate the model output, a simple behavioral experiment was performed. Results show the auditory saliency maps calculated by the model to be in excellent accord with human judgments of saliency.

**Keywords:** attention; saliency map; audition; auditory perception; environmental statistics

## Introduction

In general, attention plays a very important role in the survival of an organism, by separating behaviorally relevant signals from irrelevant ones. One approach to understanding how attention functions in the brain is to consider the “saliency map” over the sensory input space, which may determine subsequent motor control targets or selectively modulate perceptual contrast thresholds. The brain’s putative saliency maps can be thought of as interest operators that organisms use to enhance or filter sensory signals.

Many visual saliency models have been investigated, but relatively little attention has been paid to modeling auditory saliency. However, since the fundamental necessity for perceptual modulation remains the same regardless of modality, the principles of visual saliency models should apply equally well to auditory saliency with appropriate sensory input features. Two representative visual saliency models are the center-surround contrast model (Itti, Koch, & Niebur, 2002) and the SUN (Saliency Using Natural Statistics) model (Zhang et al., 2008). Itti et al.’s model is neurally-inspired, with the response of many feature maps (e.g., orientation, motion, color) combined to create a salience map. The SUN model uses a single feature map learned using Independent Components Analysis (ICA) of natural images, and the salience at any point is based on the rarity of the feature responses at that point - novelty attracts attention. Here, rarity is based on statistics taken from natural images, so the model assumes experience is necessary to represent novelty.

Previous works that apply the visual saliency paradigm to the auditory domain include the models of (Kayser et al., 2005) and (Kalinli & Narayanan, 2007). Both adapt the visual saliency model of (Itti et al., 2002) to the auditory domain

by using spectrographic images as inputs to the model. Although this is a reasonable approach, these models fail to capture several important aspects of the auditory modality. First, this approach treats time as simply another dimension within the spectrographic representation of the sound. Even though these models utilize asymmetric temporal filters, the resulting saliency map at each time point is contaminated by information from the future. Second, spectrographic features are not the most realistic representations of human auditory sensations, since the cochlea exhibits complex nonlinear responses to sound signals (Lyon, Katsiamis, & Drakakis, 2010). Finally, Itti et al.’s model determines the saliency values from the current input signal, with no contribution from the lifetime experience of the organism. This makes it impossible for the model to account for potential perceptual differences induced by differences in individual experience.

## The Auditory Saliency Model

In this work, we propose the Auditory Saliency Using Natural statistics model (ASUN) as an extension of the SUN model. The extension involves (1) using realistic auditory features instead of visual ones, and (2) combining long-term statistics (as in SUN) with short-term, temporally local statistics. Although the SUN model has both a top-down, task-based component and a bottom-up, environmentally driven component, here we restrict ourselves to just the bottom-up portion of SUN. SUN defines the bottom-up saliency of point  $x$  in the image at time  $t$  as:

$$s_x(t) \propto -\log P(F_x = f_x) \quad (1)$$

Here,  $f$  is a vector of feature values, whose probability is computed based on prior experience. This is also known as the “self-information” of the features, and conveys that rare feature values will attract attention. In the SUN model, this probability is based on the lifetime experience of the organism, meaning that the organism already knows when feature values are common and when they are rare. Assuming the primary purpose of attention is to separate remarkable events from the humdrum, it is logical to equate the rarity of the event with the saliency of it. For example, a loud bang may be salient not only because of its physical energy content, but also because of its relative rarity in the soundscape. An organism living under constant noise may not find an explosion to be as salient as another organism acclimated to a quieter environment.

For features, SUN uses ICA features learned from natural images, following Barlow’s efficient coding hypothesis (Barlow, 1961). This provides a normative and principled rationale for the model design. While ICA features are not completely independent, they justify the assumption that the features are independent of one another, making the computation of the joint probability of the features at a point computationally simple. This is the goal of efficient coding: By extracting independent features, the statistics of the visual world can be efficiently represented. Although the saliency filters used in Kayser et al.’s model have biophysical underpinnings, exact shape parameters of the filters cannot be determined in a principled manner. More importantly, their model does not explain *why* the attention filters should be the way they are. In contrast, by using filters based on the efficient coding hypothesis, the SUN and ASUN models make no such assumptions; the basic feature transformation used (Gammatone filters) reasonably approximate the filters learned by the efficient encoding of natural sounds (Lewicki, 2002), and the distributions of filter responses are learned from the environment as well. Assuming that the attentional mechanism is modulated by a lifetime of auditory experience is neurologically plausible, as evidenced by the experience-induced plasticity in the auditory cortex (Jääskeläinen, Ahveninen, Bellevue, Raji, & Sams, 2007).

Here, we extend this model to quickly adapt to recent events by utilizing the statistics of the recent past of the signal (the “local statistics”) as well as the lifetime statistics. Denoting the feature responses of the signal at time  $t$  as  $F_t$ , saliency at  $t$  can be defined as the rarity in relation to the recent past (from the input signal) as well as to the long-term past beyond suitably chosen delay  $k$ :

$$s(t) \propto -\log P(F_t = f_t | \underbrace{F_{t-1}, \dots, F_{t-k}}_{\text{recent past}}, \underbrace{F_{t-k-1}, \dots}_{\text{long past}})$$

In this paper, we simply define  $t - k$  as the onset of the test stimulus. Under the simplifying assumption of independence between the lifetime and local statistics, this becomes

$$\begin{aligned} s(t) &\propto -\log P(F_t = f_t | F_{t-1}, \dots, F_{t-k}) \\ &\quad -\log P(F_t = f_t | F_{t-k-1}, \dots) \\ &= s_{\text{local}}(t) + s_{\text{lifetime}}(t), \end{aligned}$$

where  $s_{\text{local}}(t)$  and  $s_{\text{lifetime}}(t)$  are the saliency values calculated from the local and lifetime statistics, respectively. By using the local statistics at different timescales, the model can simulate various adaptation and memory effects as well. In particular, adaptation effects emerge as the direct consequence of dynamic information accrual, which effectively suppresses the saliency of repeated stimuli as time proceeds. With such local adaptation effects, the model behaves similarly to the Bayesian Surprise model (Baldi & Itti, 2006), but with asymptotic prior distributions provided by lifetime experience.

## Feature Transformations

A model of auditory attention necessarily relies upon a model of peripheral auditory processing. The simplest approach to modeling the cochlear transduction is to use the spectrogram of the sound, as was done in (Kayser et al., 2005). More physiologically plausible simulations of the cochlear processing require the use of more sophisticated transformations, such as Meddis’ inner hair cell model (Meddis, 1986). However, the realism of the model comes at a computational cost, and the complexity of the feature model must be balanced against the benefit. Given these considerations, the following feature transformations were applied to the audio signals in the ASUN model:

1. At the first stage, input audio signals (sampled at 16 kHz) are converted to cochleagrams by applying a 64-channel Gammatone filterbank (from 200 to 8000 Hz.) Response power of the filters are clipped to 50dB, smoothed by convolving with a Hanning window of 1 msec and downsampled to 1 kHz. This yields a 64-dimensional frequency decomposition of the input signal.
2. At the second stage, this representation is further divided into 20 frequency bands comprised of 7 dimensions each (with 4 overlapping dimensions,) and time-frequency patches are produced using a sliding window of 8 samples (effective temporal extent of 8 msec). This yields 20 bands of  $7 \times 8 = 56$ -dimensional representation of 8 msec patches.
3. Finally, for each of the four sound collections (described below), a separate Principal Components Analysis (PCA) is calculated for each of the 20 bands separately. Retaining 85% of the variance reduces the 56 dimensions to 2 or 3 for each band.

This set of transformations yield a relatively low-dimensional representation without sacrificing biological plausibility. The result of these transformations at each time point,  $f_t$ , provides input for subsequent processing. Figure 1 illustrates this feature transformation pipeline.

## Density Estimation Method

In order to calculate the self-information described in equation 1, the probability of feature occurrences  $P(F = f_t)$  must be estimated. Depending on the auditory experience of the organism, this probability distribution may vary. To assess the effect of different types of lifetime auditory experiences, 1200 seconds worth of sound samples were randomly drawn from each of the following audio collections to obtain empirical distributions:

1. “Environmental”: collection of environmental sounds, such as glass shattering, breaking twigs and rain sounds obtained from a variety of sources. This ensemble is expected to contain many short, impact-related sounds.

Figure 1: Schematics for the feature transformation pipeline. Input signals are first converted to smoothed cochleagram. This is separated into 20 bands of 8 msec patches. The dimensions of each band are reduced using PCA.

2. “Animal”: collection of animal vocalizations in tropical forests from (Emmons, Whitney, & Ross, 1997). Most of the vocalizations are relatively long and repetitious.
3. “Speech”: collection of spoken English sentences from the TIMIT corpus (Garofolo et al., 1993). This is similar to the animal vocalizations, but possibly with less tonal variety.
4. “Urban”: this is a collection of sounds recorded from a city (van den Berg, 2010), containing long segments of urban noises (such as vehicles and birds), with a limited amount of vocal sounds.

In the case of natural images, ICA filter responses follow the generalized Gaussian distribution (Zhang et al., 2008). However, the auditory feature responses from the sound collections did not resemble any parameterized distributions. Consequently, a Gaussian mixture model with 10 components was used to fit the empirical distributions for each band from each of the collections. Figure 2 shows examples of density model fits against empirical distributions. The distributions from each collection represent the lifetime statistics portion of ASUN model, and each corresponds to a model of saliency for an organism living under the influence of that particular auditory environment.

The local statistics of the input signal were estimated using the same method: at each time step  $t$  of the input signal, the probability distribution of the input signal from 0 to  $t - 1$  was estimated. For computational reasons, the re-estimation of the local statistics were computed every 250 msec. Unfortunately, this leads to a discontinuity in the local probability

Figure 2: Gaussian mixture model fits (red) against the empirical distribution of feature values (blue). The mixture model is used to estimate  $P(F_t = f_t | F_{t-k-1}, \dots)$ .

Figure 3: Spectrograms and saliency maps for simple stimuli. Left columns are the spectrograms of the stimuli, and right columns are the saliency maps (top) and saliency values summed over frequency axis (bottom). Due to the nonlinear cochleogram transform, the y-axes of the two plots are not aligned. (a) Between short and long tones, the long tone is more salient. (b) Silence in a broadband noise is salient compared to the surrounding noise. (c) Amplitude-modulated tones are slightly more salient than stationary tones. (d) In a sequence of closely spaced tones, the second tone is less salient.

distribution every 250 msec. This will be improved in future work, where we plan to apply continually varying mixture models to eliminate such transitions.

## Qualitative Assessments

In (Kayser et al., 2005), the auditory saliency model reproduces basic properties of auditory scene perception described

in (Cusack & Carlyon, 2003). Figure 3 shows the saliency maps of the ASUN model using the “Environmental” lifetime statistics. These examples demonstrate that the model is capable of reproducing basic auditory salience phenomena.

## Human Ratings of Saliency

In order to test the validity of the model in a more quantitative manner, a human rating experiment similar to (Kayser et al., 2005) was performed. In this experiment, seven subjects were asked to pick the more “interesting” of two stimuli. The goal of the experiment was to obtain an empirical rating of the “interestingness” of various audio stimuli, which we conjecture is monotonically related to the saliency. By presenting the same set of stimuli to the saliency models, we can also calculate which of the sounds are predicted to be salient. We assume that the correct model of saliency will have a high degree of correlation with the human ratings of saliency obtained this way.

## Materials

Audio snippets were created from a royalty-free sound collection (SoundEffectPack.com, 2011), which contains a variety of audio samples from artificial and natural scenes. In order to normalize the volume across samples, each sample was divided by the square root of the arithmetic mean of the squares of the waveform (RMS). To create snippets used in the experiment, each sample was divided into 1.2-second snippets, and the edges were smoothed by a Tukey window with 500 ms of tapering both sides. Snippets containing less than 10% of the power of a reference sinusoidal signal were removed in order to filter out silent snippets.

From this collection, 50 high-saliency, 50 low-saliency and 50 large-difference snippets were chosen for the experiments. The first two groups contained snippets for which the Kayser and ASUN models agreed on high (or low) saliency. Snippets in the last group were chosen by virtue of producing highest *disagreements* in the predicted saliency values between Kayser and ASUN models.

With these snippets, 75 trial pairs were constructed as follows:

- (1) *High saliency difference* trials (50): Each pair consists of one snippet from the high-saliency and another from the low-saliency groups.
- (2) *High model discrimination* trials (25): Both snippets were drawn from the large-difference group uniformly.

We expected both models to perform well on *high saliency difference* trials but to produce a performance disparity on the *high model discrimination* trials.

## Procedure

In each trial, each subject was presented with one second of white noise (loudness-adjusted using the same method as above) followed immediately by binaural presentation of a pair of target stimuli. The subject would then respond with

the left or right key to indicate which stimuli sounded “more interesting” (2AFC.) Each experiment block consisted of 160 such trials: 75 pairings balanced with left-right reversal, plus 10 catch trials in which a single stimulus was presented to one side. Each subject participated in a single block of the experiment within a single experimental session.

## Model Predictions

To obtain the model predictions, the same trial stimuli (including the preceding noise mask) were input to the models to produce saliency map outputs. To reduce border effects, 10% buffers were added to the beginning and end of the stimuli and removed after saliency map calculation. The portion of the saliency map that corresponded to the noise mask were also removed from peak calculations.

In (Kayser et al., 2005), saliency maps for each stimuli pair were converted to scores by comparing the peak saliency values. It is unclear what the best procedure is to extract a single salience score from a two-dimensional map of salience scores over time. Following (Kayser et al., 2005), we also chose the peak salience over the snippet. To make predictions, the score for the left stimulus was subtracted from that of the right stimulus in each trial pair. This yielded values between  $-1$  and  $1$ , which were then correlated against the actual choices subjects made ( $-1$  for the left and  $1$  for the right.)

Seven different candidate models were evaluated in this experiment. (1) The *chance* model outputs  $-1$  or  $1$  randomly. This model serves as the baseline against which to measure the chance performance of other models. (2) The *intensity* model outputs the Gammatone filter response intensity. This model simply reflects the distribution of intensity within the sound sample. (3) The *Kayser* model uses the saliency map described in (Kayser et al., 2005). Finally, *ASUN* models with different lifetime statistics were evaluated separately: (4) “Environmental” sounds, (5) “Animal” sounds, (6) “Speech” sounds, and (7) “Urban” sounds.

## Results

To quantify the correspondence between the model prediction and the human judgments of saliency, Pearson product-moment correlation coefficients (PMCC) were calculated between the model predictions and human rating judgment results ( $N=7$ ) across all 75 trials. All subjects responded correctly to the catch trials, demonstrating that they were paying attention to the task. Figure 4 shows the correlation coefficient values for the ASUN models for each type of dataset from which lifetime statistics were learned. The correlation between the ASUN model predictions and the human subjects ( $M = 0.3262, SD = 0.0635$ ) was higher than the correlation of the Kayser model predictions ( $M = 0.0362, SD = 0.0683$ ). The result shows that the ASUN model family predicted the human ratings of saliency better than the Kayser model ( $t(6) = 7.963, p < 0.01$ .)

To evaluate the model performance in context, across-subject correlation was also calculated. Since the models

Figure 4: Correlation coefficient between various models and human ratings of saliency (N=7.) ASUN models correlated with the human ratings of saliency significantly better than the Kayser model.

are not fit to individual subjects, this value provides the ceiling for any model predictions. Because three of the seven subjects went through the same trial pairs in the same order, these trials were used to calculate the across-subject correlation value, and the model responses. Figure 5 shows the correlation values including the across-subject correlation. The result shows that the difference between the across-subject correlations ( $M = 0.6556, SD = 0.0544$ ) and the ASUN model predictions ( $M = 0.4831, SD = 0.0432$ ) was significant ( $t(2) = 16.9242, p = 0.0035$ ), indicating that the models do not yet predict saliency at the subject-consensus level. Nevertheless, the ASUN model correlations were still significantly higher than the Kayser model ( $M = 0.1951, SD = 0.0815$ ) at ( $t(2) = -9.855, p = 0.0101$ ).

The performance for the Kayser model in this experiment was notably worse than what was reported in (Kayser et al., 2005). There are several possible explanations for this. First, the audio samples presented in this experiment were roughly normalized for the perceived loudness. This implies that a saliency model that derives saliency values from the loudness measure in large part may not perform well in this experiment. Indeed, the intensity model does not predict the result above chance ( $t(6) = 0.66, p = 0.528$ ). Although the Kayser model does combine information other than the intensity image alone, it is possible that the predictive power of the model is produced largely by loudness information.

Second, as described previously, some of the trial pairs were chosen intentionally to produce maximal difference between the Kayser and ASUN models, and this produced the large performance disparity. Figure 6 support this hypothesis: in the *high saliency difference* trials, both models performed

Figure 5: Correlation coefficient between various models and human ratings of saliency. A subset of data for which the same trial pairs were presented was analyzed (N=3). Across-subject performance was estimated using the correlation coefficients for all possible pairs from the three subjects.

equally well ( $t(6) = 0.3763, p = 0.7091$ .) In contrast, in *high model discrimination* trials, ASUN models performed significantly better than the Kayser model ( $t(6) = 17.31, p < 0.01$ .) Note that the *high model discrimination* group was not picked based on the absolute value (or “confidence”) of the model predictions, but rather solely on the large difference between the two model predictions. This implies the procedure itself does not favor one model or the other, nor does it guarantee performance disparity on average. Nevertheless, the result shows that the ASUN models perform better than the Kayser model in those trials, suggesting the performance disparity may be explained in large part from those trials.

## Discussion

In this work, we demonstrated that a model of auditory saliency based on the lifetime statistics of natural sounds is feasible. For simple tone signals, auditory saliency maps calculated by the ASUN model qualitatively reproduce phenomena reported in the psychophysical literature. For more complicated audio signals, assessing the validity of the saliency map is difficult. However, we have shown that the relative magnitudes of the saliency map peaks correlate with human ratings of saliency. The result was robust across different training sound collections, which suggest a certain commonality in the statistical structure of naturally produced sounds.

There are aspects of the saliency model that may be improved to better model human physiology. For example, there is ample evidence of temporal integration at multiple timescales in human auditory processing (Poeppel, 2003). This indicates that the feature responses of the input signal

(a) High saliency difference trials

(b) High model discrimination trials

Figure 6: Correlation coefficients for the subsets of trials. (a) For *High saliency difference* trials, both Kayser and ASUN models show high correlation to human rating of saliency, and there are no significant differences between them. (b) For *High model discrimination* trials, ASUN models show significantly higher correlation with human ratings of saliency compared to the Kayser model.

may be better modeled by multiple parallel streams of inputs, each convolved with exponentially decaying kernels of varying timescales. This may be especially important for calculating saliency of longer signals, such as music and spoken phrases. In order to accommodate higher-level statistical structure, the model can be stacked in a hierarchical manner as well, with appropriate feature functions at each level. These expansions will provide insights into the nature of attentional modulations in human auditory processing.

## Acknowledgments

We thank Dr. Christoph Kayser for kindly providing us with the MATLAB implementation of his model. We also thank Cottrell lab members, especially Christopher Kanan, for insightful feedback. This work was supported in part by NSF grant #SBE-0542013 to the Temporal Dynamics of Learning Center.

## Abstract

The similarity, attraction, and compromise effects warrant specific investigation in multi-attribute decision making. To examine these effects concurrently, we assigned 145 undergraduates to three context effect conditions. They were requested to solve 20 hypothetical purchase problems that had three alternatives described along two attribute dimensions. We measured their choices, confidence ratings, and response times. We found that adding the third alternative had significant effects for choice proportions and confidence ratings in all three conditions. The attraction effect was more prominent than the other two effects with regard to choice proportions. The compromise effect condition yielded low confidence ratings and long response times, although the choice proportion was high for the third alternative. These results indicate that the mutual relationship among choice proportions, confidence ratings, and reaction times requires theoretical investigation.

**Keywords:** decision making; choice; context effects; similarity effect; attraction effect; compromise effect

## Introduction

Theories of rational decision making suggest that choice is intrinsically determined by the utilities of the individual alternatives and thus unaffected by the relationships among the alternatives in the choice context. However, many studies have found violations of this tenet (Busemeyer, Barkan, & Chaturvedi, 2007; Tsetsos, Usher, & Chater, 2010). Three much-studied findings regarding such context-dependent choice effects warrant specific attention since they constitute violations of axioms fundamental to rational choice. The present paper collectively addresses these effects because they share important commonalities and can be explained using a unified framework. These findings include the attraction, similarity, and compromise effects.

These effects occur with the addition of a third alternative (decoy) to the two-alternative choice set (Roe, Busemeyer, & Townsend, 2001; Tsetsos et al., 2010; Tsuzuki & Guo, 2004; Usher & McClelland, 2004). Consistent with established research, the present paper examines these effects in a two-attribute form (see Figure 1). The alternatives that constitute the core two-alternative set are

commonly referred to as the target and the competitor. The target and the competitor form a trade-off—one is better than the other on one attribute, but worse on the other attribute. The third alternative is then added to this core set.

Depending on the relative position of the third alternative with respect to the target, three types of phenomena are likely to occur. Two arise when the third alternative is more similar to the target than it is to the competitor. However, if a trade-off exists between the third alternative and the target, the choice probability of the target decreases relative to that of the competitor. This is called the similarity effect (Brenner, Rottenstreich, & Sood, 1999; Tversky, 1972). In contrast, if the third alternative is inferior to the target on all attributes, the choice probability of the target should increase relative to that of the competitor. This is called the attraction effect (Hedgcock & Rao, 2009; Huber, Payne, & Puto, 1982).

The third phenomenon occurs when the third alternative rests between the target and the competitor, in which case the third alternative, now constituting a compromise between the core items, would be chosen most often. This is called the compromise effect (Mourali, Böckenholt, & Laroche, 2007; Simonson, 1989). All three of these phenomena constitute a violation of the axioms of rational choice.

Numerous explanations have been provided for each of the three kinds of decoy effects (Simonson & Tversky, 1992; Tversky, 1972; Tversky & Simonson, 1993). However, Roe et al. (2001) were the first to explain all three within a single framework that was implemented in a connectionist model derived from a previous stochastic mathematical theory (Busemeyer & Townsend, 1993; Tsuzuki, Kawahara, & Kusumi, 2002). Their model (the multi-alternative decision field theory, MDFT) accounts for these findings specifically with the aid of variable lateral inhibition, which is due to similarity relations among alternatives and the momentary shifting of attention from one attribute to another.

Tsetsos et al. (2010, p. 1280) remarked that “before we start, we note that these effects (the similarity, attraction, and compromise effects) were so far obtained in different studies, so until a study reports all three effects with the same

Figure 1: A summary of the phenomena simulated. The letters *S*, *D*, and *C* stand for the third alternatives for the similarity effect, attraction effect, and compromise effect, respectively.

materials, procedures, and subjects, there is the possibility that more freedom exists if parameters (noise) can be modified for various decoy effects.” Therefore, empirical studies are needed to test if the three effects can be replicated using the same experimental design and materials.

The present experiment focused on the functioning of all three major context effects in multi-attribute, multi-alternative decision-making processes using the same materials and procedures. This was done using valid choice sets (hypothetical purchase problems) based on preliminary research. In the three-choice session, participants made a selection, gave confidence ratings for the alternatives, and were measured for response times in 20 different choice sets.

## Method

### Participants and Design

One hundred and forty-five university undergraduates participated in this experiment, for which they received course credit. The basic design variables were (a) the type of the third alternative (corresponding to the similarity, attraction, or compromise effect), which was manipulated between subjects and (b) the type of the alternative (target, competitor, or a third alternative). The participants were randomly assigned to the between-subjects conditions. For the similarity, attraction, and compromise effect condition, 48, 49, and 48 undergraduates were assigned, respectively. The presentation of choice sets was quasi-randomized for each participant in each condition.

### Materials and Apparatus

Based on the stimuli of previous studies (Okuda, 2003; Pettibone & Wedell, 2000; Wedell & Pettibone, 1996), we conducted four preliminary surveys and subsequently

developed 20 choice sets (see Appendix). Each set contained alternatives from a single type of consumer product or service and consisted of two core alternatives (the target and the competitor) and a third alternative that was described on two dimensions (see Figure 1). Across the 20 choice sets, the average choice proportion for the target vs. the competitor was 51.32 vs. 48.27; these two proportions were not significantly different ( $n = 77$ ,  $\chi^2 = 0.16$ ,  $df = 1$ ).

For the similarity effect condition, the third alternative was created by lowering the value of the target on one of its dimensions by one-fourth of the difference between the target and the competitor and by raising the value of the other dimension of the target by one-fourth of the difference between the target and the competitor. For the attraction effect condition, the third alternative was created by lowering the values of the target on both its dimensions by one-fourth of the difference between the target and the competitor. Finally, for the compromise effect condition, the third alternative was created by lowering the value of the target on one of its dimensions by half of the difference between the target and the competitor and by raising the value of the other dimension of the target by half of the difference between the target and the competitor. All materials and instructions were presented using personal computers.

Figure 2: A screen image of the task used in the experiment with English translation (attraction effect condition).

## Procedure

**A session with three alternatives.** Participants were informed that they would be presented with many sets of three alternatives (the target, the competitor, and the third alternative), and that they would need to indicate their preference for each set. Each choice set was represented by three alternatives, each constructed using two values of differing dimensions (see Figure 2). The arrangement of the alternatives and dimensions on the screen was quasi-randomized in each trial. Choice sets were presented

on the screen and remained on the screen until the preference choice was made. The reaction time between the start of the presentation of the choice set and the choice response was measured using a personal computer. Following this, a confidence rating of the choice was provided based on a 9-point scale.

**A session with two alternatives.** Participants performed a similar experimental session using two alternatives (the target and the competitor).

## Results

### Binary Choice Session

In the binary choice session, the average choice proportions for the target vs. the competitor were 51.42 vs. 48.58 in the similarity effect condition, 48.61 vs. 51.39 in the attraction effect condition, and 51.42 vs. 48.58 in the compromise effect condition. The two choice proportions were not significantly different in any of the conditions ( $\chi^2 = 0.54$ ,  $df = 1$ ;  $\chi^2 = 0.53$ ,  $df = 1$ ;  $\chi^2 = 0.01$ ,  $df = 1$ , in the similarity, attraction, and compromise effect conditions, respectively). These results confirm the equivalence of the binary choice sets in this experiment as the baseline data.

### Choice Proportion in the Three-Choice Session

The arcsin transformed choice proportions were analyzed by two-way ANOVA (3 [type of context]  $\times$  3 [type of alternative]) with repeated measures (see Figure 3; Greer and Dunlap [1997] demonstrated that ANOVAs are applicable for the ipsative measures). Context type was a between-subjects factor and alternative type was a within-subjects factor.

The main effects of context type,  $F(2, 142) = 48.88$ ,  $p < .001$ , and alternative type,  $F(2, 284) = 55.45$ ,  $p < .001$ , and the interaction of the two factors,  $F(4, 284) = 80.33$ ,  $p < .001$  were significant. The simple main effects of alternative type were significant in the similarity, attraction, and compromise effect conditions ( $F(2, 426) = 5.74$ ,  $p < .01$ ;  $F(2, 426) = 129.20$ ,  $p < .001$ ;  $F(2, 426) = 105.68$ ,  $p < .001$ , respectively).

A multiple comparison (Tukey's *WSD* test) was performed on the three conditions of alternative type. In the similarity effect condition, the proportion of the competitor was significantly higher than that of the target and third alternative (both  $ps < .05$ ). In the attraction effect condition, the proportion of the target was significantly higher than those of the competitor and third alternative (both  $ps < .01$ ). Furthermore, the proportion of the competitor choice was significantly higher than that of the third alternative,  $p < .01$ . In the compromise effect condition, the proportion of the third alternative was significantly higher than that of the competitor,  $p < .05$ . Overall, these results indicate that the three kinds of decoy effects were replicated in the choice proportions for each of the three context effect conditions.

### Confidence Rating in the Three-Choice Session

The confidence rating scores were analyzed using a two-way mixed model ANOVA (3 [type of context]  $\times$  3 [type of alternative]) with repeated measures (see Figure 4). The main effects of context type,  $F(2, 153.44) = 3.65$ ,  $p < .05$ , and alternative type,  $F(2, 215.91) = 15.60$ ,  $p < .001$ , and the interaction of the two factors,  $F(4, 205.99) = 7.63$ ,  $p < .001$ , were significant. The simple main effects of alternative type were found to be significant in the similarity, attraction, and compromise effect conditions ( $F(2, 2.99) = 15.23$ ,  $p < .001$ ;  $F(2, 29.83) = 4.49$ ,  $p < .05$ ;  $F(2, 61.11) = 26.02$ ,  $p < .001$ ).

A multiple comparison was performed on the three conditions of alternative type. In the similarity effect condition, the confidence rating for the third alternative was significantly lower than those of the target and the competitor (both  $ps < .001$ ). In the attraction effect condition, the confidence rating of the target was significantly higher than that of the competitor,  $p < .05$ . In the compromise effect condition, the confidence rating of the third alternative was significantly lower than those of the target and competitor (both  $ps < .001$ ).

Figure 3: Mean choice proportions (%) of three alternatives in three context conditions. Error bars show standard errors.

In the similarity and attraction effect conditions, the confidence rating scores were largely consistent with the choice proportions. However, in the compromise effect condition, the confidence rating scores were reversed in magnitude relative to the choice proportions.

### Reaction Time in the Three-Choice Session

Choice latencies more than 2 *SD* above the mean for each subject were classified as errors and excluded from the RT analysis. The log-transformed choice latencies were analyzed in a one-way repeated-measures ANOVA (three-alternative types) in each of the three context conditions (see Figure 5).

Although the compromise effect condition yielded a

significant main effect,  $F(2, 93.87) = 4.58, p < .05$ , no such significant effects were found for the similarity or attraction conditions,  $F(2, 60.42) = 0.25$  and  $F(2, 73.88) = 2.17$ , respectively. For the compromise effect condition, a multiple comparison performed on the alternative type indicated that the decision time of the third alternative was significantly longer than those of the target and competitor, (both  $ps < .05$ ). These results are consistent with those of the confidence ratings.

Figure 4: Mean confidence ratings of three alternatives in three context conditions. Error bars show standard errors.

Figure 5: Mean response time (ms) of three alternatives in three context conditions. Error bars show standard errors.

### Discussion

Subsequent to the integrated account of three decoy effects by the MDFT model (Roe et al., 2001), Guo and Holyoak (2002) proposed a connectionist model that accounts for the attraction and similarity effects; this model

was also based on inter-alternative similarity. According to this model, the decision process is divided into two stages in which the two most similar alternatives (i.e., the target and the third alternative) are compared first, followed by the incorporation of the competitor.

Despite its explanatory simplicity and consistency with some established experimental data, the two-stage model appears to be oversimplified for the purpose of describing human behavior. Studies have demonstrated that in multi-alternative choice tasks similar to those of the similarity, attraction, and compromise effects mentioned above, (1) people momentarily shift their attention across pairwise comparisons and (2) similar pairs are compared more frequently than dissimilar pairs (Russo & Rosen, 1975; Satomura, Nakamura, & Sato, 1997).

Based on the data collected from these studies, Tsuzuki and Guo (2004) proposed a stochastic comparison-grouping model in which all possible types of comparisons are performed momentarily using differential frequencies (Figures 6, 7). In addition, while Guo and Holyoak's model uses a mathematical conversion to estimate choice probabilities from the results of only one simulation, Tsuzuki and Guo's model runs a large number of simulations in order to represent decisions across individuals, thereby directly estimating choice probabilities (Table 1).

In contrast to this research, Usher and McClelland (2004) offered an alternative to previous models that account for the three major context effects simultaneously. Their model, the leaky competing accumulator (LCA), shares many of the same principles of the MDFT model but makes different assumptions about loss aversion and the non-linear activation function (Busemeyer, Townsend, Diederich, & Barkan, 2005).

Figure 6: The architecture of the model (Tsuzuki & Guo, 2004). External Input represents the motivational and attentional sources that drive the decision process.

Figure 7: The time-series image of the dynamic fluctuation of the stochastic comparison (Tsuzuki & Guo, 2004). The dark color of the node reflects high node activation.

Table 1: Simulation results as choice probability (estimated from 10,000 simulations; Tsuzuki & Guo, 2004).

Choice scenarios	Choice probability		
	Target	Competitor	Decoy
Binary choice	0.504	0.496	-----
Attraction effect	0.587	0.366	0.048
Similarity effect	0.278	0.397	0.326
Compromise effect	0.213	0.219	0.568

In the present experiment, significant effects of manipulating the third alternative with respect to the similarity, attraction, and compromise effects were found for choice proportions, confidence ratings, and reaction times. Specifically, we found significant effects for choice proportions and confidence ratings in all three of these context-effect conditions, with partially significant effects in response time.

Furthermore, the attraction effect was more prominent than the other two effects with regard to choice proportions. The compromise effect condition yielded low confidence ratings and long response times, although the choice proportion of the third alternative was high. One possibility is that for participants in the compromise effect condition, one kind of selection effect happens for the participant confidence rating for the third alternative in the context of a trade-off or conflict with regard to the evaluation of both attributes. In order to further test this conjecture, we have begun experiments to study the role of eye movements in multi-attribute, multi-alternative processes (Tsuzuki, Shirai, Ohta, Matsui, & Honma, 2008).

Our experimental results support not only our stochastic comparison-grouping model but also the other major models of multi-attribute, multi-alternative choice processes. These results indicate that the relationship between choice proportions and confidence ratings requires theoretical investigation (Pleskac & Busemeyer, 2010), and also suggest that further examination of process-tracing data is needed to

determine the mechanisms underlying these three effects (Schulte-Mecklenbeck, Kühberger, & Ranyard, 2011; Willemsen, Böckenholt, & Johnson, 2011).

## Acknowledgments

We are grateful for comments from James L. McClelland. We are also appreciative of Hiroshi Matsui for his assistance in data collection.

## Appendix

Binary choice sets used in the experiment: 20 consumer products or services and their two attributes

Consumer product or service	Two attributes
Cell-phone	Number of distinctive functions Weight (g)
Electronic dictionary	Types of useful dictionaries Weight (g)
MP3 Player	Recording capacity (Number of tunes) Weight (g)
Digital watch	Quality of design (1–100) Price (thousand ¥)
Notebook computer	Screen size (inch) Weight (g)
LCD TV	Screen size (inch) Price (thousand ¥)
HDD DVD Recorder	Video recording time (hour) Price (thousand ¥)
Digital camera	Image quality (megapixels) Weight (g)
Video camcorder	Image quality (megapixels) Weight (g)
Component stereo	Sound quality (1–100) Price (thousand ¥)
Sport shoes	Quality of design (1–100) Price (thousand ¥)
School bag	Quality of design (1–100) Weight (g)
Single sofa	Comfort in seating (1–100) Price (thousand ¥)
City bike	Quality of design (1–100) Price (thousand ¥)
Gas scooter	Quality of design (1–100) Gas mileage (km per liter)
Rented apartment	Monthly rent (thousand ¥) Walking distance from the station to the apartment (min)
Fitness club	Repletion of equipment (1–100) Time taken to reach the fitness club from home (min)
Hair saloon	Magazine's rating of skill (1–100) Time taken to reach the saloon from home (min)
Restaurant	Magazine's rating of skill (1–100) Time taken to reach the restaurant from school (min)
Part-timer at eating and drinking place	Hourly wage (¥) Time taken to reach from home to that place (min)

# Mental Arithmetic Efficiency: Interactivity and Individual Differences

Frédéric Vallée-Tourangeau

Department of Psychology, Kingston University  
Kingston-upon-Thames UNITED KINGDOM KT1 2EE  
f.vallee-tourangeau@kingston.ac.uk

## Abstract

Thinking efficiency as a function of interactivity was examined in a mental arithmetic task. Participants carried out single-digit additions, involving either 7 or 11 numbers, as fast and as accurately as possible. They completed the sums in blocks, five from the 'easy' set first, and five from the 'hard' set second. These sets were interpolated among a series of other tasks that measured numeracy, working memory capacity, visuo-spatial processing speed and attention switching, in such a way as to permit the presentation of the sets twice, once with each of the sums presented on a piece of paper and participants placing their hands flat on the table and once with the sums presented as a set of manipulable tokens. Efficiency was measured as the ratio of performance over time invested. A significant interaction between condition and difficulty was observed: Efficiency was slightly better in the static condition for easy sums but declined substantially relative to the interactive condition for hard sums. Regression analyses revealed that in the static condition 22% of the variance in efficiency for the harder sums was explained by numeracy and working memory capacity, but 45% by numeracy, working memory capacity and attention switching skills in the interactive condition. Verbal protocols revealed that paths to solution and arithmetic strategies were substantially transformed by the opportunity to manipulate tokens.

**Keywords:** Mental arithmetic, interactivity, efficiency, individual differences, distributed cognition

## Introduction

Mental arithmetic is clearly an important skill with many quotidian applications. It is the quintessential example of what Kahneman (2011) calls "slow thinking": "(a) deliberate, effortful, and orderly" (p. 20) mental process that can be slowed down by a working memory busy holding information about interim steps and selecting strategies to proceed closer to the result. To be sure, for very simple arithmetic problems, answers are retrieved rather than computed; but as problem complexity increases, performance is constrained by limited internal resources.

The role of working memory in mental arithmetic is clearly revealed with experiments employing a dual-task methodology: Performance is significantly impaired by concurrent tasks that tax different components of working memory (e.g., Logie, Gilhooly, & Wynn, 1994). There is

a substantial body of evidence that implicates working memory deficits and poor maths performance in primary school children (e.g., McLean & Hitch, 1999). In adults, the impact of maths anxiety (Ashcraft & Kirk, 2001) and test pressure (DeCaro, Rotar, Kendra, & Beilock, 2010) is explained in terms of the rehearsal and retrieval of performance related thoughts and memories that limit the working memory resources that can be committed to solving the problem.

## Interacting with External Resources

When confronted with internal resource limitations, reasoners naturally mine their surrounding physical space for additional resources. "Artifacts saturate everyday environments" (Kirsh, 2009a, p. 284) and they are routinely recruited to supplement and augment internal cognitive resources. Within such an extended cognitive system (Wilson & Clark, 2009) internal and external resources are coupled by actions, producing a dynamic distributed problem representation. As a result, performance may surpass a level of accuracy and efficiency achievable on the basis of resources internal to the reasoner alone.

Recent experiments on insight and non-insight problem solving reveal how interactivity transforms performance. For example, release from mental set in Luchins's well known volume measurement problems is significantly facilitated when participants interact with actual jars with water (Vallée-Tourangeau, Euden, & Hearn, 2011). Additionally, insight in matchstick algebra problems is substantially enhanced when participants solve these problems with actual matchstick-like objects that permit the physical re-arrangement of the problem representation (Weller, Villejoubert, & Vallée-Tourangeau, 2011). Performance is facilitated by the affordances offered by a modifiable problem representation. In the case of mental set, the physically available resources are more easily perceived as offering simpler and less costly solutions (in terms of pouring and transposing) and help defuse mental set. As for matchstick algebra, the physical movement of a matchstick transforms the presentation of the problem which anchors new mental projections of potential solutions that in turn can be reified by additional physical modification. Insight is thus better driven by a concrete and explicit project-create-project cycle (Kirsh, 2009b).

**Mental Arithmetic.** As for mental arithmetic, recruiting artifacts, such as pen and paper, substantially augments performance largely because working memory content is nearly completely off-loaded onto the external environment. In this case, potential working memory limitations can be compensated by externalising the algorithmic process. While measures of working memory processing capacity may well be correlated with unaided mental arithmetic performance, these correlations would likely disappear when the process is completely externalised (or indeed delegated to a computational device). Thus, examining the role of interactivity in mental arithmetic may more fruitfully proceed in a cognitive system where reasoners cannot record subtotals and remainders in arriving at a solution, but still can interact and modify a physical problem representation (Neth & Payne, 2011).

The experiment reported here examined the impact of interactivity on mental arithmetic. Participants completed simple additions involving single-digit numbers. These additions were carried out for sets of 7 or 11 numbers. Thus one of the independent variables was problem difficulty. The second independent variable was interactivity. In one condition, participants completed the sums by looking at the set of numbers with hands down on the table in front of them. In a second condition, the sums were presented as a set of movable tokens: Participants were free to manipulate and re-arrange the tokens to arrive at a solution. Engineering an extended cognitive system such as the one created through interacting with number tokens may augment performance and enhance reasoning efficiency. The shaping and re-shaping of the physical representation of the problem may encourage and cue different paths to solution and different arithmetic strategies. Limited internal resources in the absence of interactivity may constrain the manner with which participants arrive at a solution.

Measuring efficiency involves assessing the benefits accrued as a function of cost or resources invested. An index of efficiency was calculated as the ratio of performance accuracy –proportion of correct answers– over the proportion of time invested to solve the problem out of the maximum time the slowest participants required to solve the task (Hoffman & Schraw, 2010, refer to such a measure as a likelihood model). Efficiency might be improved in an interactive context because some aspect of executive control is governed, guided and constrained by the shifting physical representation of the problem, freeing internal resources to ensure arithmetic accuracy. In other words, fewer resources are devoted to rehearsing subtotals or identifying and re-identifying the numbers to be added with a dynamic configuration of the sum to complete, enabling participants to devise more creative and efficient ways to solve the problems.

Finally, individual differences in terms of skills and

working memory processing capacity were measured and correlated with performance in the different experimental conditions. Patterns of correlations can help understand more precisely how coupling of internal and external resources lead to better performance. Importantly, the experiment employed a repeated-measures design. Thus the same participants completed the easy and hard sets in both the static and interactive conditions: Between-subjects variance could not explain differences in performance across the experimental conditions.

## Method

### Participants

Forty two university undergraduates (35 females, overall mean age = 21.8,  $SD = 6.8$ ) received course credit for their participation. Three additional participants (all females, mean age 23.0) were later recruited to provide verbal protocols while they performed the easy and hard sums in both conditions.

### Material and Measures

**Numeracy.** Numeracy was measured using the subjective numeracy scale developed by Fagerlin, Zikmund-Fisher, Ubel, Jankovic, Derry, and Smith (2007) which consists of eight questions (such as “how good are you at calculating a 15% tip”). Participants answer using a 7-point scale (1 = “not good at all” and 6 “extremely good”). An objective measure of arithmetic skill was designed by having participants complete as many simple problems (such as  $11 - 9 = ?$ ) as they could in 60 seconds.

**Visuo-spatial information processing speed.** The clerical checking subtest of the Beta III (Kellog & Norton, 1999) was used to measure visuo-spatial processing speed. In this test, participants must identify whether two symbols, figures or strings of digits are identical or not. The measure is the number of correct judgments out of a possible 55 in a 2-min period.

**Executive function: Shifting.** Attention switching skills were measured using the plus-minus task (Miyake, Friedman, Emerson, Witzki, & Howerter, 2000). Using three different series of 30 double-digit numbers, participants were instructed to add 3 to each in the first series, subtract 3 to each in the second series, and alternate between adding and subtracting 3 with the third series. The switching cost, measured in seconds, was the difference in completion time for the third series minus the average completion time for the first two.

**Working memory capacity.** Working memory capacity was assessed with a modified reading span test. Sentences in series ranging in number from 3 to 6 were presented on index cards to participants which they read aloud. At the

end of a series they were prompted to recall the last word of each sentence in that series. There were two different series for each sequence length for a total of 36 sentences. Working memory performance was measured as the total number of words recalled.

**Arithmetic Task.** Participants carried out single-digit additions, involving either 7 or 11 numbers (see Fig. 1), as fast and as accurately as possible. They completed the problems in blocks, five from the ‘easy’ set first, and five from the ‘hard’ set second. Performance was measured as the proportion of correct sums, the mean absolute deviation from the actual sums, the mean latency to announce a solution, and in terms of efficiency. Efficiency was measured as the ratio of addition accuracy (proportion correct sums) over time invested in the task. The latter was measured as the proportion of actual time to complete the sums divided by the maximum time needed to complete them in that condition; this maximum was determined by taking the average of the top quartile latencies. A ratio smaller than 1 meant that proportion accuracy was smaller than proportion time invested, indicating inefficient performance.

Figure 1: Examples of single-digit additions from the ‘easy’ set (7-digit additions) and the ‘hard’ set (11-digit additions). Participants performed 5 additions from both sets for a total of 10.

## Procedure

Participants first completed the 8-item subjective numeracy scale, followed by the objective arithmetic test, the clerical checking subtest from the Beta III, and the plus-minus task. They were then presented with the five additions from the ‘easy’ set. After a 2-min distractor task (a word search puzzle), participants were presented with the five additions from the ‘hard’ set. These two sets of sums were presented twice to the participants. For one presentation participants performed the additions with their hands on the table facing them (the static condition) and announced their answer out loud; for the second presentation, numbered tokens (2-cm in diameter) were used, and participants were encouraged to move the tokens about in helping them add the numbers (the interactive condition); as in the static condition, participants announced the solution for each problem out loud. While the hard set always followed the easy set, the order of condition (static, interactive) was counterbalanced across participants. With 10 different problems, involving 10

unique configurations of digits, and 90 digits across the two sets, it was unlikely that participants remembered the solution to each problem when presented a second time. Still, to prevent a direct retrieval of solutions during the second presentation, the participants completed the reading span test which lasted approximately 10 minutes. After this test of working memory, participants were presented with the 10 sums again (either in the interactive or static condition depending on which they had experienced first). Thus set size (with two levels) and interactivity (with two levels) were independent variables that were manipulated within subjects in a 2x2 repeated measures design. The experimental session lasted approximately 45 minutes.

## Results

The order of presentation of the interactivity conditions did not significantly influence performance on any of the dependent measures nor did set repetition: Performance on the first 10 sums was no different than performance on the second iteration of the same 10 problems within each experimental condition. Hence, order and repetition were not included in any of the analyses reported below.

### Percent Correct

The mean percent correct solutions for the easy and hard sums are plotted in the top left quadrant of Figure 2. Interactivity did not influence performance for the easy sums, but substantially enhanced performance for the hard sums. In a 2x2 repeated measures analysis of variance (ANOVA), the main effect of condition was significant,  $F(1, 41) = 6.58, p = .014$ , as were the main effect of difficulty,  $F(1, 41) = 20.9, p < .001$  and the interaction,  $F(1, 41) = 12.5, p = .001$ .

### Absolute Error

Non-interactive mental addition did not lead to larger absolute deviations from the correct solution for the easy set, but did for the hard set (see top right quadrant of Fig. 2). In a 2x2 repeated measures ANOVA, the main effect of interactivity was significant,  $F(1, 41) = 13.8, p = .001$ , as was the main effect of difficulty,  $F(1, 41) = 28.6, p < .001$ ; the more important pattern was the significant interaction between condition and difficulty,  $F(1, 41) = 28.9, p < .001$ .

### Latency to Solution

Set size had a large impact on solution latencies (see Fig 2. bottom left quadrant). Interactivity influenced latencies in an interesting manner: For the easy sums, interactivity slowed down participants (by nearly 2.5 s), but marginally reduced latencies (by .4 s) with the hard sums. In a 2x2 repeated measures ANOVA, the main effect of interactivity was not significant,  $F(1, 41) = 1.45, p = .236$ , but the main effect of difficulty was significant,  $F(1, 41) =$

182,  $p < .001$ , as was the interaction,  $F(1, 41) = 6.64$ ,  $p = .014$ .

## Efficiency

Participants were more efficient when solving the easy problems without the tokens (see bottom right quadrant of Fig. 2). Efficiency dropped marginally for the hard sums when participants could use the tokens, but dipped substantially without the tokens. In a 2x2 repeated measures ANOVA, the main effect of condition was not significant,  $F < 1$ , but the main effect of difficulty,  $F(1, 41) = 13.3$ ,  $p = .001$ , as well as the condition by difficulty interaction,  $F(1, 41) = 10.6$ ,  $p = .002$ , were significant.

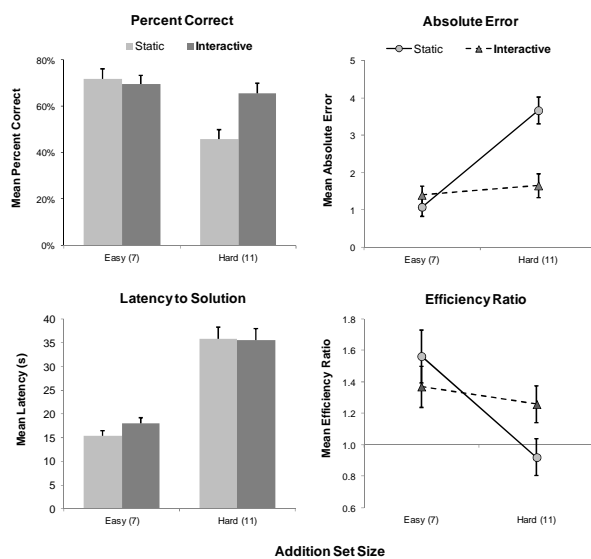

Figure 2: Mean percent correct additions in the static (light bars) and interactive (dark bars) condition (top left quadrant); mean absolute error per sum in the static (circles) and interactive (triangle) conditions (top right quadrant); mean latencies in the four conditions (bottom left quadrant); mean ratio of correct proportion over proportion of maximum time to complete problem (or efficiency ratio) in all four conditions (bottom right quadrant) as a function of set size. Error bars are standard error of the means.

**Predictors of efficiency.** To better understand the relative contribution of different internal resources to performance in the hard set of additions, initial analyses determined the nature of the correlations between efficiency and individual differences (see Table 1). The strongest correlations were observed in the interactive condition with objective numeracy,  $r(40) = .43$ ,  $p = .005$ , and attention switching,  $r(40) = -.39$ ,  $p = .01$ ; in the static condition, objective numeracy was significantly correlated with efficiency,  $r(40) = .32$ ,  $p = .04$ . A stepwise regression analysis for the static condition produced a significant model,  $F(2, 41) = 5.40$ ,  $p = .009$ , composed of objective numeracy ( $\beta = .400$ ) and reading span ( $\beta = .350$ ) that

explained 22% of the variance in efficiency. In the interactive condition, the analysis identified a significant model,  $F(3, 41) = 10.2$ ,  $p < .001$ , that explained 45% of the efficiency variance; the model included objective numeracy ( $\beta = .447$ ), reading span ( $\beta = .426$ ) and attention switching ( $\beta = -.398$ ).

Table 1: Correlation matrix involving individual differences in terms of subjective and objective numeracy, clerical checking, attention switching, reading span and the efficiency ratio in the static and interactive condition for the hard set (involving 11 single digit numbers);  $df = 40$ .

	1	2	3	4	5	6	7

Note: \*  $p < .05$  \*\*  $p < .01$ . SBJ-N = Subjective numeracy; OBJ-N = Objective numeracy (basic arithmetic skill); C-C = Clerical Checking; Att-S = Attention Switching; Span = Reading Span; ER-S = Efficiency in the static condition; ER-I = Efficiency in the interactive condition.

## Path to Solution and Strategies

In order to obtain a window onto the paths to solution and the strategies employed to chart these paths in both conditions, three additional participants completed the mental arithmetic tasks while verbalising their progress – the sessions were also videotaped. Inferential statistics could not be performed on data from such a small sample, but very clear differences in strategies emerged in the two conditions.

The simplest strategy, and in the static condition the one that taxes working memory the least, is to add the numbers in the order scanned, without seeking to group numbers to create more congenial sub-totals. Across the three participants, and over all problems, the sequential scan strategy was used exclusively 15 times in the static condition (or for 50% of the problems) and twice in the interactive condition. There were 26 instances of grouping numbers (mostly in pairs) on the path to solution in the static condition, but 75 instances of such groupings in the interactive condition. Congenial sub-totals (defined as  $\Sigma \text{MOD } 5 = 0$ ) on the path to solution was observed 28 times in the static condition but 53 times in the interactive condition. Figure 3 below illustrates the paths to solution and strategies employed by participant 44 for problem A, a 7-number addition. She clearly employed a sequential scanning strategy in the static condition, but was much more creative in the interactive condition, grouping numbers to produce convenient sub-totals to arrive at the solution.

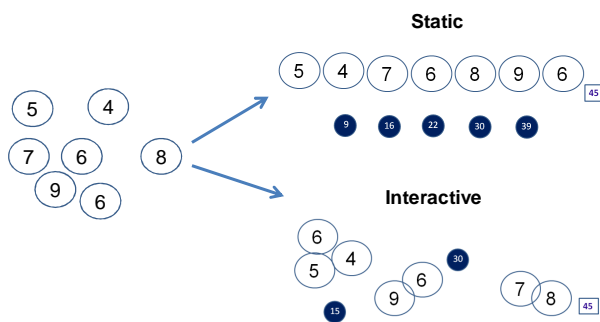

Figure 3: Path to solution and strategy employed for problem A (a 7-number problem) by participant 44 in the static and interactive condition.

## Discussion

This experiment examined mental arithmetic in conditions where participants only used their internal cognitive resources to complete easy and hard sums of single digit numbers or where they could couple their cognitive resources to modifiable external resources in completing the sums. The experiment employed a repeated measures design such that the same participants completed the arithmetic problems in both conditions, thus eliminating between condition variance due to between-subjects differences. This is a particularly important feature of this experiment because it ensured that whatever benefits were conveyed in the interactive condition, these could not be attributed to better or different internal resources brought to the task by a different group of participants.

Interactivity substantially enhanced performance in terms of accuracy and efficiency with the harder sums involving 11 single-digit numbers: Participants were more accurate and the wrong answers were closer to the actual sums in the interactive condition than in the non-interactive condition. Solution latencies offered a gauge of the effort invested to solve the additions. With the hard sets the mean latencies were nearly identical between conditions (35.9 s vs. 35.5 s in the static and interactive condition, respectively) but mean percent accuracy was 20% higher in the interactive condition. Hence, reasoning efficiency was substantially enhanced by allowing participants to couple and regulate their cognitive efforts with a continuous reconfiguration of the tokens in a manner that best served their goal. With the easier sums participants performed marginally better without manipulating tokens, relying solely on their internal resources. The degree to which the design of an extended cognitive system can augment performance is clearly relative to the degree of task difficulty and the cognitive ability of the reasoner (Webb & Vallée-Tourangeau, 2009).

Interactivity offered the opportunity to deploy more creative and efficient paths to solution, which was clearly beneficial for the harder sums. The improvement in performance and the greater efficiency in the interactive

condition was not simply a matter of off-loading content from working memory onto the environment. Rather, a shifting environment suggests different arithmetic paths and permits the identification of congenial interim sums that simplify the task and enhance efficiency. Thus the opportunity to interact with the tokens substantially transformed the nature of strategies employed and the paths to solution. Some of these paths might have been discovered strategically or accidentally by moving the tokens. Still, a dynamic physical presentation of the problem shouldered some of the executive functions freeing resources to better plan how to achieve the goal efficiently. These data support the conjecture that reasoners are better able to deploy arithmetic skills, and may be more receptive to learning new ones, in an environment that augments storage and processing capacity through the coupling of internal and external resources.

## Individual Differences

Profiling participants in terms of cognitive skills and capacities and then correlating these measures with indices of performance help identify the cognitive factors that drive mental arithmetic. This approach has been employed with some success to identify the skills and capacities implicated in insight and non-insight problem solving (Gilhooly & Fioratou, 2009). The resulting data inform the development of process models of performance in these problems. Such process models will likely differ for tasks that are purely reliant on internal cognitive resources in comparisons with tasks that afford a tighter reciprocal influence between cognition, perception and action.

In the static condition, basic arithmetic skills and working memory capacity explained 22% of the variance in efficiency for the harder sums. In the interactive condition, nearly 50% of the variance in efficiency was explained by a model composed of arithmetic skill, working memory capacity and attention switching. These findings suggest that participants with better arithmetic skills, larger working memory capacity and swifter attention switching abilities were more likely to benefit from interacting with tokens in arriving at a solution. In other words, the coupling of internal and external resources was more effectively deployed by participants with better internal resources. This pattern of results was also observed in a recent experiment that contrasted non-interactive and interactive version of Luchins's volume measurement problems: Participants scoring higher in fluid intelligence performed better with the interactive version of the task (Vallée-Tourangeau et al., 2011). Designing an interactive version of an otherwise non-interactive static problem solving task does not benefit every reasoner in the same way. Future research should also determine whether non-intellectual factors such as anxiety or self-efficacy mediate the impact of interactivity on problem solving performance.

The measure of working memory capacity explained unique variance in performance efficiency in the non-interactive context for the hard sums. Still, the correlation between performance and working memory capacity was modest. This finding suggests one of two things. The first is that the task may not have taxed working memory that much. Certainly the degree of absolute departure from the correct answers in the non-interactive condition suggests that participants rarely miscalculated sums by a substantial margin. Future research may thus more fruitfully contrast non-interactive and interactive conditions with a more challenging arithmetic task, either by using larger single-digit sets (e.g., sums including 15 or more numbers) or by using double-digit numbers. A better window onto the role of interactivity in supplementing working memory capacity might be proffered by a task that is more reliant on working memory when it is completed without interaction. Second, the exact composition of the complex span measure of working memory should include arithmetic material and operations. There is evidence to suggest that span and outcome measures are better correlated when they share a domain (DeStefano & Lefevre, 2004).

### Acknowledgments

I would like to thank Ellie McCourty, Angie Makri, Svetlana Stefanova, and Joakim Westh Wiencken for recruiting and running the participants; as well as Ken Gilhooly, David Gilmore, David Kirsh and Gaëlle Villejoubert for helpful comments on an earlier version of this manuscript. Financial support from the Kingston University Faculty of Arts and Social Sciences Research Capability Fund is gratefully acknowledged.

# Conceptual alignment in reference with artificial and human dialogue partners

## Abstract

Previous work on reference in dialogue has shown that speakers adapt to the concepts that were used in earlier references during an interaction (such as orientation when a dialogue partner describes a chair as “the chair seen from the front”), even if these concepts are generally dispreferred. Here, we investigate to what extent it matters whether speakers interact with an artificial or a human dialogue partner (Study 1) and whether this adaptation indeed takes place at the conceptual level (Study 2). For Study 1 participants interacted either with a computer or with a human confederate and it was found that participants adapt in similar ways and just as much to a human dialogue partner as to a computer. Study 2 used a cross-language interaction paradigm, in which bilingual participants listened to English descriptions after which they had to refer in Dutch (thereby reducing the possibilities for lexical and syntactic alignment). The results showed that even with crosslinguistic prime-target pairings, participants aligned with the attributes used by their dialogue partner, providing further evidence for alignment at the conceptual level.

**Keywords:** referring expressions, alignment, human-computer interaction, conceptual alignment

## Introduction

During conversations, people continuously refer to other people, objects or events, for example using descriptions such as *the man with the beard* or *the blue chair*. Since such descriptions are so common (Poesio & Vierra, 1998), their underlying production process has drawn many researchers’ attention, both from a computational and from a psycholinguistic perspective. Much of this research focusses on the question of what makes people choose one possible way of referring to an object over another. Why do speakers include certain properties in their descriptions and others not?

Computational studies of reference often frame the production of referring expressions as a problem of choice where a (usually fixed) preference order determines the order in which attributes (such as color or orientation) are considered for inclusion in a referring expression. The Incremental Algorithm (Dale & Reiter, 1995), for instance, which is probably the most widely used algorithm in this field, operates according to this principle, assuming the existence of a domain-dependent preference order on the

relevant attributes, and first tries out preferred attributes before less preferred ones are considered, thereby modeling the intuition that speakers prefer certain attributes over others, partly based on findings of Pechmann (1989). For example, when referring to a chair, speakers are more likely to refer to its color (*the blue chair*) than to its orientation (*the chair facing left*) even though both may be successful in singling out a particular chair.

However, one could argue that the Incremental Algorithm is “addressee-blind” (Clark & Bangerter, 2004) in that it pays no attention to references that were produced earlier in an interaction (the same holds, incidentally, for the various alternatives that have been proposed to the Incremental Algorithm and which are surveyed in Krahmer and van Deemter, 2012). Indeed, it has been shown that speakers do take prior references into account during reference production. One study, for example, found that if one dialogue participant refers to a couch as a *sofa*, the next speaker is more likely to use the word *sofa* as well (Branigan, Pickering, Pearson, & McLean, 2010). This can be seen as a lexical form of “alignment” (Garrod & Pickering, 2004; Pickering & Garrod, 2004) between speaker and addressee. Pickering and Garrod argue that alignment may take place on all levels of interaction, and indeed it has been shown that participants also align, for example, their intonation patterns and syntactic structures.

Goudbeek and Krahmer (2010, 2012) have shown that a similar kind of adaptation can take place at the conceptual level of attributes. While the Incremental Algorithm and its ilk only predict the use of dispreferred attributes when preferred attributes alone are unable to uniquely identify a given target object, Goudbeek and Krahmer showed that participants do use dispreferred attributes when these were used earlier in an interaction. In particular, they found that when one dialogue partner used a dispreferred attribute to refer to an object, the other dialogue partner was more likely to use values of that attribute in subsequent references as well. For example, in the furniture domain used in their experiments, participants could always uniquely identify an object by using its color (e.g., *the green chair*<sup>1</sup>) or its orientation (*the chair seen from the front*). Of these two attributes, color is the preferred one, in the sense that

---

<sup>1</sup> Here and elsewhere we provide English translations of Dutch originals.

without prior context speakers are more likely to use color than orientation, as was firmly established independently for Dutch (Koolen, Gatt, Goudbeek, & Krahmer, 2011) and English (van Deemter, Gatt, van der Sluis, & Power, 2012). Yet, Goudbeek and Krahmer found that when the participants had been exposed to descriptions such as *the chair seen from the front*, they were themselves more likely to use the dispreferred orientation attribute in their own references, despite the fact that using color would have been perfectly sufficient. Goudbeek and Krahmer (2010, 2012) established these effects in two different referential domains (people and furniture).

Crucially, Goudbeek and Krahmer suggest that their findings cannot be explained in terms of lexical alignment: participants were primed, for instance, with *seen from the front*, while the target was *facing left*. They argue that instead they found evidence for what they call “conceptual alignment”, where participants align at the level of attributes (such as orientation) and not values (such as seen from the side). However, two potential criticisms could be levelled against this claim: first, in their experiments, participants interacted with a computer rather than with another participant, and it is conceivable that this influenced the conclusions; and second, given that primes and targets were always referred to using Dutch descriptions, the possibility that some, possibly indirect, form of lexical alignment influences the results cannot be discarded. In this paper, we address these two criticisms.

The first question we therefore ask is to what extent the results obtained with participants interacting with a computer, using a procedure in which participants had to repeatedly listen to a prerecorded description and respond with a description in front of a computer screen, are representative for human-human interaction. While using a computer-based paradigm offers several advantages in an experimental context (especially concerning controllability), Branigan et al. (2010) point out some dangers in drawing conclusions about alignment in human-human interactions from human-computer interactions (HCI). They indicate that alignment in the latter kind of interactions is mainly based on considerations of communicative success, the speaker’s model of the computer and what they think the computer might or might not be able to know. Such considerations can override strong linguistic preferences, which Branigan and colleagues interpret as signs of HCI not always being a reliable predictor of real interactions between humans. Branigan et al. (2010) also argue that alignment in HCI is potentially stronger than alignment in interactions between humans; humans, they reason, may have doubts about the communicative capabilities of computers, and hence might be more inclined to adapt to the computer. This suggests that the previous findings of Goudbeek and Krahmer could have overstated the amount of alignment in interactive referring expression generation.

On the other hand, one could also argue that the participants in these studies did not strictly engage in human-computer interaction, but rather could be argued to

be interacting with an “imaginary audience”. Various recent studies, including Ferreira, Slevc and Rogers (2005) and Van der Wege (2009), have shown that there generally are only small differences between referring for a real and an imagined audience. References produced by participants are not more precise when they are interacting with a real instead of an imaginary addressee (Van Der Wege, 2009) nor do participants avoid potential ambiguities in their references more when they are speaking to a real addressee (Ferreira et al., 2005).

Ultimately, however, this an empirical question, which we address in Study 1. In this study, we attempt to replicate the previous findings from Goudbeek and Krahmer with human dialogue partners. Here, participants took part in an otherwise identical interactive alignment paradigm, the only difference being that instead of with a computer, participants communicated with another person which (unbeknownst to them) was a confederate of the experimenter. The participants and the confederate took turns in referring to objects and identifying objects based on the descriptions produced by their dialogue partner. As in the original paradigm of Goudbeek and Krahmer (2010), participants could always use either a preferred or a dispreferred attribute to refer to an object, and depending on the condition, the confederate either included a preferred or a dispreferred attribute when referring to an object. We compute the amount of alignment, and compare it with the amount of alignment observed in the earlier, computer-based study.

The second question we address in this paper is to what extent the alignment observed in the referential tasks indeed occurs at the *conceptual* level. In Levelt’s model of speech production (Levelt, 1989; 1999), the conceptual level is the level at which the speaker decides which information to put into an utterance. In contrast to lexical alignment, where the use of *sofa* by one dialogue partner may trigger the switch from *couch* to *sofa* in the other partner, conceptual alignment refers to alignment with respect to the attribute and not necessarily with the value used by the speaker. In the previous experiments, there certainly was no direct relation between the attribute value of the prime and that of the target (and the prime and target were always separated by a pair of unrelated fillers). Nevertheless, it could be that attribute values occurring elsewhere in the experiment as primes somehow lexically primed values over longer distances, or that some other form of lexical or syntactic alignment played a role in one way or another.

To more directly test the claim of conceptual alignment, a crosslinguistic version of the interactive alignment paradigm was devised, inspired by earlier crosslinguistic priming experiments (e.g., Loebell, & Bock, 2003; Schoonbaert, Hartsuiker, & Pickering, 2007). In this experiment, described as Study 2, bilingual participants are exposed to primes in English (*the chair seen from the side*), and subsequently have to describe (after two fillers items) a target in Dutch (e.g., *de stoel van voren*; English (literally) “the chair from the front”). If Dutch participants align

equally frequent with English as with Dutch primes, this would be further, and arguably more compelling evidence for conceptual alignment, since lexical and syntactic priming are relatively less likely between two different languages, even when they are relatively similar as Dutch and English (Schoonbaert et al., 2007). Again, we compare the amount of alignment when primes are in Dutch (as in the original studies) with the amount of alignment when primes are in English.

## Study 1: Artificial vs. Human Partner

This first experiment tests whether the finding of Goudbeek and Krahmer (2010), that people align with their interaction partner by using a dispreferred target attribute in their referring expressions, also holds when the interaction partner is a real person rather than a computer.

### Method

**Participants** 29 Students (23 female) from Tilburg University participated in this experiment, either for partial course credit or a small payment. All participants were fluent speakers of the Dutch language, and had normal hearing and normal (or corrected to normal) vision. None had participated in one of the earlier studies of Goudbeek and Krahmer (2010; 2012).

**Materials** The stimulus material for this study consisted of a set of furniture images and images of people, which have frequently been used in previous research on the production of referring expressions (e.g., van Deemter et al., 2012) and which were also used in Goudbeek and Krahmer (2010; 2012)<sup>2</sup>. The target images were always one of five different furniture items, which varied in both color and orientation. An overview of the possible combinations is provided in Table 1.

The pictures from the people domain (all black and white photographs of famous mathematicians) served as filler images, and were included to distract participants' attention from the goal of this study. Target images were always presented together with two distractors from the same domain, and were shown to participants on two synchronized monitors, to ensure that the set up was identical for the confederate and participant, in order to not raise any suspicions about the confederate with the participants. Targets could always be distinguished both in terms of color (preferred) and in terms of orientation (dispreferred). That color information is preferred and orientation information is not was determined independently from corpus data for Dutch and English (van Deemter et al., 2012; Koolen et al., 2011), showing that speakers frequently

use color spontaneously and that they rarely use orientation when referring to the furniture items under study here.

Table 1: The attributes and their possible values.

Attribute	Possible values
type	chair, desk, fan, sofa, television
color	red, green, blue, grey, black
orientation	front, back, side

**Procedure** Participants took part in an interactive understanding and referring task, closely modelled on the paradigm presented in Goudbeek and Krahmer (2010). In this study, however, participants interacted with a female confederate (a student of the same age as the participants) instead of with a computer. The experiment consisted of two blocks, each featuring 30 trials<sup>3</sup>. During block one, the confederate systematically used preferred attributes when referring to furniture items (e.g., *the green chair*), during block two, the confederate systematically used dispreferred attributes (e.g., *the chair seen from the front*). The order of blocks was counterbalanced across participants. In every trial, participants first had to listen to the confederate describing a critical target (to which we refer as the prime), who referred to one of three pieces of furniture, which participants subsequently had to identify on their screen. After doing so, the next slide of images (three persons) appeared for both participant and confederate, and the participant had to describe a filler target from the person domain to the confederate, who identified it on her screen. Third, the confederate would describe a filler target (again from the people domain). In the fourth turn, the participant described a critical target that could be described with a preferred or dispreferred attribute (or both) to the confederate. Figure 1 shows an example of a critical trial.

Figure 1. Example of a critical trial. The target is indicated by a red border and can be distinguished both in terms of its color (blue) or its orientation (facing left).

The use of a confederate was motivated from the fact that participants were unlikely to systematically use dispreferred properties, which would hinder a direct comparison with the results of Goudbeek and Krahmer (2010; 2012). The confederate was instructed to engage in each interaction and ask questions when participants provided insufficient information to identify a target. After

<sup>2</sup>The pictures of furniture items were taken from the Object Databank, developed by Michael Tarr at Brown University and are freely distributed. URL: <http://titan.cog.brown.edu:8080/TarrLab/stimuli/objects/>

<sup>3</sup> The order of the trials within a block was the same for every participant

the experiment participants were debriefed. None suspected the other person to be a confederate.

## Results

The number of times participants aligned with the attribute they were primed with was used as the dependent variable. This includes cases in which participants used an overspecified referring expression, where both preferred and dispreferred attributes of the target were used by the participant, even though only one of them would suffice for the purpose of identification.

The analysis focuses on the proportional use of dispreferred attributes (orientation) when participants are exposed to dispreferred primes (note that when participants use a preferred prime, i.e., color, we cannot tell whether they used it because it is preferred or because it was primed). The results show that with dispreferred primes, the proportion of dispreferred attributes used by participants is considerable ( $M = 0.41$ ,  $SD = 0.46$ ). Contrary to the predictions of the Incremental Algorithm, the proportion of dispreferred attributes is significantly larger than zero;  $t(28) = 4.82$ ,  $p < .001$ .

To investigate whether it matters if participants were interacting with a computer or a real person, the data of Goudbeek and Krahmer (2010) was compared with the data from the current experiment. Figure 2 displays the proportion of alignment of the participants who had been interacting with a computer ( $M = 0.53$ ,  $SD = 0.43$ ) and those of who interacted with a confederate ( $M = 0.41$ ,  $SD = 0.46$ ). A one-way analysis of variance with interaction partner (computer versus confederate) as the independent variable and proportion of alignment as the dependent variable showed no significant difference between interacting with a computer and interaction with a human  $F(1,48) = 2.20$ ,  $p = .14$ ).

Study 1 revealed that participants have a strong tendency to align with their conversation partner; when their partner uses a dispreferred attribute (referring to a piece of furniture in terms of its orientation) they are more likely to do so themselves later on. Whether their conversation partner is a computer of person has no significant influence.

Figure 2. The proportion of alignment in human-computer and in human-human interaction

## Study 2: Crosslingual priming

The second study aims to find more conclusive evidence for the claim that the kind of alignment under discussion here takes place at the conceptual level, rather than the realization one. This is addressed using a cross-language priming experiment, where bilingual participants are not primed in their native Dutch, but in English. They do have to refer in Dutch, however, as in the previous experiment.

## Method

**Participants** 40 Students (31 female) participated in this experiment in exchange for partial course credit. All were unbalanced bilinguals, namely native Dutch speakers with formal instruction in English for 7 years or more. All had normal hearing and (corrected to normal) vision. None had participated in Study 1 or in any of the other studies described in Goudbeek and Krahmer (2010; 2012).

**Materials** The stimuli were identical to those described in Study 1, except that primes were now pre-recorded descriptions produced by a native English speaker (of roughly the same age as the participants), that referred to the objects (e.g., *the chair seen from the left*) with the same preferred and dispreferred attributes (colour and orientation, respectively) as before.

**Procedure** Before starting the experiment, participants were told they had to identify pre-recorded descriptions provided by an English speaker but had to describe the objects themselves in Dutch. In this experiment, following Goudbeek and Krahmer (2010), descriptions were once again produced by a computer, which was warranted by the findings of Study 1. The remainder of the procedure was identical to that of the previously described study.

## Results

As in Study 1, the number of times participants aligned with the dispreferred attribute when this attribute was used earlier in the interaction was used as the dependent measure. If this alignment indeed takes place on the conceptual level, it should not matter whether primes were in English or in Dutch. If, however, the alignment that participants' showed in Krahmer and Goudbeek (2010) was of a lexical or syntactic nature, we predict that people in this study will align not or to a lesser extent with the dispreferred primes, since the linguistic realization of the prime and the target differ considerably.

Figure 3 shows the use of color (the preferred attribute) and orientation (the dispreferred attribute) for each prime type. Clearly, when participants were primed with the dispreferred attribute orientation, they start using that attribute themselves more often (and the color-attribute less).

Figure 3. Participants' proportional use of the preferred and dispreferred attribute following preferred and dispreferred primes.

Statistical analysis of the data shows that despite the primes being in English, people still use the dispreferred attribute orientation significantly more than zero with  $t(39) = 7.29$ ,  $p < .001$ , contrary to the prediction of the Incremental Algorithm. Moreover, participants used the dispreferred target attribute more often when they had been primed with a dispreferred attribute than when they had been primed with a preferred attribute,  $F(39) = 10.92$ ,  $p < .005$ .

Furthermore, a comparison was made between the current data and the data that was collected through the experiment conducted by Goudbeek and Krahmer (2010) to test whether the language of the primes influenced the level of alignment. The results of this comparison are depicted in Figure 4. A statistical analysis showed no significant effect of the language of the primes on the amount of alignment with the dispreferred target attribute, with  $t(57) = 0.83$ ,  $p = 0.41$ . Given that the experimental set-up was exactly the same, apart from the manipulation of the primes (English here, Dutch in the earlier study), this shows that the language of the prime has no impact on the amount of alignment with the dispreferred attribute, which we take as further evidence for the claim that the kind of alignment observed here is conceptual rather than lexical.

Figure 4. A comparison of the amount of alignment with the dispreferred attribute as a function of the language of the prime.

## Discussion

In this paper, we studied how speakers refer to objects in an interactive setting, and how this influences speakers' decision of which attributes to include in a description. In both studies, we found that speakers have a strong tendency to use dispreferred attributes in their descriptions when these were used earlier in the interaction, even though there was always the possibility to rely only on a preferred attribute. These results replicate the earlier findings of Goudbeek and Krahmer (2010; 2012), and extend them in two important directions.

The results of the first study show that alignment between humans is statistically indistinguishable from alignment between humans and computers. This indicates that the use of a pre-recorded conversation partner in the earlier studies did not influence the results, and is in line with the claims from Ferreira et al. (2005) and van der Wege (2009) that referring for an "imaginary audience" is similar to referring for a real audience. The results of the second study show that participants which are primed with dispreferred attributes in English, use these attributes to the same extent in their descriptions in Dutch as participants that were primed with dispreferred attributes in Dutch. This strongly suggests that the kind of alignment under study here is conceptual, rather than lexical or syntactic. What seems to be primed is a way to conceptualize or look at an object (in terms of orientation rather than color, for instance), rather than a specific property (such as facing left or being blue).

It is interesting to contrast the current findings with the predictions of state-of-the-art computational models for Referring Expression Generation (REG), including the Incremental Algorithm (Dale & Reiter, 1995) as well as more recent extensions and variations of these models. Generally, these models fail to account for the alignment results presented here; the Incremental Algorithm, for instance, predicts that a dispreferred attribute would never be used if a preferred attribute is sufficient to uniquely characterize a target object. The basic problem is that these algorithms treat the decision of which attributes to include in a description as a decision that can be made independent of context, and hence does not need to take into account the reference history, something which our data clearly contradict.

To make these algorithms suitable for the generation of referring expressions in interactive settings (as is required for many applications), they should become more sensitive to the preceding interaction and the references that were produced in it. For the Incremental Algorithm, this could be achieved, for example, by combining the (fixed, domain dependent) list of preferred attributes with a (flexible) list of "previously mentioned" attributes. The relative weighting of these two lists can be estimated based on data such as those presented here.

Gatt, Goudbeek and Krahmer (2011) go one step further, proposing a new model for alignment in reference production that integrates alignment and preference order

based attribute selection. Their model consists of two parallel processes: a preference-based search process based on the Incremental Algorithm, and an alignment-based process. These two processes run concurrently and compete to contribute attributes to a limited capacity working memory buffer that will produce the referring expression. Gatt et al. (2011) show that their model can account for the alignment findings well.

## Conclusion

When producing referring expressions in interactive settings, speakers have a strong tendency to re-use attributes that were used before, even if these attributes are otherwise dispreferred. The frequency with which dispreferred attributes are re-used does not depend on whether the interaction is with a computer or with another person, nor on whether the preceding primes were produced in a different language or not. Taken together, these results suggest that the alignment is automatic, and of a conceptual nature. Current state-of-the-art computational models of reference production fail to account for this, since they tend to be “addressee-blind” and mostly rely on domain-dependent preferences only.

## Acknowledgments

The research reported in this paper forms part of the VICI project “Bridging the gap between psycholinguistics and Computational linguistics: the case of referring expressions”, funded by the Netherlands Organization for Scientific Research (NWO grant 277-70-007). We thank Manon Yassa for serving as the confederate in Study 1 and Elsa Jonker for assistance in running Study 2.

## Abstract

Humans are remarkably good at recognizing spoken language, even in very noisy environments. Yet, artificial speech recognizers do not reach human level performance, nor do they typically even attempt to model human speech processing. In this paper, we introduce a biologically plausible neural model of real-time spoken phrase recognition which shows how the time-varying spiking activity of neurons can be integrated into word tokens. We present a proof-of-concept implementation of the model, which shows promise both in terms of recognition accuracy as well as recognition speed. The model is also pragmatically useful to cognitive modelers who require robust any-time speech recognition for their models such as real-time models of human-robot interaction. We thus also present such an example of embedding our model in a larger cognitive model, along with offline analysis of its performance on a speech corpus.

**Keywords:** Liquid State Machine; Neural Network Model; Any-Time Speech Recognition

## Introduction

The mechanisms that convert physical signals such as light and sound into firing rates of neurons are well-studied. However, the way these signals subsequently influence behavior, especially cognitive behavior, is less well understood. In particular, the progression from continuous real-time input streams at the physical transducer level to high-level cognitive processes that abstract over many physical characteristics is challenging, so much so that classical cognitive architectures simply assume higher-level representations such as word tokens instead of modeling the processes that generate them. While these assumptions do not pose problems for disembodied models (e.g., of higher-level cognitive processes such as analogical reasoning in language), they are critical showstoppers for embodied situated models that depend on being implemented on robots that interact with their environments in real-time (e.g., in the context of human-robot interactions in natural language). In such models, sensory processing must be performed one way or another, and while it is sometimes possible to substitute engineering solutions for biologically plausible sensory modules (e.g., artificial speech recognizers instead of biologically plausible models of speech recognition), those substitutions often come at a price that assumptions have to be made about the nature of the interface between those parts of the model that are meant to be biologically plausible and those parts that function as proxies for yet-to-be-developed biologically plausible parts. Specifically, the sensory modules must be able to perform their function (e.g., recognizing words or objects) *at least* as well as humans, or else other components of the model have to account for errors in perceptual processing (e.g., word recognition errors).

Moreover, the sensory module must be able to perform its task and make its result available *at least as fast as* the corresponding module would in humans to be able to respect human timing (e.g., the human expectation to hear a verbal acknowledgment at the right time in response to an utterance). As a result, these two requirements often pre-empt the use of traditional computational methods that perform sensory-input-to-token conversion.

In this paper, we will address the problem of biologically plausible real-time sensory processing of speech signals with a two-fold goal: (1) to provide a biologically plausible neural model of human spoken phrase recognition, and (2) to provide a sensory module that can be embedded in classical cognitive architectures for the study of embodied situated models of natural language interactions. Specifically, we propose a new approach to robust speech recognition which gives continuous access to meaningful partial results, and returns word or phrase tokens that can be directly used by higher-level cognitive models. The model includes several parts of the early auditory processing system in humans: the cochlea (converting time to frequency domain), parts of the olivary complex (applying several filters to the cochlear-processed signal), and a sensory cortical area (comprising a recurrent spiking neural circuit to integrate the signal). Category separation is performed by “readout neurons” (one per category) that respond continuously to ongoing activity in the recurrent circuit based on the particular weighted projection they receive, as is customary for the employed *liquid-state machine* (LSM) neural model (Maass, Natschlager, & Markram, 2002). The weighted projection received by each readout neuron is determined before-hand based on offline training on a speech corpus. The main contributions are thus the implementation of the speech processing neural architecture and the method of converting the instantaneous output of readout neurons to the token-type output for use by subsequent cognitive processes. The paper starts by laying out the background and the problems to be solved by a model that has to convert time-varying instantaneous neural-readout behavior to discrete categories. The subsequent model section then describes the neural speech-encoding and integration parts of the model. Then an analysis of the performance of the model on subsets of a speech-corpus from human-human interaction experiments is presented together with links to videos in which the model is used as part of a larger cognitive model for situated embodied human-robot interaction experiments where speech utterances are used to control the robot’s ongoing behavior.

## Background

Liquid state machines have been proposed as neurologically plausible models of cortical microcircuits (Maass et al., 2002) which can be used for time-invariant categorization of continuous-time signals by way of simple linear “readout units”. The conversion from instantaneous readout activity to discrete tokens that accurately encode the temporally-extended category, however, is not a trivial task as the instantaneous activity of a readout neuron only reflects that the very recent activity (e.g., tens of milliseconds) of the recurrent circuit is similar to what its activity was *at some point* during its response to the category on which the readout neuron was trained. In other words, if a readout neuron  $R$  is trained to respond to an isolated category, e.g., a word  $W$ , and is firing vigorously to a stimulus  $S$  presented to the circuit, it is not clear which part of  $S$  is recognized by the readout as being similar to  $W$ . It is possible that the readout will fire (entirely by coincidence) in response to a 20 ms segment of  $S$  but remain silent otherwise (as that part of the speech signal bears resemblance to patterns that occur in typical speech signals for  $W$ , e.g., similar phones). Obviously, it would be premature in this case to conclude that  $S$  is an instance of the category  $W$  – after all,  $W$  might be typically 500 ms long, and parts of it will be similar to parts of many other words. This dissociation between recognizing matching parts of a word versus recognizing the whole word (or phrase, for that matter), is the first problem to be solved: the challenge here is to produce a mechanism for filtering out coincidental noise and choosing a single “winning” category from among all readout neurons that will have time-variant activations throughout the presentation of  $S$ .

The second problem to be solved is to determine *when* to select a winner (clearly a winner cannot be select at very small time intervals as this would be tantamount to recognizing new words all the time). Since a single stimulus can span thousands of time-steps at which neurons can fire, the model should return a single token exactly once per stimulus and only if the stimulus is one of the categories that it has been trained on. Even if there is a stimulus-length patch of noise, the model should not recognize it as being similar to the readout with the highest activation, but should not detect any word token at all (alternatively, it could detect a “noise token”).

Liquid state machine models have been previously applied to cases where the speech corpus was pre-processed into frequency channels that were guaranteed to have only one spike per word (coding onset, offset, or peak of that frequency band) (Maass et al., 2002). However, these assumptions are unrealistic and it is difficult if not impossible to produce this type of encoding in real-time from raw audio streams. Another approach addressed this encoding limitation and compared the performance of LSMs using different sound-coding front-ends (Lyon cochlear vs. MFCC) as well as different methods for converting the front-ends’ analog output into input spike trains for the LSM (Verstraeten,

Schrauwen, & Stroobandt, 2005). While both approaches performed category-token recognition well by their own metrics (i.e., the ratio of the number of correct readout spikes to total time points in (Maass et al., 2002) and the class with the most readout spikes in response to a given word file in (Verstraeten et al., 2005)), neither method is applicable to real-time speech recognition, since real continuous-time audio is not separated into “files” with a clear stimulus onset and offset. Rather, it is non-trivial to detect the onsets and offsets of real utterances from continuous speech streams, which are often full of non-word noises, variations in word pronunciation, or words on which the system has not been trained.

Hence, we developed novel and realistic neural implementations of onset/offset detectors to increase recognition performance and aid in utterance detection and classification. Specifically, the model is based on the approach of Smith and Faser (2004) who, inspired by Ghitza (1987), present a biologically inspired onset-detection regime using depressing synapses. This implementation via short-term plasticity (STP) synapses is justified based on the evidence provided by MacLeod, Horiuchi, and Carr (2007), who argue that not only synaptic depression, but also facilitation, can play a critical role in auditory processing. Finally, for auditory input signal processing we utilize the Lyon cochlear model (Lyon, 1982; Slaney, 1998) which effectively applies band-pass filters and transformations to sound waves to approximate the firing activity of a set of neural channels along the cochlea.

## Model Architecture and Implementation

Figure 1 is a visualization of the neural circuits implemented for speech recognition without the learned components (i.e., readout neurons and readout integrators). Here, we describe the components of the model together with all parameters used for the empirical evaluation presented later.

### Neural and Synaptic Models

The neural model uses Leaky Integrate-and-Fire (LIF) neurons, whose membrane potential  $V_m$ :

$$\frac{\partial V_m}{\partial t} = \frac{-(V_m - V_{rest}) + R_m \cdot (I_{bg} + I_{syn})}{\tau_m} \quad (1)$$

where  $R_m$  is the membrane resistance,  $I_{bg}$  the background current, and  $I_{syn}$  the total current impinging from afferent synapses.  $-V_m$  represents the leakage term, causing the membrane potential to decay exponentially with time constant  $\tau_m$ . When  $V_m$  reaches the threshold value  $V_{thresh}$ , the neuron “fires” and  $V_m$  is reset to  $V_{reset}$  and enters a refractory period during which it does not update.

The model uses static or dynamic synapses to connect neurons. A static synapse has a post-synaptic response (PSR) that decays exponentially with time constant  $\tau_{psr}$ . The dynamics of the post-synaptic response  $q_{psr}$  of a synapse is thus:

$$\frac{\partial q_{psr}}{\partial t} = \frac{-q_{psr}}{\tau_{syn}} \quad (2)$$

Figure 1: 3-D visualization the neural model described in this paper. The pictured circuit has only 4 input channels, and a  $3 \times 3 \times 10$  recurrent circuit. The actual circuit has 52 input channels and a  $5 \times 5 \times 15$  recurrent circuit. Readout neurons not shown (they would be on the right of the recurrent circuit, receiving input from it).

Synaptic dynamics (short-term plasticity, STP) are implemented following (Legenstein, Naeger, & Maass, 2005) using the UDF model. The arrival of a spike  $k$  after interspike interval  $\Delta_{k-1}$  induces an increase in the post-synaptic charge of amplitude  $A_k$ :

$$A_k = w \cdot u_k \cdot R_k \quad (3)$$

$$u_k = U + u_{k-1}(1 - U)e^{-\Delta_{k-1}/F} \quad (4)$$

$$R_k = 1 + (R_{k-1} - u_{k-1}R_{k-1} - 1)e^{-\Delta_{k-1}/D} \quad (5)$$

where  $w$  is the weight of the synapse (synaptic efficacy),  $u_k$  and  $R_k$  are hidden dynamic variables maintaining the facilitatory and depressionary tendencies of the short-term plasticity of the synapse, and  $U$ ,  $D$  and  $F$  are the parameters modulating synaptic use, time constant of depression (in seconds), and of facilitation. Initially,  $R_k = 1$  and  $u_k = U$ . Each spike contributes  $A_k$  to its PSR at the time it hits.

### Recurrent Circuit (Liquid)

The auditory recurrent circuit (“liquid”) is a  $15 \times 5 \times 5$  column of current-based leaky integrate-and-fire (LIF) neurons (for a total of 375 neurons; 20% are randomly chosen to be inhibitory).

For the neurons in the liquid,  $I_{bg} = 13.5$  mV uniformly and  $\tau_m = 30$  ms.  $V_{rest}$  is 0 mV. When the membrane potential of a neuron exceeds  $V_{thresh}$  (15.0 mV), the membrane potential is reset to  $V_{reset}$  (13.5 mV) and the neuron enters a refractory period during which its dynamics are frozen. For excitatory neurons this is 3 ms (inhibitory 2 ms).  $I_{syn}$  is equal to the difference of the post-synaptic responses (PSR) of excitatory afferent synapses and the PSRs of inhibitory afferent synapses.

The probability that a synapse exists between neurons at 3-D points  $a$  and  $b$  is  $C \cdot e^{(-D(a,b)/\lambda)^2}$ , where  $\lambda$  is a global parameter controlling the density of connections ( $= 2.0$ ),  $D(\cdot)$  is

the Euclidean distance function, and  $C$  is a parameter to modulate the probability of a synapse depending on properties of the connected neurons. In our case,  $C = 0.3$  if  $a$  is an excitatory neuron and  $b$  is an excitatory neuron (EE),  $C = 0.2$  for excitatory and inhibitory neurons (EI),  $C = 0.4$  for inhibitory and excitatory neurons (IE), and  $C = 0.1$  for two inhibitory neurons (II).

The parameters ( $U, D, F$ ) were selected for each synapse depending on the type of neurons that were connected and were drawn from a Gaussian distribution with means (0.5, 1.1 s, 0.05 s) for EE, (0.05, 0.125 s, 0.120 s) for EI, (0.25, 0.7 s, 0.02 s) for IE, and (0.32, 0.144 s, 0.06 s) for II (standard deviation 50% of the respective means). Negative results were redrawn from a uniform distribution between 0.001 of the mean and double the mean. The weights  $w$  of the synapses were drawn from Gamma distributions with means 30.0 (EE), 60.0 (EI), 19.0 (IE), and 19.0 (II); SD 100% of mean, with negative results redrawn from a uniform distribution as described above. In addition, a synaptic delay of 1.5 ms was implemented for EE synapses, 1.0 ms otherwise.

### Input Neurons

Raw audio streams (PCM 16 kHz) are converted into firing probabilities by a cochlear model (Slaney, 1998) which approximates the instantaneous firing activity of the auditory nerve at different points along the cochlea (“cochlear input”, gray neurons in Fig. 1). These probabilities are linearly scaled and injected as current into a set of “spike generating” LIF neurons (“spike generation”, blue neurons in Fig. 1). There are three differently parameterized classes of spike generating neurons (the three columns of neurons), for onset, offset, and passthrough. The onset spike generating neurons have a low (no firing without input) baseline firing rate ( $I_{bg} = 13.5$  mV), and receive strong positive input from the cochlear model in the form of the spike probability for that channel  $\times 20000$  nA (thus increasing activity when input is present in that channel). The offset spike generating neurons have a higher (firing without input) baseline rate affected by Gaussian noise  $I_{bg} = 13.5 + \Gamma(3.0, 0.05)$  nA, where  $\Gamma$  indicates a value drawn from a Gaussian distribution mean 4.0 and standard deviation of 0.05. The input from the corresponding cochlear channel is scaled by  $-20000$  nA, thus suppressing activity when input is present in that channel. The passthrough (direct) spike generation neurons have the same parameters as the onset spike generation neurons.  $V_{thresh} = 15.0$  mV for all these neurons.

The actual onset and offset detector neurons (green input neurons in Fig. 1) receive dynamic synapses from the surrounding three spike generation channels of their corresponding class of spike generating neurons. These synapses modulate the current injected into the post-synaptic neuron based on pre-synaptic firing activity. Large pre-synaptic activity will cause an initial facilitation, followed by a longer depression in the strength of injected post-synaptic current per action potential. Thus, they will inject strong current for the first few pre-synaptic spikes, followed by less current for a period thereafter. This, combined with the different baseline

firing rates of the spike generators, is what implements the onset/offset detectors. The passthrough neurons have quickly-recovering dynamic synapses and perform more like static synapses, but limit their firing rate to a slower rhythm.

$V_{thresh}$  for each sensitivity level of onset/offset/passthrough detector is:

$$V_{thresh} = V_{reset} + E_0 \cdot (D^i \cdot (c + 1)) \quad (6)$$

where  $E_0 = 1.0$  for onset/offset detectors and  $E_0 = 0.2$  for passthrough neurons.  $D = 1.414$ , with  $i$  from  $c = 0$  to  $c = N$  for each of the  $N$  sensitivities of onset/offset detectors ( $N = 1$  for the experiments, i.e. only one sensitivity level for onset/offset detectors). For the one passthrough level,  $D$  is scaled by a factor of 9.0.

For the dynamic synapses between the spike generation and the onset/offset/passthrough neurons, the UDF parameters are (0.5, 1.1, 0.05) and  $w = 3.0$  (onset), (0.5, 0.025, 0.5) and  $w = 9.0$  (offset), and (0.5, 0.025, 0.5) and  $w = 9.0$  (passthrough).

Input (offset/onset/passthrough) neurons synapse into a randomly selected 30% of circuit neurons via static synapses. The weight  $A$  of each of these input synapses is drawn from a Gamma ( $shape = 1$ ) distribution with mean  $A_{mean} = 18.0$  when the post-synaptic neuron is excitatory and  $A_{mean} = 9.0$  when it is inhibitory. Negative weights are set appropriately from a uniform distribution between  $0.001 \cdot A_{mean}$  and  $2 \cdot A_{mean}$ .

The cochlear model described in (Slaney, 1998)<sup>1</sup> was modified and updated to run in real time. Parameter defaults are retained (except for:  $breakf = 500$ ,  $qconst = 8.0$ ,  $stepfactor = 0.5$ ,  $sharpness = 5.0$ ,  $notchoffset = 1.5$ ,  $preemphfreq = 300$ ,  $taufactor = 3.0$ ) producing 52 output channels which encode on each simulation step the probability that a spike occurs in that channel on that time step.

## Readout Neurons and Phrase Integration

A final set of neurons (readout neurons) serve as classifiers ( $r_n$ , one for each category  $n$ ). They receive as input a weighted projection of the liquid's instantaneous firing activity (if spiked +1, otherwise -1), low-pass filtered to mimic the change in post-synaptic membrane potential had the readout been modeled as an LIF neuron (time constant 30 ms). A readout neuron is said to fire at a given time point if the sum of its inputs exceeds a threshold (the bias term determined by the linear regression below). The shape of the weighted projection is determined by supervised learning on a training corpus for each readout neuron independently. This is achieved by linear regression of the matrix of the liquid response to all stimuli (with an additional bias column which is always -1), with a supervisor vector which contains +1 for every time point during which input was from the target word class, and -1 otherwise.

Phrase Integration is performed by injecting 1.0 nA per  $r_n$  spike into a corresponding readout integration neuron  $i_n$  (with

membrane time constant  $\tau_m = 50$  ms). The readout integration neuron is considered to be active when  $V_m > 0.25$ , with no reset or refractory period. These readout integrators provides a more continuous picture of the readout activity that is robust to small recognition errors.

Utterance onset and offset detection (modeled as a neuron with membrane potential  $V_{utter}$ ) is performed by combining input from the onset/offset/passthrough input neurons with the current readout firing activity. Each spike of an onset/offset/passthrough neuron imparts directly 1.0/-0.5/0.7 mV to  $V_{utter}$ , which decays exponentially with  $\tau = 200$  ms. For a word onset to be detected,  $V_{utter} > 1.0$ , and the highest value of all  $n$ ,  $i_n > 0.25$ . An offset occurs when either of these variables falls below the threshold. On onset, an accumulator neuron  $a_l$  increases its voltage at a constant rate of 0.002 mV/ms, with a threshold of 0.3 mV. An utterance is only considered to be an instance of a category (i.e. not noise) if  $a_l$  is over threshold. The accumulator is reset to 0 mV at offset. Another set of accumulators  $a_n$  (one for each readout integrator  $i_n$ ) sums the value of its corresponding readout integrator  $i_n$  from the point an onset is detected, and are reset at offset.

When an utterance that meets all the above conditions is detected, its category is determined by dividing each readout accumulator by the length accumulator. If the highest value is greater than the  $i_n$  threshold (0.25), the utterance is classified as being an instance of the winning category  $n$ . A token (e.g. a textual representation of it, or a number) indicating that category is returned.

## Experimental Validation, Analysis and Results

The model was tested on part of the "CReST corpus" developed from human-human interactions in a search task (K. Eberhard, Nicholson, Kuebler, Gundersen, & Scheutz, 2010) (<http://www.cs.indiana.edu/~riveale/hricorpora.html>). The liquid was trained 10 times each on 9 audio samples each for each of ten phrase categories. In addition, it was "counter-trained" on a sample of recorded microphone noise (that portion of the supervisor vector for all categories was -1 for all time-points for the linear regression). The final two audio samples for each category were set aside for testing.

To test phrase recognition, a new audio stream was created by concatenating the 10 test samples which were presented to the model in real-time. The returned categories were verified to be recognized only once during the correct portion of the audio stream. The best liquid was able to correctly recognize all ten phrase categories. 50 liquids were randomly generated and trained. All were able to recognize at least 7 of the categories, with the exception of 3 liquids that only recognized 5 of them (recall that liquids are randomly generated). By observing the readout behavior during recognition, it was determined that the primary reason for failure was similarities in the categories (e.g. it was most likely to fail when phrases shared similar words, or words had large regions that were similar-sounding).

<sup>1</sup>Code from <http://www.slaney.org/malcolm/pubs.html>

Figure 2: *Top*: Readout (spike) and integrator (lines) response of each trained category from the best liquid to a test case of its own class. *Center*: Readout integrator responses of 5 phrases uttered sequentially, along with scaled utterance detector. Horizontal line is threshold. Note each “correct” readout is active during its own category and relatively inactive otherwise. *Bottom*: Proportion of correctly spiking and correctly not spiking time points for each trained readout (corrected for large leading/trailing silence).

Figure 2 shows the time-line of phrase recognition over the course of the test speech stream in two different ways (including the raw spiking characteristics of the best liquid for the auditory corpora used). Note that even *during* an utterance, it can be predicted based on readout integrator levels whether the utterance stream is probably of a given class. This information can be used to prepare (pre-cache or “prime”) responses to that phrase.

The model has also recently been used for speech recognition embedded in a larger cognitive model of embodied situated human natural language interactions in human-robot interactions tasks, thus providing evidence for its utility in real environments (video at <http://www.cs.indiana.edu/~riveale/muridemo.html>). In this task, the model played the role of a speech recognizer that sends processed tokens representing whole phrases to a natural language parser and understanding system. This system processed the meaning of

the phrase, and passed it on to a cognitive architecture (planner, etc.) which was able to initiate actions (such as changing its own goal state, change its behavior, learn new actions such as door-pushing) based on the content of the phrases (Cantrell, Talamadupula, Schermerhorn, Benton, & Scheutz, 2012).

## Discussion

While previous research has presented methods for converting spike-encoded streams (generated offline from audio input) into liquid activity and, subsequently, liquid activity into instantaneous category readout firing, the problem of using readout firing activity to generate category-tokens of the kind used by most higher-level cognitive models has not been sufficiently addressed. Moreover, the method of encoding sound as spikes did not take into account the onset/offset-detection capabilities of the human auditory system, which contributes significantly to the robust recognition of shorter phonemes like consonants. The model presented in this paper addresses both shortcomings by processing sound in a realistic way up to the neural readout-level and being capable of returning correct word tokens based on readout activity at the right time. One limitation of the current model that must be addressed in the future is that some aspects of the token conversion (the conversion from raw spiking activity to phrase-tokens) are not guaranteed to work well in all speech situations. For example, the assumption that phrases will be preceded and followed by silence may not hold in situations where speech is very fast. In those situations recognizing phrases based on other information such as prosody could lead to better results (Christiansen, Allen, & Seidenberg, 1998).

In addition to the practical benefits of having a real-time model that shows promising performance on natural speech, the model makes important predictions about the mechanisms by which humans are capable of extracting discrete category information from a continuous real-time stream of sensory data. For example, the model proposed an explanation for how category priming or biasing effects come about, as the ongoing activity of each readout integrator can be viewed as the probability that the category it represents is currently present in the stimulus stream. This probability can be made to bias ongoing behavior even before the stimulus signal ends. To see this, imagine an experimental paradigm (e.g., the visual world paradigm (K. M. Eberhard, Spivey-Knowlton, Sedivy, & Tanenhaus, 1995)) in which an auditory cue (e.g., a color word) determines to which of two locations the subject should direct her eyes – it is well-known that humans in that case are capable of performing eye saccades shortly after the onset of the color word (even though they will not always perform them right away). For computational models of these human behaviors it means that a decision for eye movements has to be reached before the word stimulus ends. Specifically, if there are two category readouts, one for “Red” and one for “Blue”, and the first phoneme of “Red” is presented, the model could use the already high activity of the “Red”

category to bias its looking behavior even before the stimulus has ended and the category word “Red” is fully recognized.

This example demonstrates that there can be multiple routes from the “readout” level to other parts of the cognitive system that can influence and bias behavior (one being the route where recognized word tokens are passed on to higher syntactic and semantic processing areas, while another being the more direct, intermediate route that can bias looking behavior). The current model is silent about the exact nature of these routes, as this would require additional specifications of those higher-level cognitive components and behavior-generating components, an important direction for future work. The current model is also silent about the important top-down biases coming from various other parts of the human cognitive system such as the syntactic and semantic biases as well as other biasing information based on perceptual, dialogue, task, and goal information. These top-down biases are critically involved in human speech processing and contribute to the robustness of human speech recognition in noisy environments. However, we believe that the particular model architecture will directly allow for this kind of information integration by way of appropriate top-down connections to the readout units whose activations represent the dynamically changing hypotheses about recognized words. We are currently investigating extended versions of the model that include additional perceptual areas (e.g., as described in (Veale, Schermerhorn, & Scheutz, 2011)) to test the extent to which perceptual biases can influence recognition rates and behavior (such as eye saccades).

Different from our previous models (Scheutz, Eberhard, & Andronache, 2004) which only at a high level of abstraction resembled the human cognitive architecture and only modeled the human data qualitatively, the goal for these new models is to be fully realized in neural architectures and to model the human data quantitatively.

## Conclusions

In this paper, we presented a novel biologically plausible model for human speech recognition together with a proof-of-concept implementation and evaluation of the model. As part of the model, we introduced new methods for any-time phrase recognition based on the human early auditory system coupled with biologically plausible methods to produce word category tokens from a continuous auditory stream. We also introduced biologically plausible implementations of onset/offset detectors for word signals. Future work will include the already mentioned extensions by perceptual areas to be able to allow for biologically plausible quantitative neural models of human eye gaze behavior during reference resolution. In addition, we will also investigate mechanisms for improving noise-robustness with multiple sensitivity levels at the onset/offset stage and online learning of novel word categories.

## Abstract

Any successful attempt at explaining and replicating the complexity and generality of human and animal learning will require the integration of a variety of learning mechanisms. Here we introduce a computational model which integrates associative learning and reinforcement learning. We contrast the integrated model with associative learning and reinforcement learning models in two simulation studies. The first simulation demonstrates performance advantages for the integrated model in an environment with a dynamic and diverse reward structure. The second simulation contrasts the performances of the three models in a classic latent learning experiment (Blodgett, 1929), demonstrating advantages for the integrated model in predicting and explaining the behavioral data.

**Keywords:** Associative Learning, Reinforcement Learning, Model Integration, Cognitive Modeling, Cognitive Systems, Latent Learning

## Introduction

Integration of computational cognitive models is critical for accelerating progress in the field of cognitive modeling (Gray, 2007a). By means of integrative approaches the field can begin to predict and explain the robustness and flexibility of human behavior in complex, uncertain, non-stationary environments (or *large worlds*, Binmore, 2009). Specifically, Choi & Ohlsson (2011) assert that the integration of *learning mechanisms* is essential to improving the predictability and explanatory power of cognitive models.

There is no denying that people are adaptive – for example our memories are retrieved based on their recency and frequency of use (Anderson & Schooler, 1991), visual search is adapted to the structure of the task environment (Shen, Reingold, & Pomplun, 2000; Myers & Gray, 2010), and problem solving strategies are adapted with increasing task experience (Siegler & Stern, 1998). People’s ability to adapt allows them to persist and thrive in large worlds. If we are to build cognitive models for large worlds, we have to endow them with human learning mechanisms. Hand-coded knowledge engineering results in brittle and expensive models, and is a method that does not scale well beyond simple laboratory environments (Gluck, 2010). Our hypothesis is that models may begin to demonstrate human-like flexibility and adaptivity in large worlds through the integration of multiple human learning mechanisms.

In the current paper we present an integrated model of associative and reinforcement learning, as it is evident that humans are capable of learning both the spatiotemporal contingencies and the reward structures of their environment

(Stevenson, 1954; Chun, 2000; Myers, Gray, & Sims, 2012). We demonstrate that model integration improves flexibility and adaptability, provides better predictions of behavioral data, and produces more efficient behavior in environments with diverse and dynamic reward structures when compared to each of the individual models.

In the following sections we first provide background on associative and reinforcement learning theories and models. Next we describe the integrated model. Finally, two simulations are presented. Simulation 1 contrasts the associative and reinforcement learning models with the integrated model in their ability to efficiently adjust to novel goals and diverse reward structures in a grid-navigation environment. Simulation 2 contrasts the associative and reinforcement learning models with the integrated model in their ability to predict behavioral data from a classic latent learning experiment.

## Reinforcement Learning

Reinforcement learning (RL) is a formal model of action selection where the utility of different actions is learned by attending to the reward structure of the environment. It has been used in a wide array of domains, from robotics (Peters, Vijayakumar, & Schaal, 2003) and artificial intelligence (Russell & Norvig, 1995) to cognitive architectures (Fu & Anderson, 2006; Nason & Laird, 2005) and cognitive neuroscience (Holroyd & Coles, 2002).

Generally speaking, RL works in a trial-and-error fashion – attempting various actions and recording the reward gained for those actions (for a review see Sutton & Barto, 1998). More formally, given the state that an agent is experiencing, the action most likely to be chosen is the one with the highest learned utility, plus or minus some exploratory noise. The utility of any given state-action pair, *SA*, in turn, is directly proportional to the value of the reward, that the agent receives after *SA* is executed. Hence, state-action pairs are *reinforced* when they result in a reward; and the likelihoods of their future selection are directly proportional to the values of the experienced rewards.

There are several variations on how utility is learned in RL (for an introduction, see Sutton & Barto, 1998). For example, Temporal Difference RL (TDRL), a version commonly used to model human behavior (Anderson, 2007; Holroyd & Coles, 2002), propagates the received reward to past actions. Reward is discounted as a function of time, so that actions taken just prior to the reward are strengthened more than earlier actions. In this way, TDRL reinforces a sequence of actions that lead to the reward, rather than just a single state-

action pair, helping to obtain a solution in a more efficient manner.

Some RL approaches take into account transitions between  $SA$ , the resultant reward  $R$ , and the utility of the next  $SA$  (SARSA). SARSA models update the utility of the state-action pair executed at time  $t$ ,  $SA(t)$ , by a function of the reward that follows it,  $R(t+1)$ , combined with a function of the utility of the state-action pair that follows it,  $SA(t+1)$ . SARSA models are not as efficient as TDRL, but are guaranteed to converge on an optimal solution.

The Model-based RL approach extends RL by learning the structure of the world beyond utilities. The term *model* in “model-based RL” refers to an agent’s internal representation of the environment, and an agent developed in this framework is capable of planning its route before execution. This is extremely useful when memory and decision cycles are less expensive than actions (e.g. robotics).

One of the limitations of RL as a complete model of human decision-making becomes apparent in environments where goals change. Imagine that on your way to work each day you pass a post office. One day you need to mail a letter. At this point, an RL agent would consider, “let’s try a random action, see how that works.” This is because, by definition, RL models make decisions based solely on the learned state-action utilities. If the goal changes, the utilities representing the reward structure from the initial goal become irrelevant at best, or subversive at worst. Humans and animals, of course, will employ their knowledge of the environment (e.g. that there is a post office on the way to work) to make better-than-chance decisions for achieving new goals (Stevenson, 1954; Tolman, 1948; Quartermain & Scott, 1960).

The SARSA and Model-based approaches are major steps toward more flexible behavior. The SARSA approach considers the state-action-state transitions when learning utilities, but stops short of learning these transitions. The Model-based RL approach learns such transitions, but employs them strictly to enable planning. The decision process during the planning stage, however, is still based on the learned utilities. Thus, when presented with a new goal a Model-based RL agent will still begin to plan its route by considering random actions.

## Associative Learning

Another class of decision models relies on associative learning. Associative learning (AL) models focus on acquiring the spatiotemporal contingencies of the environment and employing these in action-selection. The utility of any given choice is estimated as a function of previously experienced spatiotemporal proximity between this choice and the current goal. The advantage of this approach over RL is that the stored knowledge is goal-independent. Whenever a new goal is given, an AL model can employ its knowledge to make informed goal-directed decisions.

Voicu and Schmajuk (2002) implemented a computational model that learns the structure of the environment as a network of adjacent cells. Once a goal is introduced, reward signal spreads from the goal-cell through this network, such that the cells farther from the goal-cell receive less activation than those that are close. Goal-driven behavior in this model comprises moving towards the cells with the highest activa-

tion. Once this model memorizes the map of the environment, it does not need to learn the reward structure through trial-and-error; rather, the utility of each action-path is identified through spreading activation from the goal.

SNIF-ACT (Fu & Pirolli, 2007) is another model that employs associative rather than reward knowledge for action-selection. SNIF-ACT is a model of human information-seeking behavior on the World Wide Web. The World Wide Web is unpredictable in the sense that there is no way for any of its users to know what links they will encounter during web browsing. The utility of selecting a link in SNIF-ACT is not based on any prior reward, but rather on the semantic association of a link’s text to the current goal (i.e., *information scent*). This mechanism allows SNIF-ACT to make non-random decisions in novel situations based on associative knowledge.

A limitation of SNIF-ACT is that it does not learn the association strengths between links and goals, but rather imports these values from an external source. The Voicu & Schmajuk model learns association strengths in a psychologically implausible manner. The Goal-Proximity Decision-making model (GPD; Veksler, Gray, & Schoelles, 2009) mends this by employing the psychologically-plausible delta learning rule (Rescorla & Wagner, 1972; Widrow & Hoff, 1960) to update association strengths. Like the other two models, GPD then estimates the utility of a path based on its association strength to the current goal. Veksler, Gray, & Schoelles demonstrate that in an environment where goals continue to change, GPD is able to replicate human performance and RL cannot.

A limitation of AL models is that no reward information is learned. In this class of models decisions are based on explicitly specified goals. Associative learning does not help to understand a diverse reward structure, where some actions may result in less reward and some in greater reward. Hence, AL models cannot explain why an organism might learn to prefer actions leading to one goal-state over another.

## Integrating Associative and Reinforcement Learning

It is our opinion that AL and RL complement each other. As discussed above, RL models capture behavior based on a given reward structure. However, as agent goals change, so does the reward structure of the environment. Since RL fails to capture environmental contingencies beyond the original reward structure, it cannot predict the efficiency of human behavior in environments where goals tend to change. Contrariwise, AL models store the the spatiotemporal contingencies of the environment independent of the reward structure, and are more flexible in adapting to new goals. However, in ignoring the reward information in the environment, association-based models cannot capture people’s sensitivity to the value of reward. In this section we describe how the two learning approaches can be integrated to produce more flexible behavior in environments where the reward structure is both diverse and dynamic.

Given some agent state,  $S$ , and a possible action,  $A$ , RL models learn the utility,  $u$ , of the  $SA$  state-action pair as directly proportional to the reward that has been experienced after prior executions of  $SA$ , and, in models like TDRL, inversely proportional to the length of time between  $SA$  and the

reward in prior experience. AL models do not learn the utility of  $SA$ , but estimate it based on the strength of association,  $w$ , between  $SA$  and the current goal,  $G$ , where  $w$  is inversely proportional to the length of time (or distance) between  $SA$  and  $G$  in prior experience. From the perspective of what is stored in model memory, the RL models store the values of  $u$  for each state-action pair,  $SAu$ , and AL models store the values of  $w$  for each state-action-state transition,  $SAwS$ .

To integrate these two models, we propose that the association strength,  $w$  should continue to be recorded as in the AL models, whereas the utility  $u$  should be recorded for each state,  $S$ , rather than for each state-action pair  $SA$ . Thus, what will be stored in memory and used for action-selection in the integrated model is both  $w$  and  $u$  for each state-action-state transition,  $SAwSu$ . The strength of association,  $w$ , is useful as an estimate of the probability that a state might follow a given state-action pair and the length of time of this transition. The utility,  $u$ , is useful as an estimate of the reward probability/value to be received after a transition occurs.

The integrated model uses the delta learning rule to update both utilities and association strengths. For each previously executed state-action pair  $j$  and each new state  $i$ , the strength of association between  $j$  and  $i$ ,  $w_{ji}$ , at current time,  $n$ , is increased in the following manner:

$$\Delta w_{ji}(n) = \beta[a_i(n) - w_{ji}(n-1)] \quad (1)$$

where  $\beta$  is the learning rate parameter, and  $a_i$  is the activation of  $i$  ( $a_i = 1$  if  $i$  is present, else 0). The utility for each new state  $i$ ,  $u_i$ , at current time,  $n$ , is increased in the following manner:

$$\Delta u_i(n) = \alpha[r(n) - u_i(n-1)] \quad (2)$$

where  $\alpha$  is the learning rate parameter, and  $r(n)$  is the reward experienced at time  $n$ .

At each decision point, the utility of a given state-action pair,  $j$ , is calculated as follows:

$$U_j = \sum_{\forall i} (w_{ji} \times u_i \times \delta^t) + N \quad (3)$$

where  $\delta$  is a discount parameter ( $0 < \delta < 1$ ),  $t$  is the temporal distance between  $j$  and  $i$ , and  $N$  (exploratory noise) is a number drawn randomly from a normal distribution with a mean of zero and a standard deviation set to some parameter,  $\sigma$ .

In the following section the  $SAwSu$  model is examined in terms of efficiency and psychological validity within environments with diverse and dynamic reward structures.

## Simulations

The following subsections compare the integrated AL+RL model ( $SAwSu$ ) with AL-only and RL-only models. First, the models are evaluated based on the efficiency of finding rewarding states in a  $10 \times 10$  grid. Second, the models are evaluated based on the ability to match data from a classic latent learning experiment. A single value for the discount parameter ( $\epsilon = .9$ ) was used for both simulations.

### Simulation 1: Dynamic & Diverse Reward Structure

As pointed out in the Introduction, the strength of RL is in learning a diverse reward structure, where some actions may lead to greater reward than others; AL excels at learning the environmental structure independent of rewards, such that this knowledge may be applied in purposive behavior whenever new goals arise. However, large worlds are both diverse and dynamic. The following simulation was conducted to *highlight the conditions under which the RL and AL approaches begin to falter*, and how an integrated approach addresses these limitations.

A  $10 \times 10$  navigation grid was used, where a model's state was uniquely identified as one of the cells in the grid, and the model had four possible actions from each cell – to move north, south, east, or west<sup>1</sup>. If an illegal move was selected (i.e. a move that would take the model off the grid), the model's state was not changed. For each model run, a model was placed in a random cell on the grid. Each time the model reached a reward state, the model would again be placed in a random cell on the grid. Before the model began the task of locating a reward, a reward of 1.0 was placed in a random cell on the grid. After 4000 steps, the reward was cleared, and placed in a different random cell. Following the next 4000 steps (8,000 total steps), the reward was cleared, and rewards of 1.0 and 0.1 were placed in two randomly selected cells. Finally, after the next 4000 steps (12,000 total steps), the reward was cleared again, and replaced with rewards of 1.0 and 0.1 in two randomly selected cells.

The integrated AL+RL model ( $SAwSu$ ) was compared with Random-walk, AL (GPD), and two RL models – Temporal-Difference RL (TDRL), and Q-learning (Q-RL). As discussed above, TDRL is the version of RL most commonly used in modeling human/animal behavior. Q-RL is a popular SARSA model that is not as efficient as TDRL, but is guaranteed to converge on an optimal solution (Sutton & Barto, 1998). The results, averaged over 100 model runs for each model type, may be observed Figure 1.

AL+RL was the best overall model, averaging a total score of 1328.4 for the entire run in this environment, whereas AL (GPD), TDRL, Q-RL, and Random models scored 1107.8, 362.2, 237.1, and 66.1, respectively. Q-RL is guaranteed to converge to an optimal solution for any one reward structure in the environment, but it is too inefficient to find such a solution within the 4000 trials allotted in this task (though its efficiency improves after the first 8000 steps, where there is more than one goal-state).

TDRL, AL, and AL+RL produce indistinguishable performance until the first goal change (see Figure 1, first 4000 steps). However, once a new goal is presented, TDRL struggles to relearn the reward-structure of the environment, as all of the state-action utility values need to be relearned (these may be relearned faster if the exploratory noise was increased, but this would come at the expense of performance, even for the first goal). Q-RL struggles with the same issue, as both RL models drop to random-level performance once a new reward-structure is introduced. In contrast, AL and

<sup>1</sup>This is a standard simulation environment for performance examination of computational agents, as it aims to represent a generic problem space.

Figure 1: Simulation 1 results.

AL+RL can employ all of the associative knowledge that was gathered in the first 4000 steps, and apply it to achieving the new goal.

Where AL+RL begins to differ from AL is when the reward structure of the environment becomes more diverse. After 8000 steps, there are two rewarding states introduced into the environment, one of these having a high value (1.0) and the other having a low value (0.1). The AL+RL model learns the correct reward values of these states. AL, however, cannot distinguish between the two types of goals, as it records no information corresponding to varying reward values.

In summary, the integration of associative and reinforcement learning results in better performance than could be achieved by either model alone in an environment where the reward structure is dynamic and diverse. The AL+RL model displays more flexibility than RL in adapting to changing goals, and more flexibility than AL in adapting to a varying reward structure.

## Simulation 2: Blodgett, 1929

Latent learning is a classic behavioral paradigm that focuses on performance in an environment with a dynamic reward structure, and often involves a diverse reward structure. In this paradigm, after having spent some time in an environment, subjects are presented with some goal. Upon the introduction of the goal, subjects display a higher level of performance than would be expected if they had not spent any time in the environment prior to the goal introduction. This phenomenon is observable in children, adults, and animals (e.g. Quartermain & Scott, 1960; Stevenson, 1954; Tolman, 1948).

For example, Blodgett (1929) ran three groups of rats in a maze-learning experiment. One group (the control) was rewarded upon reaching the end of the maze on every trial (R1). The second group began receiving rewards on trial 3 (R3). The third group began receiving rewards on trial 7 (R7). Results demonstrate that subjects in groups R3 and R7 began to perform at the level of control subjects immediately upon the introduction of the reward, producing much steeper error-reduction slopes in these groups than that of R1 (see Figure 2, top-left panel). An associative learning model can predict this

phenomenon. Such a model would learn the structure of the maze and begin to employ its knowledge immediately once the reward is introduced.

Figure 2: Maze Performance: Avg. Errors by Trial. Data adapted from Blodgett, 1929 (top-left) and simulation results from Reinforcement Learning (bottom-left), Associative Learning (bottom-right), and integrated (top-right) models.

Interestingly, groups R3 and R7 did not continue to display random-level performance until the introduction of the reward. Rather, these groups displayed a shallow error-reduction curve, indicating that there was at least some intention to complete the maze even in the “no-reward” trials (“low-reward” from hereon)<sup>2</sup>. An RL model can predict this phenomenon, producing a shallow learning curve for the “low-reward” trials (R3 until trial 3, R7 until trial 7), and a steeper learning curve for the high-reward trials (R1).

A model that integrates RL and AL should reproduce both (1) the better-than-random level of performance in groups R3 and R7 prior to the introduction of reward, and (2) the steep improvements in performance once this reward is introduced.

The integrated AL+RL model (SAwSu) was compared with AL (GPD) and RL (TDRL) models. A parameter search was performed, seeking the model parameters that produced the best fit (least sums of square differences) to data in the constant-reward (R1) and the “low-reward” (R7, trials 1-7) conditions. Three parameters were varied for each model: learning rate, amount of exploratory noise ( $\sigma$ ), and the perceived low-reward ( $LowR$ ) for finishing the maze on the “low-reward” trials. The learning rate parameter varied for RL was the utility-learning constant,  $\alpha$ , and for AL and AL+RL it was the associative-learning constant,  $\beta$  ( $\alpha$  remained unvaried for AL+RL at 1.0).

Once the best parameter values were found (RL:  $\alpha = .4, \sigma = .08, LowR = .15$ ; AL and AL+RL:  $\beta = .2, \sigma =$

<sup>2</sup>We interpret the shallow learning curves as resulting from a low reward, such as being taken out of the maze.

Table 1: Root Mean Square Difference to Blodgett, 1929.

Model	Best fit to data		Predicted	
	R1	R7 [trials 1-7]	R3	R7*
AL+RL	0.21	0.14	0.11	0.15
RL	0.26	0.17	0.19	0.32
AL	0.22	0.56	0.23	0.50

\*Only trials 8 and 9 are predicted.

.05,  $LowR = .15$ ), the full simulations were executed to get model predictions for R3 and for R7 after the introduction of reward (these conditions were not included during the parameter search). Results may be observed in Figure 2 and Table 1. As expected, AL and AL+RL produced steeper performance improvements than RL upon the introduction of the reward by the experimenter on trials 3 and 7. As expected, RL and AL+RL replicated the shallow error-reduction curves in trials 1-3 for condition R3 and 1-7 for condition R7, and AL did not.

AL+RL produced a better overall fit to data than did the other two models (see Table 1). The advantages become more apparent when we focus on the error-reduction after the introduction of reward. Figure 3 demonstrates model predictions for error reduction in the R3 group between trials 3 and 5, and the R7 group between trials 7 and 9. The AL model predicts too high a performance improvement (because the initial performance is underestimated), and the RL model predicts too low a performance improvement in these trials.

Figure 3: Error reduction after the introduction of reward in Blodgett, 1929.

## Summary and Discussion

In this paper we described how two learning mechanisms widely supported in the psychological literature, reinforcement and associative learning, may be integrated. In contrast with RL-only and AL-only models, the integrated model, SAwSu, was shown to produce more efficient, higher fidelity behavior in environments where the reward structure is both diverse and dynamic.

Gläscher, Daw, Dayan, and O'Doherty (2010) propose an alternative integration of AL and RL by including a supervisory mechanism that learns to arbitrate between AL and RL. This implementation seems less parsimonious than SAwSu –

it has three learning and three decision mechanisms, whereas SAwSu has two and one, respectively. Further comparison of the two approaches is warranted.

To the best of our knowledge there are no other computational frameworks that learn the reward structure and the spatiotemporal predictions of the environment, and employ both in the decision-making process. Frameworks that employ some form of Model-based planning (e.g. Daw, Niv, & Dayan, 2005; Sutton & Barto, 1998) include both AL and RL, but these tend to focus on the trade-off between planning in the head and acting in the world. Associative knowledge in this class of models is used to enable planning rather than to determine how a path of actions, whether in the head or in the world, is chosen.

The overall scarcity of decision models that employ AL and RL together is rather surprising given the long history of research on learning in experimental psychology, cognitive science, and artificial intelligence. Ohlsson (e.g. Choi & Ohlsson, 2011) has been promoting the integration of learning mechanisms, including AL and RL, and Alonso & Mondragón (2006) and Dickinson & Balleine (1993, 1994) call for AL+RL integration. None of these proposals, however, has been implemented as a computational model, and thus cannot be easily contrasted with the SAwSu implementation.

The Voicu & Schmajuk (2002) model mentioned in the Introduction, does employ AL in action-selection, and even considers variable utility of the goal state in the decision phase. However, the Voicu & Schmajuk model does not specify any way of actually learning state utilities.

Earlier versions of the ACT-R integrated cognitive architecture included both RL and AL (see Anderson, 1993; Anderson & Lebiere, 1998). However, according to Anderson (2001), the particular form of associative learning implemented in ACT-R turned out to be “disastrous,” and produced “all sorts of unwanted side effects” (p. 6). Thus, as it stands, the implementation of associative learning in ACT-R 6 has been reduced to a single equation that relates the fan effect to spreading activation. This limits AL to chunks that have a direct symbolic relationship, where associative strengths can only decrease as more knowledge enters the system and the “fan” of associations to each chunk increases.

The current effort to integrate AL and RL is in accord with the many calls for the integration of cognitive mechanisms within a unified computational framework (e.g. Gray, 2007b; Choi & Ohlsson, 2011). However, the current work presents the integration of only two learning mechanisms, addressing only some of the complexities of large worlds. In the pursuit of models that can produce persistent, adaptive, and flexible behavior in large worlds, it is required that we address how a model like SAwSu might be incorporated into a broader cognitive architecture such as ACT-R. Further integration of AL and RL with other cognitive mechanisms is the necessary next step for this research.

## Abstract

It has often been observed that colour is a highly preferred attribute for use in distinguishing descriptions, that is, referring expressions with the purpose of identifying an object within a visual scene. However, most of these observations were based on visual displays containing only colours that were maximally different in hue and for which the language of experimentation possessed basic colour terms. The experiment described in this paper investigates the question whether people's preference for colour is reduced if the colour of the target referent is similar to that of the distractors. Because colours that look similar are often also harder to distinguish linguistically, we also examine the impact of the codability of the used colour values. The results of our experiment show that, while people are indeed less likely to use colour when the colours in the display are similar, this effect is entirely due to the difficulty in naming similar colours. When the colours of target and distractors are similar but can be named using different basic colour terms, no reduction in colour use was observed.

**Keywords:** reference production, language production, colour

## Introduction

Referring expressions are an essential part of communication. Whenever people engage in any type of discourse they use referring expressions to encode the entities that they are talking or writing about. Sometimes it suffices to use a pronoun to let the addressee know what is meant, but often a distinguishing description, a noun phrase differentiating the target referent from all other visually available distractor objects, is necessary. The production of such distinguishing descriptions has been a central theme for researchers both in psycholinguistic and in computational research on reference production. One particular question of interest is which attributes should be chosen for realisation in a distinguishing description, the problem of semantic content selection.

One of the most often made observations in psycholinguistic research regarding the choice of attributes for distinguishing descriptions is that people seem to favour colour over almost all other attributes when describing a target referent with the aim of identification (cf. Pechmann, 1989; Belke & Meyer, 2002; Sedivy, 2003; Brown-Schmidt & Tanenhaus, 2006; Arts, Maes, Noordman, & Jansen, 2011). This includes frequent redundant use of colour; cases in which the referring expression would be equally as distinguishing if colour was not mentioned. In some cases, people even use colour when all objects in a scene are of the same colour (Koolen, Goudbeek, & Krahmer, 2012).

However, as far as we know, all of this research was based on stimulus material using prototypical primary colours with clearly defined basic colour terms. In this paper, we investigate the question of whether people's preference for using the colour attribute diminishes or remains the same when the colour values in a visual scene are more similar to each other, and when no different basic colour terms exist for them.

Various researchers have argued that colour is preferred over, for example, size, in reference production, because it expresses absolute rather than relative information. In particular, Pechmann (1989) found in an early eye-tracking study that people usually begin to verbalise a description before they have fully scanned the scene. He found that a third of the descriptions in his data that contained both size and colour did not follow standard word order by mentioning colour before size (e.g., *the blue small car*).<sup>1</sup> He also noted that the first-mentioned attribute in overspecified descriptions was almost always colour, which often was ultimately not useful for the task of distinguishing the target referent from the visual context. He argued that both these observations might be due to the fact that colour is more easily cognisable than the other distinguishing features in his experiment because it can be perceived without having to compare the target referent to the other objects in the scene.

Belke and Meyer (2002) found similar overspecification effects for colour and size as Pechmann. They additionally provided eye-tracking evidence from a same-different judgement task for an account which credits this effect to differences in the way absolute and relative attributes are processed at a perceptual level. Based on experiments using the Stroop paradigm, Naor-Raz, Tarr, and Kersten (2003) even argued that an object's colour is an intrinsic component of the visual representation retained in long-term memory.

Another prominent source of evidence for people's preference for colour comes from corpus studies on purpose-built collections of referring expressions. The furniture section of the TUNA Corpus is a collection of human-produced distinguishing descriptions for furniture items differing in type, colour, size and orientation. In this corpus, colour is used redundantly more than three times as often as the other at-

<sup>1</sup>The standard word order is in this case identical for English and Dutch, the language of Pechmann's experiment.

tributes (Gatt, 2007, p. 82). In their recent experiments on semantic alignment in referring expressions, Goudbeek and Krahmer (2012) examined whether people can be primed to use a dispreferred attribute over a preferred one. Because they re-used the visual stimulus objects from the TUNA Corpus, they made the much higher frequency of colour over that of orientation in that corpus an underlying assumption in their experimental design.

A further corpus analysis by Viethen and Dale (2011), based on a large set of referring expressions for simple 3D scenes, also found that people mentioned the colour of the target object in a large proportion of the cases in which it was not necessary for identification. For size, on the other hand, their analysis found that its use depended highly on how well it distinguished the target from the other distractors, especially those of the same type as the target, pointing to a much more ‘utilitarian’ attitude towards size than towards colour. This is in line with findings from eye-tracking experiments which have shown that size is rarely used in situations where it adds no discriminatory power to the referring expression at all, while the same is not true for colour (Sedivy, 2003; Brown-Schmidt & Tanenhaus, 2006).

In light of this evidence, it is uncontroversial that colour plays a special role in referential communication. Yet, it must be noted that all of these results are based on stimuli with objects coloured in a small number of very different hues (red, blue, green, yellow, grey), sometimes even only black and white. In other words, the colour differences between the objects presented to participants were as large as possible.

No research exists using stimulus objects in similar colours. An intuitively plausible prediction is that the use of colour decreases as the similarity between the colours in the scene increases. This prediction follows also from Deutsch and Herrmann’s (1976) third postulate (p. 43). They show that in a situation with two identical objects that only differ in width and height, with a large difference in width and a small difference in height, people tend to use only the width attribute in a distinguishing description, and vice versa. Herrmann and Deutsch extrapolate from these findings that, in any situation in which more than one attribute can be used for identification, people will tend to use the one in which the objects differ most. If, on the other hand, the observed high rate of colour use in referential communication is indeed due to a smaller cognitive effort involved in mentioning it, as many other psycholinguists and computational linguists have argued, it should be unchanged in situations with colours that are not maximally different.

A confounding factor lies in the varying codability of different colour values. The more similar two colours are, the more likely it is that they fall within the range of the same basic colour term, such as *red*, *blue* or *yellow*, depending on the basic colour terms that exist in a given language.<sup>2</sup> In such

a case, more complex colour terms, such as *dark red* or *light blue* have to be constructed. It is conceivable that a colour value that is harder to encode is less likely to be verbalised.

Regarding the effect of colour difference, two conflicting hypotheses can be formulated:

1. The colour of an object is perceived independently from the colours of surrounding objects and gets included in distinguishing descriptions reflexively rather than based on a consideration of its usefulness. This hypothesis is in line with most claims in the literature and predicts that the extent of the difference between the target’s colour and that of the distractor objects has no impact on people’s reference behaviour.
2. The high use of colour is based to some extent on an assessment of the difference in colour between the target item and the distractors. Following from (Herrmann & Deutsch, 1976), a lower use of colour should be expected when the colours are similar than in situations where the colours are as different from each other as possible.

For the effect of colour codability our hypothesis is:

3. The codability of a target’s colour with respect to distractor colours effects the likelihood of it being used in a distinguishing description. Colours that can be named by a basic colour term are more likely to be included than those for which a complex term has to be used.

In the following, we describe an experiment designed to arbitrate between Hypotheses 1 and 2 and to test Hypothesis 3. Our results support the assumption of Hypothesis 3 that the use of colour is reduced when the codability of the colour value of an item is reduced, and advocate Hypothesis 1 over Hypothesis 2.

These results can inform ongoing research on developing computational models of reference production, as this work has begun to align its focus with that of psycholinguistic research. Researchers from the computational field are looking more and more for evidence about how humans solve the problem of content selection for reference production, in order to inform their models (cf. Dale & Reiter, 1995; Kelleher & Kruijff, 2006; Viethen & Dale, 2006; Deemter, Gatt, Sluis, & Power, 2012). One main reason for this move towards human-likeness as a criterion for task success of reference generation systems is the aim to create computational models that are in some sense cognitively plausible. The results of our experiment show that even computational models that are solely focussed on content selection for reference production need to pay more attention to the problem of lexical choice, as these two issues appear to be more closely intertwined than most existing models acknowledge.

## Experiment

The experiment took the form of a reference production task, in which participants were shown displays of simple geometric objects on a computer screen. They were asked to describe

<sup>2</sup>Which hues are grouped under the same basic colour terms differs for different languages, as they carve up the colour spectrum in different ways and at different granularities (Kay, Berlin, Maffi, Merrifield, & Cook, 2010).

(a) A hidiff item: one large red and two small blue squares. (b) A lodiff item: one small dark blue and two large light blue diamonds.

Figure 1: Example stimuli from the two colour-difference conditions.

one of the objects in such a way that an imaginary partner would be able to identify it.

## Method

**Participants** 63 undergraduate students of Tilburg University took part in the experiment in return for course credit. 48 were female and 15 male. Their age ranged from 19 to 26 years ( $M = 20$  years and 10 months). They were all fluent speakers of Dutch, the language of the experiment.

**Materials and Design** Each participant was shown 32 critical items and 64 filler items. The critical trials consisted of simple scenes containing three two-dimensional geometrical figures: one intended referent and two distractor objects. In order to keep the design as simple as possible, the two distractor objects were identical. However, the target item differed in both colour and size from the two distractors, so that either of these two attributes was sufficient to fully distinguish it.

Our main manipulation concerned the difference in colour between the target and the distractors. In half of the trials this difference was large (hidiff condition), in the other half it was small (lodiff condition). Figure 1(a) shows a trial from the hidiff condition, and Figure 1(b) is an example from the lodiff condition.

As discussed above, the more similar two colours are, the less likely it is that they can be distinguished by basic colour terms. For example, the basic colour term *blue* is not sufficient to distinguish the target in Figure 1(b) from the distractors; instead, the complex colour term *dark blue* has to be used. This applies in Dutch in the same way as in English. To test the impact that the codability of different colour values might have on the content of referring expressions (see Hypothesis 3), we used a nested variable within the lodiff condition, by including two different hues: red and blue. For red hues, Dutch (just as English) possesses two different basic colour terms, even at a low difference, namely *rood* (red) and *roze* (pink). Thus, stimuli with red and pink objects, such as the one in Figure 2(a), form the hicode condition. For blue, the complex colour terms *donkerblauw* (dark blue) and *lichtblauw* (light blue) have to be used, resulting in a locode condition (an example stimulus is shown in Figure 2(b)). The lodiff items were equally divided between the hicode condi-

(a) A hicode item: one large pink and two small red triangles. (b) A locode item: one small light blue and two large dark blue circles.

Figure 2: Example stimuli from the two colour-codability conditions.

tion and the locode condition.

To determine the exact colour values to use we referred to the Hue Saturation Brightness (HSB) colour model. For the two dark colours we used the canonical values for blue ( $H = 245^\circ$ ) and red ( $H = 0^\circ$ ), 100% saturation, and a slightly lowered brightness (75%). For the lighter colours, we subtracted  $35^\circ$  from the original hue values, decreased the saturation and increased the brightness. We finetuned the values for the lighter colours based on a pretest, to ensure that people would agree on calling them *roze* and *lichtblauw*. This resulted in the HSB values ( $215^\circ$ , 70%, 100%) for light blue and ( $320^\circ$ , 58%, 95%) for pink.

To ensure that there were the same number of target objects in each of the four colours (red, pink, dark blue and light blue), half the items in the hidiff condition used red and dark blue objects, and the other half pink and light blue ones. The position of the target was balanced across items. Furthermore, each condition contained a balanced number of trials using each of the four object types.

The type of the distractor objects was always the same as that of the target, so that type was never distinguishing. However, the size of the distractors was different from that of the target object, in order to give the participants an alternative option to using colour. It would not make sense to measure the rate of colour use, if colour was the only distinguishing feature in some or all trials.

We aimed to keep the size difference between target and distractors constant across all trials. To this end, we defined the size of an object by the length of its longest internal distance (the diameter for a circle, the diagonal for a square, an edge for a triangle, and the vertical line in a diamond), rather than, for example, its area. The longest internal distance of the large objects was set to twice that of the small objects.

**Filler Items** We included two types of fillers, which were carefully designed to mislead the participants regarding the exact aims of the experiment.

The 32 geometrical fillers were similar to the critical stimuli in that they showed three geometrical objects, but they used type and pattern as distinguishing attributes. Colour and size were never fully distinguishing in the fillers, in order to avoid priming the use of these two attributes. The target was

Figure 3: Two example filler items.

either striped or checkered so as not to prime the use of *solid* as a pattern which might then also show up in the critical trials where it was non-distinguishing. Half of the geometrical fillers were in black and white and in 9 of them the target was green, in order to distract from the small set of colours used in the critical trials. Again, the target referent's type and size was balanced across the whole set. Figure 3(a) shows an example of a geometric filler.

The 32 'Greeble' fillers each showed two novel 3D figures in purple.<sup>3</sup> We chose pairs such that the target object could always be distinguished from the distractor object by its main shape and the direction in which its protrusions were pointing. Because these objects are designed to be difficult to describe and look very different from the geometric items, we hoped they would prevent the participants from adopting a standard strategy for describing the geometric items. An example Greeble filler is shown in Figure 3(b). Debriefing revealed that the participants were not aware of the purpose of the experiment, and the majority of participants believed that the Greeble items were the critical stimuli of the experiment.

**Procedure** Two stimulus lists were created by producing one random ordering and then reversing it for the second list. Each critical stimulus was prepended with one geometrical and one Greeble filler item, which were chosen semi-randomly in a way such that the target was never in the same position in more than four items in a row. The item directly before each critical stimulus was always a Greeble filler to minimise any possibility of lexical or semantic priming from the geometrical filler responses to the critical responses.

The Dutch instructions told the participants that they would see a number of simple scenes on a computer screen. They were asked to verbally describe the object pointed at by an arrow to an imaginary partner without using position information. They had to complete the sentence *Klik nu op de/het ...* ('Now click on the ...') which was shown underneath each item. Their voice was recorded using a headset.

Before each item, a fixation cross was displayed for 1.5 seconds, then the stimulus item was shown for 4.5 seconds during which the participants had to give their response. We introduced this relatively short response time after finding in

Table 1: Count and proportion of responses containing colour.

condition	count	mean	stdev
hidiff (N=1008)	747	.74	.35
lodiff (N=1008)	681	.68	.36
lodiff-hicode (N=504)	376	.75	.36
lodiff-locode (N=504)	305	.61	.40

a pilot experiment that participants tended to exhaustively describe the whole scene.

## Results

**Coding of the Independent Variables** As main dependent measure, we analyse the proportion of colour use in the different conditions. We consider a description to contain colour, if a colour value is mentioned that is true of the target, independently of the distinguishingness of this value. For example, we consider the description in Example (1) for the target in Figure 2(b), where all three objects are blue, as a use of colour. As a secondary measure we also look at the use of size, in order to get an insight into the question whether colour gets mostly used redundantly.

(1) de kleine blauwe cirkel

(the small blue circle) [for the stimulus in Figure 2(b)]

The responses were transcribed and coded for use of colour and size by a Dutch native-speaker.

**Data Analysis** Table 1 displays the mean proportion and standard deviation of colour use in the hidiff and lodiff conditions as well as the two nested conditions under lodiff (hicode and locode). It shows that people were more likely to use colour when the colours in the stimulus scene were very different than when they were similar. However, it also shows that the mean proportion of colour use in the lodiff-hicode condition was very similar to that in the hidiff condition.

We conducted a within-participants analysis of variance (ANOVA) to compare the three meaningful conditions (hidiff, lodiff-hicode, lodiff-locode), which showed the differences between these conditions to be highly statistically significant ( $F(2, 124) = 19.9, p < .001, \eta^2 = .24$ ). A test of planned within-participant Contrasts confirmed that the difference between the hidiff and the lodiff condition was significant ( $F(1, 62) = 18.7, p < .001, \eta^2 = .23$ ); participants used colour more in the hidiff condition than in the lodiff condition. The same is the case for the effect of codability (locode vs. hicode conditions) ( $F(1, 62) = 20.3, p < .001, \eta^2 = .25$ ), confirming that people used colour more when the colours could be distinguished by basic colour terms. However, there was no statistically significant difference between lodiff-hicode and the hidiff condition ( $F(1, 62) < 1$ ).

For size, the opposite picture emerges. Table 2 shows that people were less likely to use size when the colour difference was high than when the colours were similar, and that people used size more often in situations in which the name of the

Table 2: Count and proportion of responses containing size.

condition	count	mean	stdev
hidiff (N=1008)	584	.58	.36
lodiff (N=1008)	679	.67	.31
lodiff-hicode (N=504)	282	.56	.36
lodiff-locode (N=504)	397	.79	.30

colour was difficult to encode. Again, the difference between the hidiff and the lodiff-hicode conditions does not appear very big.

The statistical analysis with tests of planned Contrasts revealed the same pattern as for colour use: the overall difference between hidiff, lodiff-hicode, and lodiff-locode is significant with an even bigger effect size ( $F(2, 124) = 39.7, p < .001, \eta^2 = .39$ ); as are the differences between hicode and overall locode ( $F(1, 62) = 19.3, p < .001, \eta^2 = .24$ ) and between hicode and locode-lodiff ( $F(1, 62) = 52.3, p < .001, \eta^2 = .48$ ). This means that people used size less often in the hidiff and the hicode conditions than in the locode condition. Again, there was no statistically significant difference between hidiff and lodiff-hicode ( $F(1, 62) = 1.1$ ).

## Discussion

The main observation from our results is that a smaller difference in colour alone does not result in a decrease in the use of colour in referring expressions. The apparent difference in colour use between the hidiff and lodiff conditions arises solely from the difficulty in coding the colour value in the locode condition. This lends support to Hypothesis 1, stating that people's preference for colour is independent from its value. It also confirms Hypothesis 3, which predicts that colours that are difficult to name because no distinguishing basic colour term is available, are less likely to be mentioned in a distinguishing description.

Interestingly, there were 99 distinguishing descriptions that contained a non-distinguishing colour value, such as in Example (1) above. All 99 of these cases occurred in the lodiff-locode condition. It is not surprising that no such cases occurred in the other conditions, because no basic colour terms exist that encompass both red and blue, red and pink, or pink and blue. However, the fact that almost a third of all colour terms used in the locode condition were non-distinguishing further supports the hypothesis that people often mention colour not for its discriminatory power but because it is easily available perceptually. By mentioning the basic, yet non-distinguishing, colour term *blauw* they can follow their preference for using colour but avoid the difficulty involved in retrieving and uttering a more complex colour term. This raises the question whether it is indeed the complexity of a colour term that stops people from using it or rather the fact that in our locode scenes the target's colour term (e.g. *lichtblauw* in Figure 2(b)) partly overlaps lexically with that applying to the distractors (*donkerblauw* in Figure 2(b)).

Furthermore, of the 37 descriptions in which a property was mentioned that was not true of the target object, only one

used a wrong colour (*pink* instead of *red*, and in this case the participant corrected themselves). This further strengthens the argument that colour naming is an inherently easier task than naming the size made by a number of researchers including (Pechmann, 1989; Belke & Meyer, 2002; Naor-Raz et al., 2003; Kelleher & Kruijff, 2006).

The rate at which people used size was inversely proportional to the use of colour. Of course, size had to be used in descriptions not including colour in an identification task with these two attributes as the only distinguishing features. However, this does not necessarily mean that it has to be omitted in cases in which colour was mentioned. Instead, the rate of size use might have stayed constant, indicating a relatively high rate of overspecification in the hidiff and hicode conditions. Two possible explanations for the difference in the use of size between the different conditions are conceivable. First, it might be the case that the choice to use size is influenced directly by the experimental variables. This might be due to the fact that the speaker has to scan the scene in order to determine the relative size of the target object. While scanning a locode scene he might notice the usefulness of colour—which according to Pechmann's (1989) and Belke and Meyer's (2002) incrementality accounts might already have been uttered at this stage—and decide whether to use size based on this information alone, independently of whether colour is actually mentioned or not. Second, the use of size might be impacted by the use of colour. People might make their choices about which attributes to use sequentially, one attribute at a time and the decision about size succeeds the decision about colour. So, once a speaker has decided not to mention colour, size has to be included in order to fulfil the referential task of identification. Further experimentation would be required to arbitrate between these two accounts.

**Consequences for Computational Modelling** The main assumption regarding the use of colour remains unchallenged by our results: colour is highly preferred by human speakers and should therefore feature highly in the output of computational referring expression generation systems that are aimed at producing human-like output. However, our results re-emphasise the importance of an issue which seems to have lost traction in the decades since (Dale & Reiter, 1995): that of lexical choice. Dale and Reiter's original algorithm included a *FindBestValue* function, acknowledging the fact that different level values exist for many attributes and that not all values are equally adequate in a given situation. However, their algorithm makes its decision about which attributes to include based on the most distinguishing value for an attribute, meaning that a colour value expressed by a more complex term, such as *light blue*, is more likely to be included for the colour attribute than a basic one, such as *blue*. This is of course not advocated by our data.

Our findings speak loudly against the separation of semantic content selection and lexical choice present in most recent computational approaches to referring expression generation. Computational reference production models with a claim to

human-likeness need to take into account how difficult it will be to realise each attribute lexically already when they make the decision about the use of this attribute. The results presented here clearly show that even highly preferred attributes such as colour should get included less often in situations in which they are hard to code, or that in some cases a less specific value should get used.

A second point emerging from our data is that the deterministic nature of most existing computational reference production models is clearly not in line with human reference behaviour. While we can observe increases or decreases in the use of certain attributes depending on different experimental variables, there always remains a large amount of variation. Therefore, REG systems that are serious about modelling human behaviour must begin to use probabilistic mechanisms in order to be able to capture the non-deterministic choices people make when they refer. A notable first move in this direction was made by Gatt, van Gompel, Krahmer, and van Deemter (2011).

### Conclusions

Previous research often took it for granted that colour is a highly preferred attribute in reference production, but so far a serious and systematic study of this has been lacking. Existing results were based on stimuli in maximally different primary colours; this paper is the first to investigate what happens if the stimulus colours are similar to each other. Our results suggest that the similarity between the colour of the target referent and that of any distractor objects indeed has little effect on the content people choose for a referring expression, supporting the view that colour gets chosen due to being perceivable with low cognitive effort.

However, we show that colours that can be encoded using a basic colour term, such as *blue*, are more likely to be mentioned than those for which a more complex term, such as *light blue*, has to be found in order to distinguish from, for example, dark blue distractors. Current computational models of reference production do not account for this result, as they usually separate the selection of semantic content and lexical choice into two distinct processes.

### Acknowledgments

The research reported in this paper forms part of the VICI project “Bridging the Gap between Psycholinguistics and Computational Linguistics: the Case of Referring Expressions”, funded by the Netherlands Organization for Scientific Research (NWO grant 277-70-007). **Abstract**

Standard logic and probability theory are both beset with fundamental problems if used as adequacy criteria for relating logical propositions to learning data. We discuss the problems of exception, of sample size, and of inclusion. Bayesian pattern logic ('Bayesian logic' or BL for short) has been proposed as a possible rational resolution of these problems. BL can also be taken as psychological theory suggesting frequency-based conjunction fallacies (CFs) and a generalization of CFs to other logical inclusion fallacies. In this paper, this generalization is elaborated using trial-by-trial learning scenarios without memory load. In each trial participants have to provide a probability judgment. Apart from investigating logical probability judgments in this trial-by-trial context, it is explored whether under no memory load the propositional assessment of previous evidence has an influence on further probability judgments. The results generally support BL and cannot easily be explained by other theories of CFs.

**Keywords:** Conjunction fallacy, probability judgments, trial-by-trial learning, Bayesian induction, logical predication.

**Standard Logic and Probability Theory  
as Criteria for True Logical Propositions**

The relationship between general logical propositions (or sentences) and evidence is fundamental to both epistemology and psychology. We here investigate general predication of logical relationships between two dichotomous attributes (or predicates), like "ravens are black *and* they can fly" (with the conjunction 'and'). What would be an adequate justification for such a type of sentences?

Arising from an old tradition going back to Aristotle, modern formal logic uses truth table definitions for all 16 logical connectives. The truth table definition may be used as a deterministic criterion of truth for empirical relationships. With regard to a conjunctive predication, like "ravens (*R*) are black (*A*) and they can fly (*B*)" ( $A \wedge B | R$ ), the whole sentence is true (or, more correctly, 'not false') as long as one has observed only exemplars corresponding to true cells of a truth table (for the conjunction this is the '*a*-cell', ' $A \wedge B$ '). In contrast, the proposition would be falsified, if one observed a single case defined to be false (here: *b*-cell: ' $A \wedge \neg B$ '; *c*-cell: ' $\neg A \wedge B$ ', or *d*-cell: ' $\neg A \wedge \neg B$ ').

**Problem of Exceptions** Exceptions may not prove the rule, but in ordinary language exceptions are indeed regularly tolerated. This may reflect the deeper epistemological point that in the empirical world deterministic relationships are rather the exception than the rule. Actually, in philosophy of science it has been argued that strict falsificationism would absurdly imply that *all* important theories would be falsified. Even more so in normal language, as evident from our deterministic example, there exist exceptions: white (albino) ravens as well as ravens that

cannot fly. If exceptions are the rule for contingent, empirical relationships, it seems reasonable to replace the strict deterministic truth criteria of logic by a high-probability criterion (see Schurz, 2005):  $P(\text{black} \ \& \ \text{can fly} \mid \text{ravens}) > \Psi$ , with  $\Psi > .5$ . However, the following two problems beset a simple extensional probability criterion of truth as well as one based on standard formal logics.

**Problem of Sample Size** If we had to access the truth of "ravens are black and they can fly" without previous knowledge about ravens, either one confirmatory raven ( $A \ \& \ B$  case) or many cases both equally yielded the same extensional probability of 1 (the number of confirmative cases divided by all cases). In the latter case, however, a higher subjective probability of this sentence seems justified. Therefore, a kind of second order probability, a probability concerning probabilities, is needed, as introduced in the model.

**Problem of Inclusion** The extension (all cases falling into a set) of a subset can never be larger than that of a superset. Comparing conjunctions and inclusive disjunctions, it follows that  $P(\text{ravens are black AND they can fly}) \leq P(\text{ravens are black OR they can fly or both})$  [formally:  $P(A \wedge B | R) \leq P(A \vee B | R)$ ]. If we use extensional probabilities as truth criterion, the second sentence can therefore never be 'less true' than the first one. If one assumes at least some exceptions, the latter is even 'truer' in principle. Going one step further, the logical tautology, allowing for all values ("Ravens are black or not, and they can fly or not"), is *a priori* the extensionally most probable sentence [ $P(A \vee B | R) \leq P(A \text{ T } B | R)$  or even  $P(A \vee B | R) < P(A \text{ T } B | R)$ ]. Using standard (extensional) probabilities as truth criterion, one would therefore always have to choose tautologies as the most suitable hypothesis, regardless of the evidence and of the properties in question. In conclusion, if a truth criterion should be informative about the observable world, simple extensional probabilities in principle cannot provide a reasonable truth criterion.

**Bayesian Logic**

Bayesian pattern logic (or 'Bayesian logic', BL, for short) formulates a second order probability that given data may have been generated by noisy-logical patterns of probabilities. The model provides a technical, rational solution to the three mentioned problems and – in approximation – a potential psychological model of human induction of noisy-logical relationships as well. The model is part of a renaissance of Bayesian approaches in cognitive science (e.g., Chater, Tenenbaum, Yuille, 2006; Oaksford & Chater, 2007; Kruschke, 2008). The following sketch is meant to clarify the main idea of Bayesian logic (for more detail, see von Sydow, 2011).

The construction of the model starts with all 16 dyadic logical connectives known from standard propositional logic. The logical truth tables are taken as explanations that are distinguished from the data level. While standard logic makes no assumptions about probabilities of true classes in a truth table, Step 1 of BL formulates ideal explanations by assuming equi-probability of all true classes of a truth table. For instance, for the exclusive disjunction ( $X$  are *either*  $A$  or  $B$ , *but not both*) it is assumed that  $P(\text{b-cell}) = P(\text{c-cell}) = 1/2$  (for no noise,  $R = 0$ ). Thereby, 2 by 2 truth tables become 2 by 2 probability tables. Note, however, that such ideal explanations need not generate ideal data patterns. In Step 2 (cf. Fig. 1) the idea of exceptions is modeled by introducing possible levels of noise. For each possible level a uniform noise function is added to all four cells of probability table, followed by a normalization, so that the resulting sum of all four cells of a probability table adds up to unity. This results in a field of ideal (explanatory) noisy-logical patterns of probabilities, each with an additional second order probability:  $P(A \text{ connective } B, \text{ noise level } R | \text{data}) =: P(A \circ B, R | D)$ . Here flat priors for the connectives and noise levels are used for each new situation.

Figure 1: Sketch of the model of only five logical propositions and three noise levels (cf. text for details).

For the novel noisy-logical representation one can calculate the posterior probabilities for each probability table by combining some standard statistics. Given observed data about the co-occurrence of  $A$  and  $B$  (a 2 by 2 contingency matrix), one can calculate (Step 3) the likelihood of the data given a probability table,  $P(D | A \circ B, R)$ , by using the multinomial distribution, which here determines for each table of four probabilities how likely it produces the observed four frequencies. In Step 4, Bayes' theorem is used to transform the likelihood  $P(D | A \circ B, R)$  into a posterior  $P(A \circ B, R | D)$ . In a final step, one sums up the probabilities of a connector over all noise levels (here we modeled 11 equidistant levels from  $R = 0$  to 1). We obtain the requested posterior *pattern* probability,  $P_P(A \circ B | D)$ , clearly differing from the analogous *extensional* probability,  $P_E(A \circ B | D)$  (frequency of positive cases, divided by all cases).

## BL and the Conjunctions Fallacy Debate

One of the most heated and philosophically interesting psychological debates concerns the apparent inability of people to understand that conjunctions (for instance, "Linda is a Bank teller and a feminist") can never be (extensionally) more probable than their conjuncts (e.g., "Linda is a bank teller")—even for apparent feminists. This phenomenon has been called "conjunction fallacy" and first has been explained by the representativeness heuristic (Kahneman & Tversky, 1982). This heuristic, however, has been criticized as being formulated too imprecise (Gigerenzer, 1996; cf. Nilsson, Juslin, & Olsson, 2008).

There have been several other classes of explanations of CFs. One focusses on possible misunderstandings. "A and B" may actually be understood as "A or B" or to "if A then B" (Mellers, Hertwig, & Kahneman, 2001; Hertwig, Benz & Krauss, 2008). Moreover, "A" may be interpreted as "A but not B" instead of "A, whether B or not B" (Kahneman & Tversky, 1983; Hilton, 1995; cf. Sides, Osherson, Bonini, & Viale, 2002; Wedell & Moro, 2008). A second class of explanations considers different ways in which probabilities are introduced and how the probability question is posed. It has been shown that frequency presentations (Fiedler, 1988; Gigerenzer, 1996), rating formats (Sloman, Over, Slovak, & Stibel, 2003), and clear set inclusions (Johnson-Laird, Legrenzi, Girotto, & Legrenzi, 1999; Sloman et al., 2003) often substantially reduced the portion of CFs. Although these factors often do play a role, BL under certain conditions (if one is concerned with alternative hypotheses about whole situations) has predicted CFs even when all these factors apply simultaneously (von Sydow, 2011a, b). A third class of explanations specifies quantitative conditions of CFs. Most prominently, it has been suggested that the requested probability  $P(A \wedge B | D)$  is replaced by the inverse probability  $P(D | A \wedge B)$ ; cf. Wolford, 1991; Fisk & Slattery, 2005), or by a measure of support, like  $P(A \wedge B | D) - P(A \wedge B)$  (support theory, cf. Sides, et al., 2002; Lagnado & Shanks, 2002; cf. Tentori, Bonini, & Osherson, 2004; Crupi, Fitelson, & Tentori, 2008), or several other measures, like signed summation, averaging, quantum logic, or rescaling (see Wedell & Moro, 2008; von Sydow, 2009).

BL provides a rational quantitative account of frequency-based a particular class of conjunction fallacies and made several novel predictions that cannot be explained by the previous models (von Sydow, 2011). One important aspect has been the generalization of the idea of CFs into a system of logical inclusion 'fallacies' (von Sydow, 2009).

## Experiment: Trial-By-Trial Induction of Logical Relationships

The primary goal of the reported experiment is to test aspects of the postulated system of frequency-based logical inclusion 'fallacies' in a trial-by-trial way. Whereas confirmatory results for this system have already been achieved, even using trial-by-trial *presentation* of items (von Sydow, 2011b; cf. Lagnado et al., 2001), we here additionally

investigate trial-by-trial *assessment of the dependent variable*: the selection of the most probable hypotheses after each new observation. To the best knowledge of the authors, this has never been investigated before in the CF debate.

A supplementary goal is to assess whether putting evidence into language in the course of trials may have an additional top-down effect on the successive evaluation of evidence. Here the *ways* how one obtains a final (fixed) pattern of evidence are varied, so that this may affect the predicted propositional representations. In one condition the finally predicted hypothesis is expected to appear most probable all along (homogeneous condition) and in another condition different hypotheses are predicted to appear more probable throughout the first learning trials (heterogeneous condition). In its current formulation BL, as a model of data-based induction, would not be able to account for such top-down effects. This is the case although BL goes beyond naïve probability, and leaves room also for subjective priors. As we think there are top-down effects for instance of categorization (Hagmayer, Meder, von Sydow, & Waldmann, 2011) or causal coherence (von Sydow, Hagmayer, Meder, & Waldmann, 2010), we think there may well be top-down-effects of mere verbalization. In this experiment, however, participants are provided with summary statistics, excluding memory effects. In such settings, also intended as base-line for future experiments, no such additional top-down effects are expected.

	Phase 1: Pattern phase	Phase 2: First trial-by-trial phase	Phase 3: Second trial-by-trial Phase
G1	For all groups G1 to G8	C1: AND, homogeneous	C3: ><, homogeneous
G2	Pattern 1    Pattern 2	C1: AND, homogeneous	C4: ><, heterogeneous
G3	15   2    5   6	C2: AND, heterogeneous	C3: ><, homogeneous
G4	2   3    2   2	C2: AND, heterogeneous	C4: ><, heterogeneous
G5	Pattern 3    Pattern 4	C3: ><, homogeneous	C1: AND, homogeneous
G6	0   2    4   1	C3: ><, homogeneous	C2: AND, heterogeneous
G7	0   1    0   0	C4: ><, heterogeneous	C1: AND, homogeneous
G8	Pattern 5    Pattern 6	C4: ><, heterogeneous	C2: AND, heterogeneous
	8   10    2   12		
	9   9    13   3		

Figure 2: Design (see main text for details).

The design involves three phases. All phases involve a selection of the most probable logical hypothesis given some evidence. In *Phase 1*, participants in all conditions are randomly presented with six patterns of evidence, each referring to a different situation (Fig. 2, Phase 1). First, this phase should replicate previous generalizations of BL (von Sydow, 2009, 2011b). Secondly, it investigates whether participants grasp the intended meaning of logical terms, and,

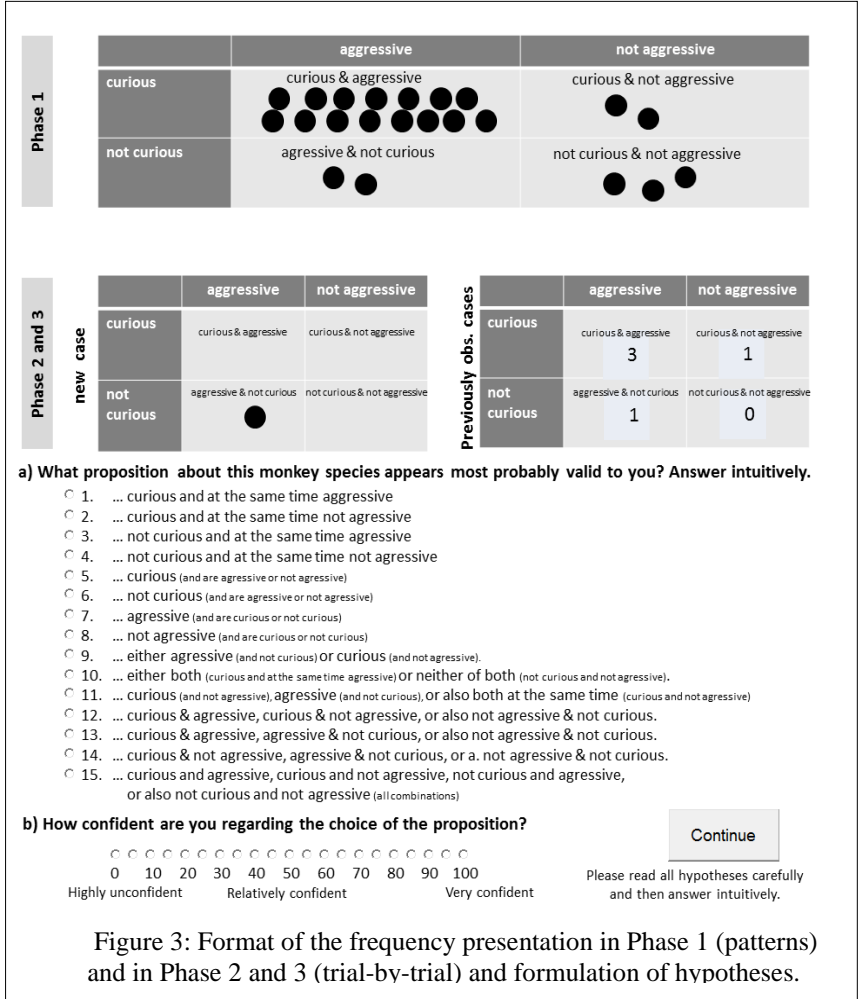

Figure 3: Format of the frequency presentation in Phase 1 (patterns) and in Phase 2 and 3 (trial-by-trial) and formulation of hypotheses.

thirdly, it excludes a deterministic understanding of the rules in the next phases by inducing a non-deterministic noise-prior (especially for few observed cases, priors may well affect the results).

Phase 2 and 3 are both trial-by-trial judgment tasks. BL predicts that various hypotheses should be selected to be most probable, each from an extensional perspective involving several logical inclusion fallacies. The sequences should end up either in an AND hypothesis (C1, C2) or an EITHER-OR hypothesis (C3, C4). Both hypothesis are extensionally less probable than the OR hypothesis or the tautology. Additionally, the order in which data is presented differs, investigating whether verbalization throughout learning affects the verbalization of identical final patterns (the probability judgments). As sketched, either a homogeneous condition (C1, C3) or a heterogeneous condition (C2, C4) is used. Finally, Phase 2 and 3 are identical, in order to assess whether the previous learning phase had an effect (as, e.g., suggested by support theory) and to find out whether participants increasingly make either extensional or BL selections.

## Material

130 participants of the University of Göttingen participated in the experiment. The participants were told about newly

discovered species of apes on a lonely island. They were in the role of ethologist concerned with statements the animals of a species are curious or not (here *A*) and whether they are aggressive or not (here *B*), as well as judging the relation of these properties.

In Phase 1 participants were concerned with six species of apes in randomized order. For each species they were shown a photo of an ape (e.g., “*P. calvus*”) with a text “The animals of this species are...”, leading to the main instructions (Fig. 3) and a contingency table summing up the observed features combinations (cf. Fig. 2, 3). For each species one had to select the most probable logical hypothesis and one had to provide a confidence rating (Fig. 3).

Phase 2 and 3 were concerned with trial-by-trial learning. Participants were randomly assigned to the eight conditions. Single events were symbolized by a circle flying to a place in the contingency table (Fig. 3, Phase 2/3, left table),

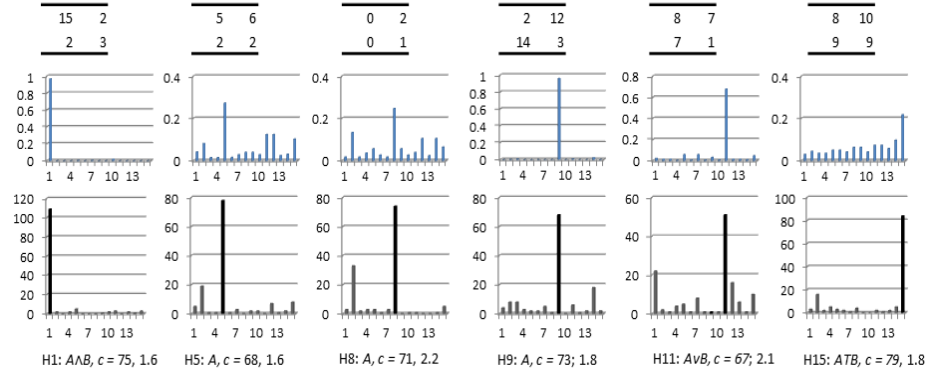

Figure 4: Six patterns of Phase 1 (first row), BL's pattern probabilities (second row) and the frequency of hypotheses (cf. Fig. 3) selected (third row).

followed by an update of a summary table (right table). Of the 18 trials the first nine are presented in Figure 5 and 6.

In all probability judgment tasks the formulations of the hypotheses were carefully chosen to rule out the plausible misunderstandings discussed in the CF debate. For instance, the conjunctions were formulated as “*A* and *at the same time B*” and the single conjuncts (the affirmations or negations) as “*A* (and are *B* or not *B*)” (Fig. 3).

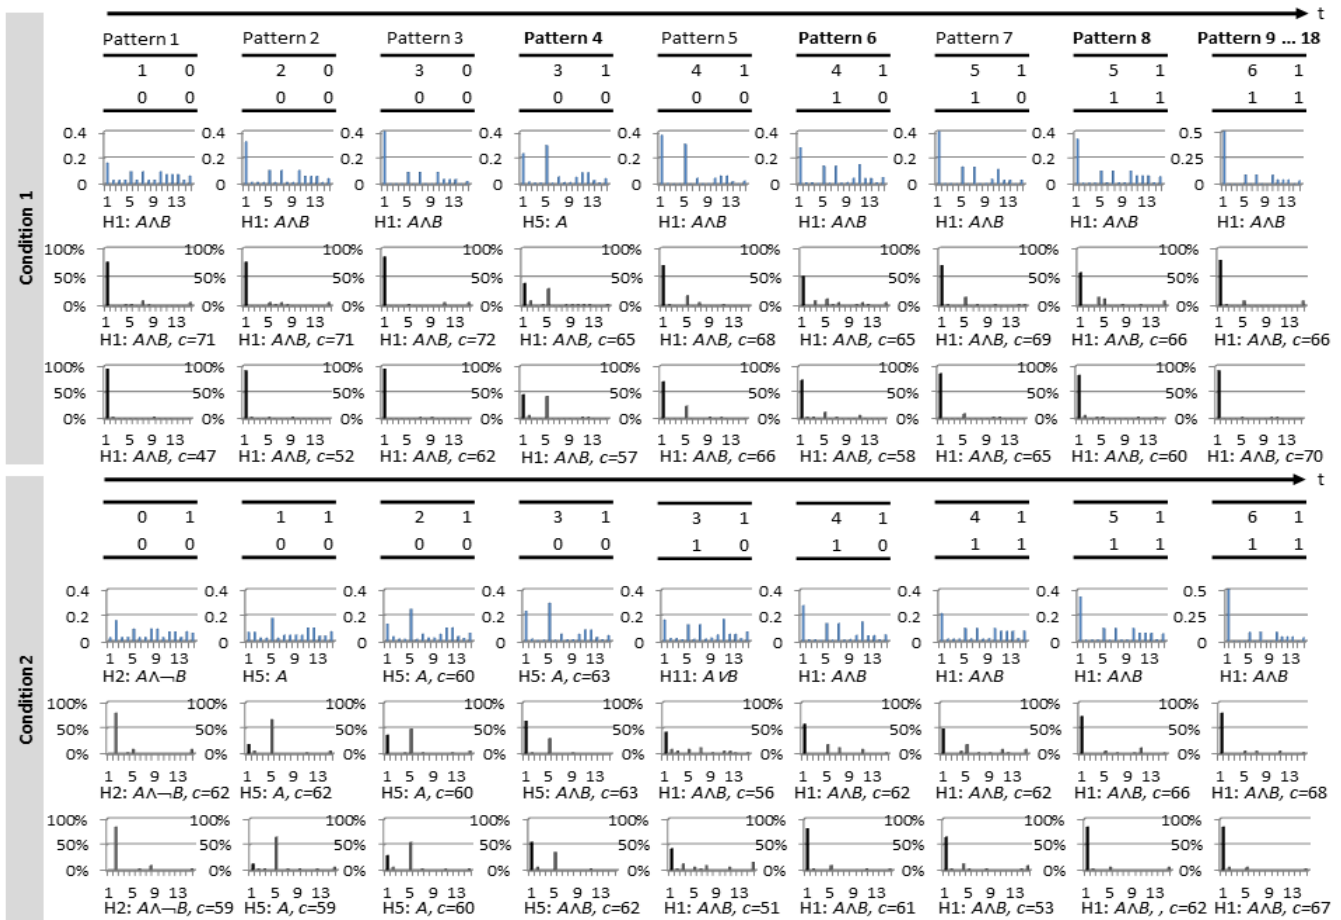

Figure 5: Patterns, predictions and results for Condition 1 and 2 (Phase 2 and 3). Within each condition, Row 1 shows the first nine shown patterns (Fig. 3, Phase 2 and 3, right). Row 2 depicts BL's pattern probabilities for 15 hypotheses (cf. Fig. 3). Row 3 and 4 show the portion of hypotheses actually selected to be most probable (in Phase 2 and 3).

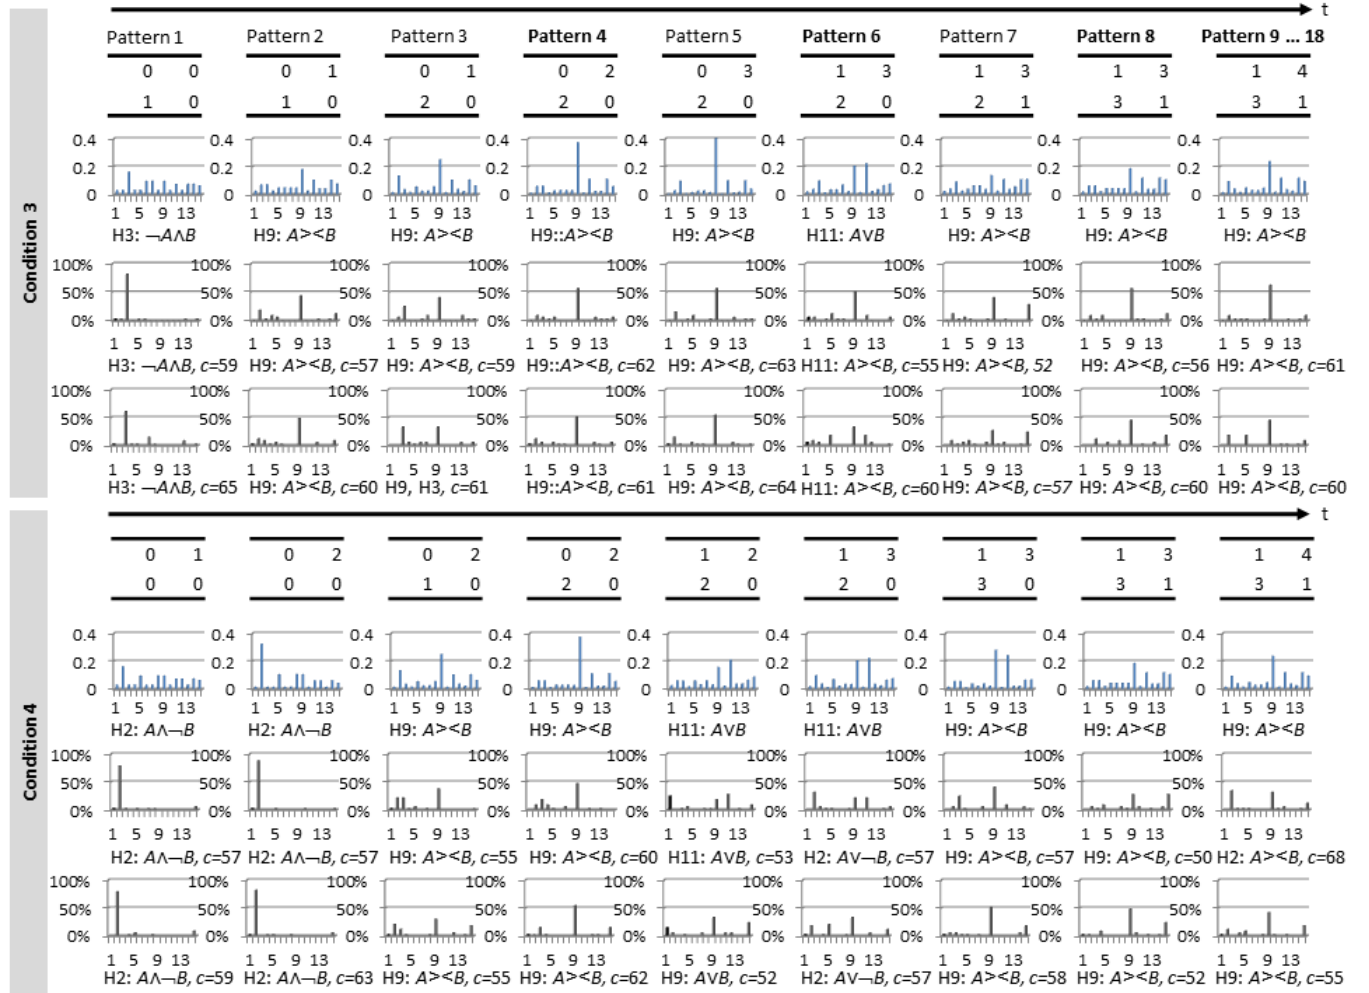

Figure 6: Patterns, predictions and results for Condition 2 and 3 (cf. Fig. 4 and main text for details).

## Results

Figure 4 shows the presented data patterns, the predicted pattern probabilities (BL), and the empirically found frequency of selected logical hypotheses for the six shown species of apes. Participants for each pattern actually selected the hypothesis that had the highest pattern probability,  $P_P(A \text{ o } B)$ ; from left to right: H1 ( $A$  and  $B$ ); H5 ( $A$ ); H8 (not  $B$ ); H9 (either  $A$  or  $B$ ), H11 ( $A$  or  $B$  or both), H15 (everything is possible). If one extended other theories so that they may predict these connectives, one would presumably not be able to explain the data (cf. von Sydow, 2010). For instance, the interesting support theory would make predictions for Pattern 6 [8, 10, 9, 9] based on the five other patterns (resulting in sum in [30, 29, 25, 10]). The highest support is suggested for the  $d$ -cell (H4) which is actually found only rarely. The strongest deviation from BL is observed in Pattern 5 where participants did *not only* select H11 but also H1. But this needs not to refer to an alternative strategy, but perhaps – and without elaborating this here – with a noise prior excluding deterministic patterns and causing the actual outcome (cf. von Sydow, 2011b).

With regard to Phase 2 and 3, Figures 5 and 6 show for all conditions the presented data sequence, the resulting BL predicted probabilities, and the actually observed frequencies of the selections of the most probable hypotheses. Even for the low trial numbers 1 to 9, reported here, the main selections are generally surprisingly in line with the pattern probabilities (presented without any fitting).

There were only small deviations. For instance, in Condition 1 only in Pattern 4 the predicted mode of answers (H5:  $A$ ) differed from the observed one (H1:  $A \wedge B$ ). However H1 has actually the second highest pattern probability and there may again have been a plausible influence of noise priors resulting from Phase 1 (lowering  $P(R = 0)$ ), which would actually increase  $P_P(H1)$ . This would likewise be coherent with Pattern 6 [4 1 0 0], where a surprisingly clear majority choose the AND-hypothesis (H1) and the extensional answer would be the  $A$ -hypothesis (H5).

The patterns that were kept identical in the corresponding homogeneous and heterogeneous conditions (the bold printed Patterns number 4, 6, 8, and 9) mostly corroborated the same results, suggesting that if memory effects are ruled out (as done here), no or only small effects of homogeneous

versus heterogeneous conditions are obtained. Furthermore, as predicted based on BL, the results were more pronounced for the conjunction conditions than for the exclusive disjunctions. Finally, the outcomes of Phase 2 and 3 did not differ much (or the results for BL even improve over time).

The confidence ratings varied less clearly than expected. One reason may be that this measure reflects not only, for instance,  $P_H(H \text{ most probable})/P_P(H \text{ second most probable})$ , but a general belief in a system of answers corresponding to BL or extensional probabilities. Furthermore, the ratings, averaged over all participants, may not be diagnostic, since they include ratings of unpredicted hypotheses (particularly relevant in C3 and C4). However, at least in the second trial-by-trial phase (Phase 3) participant's confidence ratings roughly corresponded to predictions derivable from BL: In C1 confidence increases from Pattern 1 to 3. In Pattern 9 the confidence is higher than in all previous patterns (despite more outliers). For Condition 3 and 4 the ratings show less differences, as is understandable based on pattern probabilities. Nonetheless, if one additionally takes a look at the next repeated nine trials, not reported here, Trial 18, for instance, confirmed a high confidence, leading to a median of 80 in C3 and 70 in C4. Hence, also the confidence ratings, at least in Phase 3, strongly reflect changes coherent with BL.

## Discussion

The results show correspondence with the predictions of BL also in trial-by-trial probability judgment tasks. Although other models of the CF have not been extended to all other connectives, it seems implausible that they could account for the findings (cf. von Sydow, 2009, 2011a). Without being able to discuss this here, some deviations (but clearly not all findings) may be coherent with a model that I have previously called pattern support, combining the pattern idea of BL with the idea of support. Overall, however, the results provide additional evidence for the predicted class of frequency-based CFs and for BL as a (computational level) psychological model for noisy-logical relationships.

Furthermore, as expected the results show no (or only a small) top-down effects of verbalization of hypotheses about the same situation (homogeneous vs. heterogeneous conditions). In the future it will be interesting to investigate identical settings without memory hooks (without summary statistics in Phase 2 and 3). Then verbalization may well effect represented exemplars (cf. von Sydow, 2011b). A further line of future research should be to investigate the role of noise priors on the selection of hypotheses.

## Acknowledgments

The first author has been the main author of this paper. We thank H. Wilke and J. Frisch for support. The first author is grateful for inspiring discussions at the Universities of Göttingen (M. R. Waldmann, R. Mayrhofer, Y. Hagmayer) and Heidelberg (group of K. Fiedler). This work was supported by the grant Sy 111/2-1 to M. von Sydow from the Deutsche Forschungsgemeinschaft (DFG) as part of the priority program *New Frameworks of Rationality* (SPP 1516).

## Abstract

Most current accounts of color word acquisition propose that the delay between children's first production of color words and adult-like understanding is due to problems abstracting color as a domain of meaning. Here we present evidence against this hypothesis, and show that, from the time children produce color words in a labeling task they use them to represent color. In Experiment 1, an analysis of early color word production errors finds that, before acquiring adult-like understanding, children make systematic hypotheses about color word meanings, which are best characterized as overextensions of adult meanings. Experiment 2 analyzes comprehension errors and finds that these overextensions result from overly broad categories, rather than a communicative strategy. These results indicate that the delay between production and adult-like understanding of color words is largely attributable to the problem of determining language-specific color boundaries.

**Keywords:** Concepts and Categories; Language Acquisition; Cognitive Development

## Introduction

Color words like *red*, *green*, and *blue* pose a difficult problem to children learning language. According to early reports from the turn of the 20th century, children did not acquire the meanings of color words until as late as 8 years of age. Recent reports suggest that children now acquire color words earlier around 3 or 4 years of age (possibly due to early education, see Shatz et al., 1996), but nevertheless struggle to learn them (e.g., Backscheider & Shatz, 1993; Sandhofer & Smith, 1999). The primary evidence of children's difficulty is that, similar to the domains of number (Wynn, 1990) and time (Shatz et al., 2010), children produce color words well before they use them with adult-like meanings. Also, it's often argued color word use is initially "haphazard and inconsistent" (p.70, Pitchford & Mullen, 2003). By most current accounts, this delay between production and adult-like understanding is caused by a difficulty abstracting color as a dimension of linguistic meaning (e.g., O'Hanlon & Roberson, 2006; Kowalksi & Zimiles, 2006; Sandhofer & Smith, 1999). Here we present evidence that children's initial use of color words is in fact systematic rather than haphazard, and that children have abstracted color by the time they begin using color words. We argue that the main source of children's delay is the problem of inferring category boundaries for color words.

Current accounts of color word acquisition typically assume that once children have conceptualized color as a domain relevant to word meaning, the mapping of color words to their target color categories proceeds quickly.

According to some, the moment of abstraction resembles a conceptual epiphany. For example, according to Franklin (2006), "Children seem to struggle with their first color word yet learn most of the other basic terms fairly rapidly over the next several months.... This seems to suggest that there is some kind of 'switch' for children's ability to learn and map color words correctly—" (p. 324). On this view, once children have mapped their first color word, mapping of other color words to adult-like meanings is relatively simple and fast (see Franklin, 2006; Soja, 1994).

The idea that the mapping process ought to be rapid comes from two main lines of research. First, in an often-cited study of color words in 110 languages, Kay and colleagues reported evidence for cross-linguistic universals in linguistic color categories (Kay et al., 2009) and argued that the number of color categories cross-linguistically is relatively small and constrained. Second, there is mounting evidence suggesting that pre-linguistic infants possess perceptual color categories very similar to those found in adults (e.g., Bornstein, Kessen & Weiskopf, 1976; Bornstein, 1976; Franklin et al., 2008; Franklin et al., 2005). In each case, the purported existence of constraints on language and perception have led researchers to conclude that color word learning is a simple mapping problem, whereby largely innate perceptual categories are associated with labels provided in language input.

Examples of this view are common in the literature, with important consequences for how color word learning is studied. For example, according to Pitchford and Mullen (2004), "Developmental studies have shown young children's perceptual colour space is organized in a similar manner to that of the adult... Thus, when children engage in the learning of colour terms, they already possess colour percepts on which colour concepts can be mapped." (p.53) The implication of such arguments is that, because color words can be mapped to pre-existing perceptual categories, the lag between production and adult-like understanding must not be due to the problem of determining boundaries. Instead, the delay must be due to the prior problem of identifying color as a domain of linguistic meaning.

There are good reasons, however, to believe that the acquisition of color words is not a simple mapping problem. Despite being restricted by universals of human perception, languages vary both in the number of color words they have (2 to 12) and how these words encode color (Kay et al, 2009). For example, some languages that have four basic color terms mark a boundary between red and yellow (e.g., Culina, spoken in Peru; Waorini, spoken in Ecuador) whereas others do not (e.g., Chácobo, spoken in Bolivia; Múra-Pirahã, spoken in Brazil; Kay et al.,

2009). Also, Russian, Korean and English have roughly the same number of basic color terms (11-12; Berlin & Kay, 1969), but divide the blue-green region of color space differently (e.g. Roberson et al., 2009; Winawer et al., 2007). In sum, while infants may perceive color like adults, the categories encoded by language are not fully determined by perception, suggesting that inductive learning plays a significant role in color word learning.

In the present study, we explored the idea that children acquire preliminary meanings for color words well before they converge on adult-like meanings, and thus abstract color much earlier than typically thought. On this hypothesis, the delay between color word production and adult-like understanding is mostly due to a gradual process of determining language-specific color word boundaries.

Past studies have typically failed to address the nature of the mapping problem because of how they characterized children's color word meanings. For example, researchers often classify children according to their knowledge of adult-like meanings – e.g., using *red* to label only red objects (e.g., Kowalski & Zimiles 2006; Soja, 1994; O'Hanlon & Roberson, 2006). In doing so, such studies may underestimate children's color word knowledge, and thus the point at which they first abstract color. Consistent with this concern, a number of studies have found that before children acquire all 11 adult-like color word meanings, they make errors that are systematic in nature (Pitchford & Mullen, 2003; Davies et al., 1998; Bartlett, 1977). For example, Pitchford and Mullen found that 3-year-olds often use their color words to incorrectly label hues adjacent to the target category (e.g., labeling orange as *red*). On the basis of this, they argued that pre-linguistic perceptual categories strongly constrain early color word meanings. However, proximity errors are not easily explained by this hypothesis. Instead, such errors most strongly support the existence of categories that are broader than those used by adults, and thus that are not acquired on the basis of pre-defined perceptual categories.

In the current study, we investigated the first meanings that children assign to color words by analyzing the errors they make in both language production and comprehension. Although some past studies have reported error data in early color word use (see above), here we present new evidence and analyses that directly address the nature of the delay between production and adult-like understanding. In Experiment 1, we present data from a color-labeling task sampled from a large group of children including a subset who have not yet acquired any adult-like meanings. This experiment finds that children make errors that are systematic in nature prior to acquiring any adult-like meanings. These data suggest that children in our study have abstracted color and possess partial knowledge of color words by at least the time they begin producing them. In Experiment 2, we corroborate these findings using a language comprehension task, and show that children's early overextensions of color words reflects overly broad meanings, rather than a communicative strategy.

## Experiment 1

### Methods

**Participants** 141 children (68 girls) participated. Children with a 25% chance or higher of protanopia or deuteranopia color deficiency (based on family history) were excluded (n=5). Children who made no errors (n=21), used only one color term (n=6) or did not cooperate (n=11) were also excluded. Data from the remaining 98 children (50 girls) were analyzed (mean age 3;0, range 22 to 61 months).

**Stimuli** Stimuli were constructed using 11 pieces of colored posterboard, which were chosen by a consensus of five experimenters as being prototypical of the 11 basic color terms in English (i.e., *red, orange, yellow, green, blue, purple, pink, brown, black & gray*). The posterboard was cut into a set of 11 fish shapes (Fish Task) and a set of 11 squares (Book Task). For the Fish Task the colored fish were glued to black foam and were presented on a black background. For the Book Task, the colored squares were glued onto black pages and covered with white flaps.

### Procedure

**Fish Task.** Each child was presented with a black box containing the 11 colored fish, placed color-side down. The experimenter (E) began by announcing, "My turn!" and randomly picking up one of the fish asking, "What color is it?" After the child responded, E placed the labeled fish on the table and told the child, "Your turn!", indicating that the child should pick up a fish. E and the child continued taking turns until each fish had been selected and labeled.

**Book Task.** Following the Fish Task, E presented the child with a book that contained the colored squares. For each page, the child lifted the flap that covered the color and E asked, "What color is it?" Colors were presented in the following order: orange, blue, yellow, pink, white, purple, gray, brown, green, red, black. When children did not respond, E repeated the question and gave the child another chance to respond. Trials with no response (103 trials, 4.7%) or with two responses (e.g., the child said both *blue* and *red*, 13 trials, 0.05%) were not analyzed.

### Results

**Color-Knowledge Groups** Children were separated into four groups based on the number of Basic Color Terms they used in an adult-like manner (e.g., using *red* consistently and exclusively for red stimuli).

Level 1: Adult-like knowledge of 0 color terms. Produced between 2 and 6 color terms during experiment (mean=3.1). Mean age of 2;5 (n=8, 1 girl).

Level 2: Adult-like knowledge of 1-3 color terms (mean=2.0). Produced between 3 and 9 color terms during experiment (mean=6.6). Mean age of 2;8 (n=16, 5 girls).

Level 3: Adult-like knowledge of 4-6 color terms (mean=5.1). Produced between 8 and 10 color terms during experiment (mean=9.1. Mean age of 3;2 (n=19, 9 girls).

Level 4: Adult-like knowledge of 7-9 color terms (mean=8.2). Produced between 9 and 12 terms during experiment (mean=10.3). Mean age of 3;2 (n=53, 34 girls). **Error Consistency Analysis.** Given that a child used an incorrect label for a particular stimulus color on one task (using *red* to label the orange stimulus on the Fish task), we asked how likely it was for the child to repeat the error on the other task (using *red* to label orange on the Book task). Using a binomial test, we asked whether the proportion of consistent trial pairs was greater than chance.

For this analysis, we excluded trial pairs in which the child labeled the stimulus correctly on both tasks (725 pairs). The remaining 275 pairs were classified as either consistent (the same incorrect label for a color on both tasks, 122 pairs) or inconsistent (153 pairs).

The probability of repeating any single label on two separate trials was defined as the square of the proportion of total trials a child used that label. For example, if a child used *red* on 6 of 22 trials, that child's probability of using *red* incorrectly on both the orange fish trial and the orange book trial was  $(6/22)^2$ . A child's overall chance probability of consistency was defined as the sum of the probability of repeating each label. Each color knowledge group's overall chance probability of consistency was defined as the average of the individual participant probabilities, weighted by the number of data points each individual contributed to the analysis. In other words:

$$p(\text{consistency}) = \sum_c \sum_j \left(\frac{l_j}{n}\right)^2 \left(\frac{i_c}{i}\right)$$

where  $i$  is the total number of stimulus pairs in which at least one label (either book or fish) was incorrect,  $i_c$  is the number of such incorrect pairs that each child,  $c$ , contributed to the analysis,  $l_j$  is the number of times a child produced each label  $j$  and  $n$  is the total number of responses a child produced. Note that by this definition, the chance probability of consistency appropriately decreases as a child adds more color words to his/her lexicon.

Averaged across the different Color-Knowledge groups, the proportion of incorrect trial pairs that was consistent (0.44) was greater than expected by chance (0.28), using a binomial test,  $p < 0.001$ . When this analysis was conducted separately for the different Color-Knowledge groups, rates of consistency were greater than chance for all groups except Level 1, see Table 1.

Table 1: Chance and Observed Rates for Exp 1 Analyses

	Consistency		Overextension		Proximity	
	Chc	Obs	Chc	Obs	Chc	Obs
Level 1	0.57	0.61	0.23	0.72*	0.18	0.26*
Level 2	0.27	0.41*	0.062	0.73*	0.25	0.44*
Level 3	0.14	0.31*	0.028	0.75*	0.33	0.66*
Level 4	0.11	0.43*	0.024	0.81*	0.54	0.82*
Total	0.28	0.44*	0.054	0.76*	0.27	0.52*

**Overextension Analysis** This analysis asked whether, in some cases, children's color errors were overextensions of

adult color categories. For example, a child may correctly know that *red* refers to red objects, yet have a broader meaning for *red* than adults and overextend it to orange and yellow objects. Given that a child used a label incorrectly for at least one trial (e.g., using *red* to label an orange or yellow stimulus), we asked whether they used that label consistently for its target color (i.e., using *red* to label both the red book and red fish stimulus). In other words, when a child used the word *red* to label orange and yellow, was this a case of overextension of the *red* category? For this analysis, if the child did not produce responses for the target hue on both tasks, that color word was not included in the analysis (19 incidences). Using a binomial test, we asked whether the proportion of errors that reflect overextensions was greater than chance.

As noted in the consistency analysis (above), the probability of repeating any single label on two separate trials is the square of the proportion of total trials a child used that label. In contrast to the consistency analysis in which consistent use of any incorrect label to any color stimulus was sufficient, in order for an incorrectly applied *red* label to be classified as an overextension a child must specifically use *red* (not any other color) in response to the red stimulus in both tasks. To calculate chance for this analysis, we first squared the base rates of every term a child used incorrectly (e.g., using *red* for purple) to calculate the probability that each of these incorrect terms would also be used on both trials containing the correct color stimulus (e.g., red fish and red book trial). We then took the mean of these probabilities to calculate the child's overall probability of overextension. To calculate the overall probability of overextension for each group, we calculated a group mean, weighted by how many labels each child used incorrectly. In other words:

$$p(\text{overextension}) = \sum_c \frac{i_c}{i} \frac{\sum_j \left(\frac{i_{cj}}{n}\right)^2}{i_c}$$

where  $i$  is the total number of labels that were used incorrectly at least once,  $i_c$  is the number of such incorrect labels that each child,  $c$ , contributed to the analysis,  $i_{cj}$  is the number of times a child produced each incorrect label  $j$ , and  $n$  is the total number of responses a child produced.

A very large proportion of children's errors – 0.76 – were overextensions, which was significantly greater than expected by chance (chance = 0.054), as measured by a binomial test ( $p < 0.001$ ). This high proportion indicates that if a child produced a color word, they were very likely to use it correctly when presented with its target hue. Thus, it suggests that most of children's errors were overextensions of color terms that were anchored to adult-like focal hues. Critically, rates of overextension were statistically greater than chance and above 0.72 for each Color Knowledge Group (all  $ps < 0.001$ , see Table 1), including children who had no adult-like color meanings (Level 1).

**Proximity Analysis** The overextension analysis indicates that before children acquire adult-like color word meanings, they use color words correctly for their target hues. However, the analyses described so far do not

address errors were made to proximal colors or to distant ones. An error was considered proximal if the stimulus color and the correct referent color for the misused label were from adjacent categories in Munsell Color Space (Long & Luke, 2001). Critically, although overextension to distant hues would be consistent with a gradual inductive process (e.g., since children's initial categories may be very large), the inclusion of proximal hues should be significantly more likely even in this case, since any category that includes red and yellow, for example, should also include intervening hues like orange.

Given that a child used a color label incorrectly, we asked whether the label and its referent stimulus were from perceptually adjacent categories. Using a binomial test, we asked whether the proportion of errors that were from proximal color categories was greater than expected by chance. Chance was defined using both the frequency with which children made errors for each stimulus and the frequency with which they used each label incorrectly. It was necessary to account for these base rates because some color words are proximal to a greater number of color categories than others. For example, red is considered proximal to orange, pink, purple, and brown, while gray is proximal to black and white. To determine chance, we calculated the probability of each label-stimulus error pair (the probability of using *red* for an orange stimulus) as equal to the product of the base rates. For example, if 20% (0.2) of errors were in response to an orange stimulus and 80% (0.8) of errors involved the label *red*, the probability of using *red* to label orange would be  $0.2 \times 0.8$ , or 0.16.

To compute the chance probability of proximal errors, we summed across the probability of all label-stimulus pairs that are classified as proximal. In other words:

$$p(\text{proximity}) = \sum_i \sum_j p(r|l_j \cap s_i) p(l_j|\text{incorrect}) p(s_i|\text{incorrect})$$

where,  $p(s_i|\text{incorrect})$  is the probability of a particular stimulus  $i$  given an incorrect response;  $p(l_j|\text{incorrect})$  is the probability of a particular elicited label  $j$  given an incorrect response to stimulus  $i$ ; and  $r$  is the probability of proximity. Note that  $p(r|l_j \cap s_i)$  is either 1 or 0 because a given label/stimulus pair is either proximal or not.

The proportion of total errors that were proximal was 0.52. This was significantly greater than the rate predicted by chance (0.27),  $p < 0.001$ . Rates of proximity were statistically greater than chance for all Color-Knowledge groups, including Level 1 children who had no adult-like color word meanings (see Table 1). Like the findings of the overextension analysis, this indicates that even before a child acquires the adult meanings of any color terms, they already have partial knowledge of some color words.

## Discussion

Experiment 1 examined children's color word production errors in early acquisition. Our results revealed that if children used a word in the study, they were very likely to have a systematic meaning for the word, despite the fact that these meanings were often non-adult-like in nature. Together, these results suggests that (1) children

have abstracted color around the time they begin using color words to label stimuli, and thus well before they acquire their adult-like meanings, and (2) they learn color words by making overly broad hypotheses about their meanings, and gradually narrowing these meanings as they acquire additional, contrasting words.

Several pieces of evidence support these conclusions. First, in our Error Consistency Analysis we found that all but the Level 1 children made highly consistent in their errors, demonstrating that these children were able to abstract color across different objects despite their other differences, and use this knowledge to formulate hypotheses about color word meanings. Although Level 1 errors were not consistent, these children were nonetheless highly systematic, as shown by our two other analyses. In our Overextension Analysis we found that, at all color-knowledge levels, a majority of children's errors were overextensions. This indicates that children have partial knowledge of the specific color properties denoted by a color word when they first begin producing it. Specifically, children appear to know the focal color denoted by the color words they use, though they frequently overextend these words. Finally, our Proximity Analysis revealed that the errors made by children at all levels were likely to be labels for perceptually similar colors.

In sum, the data from Experiment 1 demonstrate that children with adult-like understanding of no color words have nonetheless abstracted color. These data are consistent with the idea that children begin acquisition of color words by positing overly broad color categories and that these categories are gradually narrowed as children gain experience and acquire other color words that contrast in meaning. We refer to this as the "Broad Color Categories" hypothesis. Another possibility, however, is that overextension errors instead reflect a pragmatic strategy (for a similar discussion in the domain of nouns, see Clark 1978). For example, imagine a child who has an adult-like meaning for *red* but not for *orange*. When presented with an orange stimulus, the child may recognize that this color is not *red*, but use the word *red* to describe it nonetheless since no better word is available to them. We refer to this as the "Communicative Strategy" hypothesis.

One way of testing these hypotheses is to use a comprehension task, where the experimenter selects the label, thereby removing the possibility of communicative overextensions (Clark, 1978, Gelman et al. 1998). If a child has a broad meaning for *red* (that includes both red and orange), when asked for *red*, they should provide a stimulus that satisfies their meaning of *red* (e.g., either a red or orange one). By contrast, if the child has adult-like color categories, when asked for *red* they should always prefer a red stimulus over an orange one (even if they use *red* to label orange as a communicative strategy).

## Experiment 2

In Experiment 2 we presented children with stimuli identical to those used in the Fish task in Experiment 1 and

asked them to find fish of different colors and asked whether children made proximity errors. Note that by the Communicative Strategy hypothesis, proximal errors should not occur because responding should either be correct for known color words (above example, *red*) or random for unknown color words (above example, *orange*) because children do not possess broad categories (e.g., that include both red and orange). Proximal errors are only expected under the Broad Category Hypothesis, since it claims that children possess linguistic categories that include multiple adult categories (e.g. *red* including both red and orange).

## Methods

**Stimuli** Items were those of the Fish Task in Experiment 1.

**Participants** A total of 28 children (14 girls) participated. Children were screened for color deficiency via a family history questionnaire. Eight children were excluded because they made no errors. Data from the remaining 20 children (8 girls) were analyzed. These children ranged in age from 23 to 48 months (mean=2;10). Unlike in Experiment 1, we did not group children into different Color-Knowledge groups, for two reasons. First, children in this study were not asked to produce color labels, and we therefore could not test how many color terms they knew. Second, the number of subjects required to test the hypothesis of this experiment was relatively small, and thus there was insufficient power to analyze subgroups.

**Procedure** Children were presented with the fish stimuli placed color-side up and in a random configuration. In succession, the experimenter (E) asked the child to find a specific colored fish, "Give me a (*red*) fish. Can you put a (*red*) fish in my hand?" After the child handed a fish to E, it was returned to its place on the table (back with the other fish), and E requested the next color fish. Colors were requested in the order of Experiment 1: *red, brown, green, orange, white, blue, gray, pink, black, yellow, and purple*.

If the child did not respond on a particular trial (e.g., they got distracted), E repeated the question, giving the child an additional opportunity to respond. Trials with no response ( $n = 3$  trials) or on which two or more fish were provided ( $n = 1$  trial) were not included in the analysis.

## Results and Discussion

**Proximity Analysis.** Across all 216 trials, 79 trials (36%) were errors and were included in the analysis. The mean number of correct responses was 6.85 (range 0 to 10).

As in the proximity analysis of Experiment 1, we accounted for the base rate of errors that involved each color stimulus and the base rate of errors made to a particular request (e.g., *red*). Consistent with the results of Experiment 1, the proportion of errors that were proximal in the comprehension task was 0.58. This was significantly greater than the rate predicted by chance (0.30),  $p < 0.001$ . This suggests that the systematic production overextensions in Experiment 1 reflected broad color categories rather than a communication strategy.

## General Discussion

We tested the hypothesis that the delay between color word production and acquisition of adult-like meanings is due to the gradual construction of linguistic color categories, rather than the process of abstracting color as a domain of word meaning. Consistent with this idea, we found that if children used color words in our study, they typically used them in a meaningful and consistent way. When children made errors, the vast majority (75%) were overextensions of adult-like categories. Also, these errors were frequently to proximal hues. This was true for children at all levels of color word competence – even those who had no adult-like meanings. Further, the results of a comprehension task corroborated this finding, and indicated that overextension is not the product of a communicative strategy, but instead reflects broad linguistic color categories.

These results have important implications for our understanding of color word acquisition. First, contrary to past reports, the results suggest that children abstract color at the earliest stages of color word production, and that there is little, if any, lag between children's use of color words as labels and their construction of preliminary meanings for these words. Although abstraction may pose a problem to children early in acquisition, it is likely resolved by the time children begin using colors to label things in their environment. Second, our results suggest that the observed delay between production and adult-like understanding of color words is likely due to the problem of constructing language-specific category boundaries. Our data suggest that children begin acquisition by making overly broad inductive inferences regarding the scope of their color words, and that they gradually shrink their early categories as they gain experience with the words and acquire other color words that contrast in meaning.

These data are consistent with earlier data from Carey and Bartlett (1978), which are commonly cited as evidence for children's ability to "fast map" color words to their referents. Bartlett and Carey's fast mapping proposal, unlike some theories of color word learning that followed it, did not assume that learning color word meanings was fast, or that it was a simple mapping problem. Instead, they argued that fast mapping was a first step in the learning process, used to link labels to particular referents, and that acquiring the adult-like meanings of color words involves much more additional learning (see also Swingley, 2010; Clark, 1997). Consistent with this, many of the children in Carey and Bartlett's study used the novel word *chromium*, which was used by experimenters to refer to an olive-colored stimulus, to refer to perceptually similar colors (e.g., green, brown) and often did not converge on the intended narrower meaning for *chromium* even after many trials (also, see Bartlett, 1977; Pitchford & Mullen, 2003).

These results, like ours, suggest that color word learning is a gradual inductive process, and that children form interim meanings for their color words well before they attain adult-like understanding. However, because these

studies focused on samples of children who for the most part had acquired at least one adult-like color word, their data do not address the delay between onset of color word production and children's first adult-like color word meaning. In contrast, our study addressed this question using data from a wider range of children (including those who had not acquired any adult-like meanings of color words), and using a novel set of analyses that tested not only proximity errors but also consistency and overextension. Consequently, our study was able to show that children possess broad, overextended color categories early in acquisition, before they have acquired their first adult-like meaning, and perhaps even from the time they first begin producing color words.

This view of color word learning is consistent with findings in other domains of language and conceptual development. In the case of number, children quickly recognize that numerals form a class of words that contrast in meaning (Wynn, 1992; Brooks et al., under review), despite taking years to learn what these meanings are. Similarly, young children recognize that time words like minute, second, and hour form a lexical class, but take many years to acquire their individual meanings (Shatz et al., 2010). Finally, children produce emotion words from early in development, and understand that they belong to a class of words that describe human sentiment, but nonetheless take years to master their adult-like meanings, and form many interim hypotheses along the way (Widen & Russell, 2003). Our study suggests that the case study of color is not an exception to this general pattern, and that as in other cases that involve identifying abstract content, children begin formulating preliminary meanings early in acquisition, and take years to attain adult competence.

# The Role of the Primary Effect in the Assessment of Intentionality and Morality

Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)

## Abstract

In moral dilemmas performing an action often leads to both a good primary and a bad secondary effect. In such cases, how do people judge whether the bad secondary effect was brought about intentionally, and how do they assess the moral value of the act leading to the secondary effect? Various theories have been proposed that either focus on the causal role or on the moral valence of the secondary effect as the primary determinants of intentionality and morality assessments. We present experiments which show that these theories have neglected a further important factor, the primary effect. A new theory is proposed that is based on the key assumption that people's judgments of intentionality and morality depend on the strength of assumed reasons the agent has for the primary and secondary effects.

Keywords: intentional action; doctrine of double effect; moral dilemmas; causal structure; trade-off.

## Introduction and Overview

How do people judge whether an effect was brought about intentionally? Since Joshua Knobe's seminal paper (2003) this question has gained increasing attention in recent cognitive science (see Waldmann, Nagel, & Wiegmann, 2012, for an overview). In the present paper we focus on the following question: If an agent in a moral dilemma performs an action that leads to two effects<sup>1</sup>, a good one, which is the primary goal of the agent, and a bad secondary one, how do subjects judge whether the bad effect was brought about intentionally?

Currently two very different theories are competing to answer this question. Knobe (2003) has proposed that intentionality attributions regarding the secondary effect depend on its moral value. If the secondary effect is morally bad, his theory predicts high intentionality ratings, whereas the ratings are lowered when the secondary act is good. The second class of theories focuses on the causal structure linking primary and secondary effects. If the secondary act is a means for achieving the primary one, then high intentionality ratings and low morality judgments are to be expected. When the secondary act is just a causal side effect, intentionality ratings are predicted to be lower, and morality judgments higher (see Mikhail, 2011).

We are going to propose a third account. Our main claim is that intentionality attributions are a function of the strength of the assumed reasons that can be attributed to the

agent for causing the primary and the secondary effect. These reasons are inferred on the basis of observable cues, with the inferences being influenced by both the causal structure of the scenario, and the trade-off between good and bad effects. Morality judgments are also influenced by the trade-off, although, based on previous research, we expect that moral judgments are influenced less by causal role than intentionality judgments (see Waldmann et al., 2012; Waldmann & Dieterich, 2007). We will outline these three theories in greater detail below, and then present two experiments testing them.

## Knobe's (2003) Side-Effect Effect

Theories of intentional action have gained a lot attention since Knobe (2003) had discovered that subjects rate the assumed intentionality regarding a secondary act higher when this effect is morally bad than when it is morally good. Consider Knobe's (2003) famous vignette:

"The vice-president of a company went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us increase profits, but it will also harm the environment.' The chairman of the board answered, 'I don't care at all about harming the environment. I just want to make as much profit as I can. Let's start the new program.' They started the new program. Sure enough, the environment was harmed." (p. 191)

In a second version of this scenario, the word "harm" was replaced by "help". When subjects were asked whether they think the chairman intentionally harmed the environment, 82% answered in the affirmative. In contrast, in the help condition 23% said that the agent did bring about the good side effect intentionally. Knobe concluded that in judging whether the side effect (harming and helping the environment, respectively) was brought about intentionally, the (moral) value of the side effect is crucial. People seem considerably more willing to say that a side effect was brought about intentionally when they regard it as bad, than when they regard it as good.

In the present research we focus on moral dilemmas in which the secondary effect is kept invariant and constantly bad (killing one person). For such scenarios, Knobe's (2003) version of his theory entails two theoretical predictions: (1) As long as the secondary effect is invariant, equal degrees of intentionality ratings should be observed. Since in our cases, the secondary effect is bad, generally high ratings are to be expected. (2) The moral value of the secondary effect is an intrinsic property of the act leading to the bad outcome. For example, harming nature is bad, helping nature is good. Of course, Knobe's (2003) theory

---

<sup>1</sup> Following the literature we here use the term primary and secondary effect as referring to acts leading to a good or bad outcome (e.g., harming nature).

does not explicitly rule out that other factors, such as the primary effect, may play a role in the assessment of intentionality and moral value. However, the present version of the theory neglects the potential role of the primary effect, and solely focuses on the role of the secondary effect. This seems like a crucial oversight given that the primary effect is constitutive for assigning the other effect the role of being secondary. Moreover, it is far from clear whether this additional factor can be simply added to the present theory without changing key theoretical assumptions (see also General Discussion).

### The Doctrine of Double Effect

The Doctrine of Double Effect (DDE) is one of the oldest and best known moral principles (cf. Mikhail, 2011). There are several versions of the DDE, here is one by Timmons (2002): Whenever an action would produce at least one good effect and one bad or evil effect, then one is permitted to perform the act if and only if all of the following conditions are met:

1. The action in question, apart from its effects, must not be wrong.
2. The bad effect must not be intended by the agent. There are two principal ways in which an effect might be intended:
  - a) Any effect that is a chosen end of action is intended.
  - b) Any effect that is a means for bringing about some intended end is also intended.
3. The bad effect must not be “out of proportion” to the good effect.

To illustrate the DDE, let us apply it to two popular trolley cases (see Waldmann et al., 2012, for an overview of trolley research). In case one (“bystander”), a runaway trolley is threatening five people and the only possibility to rescue the five people is to re-direct the trolley onto another track where only one person would die. In case two (“push”), the initial situation is the same but this time the only possibility to rescue the five is to throw a heavy man from a bridge into the path of the trolley. The trolley would be stopped due to the weight of the heavy man and, not surprisingly, the heavy man would die in the collision. According to the DDE, redirecting the trolley might be permissible but throwing the heavy man from the bridge is not, since throwing the heavy man is a means for bringing about the intended end (2b).

Although the primary goal of the DDE is to offer a guide for the moral evaluation of moral dilemmas, the DDE also provides a criterion that tells us when an act or an effect is intended: Any effect that is a means for bringing about some intended end, is itself intended, whereas secondary effects that are only causal side effects are merely foreseen, but not intended. Cushman and Young (2010) have presented a series of studies in which they showed that means elicited higher intentionality ratings than side effects. This pattern holds for both moral dilemmas and isomorphic non-moral scenarios. Again, the primary effect does not figure in the predictions of intentionality. It does play a limited role in

permissibility judgments, however, but the DDE only states that the secondary bad effect must not be out of proportion to the good effect.

### Trade-Off of Lives in Moral Dilemmas

Whereas Knobe (2003) focuses on the moral value of the secondary effect in his predictions about intentionality ratings, the DDE focuses on its causal role (means vs. side effect). However, there is an additional neglected factor that is actually constitutive for the labeling of one of the effects as secondary: the primary effect. A typical feature of moral dilemmas is that they contain a trade-off between acts saving and killing people. For instance, in the standard version of the bystander dilemma, the act causes the death of one person and saves five persons. If you consider instead a version of this case in which acting kills one person but nobody is saved, it seems clear that causing the death of the one person was brought about intentionally because otherwise it is hard to explain why the agent should have intervened. However, if one person is killed and one is saved one might judge that saving the one person was the primary intended goal. If more lives are saved than killed it seems even more likely that subjects will view the good outcome as a mitigating reason for generating the bad side effect, and will therefore be less inclined to regard the bad effect as strongly intended. Thus, based on the assumption that intentionality ratings are influenced by the inferred reasons an agent might have for causing a bad secondary effect, the prediction can be derived that intentionality ratings should decrease the more reasons the agent has for causing the primary effect. In trolley dilemmas, this means that lower intentionality ratings with respect to the bad secondary effect should be expected, the more people are saved by the act. The number of saved people provides excellent reasons for acting, and allows the agent to dismiss the bad secondary effect as intentionally pursued.

The trade-off between primary and secondary effect may not only affect intentionality assessments but also moral evaluations. Again here our trade-off hypothesis makes predictions different from Knobe (2003) and the DDE. Whereas Knobe (2003) treats the badness of the secondary effect as an intrinsic feature of this effect, the DDE predicts that secondary effects should be judged generally worse when they constitute a means compared to a side effect. By contrast, our trade-off hypothesis claims that the judged badness of the secondary effect is not only based on intrinsic harmful features of the corresponding act, but also on the strength of reasons for accepting a bad secondary effect in light of a good primary goal. Thus, again we predict that moral evaluations will be sensitive to the relationship between the primary and secondary effects. Empirically this prediction is supported by research presenting trolley dilemmas with catastrophe conditions in which one person needs to be killed to save, for example, 1,000,000 (Nichols & Mallon, 2006; see also Bartels, 2008). Typically permissibility judgments rise with increasing

numbers of saved people. Intentionality judgments have not been studied in these experiments, however.

### The Role of Causal Structure

So far we have elaborated the role of the primary effect as a mitigating reason for accepting a bad side effect. However, reasons for acting are not only influenced by the size of the primary effect, but also by the causal relationship between primary and secondary effect. Following the DDE, we argue that secondary effects that play the role of means need to be intended more strongly than when they are in the position of side effects because agents should be aware of the fact that the secondary effect constitutes a necessary step on the path to the primary goal. Thus, causal structure also should determine the strength of reasons an agent has for causing a secondary effect.

### Combining Trade-off and Causal Structure

We have identified two sources of reasons an agent might have for acting in a moral dilemma in which a varying primary effect is pitted against an invariantly bad secondary effect: The causal role of the secondary effect and the trade-off between the primary and secondary effects. There are two possibilities how the two factors can be combined. One possibility would be to claim that the primary effect only matters when the secondary effect is a side effect, not when it is a necessary means for the primary effect. This pattern of interaction could be motivated by the assumption that means are necessary steps on the way to the more distant effects, and therefore need to be intended regardless of the quality of the distant (i.e., primary) effects. The other possibility might be that the strength of reasons for the primary goal affect intentionality ratings in both conditions, but to a stronger extent in the side-effect condition in which it is easier to imagine that people just foresee, but do not intend the secondary effect. In this case, we also expect an interaction but also a main effect that is driven by the strength of the primary goal.

The same alternatives also arise for moral judgments about the badness of bringing about the secondary effect (i.e., killing one person). Whereas Knobe (2003) predicts invariant ratings signifying the invariant badness of killing one person, the DDE predicts a main effect driven by the causal role of the act leading to death. By contrast, based on previous research we expect that mitigating factors arising from the evaluation of the goodness of the primary effect will also affect the moral assessment of the secondary effect. However, previous findings on moral judgments in trolley dilemmas cast doubt on the hypothesis that causal role plays the same role in moral judgments as in intentionality judgments. The empirical evidence rather points to other factors (i.e., aversiveness, attentional focus, directness) as the crucial factors affecting moral judgments whereas causal role vanishes as a factor once its confounds are controlled (see Waldmann et al., 2012). Thus, intentionality and moral judgments need not be driven by the same factors, as implied by the DDE.

## Experiment 1a

Experiment 1a focuses on intentionality attributions. To test our predictions we used two variants of trolley cases in which we manipulated the causal structure (means versus side effect) between subjects, and the number of lives saved (0, 1, 5, 100) within subjects. While the number of lives saved was manipulated across conditions, the secondary effect always involved killing one person.

Figure 1: Illustration of the bystander scenario (Experiment 1).

Figure 2: Illustration of the trap scenario (Experiment 1).

**Design, Materials, and Procedure** 140 subjects were recruited for a compensation of £0.50 via an online database located in the U.K.. Subjects were randomly assigned to the means or side-effect condition, and were then presented with the corresponding scenarios in which the number of lives saved was varied in a randomized order within subjects (0, 1, 5, 100 victims). It is important to note that the 0 condition only served as a control condition because in a condition in which one person was killed without anybody being saved, the means or side effect relations cannot be realized. This condition is expected to yield maximal intentionality and badness ratings because there are no mitigating reasons for the act.

The initial situation was identical in both conditions:

“On the test ground of a modern railroad property an unmanned speed train (that normally can be remote-controlled) is out of control due to a technical defect. This speed train is heading towards five railroad workers that are checking the tracks. Since these workers are wearing a novel type of hearing protection, they would not notice the speed train on time and hence would be run over by it. Peter, an employee of the rail track control center, recognizes the upcoming accident. However, it is not possible to stop the train on time anymore.”

Next the conditions, which were additionally illustrated (see Fig. 1, 2), varied (examples with 5 saved workers).

**Side-Effect Condition (“bystander”):**

“There is only one possibility to avoid the death of the five workers: Peter could push a button and thereby re-direct the speed train from the lower track onto a parallel upper track before it reaches the five workers on the lower track. On the upper parallel track the speed train would run into a worker maintaining the tracks. The maintenance worker on the upper track would lose his life due to the collision.”

#### Means Condition (“trap”):

“There is only one possibility to avoid the death of the five workers on the tracks: Peter could push a button that would open a trap door and thereby causing a maintenance worker on top of the bridge to fall on the tracks. The speed-train would collide with the maintenance worker and be stopped before it reaches the five workers on the track. The maintenance worker would lose his life due to the collision.”

Both scenarios ended as follows:

“Peter understands the situation and knows the consequences of the action just described. Peter decides to throw the switch and the maintenance worker dies.”

In the control condition (zero people saved) we used the same instructions mentioning re-directing of the train or the trap door but these acts were not motivated by saving anybody. After reading the scenario description, subjects were asked to judge whether Peter “caused the death of the maintenance worker intentionally” on a six-point Likert scale ranging from “certainly no” to “certainly yes.” On the last page, subjects were asked some demographic questions, and were given a simple logical question unrelated to the experiment to identify the subjects who did not pay attention to the task.

**Results and Discussion** Eight subjects were removed from the analyses because they failed to solve the logical question or completed the whole survey in less than a minute. The results for all scenarios are depicted in Figure 3.

We generally excluded the control condition in the ANOVAs of all experiments because here the difference between means and side effects could not be realized. Looking at the remaining three conditions, the intentionality ratings proved generally higher in the means than in the side-effect condition ( $F_{1, 130}=22.158, p<.0001$ ). Moreover, the analysis yielded a significant interaction,  $F_{2,260}=3.0911, p<.05$ .

More detailed planned comparisons showed that in both conditions intentionality ratings decreased with increasing numbers of lives saved. However, in the means condition the ratings were statistically equivalent in the three conditions in which the means relation could be realized (1, 5, 100). In contrast, in the three side-effect conditions (1, 5, 100) ratings dropped from 3.97 when one life was saved to 3.41 when one hundred lives were saved ( $p<0.001$ ). In both causal conditions, the control scenario in which nobody was saved by killing one received significantly higher ratings than the averaged ratings for the three other scenarios (means condition:  $p<0.01$ ; side-effect condition:  $p<0.0001$ ). Thus, in general the presence of a primary good effect lowers intentionality assessments regardless of causal status, but the influence of the quantitative size of the primary goal affects the side-effect condition more than the means condition.

Interestingly, subjects’ intentionality ratings for the cases in which 5 and 100 lives are saved did not differ. Possibly subjects are only sensitive to qualitative differences, that is, it only matters if fewer lives (0), just as much (1), or more

lives (5 and 100) are saved but not how many more are saved.

Figure 3: Results of Experiment 1a. Error bars indicate standard error of means.

### Experiment 1b

Experiment 1b uses the same conditions and manipulations as Experiment 1a. The only difference is that we asked a different test question with which we assessed the moral evaluation of the secondary effect: “How bad is Peter’s causing the one person’s death?” Subjects responded using a 6-point rating scale ranging from “not bad at all” to “very bad.”

Figure 4: Results of Experiment 1b. Error bars indicate standard error of means.

**Results and Discussion** The results are based on 147 participants from the same online site used in the previous experiment (29 from the larger sample needed to be removed). Figure 4 shows the results. Excluding the control condition (0 people saved) which yielded uniformly high badness ratings, we found a main effect between the side-effect and means condition,  $F_{(1,145)}=7.43, p<.01$ , along with a main effect of the size of the primary effect,  $F_{(2,290)}=56.004, p<0.0001$ . Thus, in contrast to the predictions of the DDE, the primary effect affects moral evaluations. The main effect between side-effect and means conditions is consistent with the predictions of the DDE, but could also indicate differences in aversiveness of death (Waldmann & Dieterich, 2007). Experiment 2 will address this question.

## Experiment 2a

One might object that in Experiment 1a the act in the means condition is more aversive than the one in the side-effect condition (falling through a trap-door and getting hit by a train vs. just getting hit by a train). In fact, the moral judgment data revealed that the trap dilemma was generally assessed as more aversive than the bystander dilemma. Hence, the difference in intentionality ratings could be caused by this factor and might not be due to different causal structures. To counter such an objection we designed a new experiment with more similar scenarios. In Experiment 2a we focused on intentionality assessment, in Experiment 2b on morality judgment.

**Design, Materials, and Procedure** 142 subjects were recruited and compensated as in Experiment 1a. The same design as in Experiment 1a was used. Moreover, we used the same side-effect scenarios except that we placed the single worker inside a train to make his death appear less cruel. Additionally, we made the means scenario less violent by using a different, more technical mechanism. The key differences between the old and new means scenarios lie in the point of intervention and in the equipment the workers are wearing. In the new means scenario it is not the runaway train that is redirected but the train containing the one worker who is going to be killed. Furthermore, the workers in the means condition are wearing a security system that causes all running trains to stop when a worker's heart stops beating. The crucial paragraph that distinguishes the means and side-effect conditions is the following:

“There is only one possibility to avoid the death of the five workers: Every worker is wearing a security system that causes all running trains to stop when a worker's heart stops beating. Peter could throw the switch (by pushing a button), and thereby redirect the yellow train carrying one worker from the parallel upper track onto the main track. The speed-train would collide with this yellow train so that the one worker in this train would instantly lose his life in this accident. However, due to the security system the one worker in the yellow train is wearing, the speed train would stop before it reaches the five workers.”

The security vest was introduced to highlight the role of the single victim as a necessary means. Without the vest one might argue that the five are saved by the train, and the single worker's death is only a side effect. The procedure and test questions were otherwise identical with the ones used in Experiment 1a.

**Results and Discussion** 22 subjects were removed for the same reasons as in the previous experiments. The results for all scenarios are depicted in Figure 5 and based on 120 subjects. Again the intentionality ratings were generally higher in the means than in the side-effect condition,  $F_{1,118} = 4.51$ ;  $p < .05$  (the control condition was again excluded from the analyses). Furthermore, this main effect was moderated by a significant interaction,  $F_{2,236} = 5.23$ ;  $p < 0.01$ . Intentionality ratings only decreased with

increasing numbers of saved lives in the side-effect but not in the means condition. In the means condition, ratings decreased from 4.42 when no lives were saved to 4.31 when one hundred lives were saved ( $p=0.55$ ). In the side-effect condition, ratings dropped from 4.20 when no lives were saved to 3.64 when one hundred lives were saved ( $p < 0.01$ ). Again, in both conditions ratings for the control scenario were significantly higher than the weighted ratings for the remaining three scenarios (means condition:  $p < 0.01$ ; side-effect condition:  $p < 0.0001$ )

Figure 5: Results of Experiment 2a. Error bars indicate standard error of means.

As in Experiment 1a there was again no difference between the scenarios in which 5 and 100 lives are saved indicating that qualitative differences rather than quantitative differences might be crucial for ratings of intentionality.

## Experiment 2b

Experiment 2b uses the same conditions and manipulations as Experiment 2a along with the moral test question from Experiment 1b.

Figure 6: Results of Experiment 2b. Error bars indicate standard error of means.

**Results and Discussion** The results are based on 114 participants from the same online site used in the previous experiments (29 needed to be removed). Figure 6 shows the results, which are clear. We apparently managed to equate the moral aversiveness of harming the one worker. Thus,

our intentionality rating patterns are not moderated by different degrees of aversiveness across conditions. The only significant effect is the overall downward trend that is driven by the size of the primary effect. The more people are saved, the less bad the secondary effect was assessed,  $F_{2,224}=54, p<0.0001$ . These results refute the assumption of the DDE that there is a general moral difference between side-effect and means conditions beyond the typically confounded differences of aversiveness of death (see also Waldmann & Dieterich, 2007; Waldmann et al., 2012).

## General Discussion

We have proposed a new theory of intentionality attributions for moral dilemmas, according to which judgments of intentionality regarding a secondary effect depend on the strength of reasons for accepting the secondary effect in the pursuit of the primary goal. We showed that this assessment is a joint function of the causal role of the secondary effect, and the size of the mitigating reasons provided by the primary goal. The more people are saved by an act that also has a bad secondary effect, the better the secondary act is evaluated on a badness scale, and the less intentionality is attributed to the agent with respect to this effect. Whereas moral evaluations were only sensitive to the size of the mitigating reasons provided by the primary cause and the general aversiveness differences between the scenarios, we found reliable interactions between the size of the primary effect and the causal role of the secondary effect in the intentionality attributions. Means generally were rated lower than ends, but beyond this effect the size of the mitigating reasons did not further affect intentionality assessments. In contrast, in the side-effect conditions intentionality assessments were lowered by the size of the primary effect.

The findings provide important constraints for theories of intentionality attributions. They show, for example, that Knobe's (2003) theory which focuses on the moral value of the secondary effect is at least incomplete. We doubt that the role of the primary effect can simply be added to the present theory, however. To explain our findings the assumption needs to be made that the moral evaluation of the secondary effect is a function of a trade-off with the primary effect. Moreover, in Knobe's (2010) theories causal structure is not viewed as a determinant of intentionality attributions. Causal intuitions are rather, similar to intentionality assessments, conceived as being triggered by moral evaluations of the outcomes. Other theories that have been proposed as competitors to Knobe's (2003) account have also difficulties with our findings since they also only focus on the secondary effect while typically holding the primary effect constant.

Theories based on the DDE are also only partially consistent with our results. In contrast to the predictions of the DDE we showed that the causal structure is not the sole determinant of intentionality attributions but needs to be augmented by our trade-off factor. Moreover, our moral evaluation data contradict the predictions of the DDE. Once

the aversiveness of death differing between the means and side-effect conditions is equated, differences in moral judgments disappeared. This finding is consistent with previous results, and casts doubt on the adequacy of the DDE as a theory of moral evaluations (see Waldmann & Dieterich, 2007).

One general important result is therefore that intentionality and moral judgments, which are closely linked in the DDE, are not influenced by the same factors. Whereas both the primary effect and the causal role of the secondary effect influence intentionality assessments, only the former factor has an impact on moral evaluations, once aversiveness is controlled. This finding casts doubt on the often held assumption that intentionality and moral judgments are closely linked.

## Abstract

Fictional information presents a unique challenge to the developing child. Children must learn when it is appropriate to transfer information from the fictional space to the real world and what contextual cues should be considered in this decision. The current research explores children's causal inferences between fictional representations and reality by examining their developing sensitivity to the proximity of the fictional world to the real world, and the effect of this judgment on their subsequent generalization of novel causal properties. By 3-years of age, children are able to evaluate the data that they receive from fictional stories in order to inform their generalization of novel story content to the real world. Additionally, as children develop, they become better able to discriminate between close (realistic) and far (fantastical) fictional worlds when assessing which stories are likely to provide relevant causal knowledge.

**Keywords:** causal inference; fiction; cognitive development; prior knowledge; representation

## The 'Reader's Dilemma'

Children's growing knowledge about the world comes from a variety of sources, including their exposure to fictional material. In fact, much of the unfamiliar information that children encounter appears in the context of stories and fantastical representations of the world. Children, like adults, therefore often encounter the "reader's dilemma": the need to compartmentalize fictional information to insulate real world knowledge from false facts, and the simultaneous need to incorporate this information due to its potential application to a host of real world topics (Gerrig & Prentice, 1999; Potts, St. John, & Kirson, 1989). There is substantial evidence in developmental psychology that indicates that the ability to distinguish reality from fiction develops significantly during the preschool years (e.g., DeLoache, Pierroutakos, Uttal, Rosengren, & Gottlieb, 1998; Flavell, Flavell, & Green, 1989; Woolley & Cox, 2007; Woolley & Wellman, 1990; Woolley & Van Reet, 2006). However, very little research has explored children's ability to learn causal information about the real world from their exposure to fictional material.

Fictional information presents a unique challenge to the developing child. Research has shown that the transfer of knowledge is generally facilitated by similarity between the context in which the information is learned, and the context in which it is to be applied (Catranbone & Holyoak, 1989; Spencer & Weisberg, 1986). However, many of the learning contexts that are created for young children act to *reduce*

this perceived similarity by presenting information in a fictional world that seamlessly interweaves fantasy and reality (Woolley & Cox, 2007). Even in explicitly pedagogical scenarios, teachers often embed their intended curriculum within a fantasy context. This decision is based on the assumption that fictional worlds are more engaging to the young child, and may therefore encourage increased sustained attention and learning of novel material (Harris, 2000; Renninger & Wozniak, 1985).

Previous research supports the proposal that fantasy contexts serve to improve children's performance on certain types of cognitive tasks, such as deductive and syllogistic reasoning and theory of mind (e.g., Dias & Harris, 1988; Dias, Roazzi, & Harris, 2005; Hawkins, Pea, Glick & Scribner, 1984; Richards & Sanderson, 1999; Lillard & Sobel, 1999; Sobel & Lillard, 2001). For example, according to Dias et al. (2005), placing an unfamiliar premise in a fantastical context – particularly when the premise directly contradicts a currently-held theory – allows children to override their natural empirical orientation, or bias to reason in line with their past experiences. It is unknown, however, how learning and generalization of novel causal information (which does not require the suspension of existing knowledge) is affected by the fantastical contexts of the fictional stories in which this information is embedded.

The ability to effectively process fictional information is dependent upon a variety of representational skills, including at least two major factors that are unique to learning from fictional material. The first includes the development of a mature concept about the boundary between the fictional and real world, as well as an understanding of what information is more appropriately quarantined to the fictional space. Second, it is necessary for children to develop an understanding of when it is appropriate to transfer information from the fictional to the real world, and what contextual cues should be considered in this decision. The current research explores the early development of each of these factors, and in particular, examines whether children's sensitivity to contextual cues in fictional worlds changes over the course of development.

## Children's Beliefs about Fictional Worlds

There is a growing literature in developmental psychology regarding when and how children distinguish between fantasy and reality. Methods for testing this distinction vary

greatly, and include assessing children's beliefs about their imaginary companions (e.g., Taylor, 1999), their beliefs in magic (e.g., Rosengren Kalish, Hickling, & Gelman, 1994), and directly asking children about their beliefs in familiar and novel fantastical entities (e.g., Clark, 1995; Woolley & Van Reet, 2006). There has also been some work specifically aimed at assessing children's beliefs about the reality status of fictional content in storybooks (e.g., Morison & Gardner, 1978; Wellman & Estes, 1986; Woolley & Cox, 2006). Taken together, this research has shown that children do distinguish fantasy characters from real ones, and that (depending on the particular method and the nature of the task) this ability matures between 3- and 6-years of age.

Related research also indicates that children differentiate the particular contexts in which they encounter information in storybooks from a relatively young age. For example, Woolley & Cox (2006; 2007) presented preschoolers with realistic, fantastical, or religious stories in a variety of contexts and found that while 3-year-olds were more likely to judge characters as real than were 4- and 5-year-olds, most children accurately judged all characters as not real for all story types. They also found that children made more claims that the realistic story events "could happen in real life" than they did for fantastical story events, which indicates that context matters in the formation of these judgments. While this work explores children's willingness to believe that the story events themselves could happen in real life, the authors do not consider whether children learn and apply the information presented in the storybook to real world scenarios.

According to a study conducted by Skolnick & Bloom (2006), children conceptualize multiple fictional worlds as separate from one another, and separate from the real world. Given children's tendency to quarantine fictional worlds from the real world, it is possible that children also consider the content of these worlds to be distinct, regardless of the assessed possibility of the events themselves.

## Learning from Stories

Despite the importance of understanding the distinction between fiction and reality, storybooks do often provide important opportunities for children to learn information about the real world that cannot be experienced directly (Ganea, Pickard, & DeLoache, 2007). There is currently a small, but growing number of researchers examining the development of children's ability to learn from picture books and the factors that affect their successful generalization of this newly learned information to the real world (e.g., Ganea, Pickard, & DeLoache, 2008; Ganea, Ma, & DeLoache, 2011; Simcock & Dooley, 2007; Walker, Walker, & Ganea, under review). To date, most of this work has focused primarily on transferring labels and simple concepts from a realistic or factual representation, rather than embedded in the context of a fictional story.

For example, Ganea, et al. (2008) demonstrated that 15- and 18-month-old infants are able to extend newly learned

labels both from picture books to real objects and from real objects to picture books. Additionally, they showed that performance was affected by the iconicity of the pictorial images, indicating that the nature of the represented content matters for transferring labels learned in the context of a picture book interaction. In related work, Ganea, et al. (2011) showed that 3- and 4-year-old children can also learn simple biological information about color camouflage in animals from a single picture book interaction, and apply this newly acquired knowledge to real world situations. These experiments indicate that from a very young age, children are able to incorporate factual information about the real world from minimal exposure to picture books, in certain highly realistic and pedagogical scenarios.

In an attempt to explore children's ability to learn from stories that include fantastical content, Richert, et al. (2009) conducted a series of studies looking at analogical reasoning from picture books to other stories and from picture books to the real world. In three experiments, 3½- to 5-year-old children were presented with analogical problems in the context of a short story which involved either real or fantasy characters. In the first experiment, children were tested on their ability to transfer a solution from a story about familiar fantasy characters to a story about realistic characters, and vice versa. In general, children were more likely to transfer the solution to the novel problem from the real source than from the fantasy source. In the second experiment, children were asked to generalize these same solutions to real world contexts (games that involved the manipulation of physical objects). Again, children were more likely to transfer the solution from the real source than from the fantasy source. Later, Richert and Smith (2011) replicated these findings using more complex stimuli that were introduced in a pedagogical context.

The results of these experiments indicate that the context of a story does affect children's ability to draw analogies between the story content and novel scenarios in the real world. One explanation for these results may be that children are sensitive to the *proximity* of the story world to reality, or the similarity of the causal structure of the fictional world to the real world.

## Assessing Proximity of the Fictional World

Fictional worlds that are closer in possibility space (i.e., have higher proximity) share more of the causal structure with the real world, while those that are further away (i.e., have lower proximity) share less. In line with this idea, research with adult participants has demonstrated that the perceived proximity of the fictional world to reality influences participants' decisions to import facts about the real world in making inferences about fictional environments (Skolnick & Goodstein, 2009).

To test this, Skolnick and Goodstein (2009) presented adult participants with three stories that varied in their similarity to reality. They found that participants were more likely to import true facts from the real world to the fictional worlds that were more similar in underlying causal

structure. Adult participants were also more likely to import facts that were considered to be more causally central to the representation of reality (e.g., mathematical facts) to all worlds (regardless of their proximity) than facts that are less central (e.g., conventional or contingent facts). Thus, adults infer that fictional worlds that are more similar to the real world, or closer in possibility space, should contain more facts that are true of the real world. It is currently unknown whether children also display this sensitivity to the distance that a story world lies from reality, and to what extent (if any) this sensitivity to world proximity would affect children’s learning from fictional representations. Examining these issues will inform us about the nature of the mechanisms that underlie learning from fictional material and contribute to a more complete understanding of how causal knowledge is acquired more broadly.

### Current Research

In the current research, we explore children’s causal inferences about fictional content and examine whether contextual information influences their subsequent generalization of novel causal properties to the real world. In particular, we examine whether the likelihood that children will generalize novel causal information varies based upon the perceived proximity of the fictional world (with far worlds generating a lower probability of generalization than close worlds), and whether sensitivity to the proximity of the fictional world changes over the course of development.

### Participants

One hundred and eight preschoolers participated in the study, including 36 3-year-olds ( $M = 43.7$ ,  $SD = 3.9$ , range = 37.2 – 48.0), 36 4-year-olds ( $M = 54.9$  months,  $SD = 3.2$ , range = 49.8 – 59.9), and 36 5-year-olds ( $M = 66.8$  months,  $SD = 2.8$ , range = 61.6 – 71.8). An approximately equal number of males and females were included at each age. Eight additional 3-year-olds and two 4-year-olds were tested, but excluded for failure on both memory questions or failure to complete the training for the sorting task. Although most children were from White, middle-class backgrounds, a range of ethnicities resembling the diversity of the local population was represented. All children were recruited from local preschools and museums.

### Materials

Two 13-page illustrated storybooks were constructed for the experiment. Both stories depicted human protagonists who go on a family camping trip. One version of the story (the close world) was realistic, including no explicit violations of reality (i.e., all events could have easily taken place in the real world), and the other version of the story (the far world) was fantastical, including major violations of reality. Both stories shared the same general structure and the same number and type of events, but varied in the degree of proximity to the real world (see Table 1 for a list of all major story events and Figure 1 for sample pages).

Table 1: Close World and Far World Story Events.

Close World Events	Far World Events
Drive in car	Fly with magic cape
Find a ladybug	Find a fairy
Climb a tree	Talk with a tree
Raining raindrops	Raining stickers
<b>Smell ‘Popple Flower’</b>	<b>Smell ‘Popple Flower’</b>
<b>Get Hiccups</b>	<b>Get Hiccups</b>
Swim in pond	Swim in chocolate pond

In both stories, a novel (plausible) causal relationship was embedded within context of the other events – smelling a ‘Popple Flower’ causes the protagonist to get the hiccups (see Figure 1). This causal relationship was identical across both versions of the story.

Figure 1: Sample pages from *close world* (top left) and *far world* (top right) versions and the target causal relationship as it appears in both storybooks (bottom).

For the sorting task, eight training cards and two sets of six story event cards were constructed. The eight training cards depicted illustrations of real and fantastical versions of events that did not appear in the story (e.g., a boy eating spaghetti vs. a boy eating lightening). The two sets of story event cards depicted each of the individual story events (see Table 1). One set was constructed for children in the *close world* condition and the other set was constructed for children in the *far world* condition. One of the six cards in each set was an identical depiction of the target causal relationship (i.e., a boy smelling a ‘Popple Flower’ and getting the hiccups).

For the generalization task, we used a 5 x 7 color photograph of a real flower that was similar in shape and color to the illustrated ‘Popple Flower’ in the stories.

### Procedure

In a between-subjects design, half of the children in each age group were randomly assigned to the *close world* or *far world* story condition. Children were tested individually, sitting next to the experimenter. The experimenter read one of the two books to the child, interacting naturally, pointing to illustrations, and asking questions in a manner that is typical of parent-child book interactions. The experimenter

introduced the story by saying, “This is a made-up story about a boy who goes on a camping trip.” While children were encouraged to engage with the content of the story, the experimenter provided no additional information over the course of the interaction.

**Memory Assessment.** Immediately after hearing the story, children were asked two memory questions intended to assess attention and recall. One question assessed recall of the novel causal relationship (“*What happened to the boy in the story when he smelled the Popple Flower?*”). The second question was open-ended, and intended to assess recall for other story events (“*What kinds of things did the boy do on his camping trip in the story?*”). Children were prompted to continue responding until they successfully recalled at least three story events. If children responded with fewer than three events, the experimenter would ask, “did anything else happen?” until the child could no longer recall any more story events. Children who failed both memory questions were excluded from the study.

**Sorting task.** Children were trained to sort picture cards into “real” and “pretend” piles. The eight training cards were presented, one at a time, and children were instructed to sort the cards into two piles: one pile for things that “can really happen” and one pile for things that “cannot really happen, and are just pretend.” This training was discontinued after children successfully sorted four cards in a row. Children who failed this training were excluded from analysis. Immediately following the training, children were asked to continue sorting, using the six test cards that depicted each of the events that took place in the story (including a card depicting the target causal relationship). As in the training, children were asked to sort each of the depicted events into the “real” pile or the “pretend” pile.

**Generalization task.** To assess generalization, children were presented with the target causal property that appeared in the story (*smelling ‘Popple Flowers’ causes hiccups*) in a real world context, and asked to judge whether this causal relationship would hold in the real world. To do so, the experimenter showed the child a realistic photograph depicting flowers that were similar in shape and color to the illustrated flowers in the story, saying, “On my way here today, I saw these. I didn’t know what kind of flowers they were, but I smelled them. What do you think happened to me, here in the real world? Do you think that I got the hiccups or that I did not get the hiccups?” The order of presentation of the potential outcomes was counterbalanced. The generalization question was presented in a forced choice format in order to eliminate a “yes” bias. Children received a score of “0” if they responded that the experimenter did not get the hiccups (no generalization) and a score of “1” if they responded that the experimenter did get the hiccups (generalization). The order of the sorting and generalization tasks was counterbalanced.

## Results

Nearly all children who were included in the final analysis answered both memory questions correctly (97% of 3-year-olds, 97% of 4-year-olds, and 100% of 5-year-olds). There was no difference found between conditions on the memory assessment,  $F(1, 106) = 1.86, p = .18$ , indicating that children in both conditions were equally able to recall the content of the story.

Analysis of sorting judgments indicates that children were also sensitive to the presence of fantastical and realistic content in the story that they heard. There were a total of five contextual story events (not including the target causal relationship). Children in the *close world* condition correctly sorted the majority of the realistic story events to the “real pile” ( $M = 4.43, SD = 0.93$ ), while children in the *far world* condition correctly sorted the majority of the fantastic story events to the “pretend pile” ( $M = 4.33, SD = 1.06$ ). While the purpose of the sorting task was to assess whether children were capable of identifying the story events as real or pretend, children were also asked to sort a story event card depicting the target causal relationship (i.e., a boy smelling a ‘Popple Flower’ and getting the hiccups), which served as an additional measure of generalization. Although this story event card was identical in both conditions, children in the *close world* condition were more likely to sort this story event in the “real pile” ( $M = .67, SD = .40$ ), while children in the *far world* condition more likely to sort this story event in the “pretend pile” ( $M = .72, SD = .45$ ), with a significant difference between conditions  $\chi^2(108, 1) = 9.69, p < .01$ .

Loglinear analysis and chi squares were conducted to assess differences in children’s responses on the generalization task at each age and for each condition. Results appear in Figure 2 below. Results of loglinear analysis demonstrate an effect of condition on generalization,  $\chi^2(108, 1) = 27.39, p < .001$ , indicating that children successfully differentiated between *close worlds* and *far worlds* when selectively generalizing novel causal information from the story to the real world.

Overall, children in the *close world* condition chose to generalize the target causal information to the real world scenario,  $\chi^2(54, 1) = 10.67, p < .01$ , with no difference between age groups,  $\chi^2(54, 2) = 0.45, p < .80$ , indicating that preschoolers are able to generalize novel causal information from realistic stories. Children in the *far world* condition made the opposite inference, with the majority of children choosing not to generalize the target causal information to the real world scenario,  $\chi^2(54, 1) = 14.42, p < .001$ . While 3-, 4-, and 5-year-olds all generalized more often from the *close world* than from the *far world* ( $\chi^2[36, 1] = 5.04, p < .05$ ;  $\chi^2[36, 1] = 7.80, p < .01$ ; and  $\chi^2[36, 1] = 14.57, p < .001$ , respectively), our results also provide evidence for a developmental change: children’s willingness to generalize novel causal information from the *far world* decreased (marginally) with age,  $\chi^2(54, 2) = 5.67, p = .059$ , with 3-year-olds more likely to generalize the target causal relationship (39%) than 4-year-olds (28%) and 5-year-olds

(6%). There was a significant difference between 3- and 5-year-olds' willingness to generalize from the *far world*,  $\chi^2(36, 1) = 5.79, p < .02$ .

Figure 2. Percentage of 3-, 4-, and 5-year-old children who generalized the target causal relationship from the story to the real world in each condition.

## Discussion

The current study examined children's generalization of novel causal information from fictional representations to the real world. Findings provide evidence that preschool-aged children are sensitive to the proximity of the fictional world when selectively learning and applying novel causal information from stories. While children in both *close world* and *far world* conditions were able to remember the target causal relationship embedded in the story, the proximity of the fictional world to reality influenced their subsequent generalization of this novel information. These results demonstrate that children begin to differentiate between close and far fictional worlds from a very early age, and that this sensitivity undergoes a process of developmental change, increasing between 3- and 5-years.

How might this sensitivity to the proximity of fictional worlds develop over time? The development of this ability requires the learner to successfully integrate the information provided in the story with their prior knowledge and beliefs about the causal structure of the real world. However, little was previously known about children's use of prior knowledge when evaluating the applicability of information learned in fictional representations, and how their reliance on this prior knowledge may change over the course of early development.

Recent probabilistic accounts of learning (e.g., Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004; Schulz, Bonowitz, & Griffiths, 2007) may provide a natural framework for addressing these questions. According to these accounts, a learner's background knowledge and prior beliefs are productively integrated with new data when forming novel inferences about the causal structure of the world. As prior knowledge increases over the course of development, children will become better able to approximate the true causal structure of the real world. As a result, children's ability to use contextual cues from the

story to inform their decision to generalize novel information should improve over time. For example, if story events are determined to have a high probability of occurring in the real world, children should be more likely to generalize novel causal information learned in this context than in cases in which the story events are determined to have a low probability of occurring in the real world. Therefore, as their prior knowledge about the causal structure of real world increases, children become better able to evaluate the information that they receive from fictional contexts to inform and structure their own learning.

Similarly, children's developing sensitivity to the proximity between fictional worlds and reality may be mediated by their increasing prior knowledge about the nature of fantastical representations. Previous research has shown that children who score higher on fantasy orientation scales (i.e., children who have more experience engaging with fantasy worlds) are less likely to transfer solutions to analogical problems from fantastical stories to real world scenarios (Richert & Smith, 2011). In other words, those children with the greatest amount of prior knowledge about fantastical representations are the least likely to draw analogies between worlds. One explanation for these findings is that children with more experience with fantastical representations have developed an increased appreciation of the distinction between the causal structure of *far worlds* and reality, which may lead to the sophisticated strategy of quarantining causal information acquired from these fantastical contexts. The developmental change that we document in the current study provides evidence for each of these related proposals. Future research should further explore the particular type of prior knowledge – knowledge about the true causal structure of the real world, knowledge about the nature of fictional representations, or some combination of the two – that is most relevant to developing this sensitivity during early childhood.

In sum, our findings demonstrate that by 3-years of age, children are already able to evaluate the data that they receive from fictional stories in order to inform their generalization of novel story content to the real world. Additionally, as children develop, they become better able to discriminate between close and far fictional worlds when assessing which stories are likely to provide relevant causal knowledge about the real world. These findings have important implications for educational contexts that rely upon children's literature to present intended curriculum. Storybooks provide rich opportunities for children to learn about aspects of the world that are otherwise inaccessible to them. However, because children's selective learning from storybooks is at least partly contingent upon the perceived proximity between worlds, the presence of fantastical events may inadvertently undermine educational goals. By explicitly directing children to the generalizable information in fictional stories, adults may help young learners to negotiate the complex relationship between fictional worlds and reality.

## Acknowledgements

This research was funded in part by the McDonnell Foundation to A. Gopnik. The authors thank Ellen Winner for her contributions to the development of this research and Ngoc Nyugen for illustrating the storybooks. We also thank Rosie Aboody, Anna Akullien, Sierra Eisen, and Brynna Ledford for their assistance with data collection.

## Abstract

In two studies, we examine how prompting 5- and 6-year-olds to explain observed outcomes influences causal learning. In Study 1, children were presented with data consistent with two causal regularities. Explainers outperformed controls in generalizing the regularity that accounted for more observations. In Study 2, this regularity was pitted against an alternative that accounted for fewer observations but was consistent with prior knowledge. Explainers were *less* likely than controls to generalize the regularity that accounted for more observations. These findings suggest that explaining drives children to favor causal regularities that they expect to generalize, where current observations and prior knowledge both provide cues.

**Keywords:** Explanation; cognitive development; causal reasoning; prior knowledge; generalization; abduction.

Since Piaget, researchers have regarded children's explanations as a window into cognitive development, revealing children's understanding of the world (e.g., Keil, 2006). More recently, however, the very process of seeking, generating, and evaluating explanations has additionally been proposed as a powerful mechanism for learning and generalization, scaffolding knowledge acquisition and contributing to theory change (e.g., Chi, DeLeeuw, Chiu, & LaVancher, 1994; Lombrozo, 2006; Wellman, 2011). Here we investigate the role of explanation in young children's causal learning, focusing on whether and how explaining influences the relative contributions of observed evidence and currently-held theories ("prior knowledge").

Discovering the underlying causal structure in the world is one of the major inductive problems that young learners face during development. By 5 years of age, children have already developed abstract, coherent representations of causal relationships in a variety of domains (e.g., Carey, 1985; Gelman & Wellman, 1991). The acquisition of this causal knowledge is supported by powerful learning mechanisms that allow children (and adults) to infer novel causal relationships from patterns of evidence and prior beliefs (e.g., Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004; Griffiths, Sobel, Tenenbaum, & Gopnik, 2011). For example, 5-year-old children can effectively track covariational evidence to identify a novel cause, but require stronger evidence to endorse a cause that conflicts with their prior beliefs than one consistent with those beliefs (Schulz, Bonawitz, & Griffiths, 2007). These findings reveal that children integrate current observations with prior beliefs in the process of learning and revising their causal knowledge. Here we propose that explaining may play a

role in this integration, by influencing the relative contributions of evidence and prior knowledge – that is, the extent to which learners revise their beliefs in light of their observations and prior commitments.

A first possibility, which we call the *evidence hypothesis*, is that explaining a set of observations directs learners to update their beliefs in light of those observations. As a result, explaining will lead learners to change their beliefs *more* than they would have in the absence of explaining. This might be expected, for example, if explanation boosts children's engagement with a task (Siegler, 2002), thereby making them more responsive to feedback and less likely to disregard relevant observations. Consistent with this possibility, a variety of studies have found that presenting young children with feedback is less effective as a means to changing their beliefs than having them explain as well (e.g., Wellman, 2011). More indirect support comes from the fact that explaining can direct children towards anomalous data, which conflicts with their prior beliefs and may therefore signal a need for belief revision (e.g., Legare, 2010; Legare, Gelman, & Wellman, 2010). In sum, the *evidence hypothesis* predicts that explaining should make children more responsive to observed data, leading to greater revision in current beliefs.

A second possibility, which we call the *prior knowledge hypothesis*, is that engaging in explanation invokes learners' currently-held theories, leading them to revise their beliefs *less* than they might have in the absence of explanation. In line with this hypothesis, several researchers have proposed that explaining encourages learners to accommodate what they are trying to explain in the context of what they already know (e.g., Chi et al., 1994; Lombrozo, 2006). Explaining could thus lead children to favor hypotheses consistent with prior knowledge, even when those hypotheses might not have been entertained or preferred on the basis of evidence alone. Kuhn and Katz (2009) further suggest that by encouraging learners to consider *why* something is the case, explaining can lead them to discount observed evidence altogether. From this perspective, learners who explain could be less inclined towards hypotheses that simply match current evidence, either because they weight prior beliefs more heavily or because they underweight current evidence.

A final possibility is that explaining does not affect the role of evidence or prior knowledge uniformly across contexts. Instead, explaining could change the criteria employed in evaluating evidence and prior knowledge in the course of learning, resulting in greater belief revision under some conditions and less belief revision under others. The version of this possibility that we explore here is the

*generalization hypothesis*, according to which generating explanations leads children to evaluate both evidence and prior knowledge as cues to which patterns in their observations are most likely to *generalize* to new cases. This proposal is motivated by the theory-theory of cognitive development (e.g., Carey, 1985; Gopnik & Wellman, 1994) as well as recent research concerning the role of explanation in adult learning (Williams & Lombrozo, 2010a, 2010b). According to the theory-theory, children construct intuitive theories that support explanation, prediction, and control, where theories are regarded as consisting in “causal-explanatory” knowledge. In order to effectively support prediction, successful theories must account for past observations as well as generalize to future observations. The process of generating explanations could therefore influence learning by directing children to construct the causal-explanatory beliefs that they judge most likely to generalize, and to consult both evidence and prior knowledge in making this assessment.

Insight into how explanation could contribute to this process comes from subsumption and unification theories of explanation from philosophy, according to which successful explanations demonstrate how what is being explained can be subsumed under a broad regularity, such as a natural law (e.g., Friedman, 1974; Kitcher, 1989). If explaining drives learners to understand current observations in terms of broadly-applicable regularities, it should facilitate the discovery and generalization of regularities that subsume the greatest number of cases. This idea has recently been developed as an empirical hypothesis concerning the role of explanation in learning, called the *subsumptive constraints account*, and is supported by studies with adults learning novel categories (Williams & Lombrozo, 2010a, 2010b).

To illustrate, consider Williams and Lombrozo (2010a), in which adults learned novel categories from observations and were prompted to either explain each observation’s category membership or to engage in a control task. The categories could be differentiated by a subtle regularity that accounted for all observations, or by a more salient regularity that accounted for only a subset of observations. Compared to participants in other conditions, those prompted to explain were more likely to discover the regularity with greater subsumptive scope (the one that accounted for more cases), and more recent evidence suggests that prior knowledge additionally serves to inform these assessments (Williams & Lombrozo, 2010b, under review). The *generalization hypothesis* proposes that explanation influences children’s causal learning in a similar way: by directing young learners to the causal hypotheses with the greatest subsumptive scope, which is assessed on the basis of both evidence and prior knowledge.

These candidate hypotheses are not intended as comprehensive accounts, but rather provide a useful framework for considering the possible mechanisms by which explanation could influence causal induction. In the two studies that follow, we manipulate both the observed evidence and children’s prior knowledge in order to test

these hypotheses and assess the role of explanation in children’s causal learning. Specifically, children learned about a novel causal system in which some objects were causally efficacious and others were not. Half of the participants were prompted to explain the causal outcomes during the training phase of the experiment, and the other half were prompted to describe these outcomes. In Study 1, the observed data suggested two candidate causal regularities that were equally consistent with prior knowledge. However, one of the two causal regularities accounted for more of the observed data. In Study 2, children were again presented with two candidate causal regularities that accounted for all or a subset of the data, but the regularity that accounted for fewer observations was more consistent with prior knowledge. In both studies, children were then asked to generate causal predictions in order to assess which causal regularity was discovered, preferred, and generalized to novel cases.

The three hypotheses outlined above generate different predictions across these two studies. The *evidence hypothesis* predicts that children will generalize according to the regularity that covers more of their observations in both studies. The *prior knowledge hypothesis* predicts that because explaining prompts children to rely upon their current theories, those who explain should respond no differently in Study 1, and be more likely to form generalizations in line with their prior knowledge in Study 2. The *generalization hypothesis* predicts that explainers should consider both the data and their prior knowledge to identify the regularity that is likely to apply most broadly, which could lead to opposite generalizations for Studies 1 and 2. Taken together, the results will thus help characterize the role of explanation in children’s causal learning.

## Study 1: Regularities in Observed Evidence

In Study 1, we present two groups of children with the task of learning a novel causal relationship from a series of observations, where one group is prompted to explain each observation (the *explain* condition) and the other to describe each observation (the *control* condition). The observed data suggest two causal regularities: a regularity that accounts for 100% of observations (the 100% regularity) and a regularity that accounts for 75% of observations (the 75% regularity). The evidence for candidate regularities is presented using a *blicket detector* paradigm (e.g., Gopnik & Sobel, 2000), in which children learn which objects have causal efficacy in activating a machine.

### Participants

Forty-two 5-year-old children ( $M = 64.2$  months;  $SD = 3.6$ , range: 59.9 – 72.7; 25 girls) were included, with 21 children randomly assigned to each condition. Children were recruited from local preschools and museums.

### Materials

The machine used in the training phase of both studies was a “blicket detector” – a box concealing a wireless doorbell.

When an object “activated” the machine, the doorbell was pressed remotely, producing a melody.

An illustration of the complete set of training blocks appears in Figure 1A. Eight 2” wooden blocks (four “Go” blocks and four “No-Go” blocks) were used during the training phase. A green plastic lego plate was affixed to the top and front of each block. Attached to each lego plate was a single, small rectangular lego of uniform size. The two causal regularities (100% and 75%) were represented by different-colored legos. For the four blocks that activated the machine (*Go* blocks), the 100% regularity was represented by a green lego and the 75% regularity was represented by a red lego. For the four blocks that did not activate the machine (*No-Go* blocks), the 100% regularity was represented by a yellow lego and the 75% regularity was represented by a white lego. For half of the children, the 100% regularity (the green/yellow lego) appeared on the top of the block and the 75% regularity (the red/white lego) appeared on the front of the block, and for half of the children, these positions were reversed.

For the testing phase, four additional blocks were used. These testing blocks were identical to the training blocks, but included only one of the four lego colors on each. Additionally, a cardboard “hiding box” was constructed, with four cut-out windows that were covered with black felt flaps. These windows were designed so the experimenter could place two blocks inside the hiding box and lift two flaps to show the participant only one of the two legos (on the top or front) of each block.

## Procedure

The experimenter introduced the machine, explaining that some things make the machine play music and some things do not. The child was then instructed to sort the blocks into two piles according to whether they activated the machine.

The experimenter placed each of the eight blocks on the machine, one at a time. After children observed each outcome, they were asked for a verbal response. In the *explain* condition, children were asked to explain the outcome: “Why did/didn’t this block make my machine play music?” In the *control* condition, children were asked to describe the outcome: “What happened to my machine when I put this block on it? Did it make music?” The order of presentation of the eight blocks was semi-random (see Figure 1A). All blocks remained visible and were grouped on the table throughout the training and test phases of the experiment to eliminate memory demands.

For the test phase, the machine was removed and the experimenter introduced the “hiding box,” saying: “This is my hiding box. I am going to put two new blocks into my hiding box, and lift these flaps so you can only see part of each block.” The child was told: “One of the blocks I put in my hiding box will make my machine play music, and one of the blocks will not. I want you to tell me which one you think *will/will not* make my machine play music.”

Each test question was designed to pit one potential causal regularity against the other. In the first set, the 100%

and 75% test items, the *Go* features were pit against the *No-Go* features for both the 100% regularity (green vs. yellow) and the 75% regularity (red vs. white). In the next set, the experimenter presented *conflict items*, in which the *Go* feature from the 100% regularity (green) was pit against the *Go* feature from the 75% regularity (red). Each time, children were asked to predict which block would make the machine play music. These questions were intended to present a conflict between the two potential causes to examine whether children would privilege one regularity over the other. Each of these test questions was repeated for a second time in which the experimenter asked the child to indicate which block *would not* make the machine play music. There was a total of six test questions in this format: four 100% and 75% test items (two green vs. yellow; two red vs. white) and two *conflict items* (two green vs. red).

Responses on the 100% and 75% test items were scored for accuracy, where accuracy reflected the correct selection of the *Go* block when asked for an item that would make the machine go, and the *No-Go* block when asked for an item that would not. Children received 1 point for selecting the correct response and 0 points otherwise. For the *conflict items*, we examined whether responses conformed to the 100% regularity (selecting the green lego over the red lego) or the 75% regularity (selecting the reverse), coding the former as “1” and the latter as “0.”<sup>1</sup>

Figure 1: Procedure for Studies 1 (A) and 2 (B).

## Results

Whereas children in both conditions were able to learn the 100% and 75% regularities, those who were prompted to explain during the training phase were more likely than controls to privilege the 100% regularity over the 75% regularity when generalizing to novel cases (see Figure 2).

We begin by reporting the results of children’s

<sup>1</sup> Both studies additionally included certainty ratings and an explanation selection task with findings that mirror those that we report; we do not report these data in the interest of space.

performance on the 100% and 75% test items. A repeated measures ANOVA was conducted with each question type (100% and 75% test items) as the repeated measure and condition (*explain* vs. *control*) as a between-subjects variable. Analysis revealed no difference in children's performance on the two question types,  $F(1, 40) = 0.195$ ,  $p = .661$ , no difference between conditions,  $F(1, 40) = 1.84$ ,  $p = .182$ , and no interaction between question type and condition,  $F(1, 40) = 0.780$ ,  $p = .382$ . Children in both the *explain* condition ( $M = 0.87$ ,  $SD = 0.23$ ) and the *control* condition ( $M = 0.77$ ,  $SD = 0.22$ ) were able to learn the 100% and 75% regularities during the training phase and use this information when generalizing to novel blocks.

To analyze children's performance on the *conflict items*, a one-way ANOVA was conducted with condition (*explain* vs. *control*) as the between-subjects variable. There was a significant difference between conditions,  $F(1, 40) = 5.79$ ,  $p < .02$ : Children in the *explain* condition were more likely ( $M = .667$ ,  $SD = .33$ ) than those in the *control* condition ( $M = .405$ ,  $SD = .38$ ) to base their generalizations on the 100% regularity. Results support the hypothesis that prompting learners to explain helps them to discover and extend causal regularities that account for more of their observations, consistent with the *evidence* and *generalization* hypotheses.

## Study 2: Conflicting Prior Knowledge

Study 1 was designed to assess the role of current evidence in children's causal learning and generalizations. However, because the two candidate causes differed only in color (green vs. red), children had no *a priori* reason to privilege either cause. Study 2 therefore examines the influence of explanation in causal learning when a candidate cause that accounts for more observations is pitted against an alternative that is more consistent with prior knowledge.

Study 2 again presented two sets of causal regularities: a 100% regularity that accounted for all observations (block color), and a 75% regularity that accounted for most observations *and* presented a plausible causal mechanism (block size). Unlike color, relative size provides a plausible cause – larger objects are assumed to be more causally efficacious. This assumption was confirmed during pilot testing. We also included two age groups in Study 2 (5- and 6-year-olds). Because 6-year-olds have more experience with mechanical systems and have begun formal schooling, they could hold stronger prior beliefs in this domain.

If explaining principally drives learners to favor regularities from the data that they observe, then we would expect to replicate the results from Study 1, with explainers more likely to generalize according to the 100% regularity. If, however, explaining prompts learners to privilege causes that are more plausible in light of prior beliefs, then children prompted to explain should be less likely to generalize according to the 100% regularity, instead favoring the prior-knowledge consistent 75% regularity.

## Participants

Seventy-two children were included in Study 2, including

36 5-year-olds ( $M = 64.4$ ;  $SD = 3.8$ ; range = 60.1 – 71.7; 20 girls) and 36 6-year-olds ( $M = 78.3$ ;  $SD = 4.1$ ; range = 72.7 – 83.7; 18 girls). Eighteen 5-year-olds and 18 6-year-olds were randomly assigned to each condition. Children were recruited from preschools and museums.

## Materials

Study 2 used the same machine as in Study 1. Training stimuli consisted of four large, 3" wooden blocks and four small, 1" wooden blocks. A strip of colored electrical tape was affixed to each of the eight blocks. The four *Go* blocks had a green strip and the four *No-Go* blocks had a yellow strip. An illustration of the complete set of training blocks appears in Figure 1B. In place of the hiding box, test blocks were hidden in an opaque bag.

## Procedure

While the procedure for the training phase and test questions was similar to Study 1, there were some changes to the procedure for the testing phase. Rather than placing the test objects in the hiding box, the experimenter looked inside the opaque bag and described one feature for each of two new blocks, saying, for example, "I see a green one and I see a yellow one. Which one will make my machine play music, the green one or the yellow one?"

## Results

As in Study 1, children in both conditions were able to learn the 100% and 75% regularities. However, unlike in Study 1, children who were prompted to explain were significantly *less* likely than controls to privilege the 100% regularity over the 75% regularity when forming generalizations about novel cases, instead favoring the regularity consistent with prior knowledge (see Figure 2).

Figure 2: Mean proportion of responses consistent with the 100% regularity on the conflict items in Studies 1 and 2.

We first report results of children's performance on the 100% and 75% test items. A repeated measures ANOVA was conducted with question type (100% and 75% test items) as the repeated measure and both age (5- vs. 6-year-olds) and condition (*explain* vs. *control*) as the between-subjects variables. Analysis revealed a significant interaction between age and performance on the two question types,  $F(1, 68) = 4.46$ ,  $p < .05$ , with 6-year-olds

showing higher accuracy ( $M = .96$ ,  $SD = 0.18$ ) than 5-year-olds ( $M = .79$ ,  $SD = 0.33$ ) on the 75% test items. However, there was no main effect of condition,  $F(1, 68) = .73$ ,  $p = .40$ , and no interaction between question type and condition,  $F(1, 68) = 0.04$ ,  $p = .85$ . As in Study 1, children in both the *explain* condition ( $M = .93$ ,  $SD = .24$ ) and the *control* condition ( $M = .89$ ,  $SD = .30$ ) were able to learn the 100% and 75% regularities during the training phase, and use this information when generalizing to novel blocks.

To analyze children's performance on the *conflict items*, a univariate ANOVA was conducted with both age and condition as the between-subjects variables. As in Study 1, there was a significant difference between conditions on the *conflict items*,  $F(1, 68) = 6.46$ ,  $p < .02$ . However, results reveal a reversal of the findings. While children in both conditions responded in line with the 100% regularity more often than chance,  $p < .05$ , children in the *explain* condition were significantly *less* likely to do so ( $M = .64$ ,  $SD = .37$ ) than children in the *control* condition ( $M = .83$ ,  $SD = .27$ ). There was no difference in performance between 5- and 6-year-olds,  $F(1, 68) = .13$ ,  $p = .72$ , and no interaction between age and condition,  $F(1, 68) = 1.18$ ,  $p = .28$ .<sup>2</sup>

## General Discussion

In two studies, young children's attempts to generate explanations influenced which candidate cause they privileged when generalizing to novel cases. In Study 1, children were presented with data consistent with two causal regularities, where one accounted for more observations. Children who were prompted to explain were more likely than controls to generalize according to the regularity that accounted for more of the observed data. In Study 2, a regularity that accounted for all observations was pitted against an alternative that accounted for fewer observations but was consistent with children's prior knowledge about plausible causes. When presented with this conflict, children who were prompted to explain their observations were now *less* likely than controls to generalize the regularity that accounted for more of their observations, instead making judgments in line with prior knowledge.

Taken together, these studies shed light on the mechanisms by which explanation informs and constrains causal learning. Our findings challenge the *evidence hypothesis*, that explaining (always) makes children more responsive to evidence. If this were the case, explaining should have led children to base their judgments on the regularity that was most consistent with their current observations in both Studies 1 and 2. Our findings also challenge the *prior knowledge hypothesis*, according to which the (primary) role of explanation is to align new information with current theories. While children prompted

to explain were more likely to form a generalization in line with their prior knowledge in Study 2, children were also more likely to generalize according to their observations in Study 1, indicating that the *prior knowledge hypothesis* is limited at best, and false at worse. Instead, these findings best support the *generalization hypothesis*, that explanation prompts children to privilege observed regularities that they expect to generalize most broadly, with both observations and prior knowledge serving as cues to generalization.

The *generalization hypothesis* is broadly consistent with the "theory-theory" approach to cognitive development, and additionally provides some insight concerning how the process of theory construction and revision occurs. Within cognitive development, researchers have suggested that children's theory-like conceptual development is largely motivated by explanation, which acts as a mechanism for building abstract causal theories. In particular, Wellman and Liu (2007) propose that explanations make a particular occurrence understandable by placing it within the context of a larger, coherent framework. In so doing, explanation must accommodate both observations and prior beliefs. Relatedly, explanations have been shown to encourage adult learners to *subsume* the observation being explained under a general pattern that is expected to generalize to novel cases (Williams & Lombrozo, 2010a, 2010b). Our current findings not only provide additional support for these ideas by demonstrating that young children are also sensitive to such constraints, but additionally shed light on how explanations contribute to the formation of causal theories: Explaining helps negotiate the critical balance between prior beliefs and novel evidence, directing learners to regularities that will generalize to new cases.

Important questions for future research include precisely *how* explanation influences the evaluation of evidence and prior beliefs, and whether this influence results in judgments that are more or less closely aligned with the predictions of normative (Bayesian) models (e.g., Griffiths et al., 2011). For example, computational approaches to cognitive development have proposed that the formation of multiple levels of generalizations, or *overhypotheses*, enables learners to make principled abstractions from a class of observations, which then serves to inform future inferences about novel cases (e.g., Kemp, Perfors, & Tenenbaum, 2007). By prompting children to evaluate which candidate regularity generalizes most broadly, explanation could play a role in pushing children to consider higher-order inductive generalizations that support abstract knowledge.

The interpretation outlined thus far has focused primarily on the impact of prompts to explain on children's causal judgments. However, it is also worthwhile to consider the performance of children who were not prompted to explain. In particular, why didn't the control children in Study 2 spontaneously consult their prior knowledge in forming causal judgments? Williams and Lombrozo (under review) report similar findings in an adult population: Only learners who were prompted to explain during learning utilized informative labels in guiding their discovery of subtle

<sup>2</sup> Due to limited space, we do not report the results of qualitative analyses examining the content of children's explanations in Studies 1 and 2. These results are consistent with the quantitative data and provide additional support for our conclusions in the General Discussion.

patterns underlying novel categories. The authors suggest that explanation can guide learners to consult prior knowledge that would otherwise remain under-utilized.

The current work also suggests a number of future directions. For example, while the results reported here demonstrate the presence of an early effect of explanation on causal learning, questions remain regarding the development of this mechanism from infancy to adulthood. Additionally, future research should consider how these findings can be productively combined with previous research on the self-explanation effect (e.g., Chi, et al., 1994; Lombrozo, 2006; Siegler, 2002), as well as examining educational implications of the present findings.

In sum, these two studies provide evidence for the mechanisms by which explaining scaffolds causal learning in early childhood and serve to inform prevailing theories of learning. Learning by explaining challenges a simple data-driven view of knowledge acquisition in which children's learning is simply a function of observation and testimony. Instead, these findings provide evidence for more complex theories of learning in which processes such as explaining to oneself influence how data and current theories inform judgments. Understanding how engaging in explanation influences learning therefore contributes to a more complete understanding of how knowledge is acquired and revised.

## Abstract

We explore ways of covertly delivering interventions into the adversary decision cycles so as to effectively shape adversary decision-making and performance without inducing much suspicion. Recognizing that completely covert interventions, while most effective, are difficult to implement, we focus on a more general mode of covertness. Based on insights from human abductive reasoning, we propose a delivery scheme that contains interventions that may be noticeable but whose true meanings are hidden or distorted (e.g., the human operators do not easily attribute the interventions to malicious attacks). We evaluate, both theoretically and empirically, the effectiveness and robustness of this scheme in escaping detection and disrupting performance.

**Keywords:** Abduction, decision making, cybersecurity, intervention.

## General Formatting Instructions

A cyber attack is more damaging and harmful if it is stealthy and escaping detection. One critical challenge in cyberspace security is therefore to find ways to effectively detect hidden or covert attacks. One approach to meeting the challenge is to look at the other side of the coin and study how and why some attacks can be delivered covertly that induce no or minimal suspicion from the human operator. The results from this approach can then be used to design better countermeasures and improve security.

Here we focus on the concept of “covertness” in cyber attacks and intend to discover the theoretical essence and practical guidelines of implementing “covertness”. Presumably, a covert attack would be one that is completely hidden and not noticed by the targeted operator at all. In this sense, covertness can be implemented as slip of attention. Examples include attention blink, change blindness, and inhibition of return, to name a few. While a large body of evidence has confirmed that attention is a fragile cognitive function that can be manipulated and exploited for the purpose of implementing covertness, it has also been suggested that the attention-based approach is quite limited and difficult to apply in the real world situations.
