misrepresentation occur primarily for low empirical feature counts, when the model relies heavily on pseudocounts from the Dirichlet prior distribution.

**Observation of semantic and phonological features on novel nouns** A second possibility is that children have little trouble perceiving, encoding and representing features on the words in their lexicon, but that the semantic features on the experimental items (as they are presented as flat pictures in a book) are unreliably perceived and encoded. We call this the Experimental Reject Hypothesis.

In this manipulation we investigate what would happen if a learner had a lexicon that faithfully represented the predictive features as they were distributed in the input and assumed both semantic and phonological features were relevant to classification, but didn't reliably encode semantic features on experimental items. To do this we use a mixture model, where some proportion of the time ( $1 - \beta$ ) an item that was supposed to have the specified semantic feature value [animate] or [female] (denoted as [spe]) it would be classified as with that value, the rest of the time ( $\beta$ ) it would be classified as if it had the unspecified value [other]. This yields the following model:

$$p(c | f_1, f_2) = (1 - \beta) \frac{p(f_1 = [spe] | c) p(f_2 | c) p(c)}{\sum_i p(f_1 = [spe] | c_i) p(f_2 | c_i) p(c_i)} + \beta \frac{p(f_1 = [other] | c) p(f_2 | c) p(c)}{\sum_i p(f_1 = [other] | c_i) p(f_2 | c_i) p(c_i)} \quad (3)$$

As with the semantic incompetence model, we found the best-fitting value of  $\beta$  and evaluated the model by comparing it to children's behavior. This model again produced a close fit for all feature values (Figure 4). The model showed a consistent degree of misperception across all semantic features and feature combinations. The best fitting level value of  $\beta$  ranged from .49 to .83, where 58% was the best fit overall. This means that children would be misperceiving semantic features on 58% of the experimental items. A generalized likelihood ratio test indicates that the experimental reject model also significantly outperforms the optimal naïve Bayesian classifier ( $p < 0.05$ ).

**Assumption that all features are relevant for classification** The asymmetry between the reliability of perceiving and encoding phonological as compared to semantic features could also engender a bias to prefer phonological information for classification decisions, as phonological information has been reliably available for a longer period of time. Our third model, embodying the Phonological Preference Hypothesis, therefore looked at what would happen if we had a learner that was biased not to use semantic features in classification some proportion of the time, even if these features were represented just as distributed in the input and accurately perceived during the experimental task. We used a second mixture model, this time looking at the mixture of a Bayesian classifier that used both semantic and phonological features, and one that only used phonological features.

Figure 4: Classification of novel nouns as predicted by a model that misobserves semantic features on experimental items 58% of the time

The crucial difference between this model and the experimental reject model is that in the experimental reject model semantic features are always used, but are encoded as the wrong value (the unspecified [other] value) some proportion of the time, whereas in the phonological preference model, semantic features do not factor into the calculation at all some proportion of the time ( $\beta$ ). The model can be seen in Equation 4.

$$p(c | f_1, f_2) = (1 - \beta) \frac{p(f_1 = [sem] | c) p(f_2 | c) p(c)}{\sum_i p(f_1 = [sem] | c_i) p(f_2 | c_i) p(c_i)} + \beta \frac{p(f_2 | c) p(c)}{\sum_i p(f_2 | c_i) p(c_i)} \quad (4)$$

Again we evaluated the model against the children's classification data and found a close fit (Figure 5). The best fitting value of  $\beta$  ranged from .49 to .83, and was .65 over all, meaning that children would be choosing not to use semantic features on 65% of classification decisions. A generalized log likelihood test showed that this model also significantly outperformed the optimal naïve Bayesian classifier ( $p < 0.0001$ ).

Figure 5: Classification as predicted by a model biased not to use semantic information 65% of the time

## Discussion

Tsez noun classes are characterized by both semantic and phonological features. Children have been shown to be able to use these features when classifying novel nouns. Here we showed that their classification patterns differ from those of an optimal Bayesian classifier when nouns have semantic and phonological features that make conflicting predictions.

We also presented three models that take into account ways in which the difference between semantic and phonological features could lead to children's apparent preference to use the less reliable phonological features. These models examined how classification would look if a learner had (a) misrepresented semantic features in the lexicon, (b) misencoded semantic features during the classification experiment, or (c) developed a bias to use phonological information in noun classification due to its higher reliability in the early stages of lexical acquisition. All three models fit children's data significantly better than the optimal naïve Bayesian classifier did. This suggests that although originally children did not look as though they were behaving optimally with respect to the input, they may well be behaving optimally with respect to their intake, that is, the input as they have represented it.

It is not obvious how one would best to evaluate the alternative models with respect to one another. For example, each model yielded a different best-fit parameter, corresponding to a different degree of misrepresentation or bias. While these best fitting parameters may differ in terms of their 'reasonableness' (i.e. misrepresenting 95% of semantic features in the lexicon at age 6 seems quite high), it isn't immediately clear how to measure reasonableness, or how to compare it across models. Furthermore, it is likely that a combination of all three of these processes (and perhaps more that we haven't considered here) is influencing children's classification decisions. This could potentially be explored through a combined model; however, as all of these models fit the data so closely, it would be difficult to determine which and to what extent each type of misrepresentation or bias is involved.

This work has several important implications for research statistical learning and language acquisition. First, and most broadly, by combining experimental data from children acquiring an understudied language with computational modeling techniques, we found a better understanding of both children's acquisition of Tsez, and the role of statistical cues in language acquisition. Tsez was an ideal language to look at, as feature types differed in their reliability as cues to noun class. However, we expect that these results will be generalizable across languages, as the relative difficulty of acquiring semantic, as compared to phonological, features of words will be consistent cross linguistically.

Second, we identified an area where children's behavior does not appear to reflect the ideal inferences licensed by the statistical patterns in the input. Three models allowed us to investigate the source of this asymmetry. While each model differed in where the asymmetry came from, all employed a weakening of the statistical import of semantic features. This is a distinct pattern from the finding that children learning an artificial language amplify an already strong statistical tendency (Hudson-Kam & Newport, 2009). Further research will determine whether or not these patterns could be in some way related.

Next, we showed that it is possible for a learner to be suboptimal and Bayesian at the same time. That is, we

demonstrated that while children's behavior does not align with the predictions made by the optimal Bayesian classifier, it can be predicted by modifying the terms of this classifier in reasonable ways. Thus we were able to model children's suboptimal behavior using a Bayesian model, rather than adopting some other system of computation.

Finally, our models showed that it is plausible that these children are indeed behaving optimally with respect to some statistical distribution, just not one directly measureable from the input. This point is crucial as researchers extend accounts of statistical learning to a greater range of problems, highlighting the fact that the critical question isn't whether or not children are using statistics to acquire language, but what statistics they are using.

## Abstract

Verbal satiation of Chinese bisyllabic words was studied in three experiments to ascertain the phenomenon, to track its time course, and to identify its locus. Experiment 1 asked the participants to judge if an exemplar matched a category in 22 blocks of 40 trials each. Within a block, one category appeared 20 times (*repeated* trials) while each of the remaining 10 categories appeared only twice (*baseline* trials). For the first 11 trials, response times (RTs) for the repeated ones were similar to RTs for the baseline ones. For the subsequent trials, *repeated* RTs were slower (by 9 ms) than *baseline* RTs, indicating a satiation effect. Its loci could be orthographic, semantic, or both, or on the associative links between form and meaning. In Experiment 2, category names were not shown. Participants judged if two exemplars belonged to the same category. *Repeated* RTs were faster (by 6 ms) than *baseline* RTs for the first 12 trials. Then, verbal satiation emerged but was short-lived (between the 13<sup>th</sup> and the 17<sup>th</sup> trial) and was of greater magnitude (20 ms) than that observed in Experiment 1. The satiation effect must be semantic, as only meanings were repeated. Experiment 3 asked participants to judge if two category names were identical, mostly an orthographic task. *Repeated* RTs were similar to *baseline* ones across all trials, suggesting no orthographic satiation. The results indicate that semantic satiation of Chinese words can be directly semantic (categorical). Its time course conforms to the habituation model described in Rankin, et al. (2009), i.e., sensitization (semantic priming) before habituation (semantic satiation) and habituation followed by dishabituation (recovery).

**Keywords:** Verbal Satiation, Semantic Satiation, Repetitive Semantic Processing.

## Introduction

For more than a century, the self-reports collected by psychologists (Moulin & Connor, 2006; Severance & Washburn, 1907) mention a loss of the meaning of an alphabetic word following its prolonged viewing (e.g., 3 min.) or its active repetition (oral or written, e.g., for 30 times). This experienced loss of meaning has been coined *semantic satiation*. The term *semantic satiation* emphasizes that the locus of satiation is thought to be semantic. In the present work, we will also use the term *verbal satiation* which is neutral regarding the locus of satiation. For the non-alphabetic Chinese script, according to the self-reports collected by Cheng and Wu (1994), prolonged viewing of a multi-component Chinese character (e.g. 臉, which means a face, can be decomposed at a first level into 月 + 僉) elicits an *orthographic satiation*. The original binding of the

different components is disrupted and the character looks weird. Hence, the primary subjective experience is an orthographic decomposition of the character, not the loss of the character's meaning. Cheng and Lan (2009) advanced that for the Chinese script there is no genuine semantic satiation but mainly orthographic satiation. To our knowledge, no one has tried to demonstrate whether for the Chinese script a verbal satiation with a unique semantic locus exists. If it does, semantic satiation would be genuine and would not be a mere by-product of orthographic satiation or of any pre-semantic satiation. Neither were we aware of any studies that examined Chinese verbal satiation at the word level rather than the character level.

In a most recent study on verbal satiation in English, Tian and Huber (2010) designed a continuous speeded category-matching task to track the time course of verbal satiation, and to identify its locus. In their Experiment 1, subjects performed for each trial a membership task for a category name (the cue) and an exemplar (the target). Half of the 20 trials of an experimental block contained a repeated category name (e.g. VEGETABLE). In half of these trials, the repeated category name was paired with exemplars of the category, producing matching trials (VEGETABLE-CARROT). In the other half of these trials, it was paired with exemplars of non-repeated categories, producing mismatching trials (VEGETABLE-GOLF). These 10 trials constituted the *satiation trials*. The other 10 trials using 10 distinct category names constituted the non-repeated trials, or the *baseline trials*. The satiation trials and the baseline trials were mixed and ordered randomly within a block. In their Experiment 1, Tian and Huber aimed at monitoring continuously the effects of repetition of a category name. They predicted that only response times for satiation trials should slow down as the task progressed if satiation occurred and if the task did not cause fatigue. The locus of any detected satiation in this experiment could be: (a) orthographic if the word's orthographic form representing the category name is satiated, (b) semantic if the meaning of the word is satiated, (c) both orthographic and semantic, or (d) on the associative link between the orthographic and semantic units. To distinguish between these four possible loci, Tian and Huber designed two more experiments based on the same speeded category-matching task. In their Experiment 2, Tian and Huber aimed at isolating a sole semantic locus of verbal satiation. They tested whether verbal satiation of the meaning of a category name (e.g.

VEGETABLE) can be induced without repeating the category name but instead by repeating many of its exemplars (e.g., CARROT, LETTUCE, ...). In this experiment, Tian and Huber used exemplars instead of category names as the repeated words. The task for their subjects was to judge whether two exemplars are members of the same category (e.g. LION-TIGER, CAR-ROSE). Within a block, exemplars of the category to be satiated made half of the stimulus words. Trials with exemplars from 10 other categories served in the baseline trials. The prevalence of the exemplars from the non-presented category name to be satiated should elicit satiation of its meaning. In Experiment 3, Tian and Huber aimed at isolating an orthographic locus of verbal satiation. Subjects had to perform lexical decisions about whether two words were the same word (e.g., VEGETABLE-VEGETABLE, ANIMAL-VEGETABLE). Within a block, the word to be satiated was used repeatedly in half of the trials. Repetition of the same word in this task was assumed to induce a verbal satiation with a lexical locus. In their experiments 2 and 3, Tian and Huber did not observe a satiation effect, but in Experiment 1 they did. Hence, Tian and Huber concluded that verbal satiation occurs in a task only when two conditions are met: (a) a word form is repeated, (b) the meaning of the repeated word is repetitively accessed. Tian and Huber posited that repeatedly viewing a word while thinking of its meaning elicits *associative satiation*: the information-flow channel from the lexical units to the semantic units is satiated which caused the subjective experience of the loss of meaning of a satiated word.

The lack of a satiation effect in Experiments 2 and 3 of Tian and Huber's (2010) study is critical to their interpretation of the satiation effect observed in Experiment 1. Therefore, the findings need to be evaluated with rigor. On the one hand, the satiation effect of Experiment 1 could be due to the concomitant loci of satiation at the levels of form, meaning, and form-to-meaning link. On the other hand, the failure to observe a satiation effect in Experiment 2 could be the result of insufficient number of repetitions (10). In previous studies, the smallest number of repetitions for which semantic satiation effects were observed was 15 (Kounios, Kotz, & Holcomb, 2000).

Our main goal was to observe whether a verbal satiation at the meaning level could occur in Chinese, and if it did, to track its time course. To pursue this goal, we adapted Tian and Huber's (2010) three experiments by doubling the number of repeated trials within a block and by using traditional Chinese multisyllabic words as visual stimuli.

## General Method

### Participants

Participants were Taiwanese students from National Cheng Kung University. The participants were different for each experiment.

### Apparatus

The experiments were programmed with DMDX (Forster & Forster, 2003).

## Materials and Design

The materials consisted of eleven Chinese category names: 蔬菜 (VEGETABLE), 動物 (ANIMAL), 水果 (FRUIT), 疾病 (DISEASE), 親戚 (RELATIVE), 運動 (SPORT), 職業 (OCCUPATION), 國家 (COUNTRY), 城市 (CITY), 公司 (COMPANY) and 樂器 (MUSICAL INSTRUMENT). Twenty exemplars were selected for each category from a Chinese corpus and word lists. Care was taken to ensure the exemplars shared no characters with the category names.

One experimental block contained 40 trials of pair of words as shown in Table 1. We detail the pairing in Experiment 1 to exemplify its general principles. Adaptations for Experiments 2 and 3 are given in the respective Experiment section. Within a block, all the 11 categories were represented but only one category (VEGETABLES in Table 1) was to be satiated through long-term repetition. This latter category is termed the *dominant* category of the block and the 10 others the *non-dominant* categories. The 11 Chinese category names listed before and their respective 20 exemplars were used respectively as cues and targets. Within a block, the 20 *repeated trials* contained as a cue the dominant category name. Ten exemplars from the dominant category served as targets to produce the *repeated match trials*. Ten exemplars from the non-dominant categories served as targets to produce the *repeated mismatch trials*. The 10 non-dominant category names served twice as a cue to produce the 20 *baseline trials*. They were randomly assigned to one or two of the (*baseline match*, *baseline mismatch*) groups to prevent any informed guessing about the pairing of a second occurrence of a non-dominant category name from viewing its first occurrence in a previous trial. Ten exemplars, distinct from the ones in the *repeated mismatch trials*, from the non-dominant categories served as targets and are paired to their respective category label to produce the *baseline match trials*. The 10 remaining exemplars from the dominant category not used in the *repeated match trials* served as targets to produce the *baseline mismatch trials*. Hence in a block, all the 20 dominant exemplars occurred once. Each of the 220 exemplars was used only twice in a set. Each of the 11 category names served as the word to be satiated in one block. The eleven blocks made a set. For the experiment, participants ran 2 sets totaling 22 blocks of 40 trials.

### Procedure

We describe the procedure of Experiment 1 to exemplify the general common procedure to all experiments. Adaptations for Experiments 2 and 3 are given in the respective Experiment section. Subjects faced a screen with a black background. For the first trial of a block, a fixation-cross appeared in white at the center of the screen for 200 ms. Then, a category name was presented in white at the center of the screen. After 1000 ms, an exemplar in white was presented below the cue. Within 2000 ms, subjects had to decide whether the exemplar matched the above category name. The two words remained on the screen until subjects pressed a Right or Wrong button on a gamepad. After pressing one of the buttons, the screen was cleared, and after

300 ms the next trial began with the presentation of the next cue word.

### Data Analysis

Both reaction time and accuracy for each trial were recorded. The first trial of each block was suppressed from the analysis because it tended to deviate from the trend of the rest of the trials which are the primary focus of the study. We analyzed both the RTs and accuracy data as a function of the trial number ranging from 2 to 40. This approach allows the most straightforward visualization of the dynamics of verbal satiation within a block as the task progresses and also equates the baseline/repetition conditions in term of general fatigue along a block. In a first statistical analysis, the range of the 39 trial numbers was a priori and arbitrarily segmented and mapped onto four equally spaced intervals. Mean RTs were calculated separately for Yes and No responses for each subject and separately for the repeated and baseline conditions for each of the four intervals over the 22 blocks. The mean RTs were subject to the analysis of variance. We run another similar statistical analysis with both the number of intervals and their unequal length informed by the data pattern over the 39 trial numbers. As the conclusions derived from the two statistical analyses were congruent, we reported only the results of the latter which offered a finer tracking of the dynamics of verbal satiation. Because of space limitation, only data for Yes responses are presented. Data for No responses were congruent with the ones from Yes responses.

### Experiment 1

In Experiment 1, we aimed at eliciting verbal satiation through 20 repetitive access to a Chinese category name's word form and meaning.

According to three accounts of satiation (associative satiation, semantic satiation, and orthographic satiation), Experiment 1 should elicit verbal satiation. Repetitive access from the same word form to the same meaning unit should satiate the associative link between orthographic and semantic units. Accessing repetitively the meaning of the category name should satiate it. Repetitive access to the same word form should elicit orthographic satiation.

### Method

Forty students (female 33) participated in the experiment. The subjects ran a category-matching task as described in the General Method section.

### Results and Discussion

One participant out of 40 was excluded based on a 90% accuracy criterion. Figure 1 plots the time course of the RTs for the correct Yes responses as a function of the trial number. Both baseline and repeated trials showed a slowing trend which revealed a general fatigue effect.

In Fig. 1, we drew a vertical line between trial number 11 and 12, a cutoff from which repeated RTs appeared to become globally slower than baseline RTs until the end of the block. From this cutoff, we defined two intervals:

position 1 for the trials 2-11 and position 2 for trials 12-40. A repeated measures two-way ANOVA was applied with repetition (2: baseline and repeated) and position (2: position 1 and position 2) as the two within-subject factors. We found both a statistically significant main effect of repetition,  $F(1, 38) = 4.13, p = .049$ ,  $GES = .0016$  ( $GES$  being the generalized eta squared, Bakeman, 2005), a statistically significant main effect of position,  $F(1, 38) = 33.65, p < .001$ ,  $GES = .031$ , and a statistically significant repetition  $\times$  position interaction,  $F(1, 38) = 9.67, p = .0035$ ,  $GES = .003$ . The interaction is characterized by the RTs for the repeated trials being comparable with the RTs for the baseline trials at position 1 but becoming slower at position 2. A paired t-test comparing RTs for repeated and baseline trials at Position 1 revealed no significant difference,  $t(38) = -0.57, p = .58$ . Another paired t-test at Position 2 showed that RTs for repeated trials were significantly slower (by about 9 ms) than RTs for baseline trials,  $t(38) = 4.7, p < .001$ .

Table 1. Block structure in Experiments 1, 2 and, 3.

Trial Number	Repetition Status	Match Status	Experiment 1	Experiment 2	Experiment 3
1	Repeated	Match	蔬菜 / vegetables 玉米 / corn	馬鈴薯 / potato 蘆筍 / asparagus	蔬菜 / vegetables 蔬菜 / vegetables
2	Baseline	Mismatch	疾病 / disease 南瓜 / pumpkin	台北 / Taipei 香菇 / mushroom	運動 / sport 蔬菜 / vegetables
3	Repeated	Match	蔬菜 / vegetables 茄子 / aubergine	茄子 / aubergine 洋葱 / onion	蔬菜 / vegetables 蔬菜 / vegetables
4	Repeated	Match	蔬菜 / vegetables 牛蒡 / burdock	南瓜 / pumpkin 紅蘿蔔 / carrot	蔬菜 / vegetables 蔬菜 / vegetables
5	Baseline	Match	職業 / profession 秘書 / secretary	法國 / France 巴西 / Brazil	親戚 / relative 親戚 / relative
...	...	...	...	...	...
38	Baseline	Mismatch	城市 / city 香菇 / mushroom	足球 / football 芋頭 / taro	城市 / city 蔬菜 / vegetables
39	Baseline	Match	運動 / sport 網球 / tennis	姑姑 / aunt 姪女 / niece	動物 / animal 動物 / animal
40	Repeated	Mismatch	蔬菜 / vegetables 吉他 / guitar	黃瓜 / cucumber 網球 / tennis	蔬菜 / vegetables 國家 / country

Figure 1. Experiment 1. Reaction times as a function of trial number for Yes responses.

The accuracy data were analyzed in the same way. We found a statistically significant main effect of repetition,  $F(1, 38) = 12.55$ ,  $p = .001$ ,  $GES = .049$ , revealing better accuracy for repeated trials. The main effect of position was not statistically significant,  $F(1, 38) = 0.44$ ,  $p = .51$ ,  $GES = .003$ . There was no repetition  $\times$  position interaction,  $F(1, 38) = 0.034$ ,  $p = .85$ ,  $GES < .001$ , suggesting that the interaction effect in the RT data was not the result of a speed-accuracy tradeoff.

Experiment 1 asked the subjects to determine if an exemplar word matched a category word. In terms of YES responses, response times for the first 11 repeated trials were similar to RTs for the non-repeated baseline trials. After that, RTs for the repeated trials became slower than RTs for the baseline trials. The increased RT difference between the repeated and the baseline trials from position 1 to position 2 was about 9 ms. Not due to a speed-accuracy tradeoff, this difference represented a verbal satiation effect brought about by the repeated processing of the same category word.

## Experiment 2

Experiment 2 investigated whether pure semantic satiation was possible by asking subjects to repeatedly process a category but not its name. According to the three accounts of satiation, Experiment 2 should elicit neither associative satiation nor orthographic satiation because there is no repetition of the category name. However, repetitive access to the meaning of an unshown category name should elicit satiation with a semantic locus.

### Method

Forty-one students (female 26) participated in the experiment. The materials for Experiment 2 were the 220 exemplars from the 11 categories used in Experiment 1. Category labels were not shown. Within a block, the 20 exemplars of the dominant category occurred twice, once as a cue in the *repeated trials* and once as a target. Exemplars from the 10 other categories served as cues in the baseline trials. Each of the 11 category names served as the unshown word to be satiated in one block. For the procedure, the cue word was no more a category name but a changing exemplar. Hence, subjects had to decide whether two exemplars belonged to the same category.

### Results and Discussion

One participant out of 41 was excluded based on a 90% accuracy criterion. Figure 2 plots the time course of the RTs for the correct Yes responses. As for Experiment 1, both baseline and repeated trials showed a slowing trend which revealed a general fatigue effect. In Fig. 2, we drew two vertical lines at trial numbers 13 and 17, two cutoff trial numbers separating the plot in three intervals: position 1 for the trials 2-12, position 2 for trials 13-17, and position 3 for trials 18-40. During position 1, repeated RTs appeared globally faster than baseline RTs which could signal a facilitatory semantic priming effect. Position 2 represents a potential verbal satiation interval during which repeated RTs became slower than baseline RTs. During position 3, the

repeated RTs recovered to be as fast as baseline RTs. This qualitative interpretation of Fig. 2 was confirmed by the thereafter statistical analysis. A repeated measures two-way ANOVA on mean correct RTs was applied with repetition (2) and position (3) as the two within-subject factors. We reported the Huynh-Feldt corrections for all statistical effects involving more than one degree of freedom in the numerator. The main effect of repetition was not statistically significant,  $F(1, 39) = 3.3$ ,  $p = .077$ ,  $GES = .0016$ .

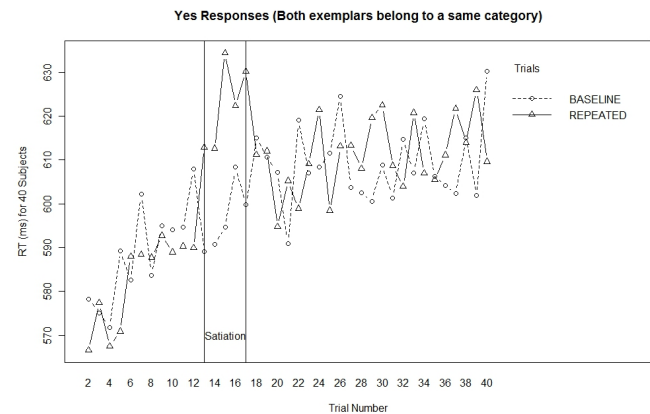

Figure 2. Experiment 2. Reaction times as a function of trial number for Yes responses.

However, we found a statistically significant main effect of position,  $F(2, 78) = 31.5$ ,  $p < .001$ ,  $GES = .026$ , and a statistically significant repetition  $\times$  position interaction,  $F(2, 78) = 11.09$ ,  $p < .001$ ,  $GES = .007$ . The interaction is characterized by the RTs for the repeated trials compared to the RTs for the baseline trials being faster at position 1, slower at position 2 and equally fast at position 3. A paired t-test comparing RTs for repeated and baseline trials at position 1 revealed marginally statistically significant faster reaction times (by 6 ms) for repeated trials,  $t(39) = -1.88$ ,  $p = .068$ , 95% CI [-12.8, 0.48]. Repeated trials are made of exemplars of a same dominant category, therefore the observed facilitation at position 1 for repeated trials revealed the occurrence of semantic priming. Another paired t-test at Position 2 showed that RTs for repeated trials became statistically significantly slower (by 20 ms) than baseline trials,  $t(39) = 4.7$ ,  $p = .003$ , 95% CI [7.5, 33.6]. Such a reversal from semantic priming at position 1 to semantic impairment at position 2 for repeated trials supported the occurrence of verbal satiation at position 2. Another paired t-test at position 3 showed that repeated RTs were no longer slower than baseline RTs,  $t(39) = 0.55$ ,  $p = .58$ , 95% CI [-4.1, 7.1]. Hence, at position 3, verbal satiation vanished.

Analysis of the accuracy data showed a statistically significant main effect of repetition:  $F(1, 39) = 6.27$ ,  $p = .017$ ,  $GES = .018$ , a statistically significant main effect of position:  $F(2, 78) = 3.3$ ,  $p = .043$ ,  $GES = .02$ , and a marginally statistically significant repetition  $\times$  position interaction:  $F(2, 78) = 3.11$ ,  $p = .058$ ,  $GES = .018$ . Of main interest to us, accuracy rates for repeated trials were

statistically significantly higher only for position 1,  $t(39) = 4.05$ ,  $p < .001$ . Then, they decreased to the level of baseline trials for position 2 and 3, ( $t(39) = 0.38$ ,  $p = .7$ ;  $t(39) = 0.54$ ,  $p = .59$ ). Hence, at position 2 RTs for repeated trials increased as shown previously whereas their accuracy rates decreased, indicating no speed-accuracy tradeoff. The RT and the accuracy data constituted convergent evidence towards the occurrence of verbal satiation at Position 2.

In Experiment 2, the main result was that repeated processing of exemplars of a same category increased the RTs differences between repeated trials and baseline trials. We posited that these RTs differences signaled the occurrence of verbal satiation. Verbal satiation occurred roughly at the same trial number than in Experiment 1. Unlike the verbal satiation in Experiment 1, verbal satiation in Experiment 2 was short-lived (limited to trials 13-17) and of higher magnitude (20 ms versus 9 ms). The verbal satiation in Experiment 2 must be purely semantic because the word form of the dominant category name was never shown and the cues in repeated trials had all a different word form. Hence, with Experiment 2, we identified a semantic locus to verbal satiation which could have contributed to the verbal satiation found in Experiment 1.

### Experiment 3

Experiment 3 investigated whether pure orthographic satiation was possible by asking subjects to repeatedly recognize the word form of a category name. According to the three accounts of satiation, Experiment 3 should elicit neither associative satiation nor semantic satiation because there is no need to access repetitively the meaning of the category name. However, repetitive processing of a same word form name should elicit its orthographic satiation as demonstrated in (Cheng & Lan, 2009).

#### Method

Forty-one students (female 20) participated in the experiment. The materials for Experiment 3 were the 11 category names used in Experiment 1. Table 1 illustrates the pairing of trials. The exemplars in Experiment 1 were all replaced by category labels. Hence, within a block, the dominant category label was repeated 20 times as a cue and 20 times as a target. Non-dominant category names served twice as a target. The task became lexical rather than semantic. Subjects had to decide whether the cue and the target were a same word.

#### Results and Discussion

Two participants out of 41 were excluded based on a 90% accuracy criterion. Figure 3 plots the time course of the RTs for the correct Yes responses. Unexpectedly, not only no occurrence of verbal satiation could be observed around the 12-13 trials as in the two previous experiments but it also appeared that repeated RTs were globally equally fast to baseline RTs. We partitioned the 40 trials into three intervals: trials 2-30, trials 31-35 and trials 36-40. The second interval could be the seat of a weak and delayed verbal satiation. We proceeded to a statistical analysis to evaluate this possibility. For Yes responses, a repeated

measures two-way ANOVA on mean correct RT was applied with repetition (2) and position (3) as the two within-subject factors. None of the main effect of repetition, the main effect of position, and the repetition  $\times$  position interaction, ( $F(1, 38) = 0.037$ ,  $p = .85$ ,  $GES < .001$ ;  $F(2, 76) = 0.7$ ,  $p = .47$ ,  $GES = .001$ ,  $F(2, 76) = 2.08$ ,  $p = .14$ ,  $GES = .001$ ) were statistically significant.

Figure 4. Experiment 3. Reaction times as a function of trial number for Yes responses.

The latter result invalidated our hypothesis of occurrence of a verbal satiation elicited by repetitive processing of a repeated word form. None of the paired t-test comparing RTs for repeated and baseline trials for each of the three positions reached statistical significance. Hence in experiment 3, speed of processing for both conditions was equal.

### General Discussion

The present study explored the existence of verbal satiation in Chinese and questioned whether its nature would be semantic. In both Experiments 1 and 2, we found within 40 trials an interval for which RTs for repeated trials became slower than baseline RTs after being equally fast over the first 11 trials in Experiment 1 and after being slightly faster over the first 12 trials in Experiment 2. In Experiment 3, RTs were similar for repeated trials and baseline trials. For Experiments 1 and 2, we ruled out a speed-accuracy trade-off strategy. Instead, we posited that verbal satiation occurred in both experiments and we advanced that its nature is semantic as it can be induced by mere repetitive processing of exemplars of a category without repetition of the word form of the category label. Before defending our viewpoint, we considered a number of alternative explanations.

#### Did subjects strategically generate exemplars impairing semantic retrieval?

If subjects on seeing a cue category name or an exemplar retrieve strategically from semantic memory a few exemplars for further responding, these exemplars could block competing exemplars impeding semantic processing if the target words differ from the expected exemplars.

Repeated RTs for Yes responses will become increasingly slower than baseline RTs because of the repetitive impediment of blocking on the exemplars of a same category in repeated trials. This specific slowing down of repeated trials should happen from the very beginning within a block. However, our results in Experiments 1 and 2 refuted this latter prediction.

### Does inhibition underlie verbal satiation?

Semantic inhibition of return (IOR) (Weger & Inhoff, 2006) refers to an attentional bias towards *semantic novelty* slowing down processing of repeated or semantically related words compared to unrelated and nonrepeated words. Weger and Inhoff (2006) found that for semantic IOR tended to not occur when repeated/related words with large item variability are mixed with a rather heterogeneous pool of nonrepeated/unrelated words. Hence, both of the designs in Experiment 1 and 2 are not propitious to semantic IOR.

### A semantic habituation model of verbal satiation

In Rankin, et al. (2009), ten characteristics of behavioral habituation are listed. We described thereafter the first five characteristics and showed that data in Experiment 2 in the light of data in Experiment 1 matched realistically a semantic habituation model of verbal satiation. The first three characteristics in Rankin, et al. (2009) shaped the usual time course of habituation: sensitization before habituation and dishabituation following habituation. In Experiment 2, the three intervals of the 40 trials in Figure 2 delineated respectively first the sensitization phase with facilitatory semantic priming for repeated trials, then a habituation phase corresponding to the semantic satiation of the unshown dominant category name, and finally a dishabituation phase for which repeated RTs recovered from habituation to return to the level of baseline RTs. The fourth characteristic of habituation (Rankin, et al., 2009) can be stated as: more frequent stimulations can result in more pronounced response decrement (slowing reaction times in our case). We considered that if we count the number of distinct stimuli to the meaning of the dominant category name, it was greater in Experiment 2 than in Experiment 1, simply because in Experiment 2 many exemplars replaced the dominant category name. We thought that the higher number of external stimuli (exemplars) in Experiment 2 could be translated as a higher frequency of external stimulation to the meaning of the category name. Following the fourth characteristic of habituation, a higher magnitude of verbal satiation could be expected in Experiment 2 than in Experiment 1. The fifth characteristic of habituation can be stated as: the weaker the stimulus, the more pronounced is habituation. We considered that in Experiment 2, the exemplars replacing the dominant category name as a cue constituted weaker semantic stimuli to the meaning of the category name than the category name itself. Hence, using weaker stimuli in Experiment 2 than in Experiment 1, we could expect, according to the fifth characteristic, again a higher magnitude of verbal satiation in Experiment 2. The

dynamics of our enduring verbal satiation in Experiment 1 is akin to the long-term semantic satiation obtained in a semantic generation task by Kuhl and Anderson (2011).

## Conclusion

The semantic satiation account of verbal satiation (Smith & Klein, 1990) which stipulates that semantic units became habituated with repetitive access to the meaning of word was newly validated for Chinese multisyllabic words. The time course of semantic satiation follows the classic habituation model (Rankin, et al., 2009): sensitization (semantic priming) before habituation (semantic satiation) and habituation followed by dishabituation (recovery).

Semantic satiation exemplifies that conceptual processing can be habituated as early suggested by Baars (1987). Hence, the cognitive system would respond to both perceptual information redundancy (see the example of stabilized retinal images (Pritchard, Heron & Hebb, 1960)) and meaning redundancy with the same habituation mechanism.

## Abstract

Agents situated in a dynamic environment with an initially unknown causal structure, which, moreover, links certain behavioral choices to rewards, must be able to learn such structure incrementally on the fly. We report an experimental study that characterizes human learning in a controlled dynamic game environment, and describe a computational model that is capable of similar learning. The model learns by building up a representation of the hypothesized causes and effects, including estimates of the strength of each causal interaction. It is driven initially by simple guesses regarding such interactions, inspired by events occurring in close temporal succession. The model maintains its structure dynamically (including omitting or even reversing the current best-guess dependencies, if warranted by new evidence), and estimates the projected probability of possible outcomes by performing inference on the resulting Bayesian network. The model reproduces the human performance in the present dynamical task.

**Keywords:** Temporal learning, causality, structure learning, Dynamic Bayesian graphical model, STDP.

## Introduction

There are many types of cues that an agent can use to learn the causal structure of its interactions with the environment, such as prior knowledge (which constrains the hypothesis space), statistical relations, intervention, and temporal ordering (Lagnado et al., 2007). Among these, temporal ordering is particularly intriguing. First, proximity among cues appears to play a central role in learning structure in time and space (Goldstein et al., 2010). Second, in causal learning, temporal ordering, similarly to intervention, carries with it information regarding the direction of causality, which is crucial for prediction. Finally, putative causal relationships between ordered events that occur in close temporal proximity can be registered by relatively well-understood computational mechanisms akin to those that support synaptic modification in nervous systems.

Both the learning of causal structure (as in model selection) and the modification of its parameters (as in classical schemes such as  $\Delta P$ , *PowerPC*, and Rescorla-Wagner) can be put on a rational basis (Griffiths and Tenenbaum, 2009; Holyoak and Cheng, 2011). Given

the special appeal of temporal proximity as a cue to causal structure and strength, a simple, incremental, heuristic approach to causal learning based on this cue is, however, worth exploring — particularly if such an approach proves effective in dealing with dynamical scenarios where irrelevant variables abound and where the model may need to be modifiable on the fly. In this paper, we describe a dynamical causal Bayesian model that uses temporal proximity among cues to learn its structure and parameters from a continuous stream of observations and action-related rewards in a computer game-related scenario.

## Dynamic causal Bayesian modeling

Consider a dynamic situation described by a set of binary variables  $\mathcal{X} = \{X_1, X_2, \dots, X_n\}$ , whose values occasionally change over time, and where  $X_i = 1$  indicates the presence of some item or feature and  $X_i = 0$  its absence. The causal relationships among the variables in  $\mathcal{X}$ , if any, are initially unknown; each one could be a cause, an effect, or neither. Our approach integrates bottom-up, event-driven learning with top-down revisions as dictated by the model’s self-maintained track record in predicting impending events or the outcomes of actions.

The graph representing the model’s current hypothesis regarding the causal relationships over the members of  $\mathcal{X}$ , which serve as its vertices, has initially no edges. As time progresses, edges are added to the graph according to the temporal order of the observed events and any interventions (the outcomes of model’s own actions). As new edges, corresponding to pairwise hypothesized causal dependencies, are added, the model attempts to integrate the subgraphs they form — “twigs” (Figure 1, left) each consisting of a pair of vertices joined by a directed edge — into a larger (eventually, global) structure.

Note that the twigs are supposed to capture causal “strength,” which we operationalize via a Hebb-like learning mechanism (detailed below), while the final causal model is intended to support probabilistic inference, by being treated as a Bayesian network. The *Union* operation (Figure 2, left), which combines twigs

Figure 1: *Left*: the two possible *Twig* structures for two variables  $X_i$  and  $X_j$ . The weights  $w_i$  represent causal strength. *Right*: a new *Twig* is added to the model if a prior event involving some  $X_i$  is found within a short time window  $\Delta t$  of a triggering event involving  $X_j$ .

Figure 2: *Left*: the *Union* operation. In this example, there are four possible *DCBN* outcomes: causal chains  $U_1$  and  $U_2$ , a common effect structure  $U_3$ , and a common cause structure  $U_4$ . *Right*: for each case where a binary effect is driven by a real-valued “strength” link, the *Union* operation adds a hidden *softmax* node, as illustrated here for  $U_3$  by the frame drawn around  $R_{i,j}$  and  $E$  (Lu et al., 2008).

into a dynamic causal Bayesian network (*DCBN*), mediates between these two aspects of the model by inserting as needed “hidden” variables that convert real-valued strength variables into probability distributions (Figure 2, right).

As the network forms, the model becomes ready for generating predictions (inference). Given the state of observations at time  $t$ , it can be used to predict the most likely value for variables of interest at a later time. During this phase, inference is alternated with learning, with the latter being driven by the model’s monitoring of its own predictions and by comparing those to the observed outcomes. The resulting changes may include the model’s representation of the causal structure of the environment: for instance, the direction of some of the twigs (cause-and-effect subgraphs) may be reversed.

**Structure and strength learning.** We now proceed to describe the operation of the model in some detail, starting with twig learning. Every elementary subgraph, or *Twig* =  $\{C, E, w\}$ , consists of a single cause  $C$ , a single effect  $E$ , and the strength or weight  $w$  of their causal connection. Initially, no connections between variables

exist. Similarly to how humans seem to handle causal cues such as temporal ordering and proximity of notable events (Lagnado et al., 2007), the model only seeks to form a *Twig* when some item or feature appears on the scene (i.e., a variable changes state from 0 to 1). The model then scans the recent past, up to a duration of  $\Delta T$ , for a potential cause of the event at hand, in the form of the change in some other variable’s value. Any variable that is on the record as having changed its value (either from 0 to 1 or from 1 to 0) is labeled as a potential causes for the event, forming a *Twig* (Figure 1).

The weight  $w$  is modified via Hebbian learning, specifically, spike timing dependent plasticity (STDP; Caporale and Dan, 2008). This family of temporally asymmetric Hebbian rules affords quick (exponential) learning, as well as unlearning (in “negative” trials, in which the purported effect precedes the cause):

$$\begin{aligned} \Delta w_+ &= A_+ \exp(-\Delta t / \Delta T) \\ \Delta w_- &= A_- \exp(\Delta t / \Delta T) \\ w(t+1) &= \min(w(t) + \Delta w, w_{max}) \end{aligned} \quad (1)$$

where the  $+$  and  $-$  subscripts denote positive and negative trials ( $E$  following or preceding  $C$ , respectively). We set  $A_+ = 1$  and  $A_- = 0.5$ , thus giving more weight to positive evidence. If some *Twig* elements share a common variable, the model attempts to combine them by applying the *Union* operation, as in  $\text{Twig}(X_i, X_j) \cup \text{Twig}(X_i, X_k) \Rightarrow \text{DCBN}(X_i, X_j, X_k)$  (Figure 2), adding, as needed, hidden variables, as described below.

**Learning the *softmax* parameters.** To integrate a representation of causal strength into a probabilistic (Bayesian) model, we follow Lu et al. (2008) by endowing the model with internal states, or hidden variables:  $R_i$  and  $R_j$  in Figure 2, right. The state of each  $R_i$  is related to that of its parent node  $X_i$  through a Gaussian distribution parameterized by the weight  $w_i$ :

$$P(R_i | w_i, X_i) \propto e^{-(R_i - w_i X_i) / 2\sigma_i^2} \quad (2)$$

The binary effect variable  $E = e_i$ ,  $e_i$  being the  $i$ th discrete value of  $E$ , is driven, in turn, by  $\mathbf{R}$  through a *softmax* function:

$$P(E = e_i | \mathbf{R}) = \frac{\exp(\mathbf{w}(:, i)^T \mathbf{R} + \mathbf{b}(i))}{\sum_j \exp(\mathbf{w}(:, j)^T \mathbf{R} + \mathbf{b}(j))} \quad (3)$$

where  $\mathbf{R}$  is the vector that comprises  $R_i$  and  $R_j$ , and  $\mathbf{w}$  and  $\mathbf{b}$  are parameters that are learned as the model is exposed to data, using an iteratively reweighted least squares (IRLS) algorithm (Green, 1984).

**Inference.** We illustrate the inference process, in which the model is used to generate predictions for some

variable values, given others, on an example with an effect  $E$  that depends on two causes,  $X_{1,2}$  (Figure 2, right). Given the values of  $X_{1,2}$ , inference requires integration over the hidden variables:

$$P(E | w_1, w_2, X_1, X_2) = \int \int P(E | R_1, R_2) \prod_{i=1}^2 P(R_i | w_i, X_i) P(X_i) dR_1 dR_2 \quad (4)$$

Because  $R_i$  are unobserved and continuous and their descendants are discrete, exact inference is impossible (Lerner et al., 2001; Murphy, 1999). As an approximation, we sample each  $R_i$ , conditioned on its parent  $X_i$  and weight  $w_i$ . Specifically, if  $X_i = 1$ , we sample from the Gaussian distribution associated with it (eq. 2); if  $X_i = 0$ , we sample from a zero-mean Gaussian distribution, which is the same for all the variables.

We then discretize the integral, with a step size of 0.1

and lower and upper bounds set to  $L = \min_{X_i}(-4\sigma_i)$  and  $U = \max_{X_i}(w_i X_i + 4\sigma_i)$ , respectively:

$$P(E | w_1, w_2, X_1, X_2) = \sum_{R_1=L}^U \sum_{R_2=L}^U P(E | R_1, R_2) \prod_{i=1}^2 P(R_i | w_i, X_i) P(X_i) \quad (5)$$

When the predicted value of  $E$  yielded by the inference step matches the observed value with a high confidence, the model is not modified. Every time the prediction falters, the model learns; both its structure and its parameters can be modified, as described in Algorithm 1.

## The experiments

To evaluate the model, we tested it in an experiment that involved learning in a dynamically unfolding game situation.<sup>1</sup> For the same experiment, we also collected performance data from human subjects.

Most of the published studies of causal learning to date have been conducted in somewhat artificial behavioral settings. In many studies, the task consists of a series of trials, in each of which the subject is presented with a few stimuli — often just two or three items on a blank screen, along with choices that can be made via a key press (e.g., Steyvers, Tenenbaum, Wagenmakers, and Blum, 2003). More elaborate tasks may involve a contraption that displays a few objects whose behaviors may be causally interlinked (e.g., Kushnir, Gopnik, Lucas, and Schulz, 2010). The narrative context that defines the task for the subjects is often couched in causal language (as in “Can you tell what makes the box go?”). In comparison, in the present study the behavioral task involved an arguably more natural situation: playing a computer game, which unfolds in real time, and requires that the subject drive down a track surrounded by various objects, while attempting to accumulate rewards.

The experimental platform we used is an adaptation of a car-racing computer game.<sup>2</sup> The virtual environment through which the subject is driving consists of tracks surrounded by scenes whose composition is controlled. It is flexible enough to support various types of cues to causal structure, including interventions (Lagnado et al., 2007). Moreover, because the game can be played against another subject or against a computer program, it affords the study of social effects in learning (Goldstein et al., 2010).<sup>3</sup>

---

<sup>1</sup>In a separate study, we used the model to replicate successfully some of the standard effects in causal learning, such as forward and backward blocking (Holyoak and Cheng, 2011).

<sup>2</sup><http://supertuxkart.sourceforge.net/> (public domain). We modified the game to support Wiimote and to incorporate our tracks, scenes, and reporting. The modified code is available upon request.

<sup>3</sup>Note that instructions that the subject receives from the experimenter may be considered a kind of social cue.

Figure 3: A typical game scene, as presented to the subjects as part of the instructions for the experiment.

scene type	<i>crate</i>	<i>dog</i>	<i>cat</i>	<i>fox</i>	box contents
1	1	[0]	1	0	$[plunger]_{t+}$
2	1	[1]	1	0	$[cake]_{t+}$
3	1	[0]	1	1	$[plunger]_{t+}$
4	1	[1]	1	1	$[cake]_{t+}$
5	0	0	1	0	$[plunger]_{t+}$
6	0	1	1	0	$[cake]_{t+}$

Table 1: The six scene types in the experiment, with the presence or absence of various objects indicated by 1/0. When *crate* is present, *dog* is hidden inside it (bracketed,  $[\cdot]$ ). The contents of the surprise box (*cake* or *plunger*) become visible only if the subject actively “takes” it (signified by  $[\cdot]_{t+}$ ). Note that *dog* perfectly predicts  $[cake]_{t+}$ , but subjects who miss the significance of *crate* will be unable to distinguish between scenes 1 and 2, or 3 and 4.

## The behavioral experiment

Given the novelty and the potential difficulty of the dynamical learning scenario, in this study we opted for a maximally simple dependency to be learned: a single causal link between two variables. Each scene in the experiment could include any or all of the following objects: a dog, a cat, a fox, and a crate (Figure 3). In addition, in each scene there was a “surprise” box which, if the subject chose to “take” it, revealed the reward: a cake or a plunger, depending on the appearance of other objects in the scene. The subjects were instructed to collect as many cakes as possible, while refraining from taking plungers. Altogether, each subject encountered 252 scenes: 6 different racetracks  $\times$  3 laps  $\times$  14 scenes drawn at random for each track from among the scene types listed in Table 1.

The subjects’ task is best *seen*<sup>4</sup> as learning a directed

<sup>4</sup>The question of what the relationship between *dog* and *cake* in this simple scenario really *is*, causal or associative, is best avoided, given the philosophical issues surrounding causality (Schaffer, 2009). Somewhat paradoxically, the distinction is easier for more complex networks of dependencies

or causal (rather than an undirected or merely associative) relationship, for two reasons: the asymmetry in the temporal structure of each scene encounter and in the functional significance of its components. First, the reward never co-occurred with any of the other variables: rather, it always followed them temporally, and then only if the subject actively intervened by opening the surprise box. Second, it made no sense for the subjects to hypothesize symmetrical functional roles for the reward and for the other variables, given that their goal was formulated exclusively in terms of the reward. In any case, no causal language was used in the instructions given to subjects, which makes the present experimental set up arguably more natural as a platform for exploring simple learning in the wild than those that explicitly require the subjects to seek causal explanations for behavioral outcomes.

Eighteen subjects, recruited online from the Cornell University subject pool, participated in the study for course credit. The dependent variable, Correct, was defined as equal to 1 in trials where the subject opened a box with *cake* or refrained from opening a box with *plunger*. A mixed model analysis using the *lmer* package (Bates, 2005), with a binomial linking function, and with Subject, Track, and Scene as random factors, yielded a significant effect of Lap on Correct ( $z = 7.53$ ,  $p = 5.1 \times 10^{-14}$ ). Averaged over tracks, the subjects’ Correct rate reached 0.61 in the third lap. The far from perfect performance is understandable, given that the inconsequential parts of the game environment (such as a stable with horses, bales of hay, etc.), as well as of the surprise-box scenes themselves, made it difficult for subjects to home in on the truly predictive variable (*dog*). Moreover, in scene types 1 through 4, the dog appears inside a crate and is thus not visible, unless the subject drives through the crate (something that few subjects ventured to do).

The evolution of subjects’ performance over time is illustrated for each scene type in Figure 4, right. Debriefing indicated that subjects generally assumed correctly that the contents of the surprise box could be anticipated by noting which of the other objects were present in the scene. Many of the subjects did not, however, allow for the possibility that a cause may be hidden, which prompted them to invent incorrect explanations for the difference between scene types (1,2) and (3,4). Some subjects also tried to find patterns in the irrelevant variables such as the distances among objects, the curving of the track, and the location of the box with respect to other items.

## Modeling results

We simulated the behavioral experiment by feeding the model incrementally the same sequence of observations among variables, such as those explored by Blaisdell et al. (2006).

Figure 4: *Left*: the performance of the algorithm on ground-truth data, for each of the six scene types. *Right*: the performance of 18 runs of the algorithm (filled circles) and of the 18 subjects subjects in a real run (means with 95% confidence intervals). The ups and downs in the algorithm’s performance over time are due to its sensitivity to the order of scene appearance (batch algorithms do not exhibit this behavior).

encountered by the human subjects, namely, the values of the four variables listed in Table 1, plus, in the cases where the model decided to open the surprise box, the value of reward. In the first lap (14 scenes; the “initial learning” phase in Algorithm 1), the model was set to open every box. Subsequently, if the model’s decision whether or not to open the box could be made with 95% confidence,<sup>5</sup> it chose the recommended action; otherwise it flipped a coin. If the decision was to open the box, the model used the outcome to adjust its parameters; if not, it simulated an outcome by adding to the predicted value of the reward a random number (distributed uniformly

<sup>5</sup>As decided by a binomial test with a confidence interval of  $\hat{p} \pm z_{1-\alpha/2} \sqrt{\hat{p}(1-\hat{p})/n}$ , where  $\hat{p}$  is the sample proportion of successes in the observed sequence of trials and  $z_{1-\alpha/2}$  is the  $1-\alpha/2$  percentile of a standard normal distribution, with  $\alpha$  being the error percentile and  $n$  the sample size. For a 95% confidence level,  $\alpha = 5\%$  and  $z_{1-\alpha/2} = 1.96$ .

in  $[0, 1]$ ) and used that outcome to learn.<sup>6</sup>

As can be seen in Figure 4, left, when fed ground-truth data, the model learned quickly and reliably.<sup>7</sup> More to the point, when presented with the real sequence of observations, it generally behaved similarly to human subjects (Figure 4, right), reaching a comparable level of performance: 0.66 accuracy in the third lap. As with the human subjects, the effect of Lap was significant ( $z = 2.56$ ,  $p = 0.01$ ). In Figure 4, right, in those cases where the dog was hidden from view (scene types 1 through 4; see Table 1), the human subjects performed poorly, and the algorithm too converged to a chance-level performance.

## Conclusions

Similarly to some other recent studies and models of causal learning (Lu et al., 2008; Lagnado and Speekenbrink, 2010; Bonawitz et al., 2011), the present work focuses on sequential learning and inference. There are also important differences. First, our behavioral setup uses a dynamic video game that subjects readily relate to. Second, the model we develop is rooted in some basic intuitions regarding how animals learn the causal structure of dynamic situation: (1) the importance of close temporal succession of events and outcomes, (2) the utility of neural-like mechanisms that may register it, and (3) a heuristic approach to bootstrapping causal learning from very simple pairwise dependencies gleaned from the data. In those respects, the algorithm we offer is a special-purpose model rather than a general learner.

To ascertain that subjects in our game scenario engage in causal learning and inference, rather than in memorization of contextual cues they believe to be associated with particular outcomes, future experiments will need to include explicit intervention-based tests (cf. Blaisdell, Sawa, Leising, and Waldmann, 2006), including having the subjects manipulate the variables of their choice to test any hypotheses that they may have formed. It would also be interesting to analyze the evolution over time of the subjects’ choices in opening or avoiding reward boxes: early in the experiment, it is rational to open boxes, so as to gather data; as the subjects develop an ability to predict the reward, they should become more choosy. This sequential behavior can then be compared to that of the model (Bonawitz et al., 2011).

The model itself can be improved and extended in several ways. For instance, as it is tested on learning

<sup>6</sup>Without some such mechanism, the model would have no way of recovering from a string of “don’t open” decisions — a problem that is peculiar to models that intersperse learning with inference.

<sup>7</sup>In comparison, a straightforward model selection approach based on maximum likelihood or AIC/BIC optimization, implemented with the Bayes Network Toolbox for Matlab (Murphy, 2001), trained incrementally on the ground truth data, did not converge to the right causal graph for this experiment.

tasks that involve more complex causal structure than that in the present study, it may be necessary to include methods for detecting and “defusing” loops that would otherwise complicate inference. Furthermore, the model can be made to incorporate additional cues to causal structure, in particular, interventions (Steyvers et al., 2003), global contextual cues, and factors such as eligibility traces (Izhikevich, 2007) that would allow it to learn from such cues across multiple time scales. Finally, if equipped with a vision front end and real-valued outputs, a model rooted in the present approach may employ reinforcement learning (Fox et al., 2008; Hosoya, 2009) to master driving around the track and competing directly with a human participant.

## Abstract

There is a long tradition in both philosophy and psychology to separate process accounts from dependency accounts of causation. In this paper, we motivate a unifying account that explains people's causal attributions in terms of counterfactuals defined over probabilistic generative models. In our experiments, participants see two billiard balls colliding and indicate to what extent ball A caused/prevented ball B to go through a gate. Our model predicts that people arrive at their causal judgments by comparing what actually happened with what they think would have happened, had the collision between A and B not taken place. Participants' judgments about what would have happened are highly correlated with a noisy model of Newtonian physics. Using those counterfactual judgments, we can predict participants' cause and prevention judgments very accurately ( $r = .99$ ). Our framework also allows us to capture intrinsically counterfactual judgments such as *almost* caused/prevented.

**Keywords:** causality; counterfactuals; attribution; physics.

## Introduction

There has been a longstanding divide in philosophy between two fundamentally different ways of conceptualizing causality. According to *dependency accounts* of causation, what it means for A to be a cause of B is that B is in some way dependent on A. Dependence has been conceptualized in terms of regularity of succession (A is regularly succeeded by B; Hume, 2000 [1748]), probabilities (the presence of A increases the probability of B; Suppes, 1970) or counterfactuals (if A had not been present B would not have occurred; Lewis, 1970). For *process accounts*, in contrast, what it means for A to be a cause of B is that a physical quantity is transmitted along a pathway from A to B (Dowe, 2000).

The psychological literature on causal learning and attribution neatly maps onto the two major accounts in philosophy. On the one hand, people have been shown to use contingency information when drawing inferences about whether and how strongly two events are causally linked (Cheng, 1997). On the other hand, people display a preference to choose causes that influence an effect via a continuous causal mechanism over causes that are connected with the effect through mere dependence (Walsh & Sloman, 2011).

A point that has been raised in favor of process accounts is that they are capable of capturing the semantics of different causal terms. Whereas dependency accounts have mostly focussed on causation and prevention, Wolff (2007) has provided a process account that not only predicts when people use the terms *cause* and *prevent* but also *enable* and *despite*. Following a linguistic analysis of causation by Talmy (1988) in terms of force dynamics, Wolff (2007) argues that the aforementioned causal terms can be reduced to configurations of force vectors. For example, what it means for a patient (P) to

have been caused by an affector (A) to reach an endstate (E) is that P did not have a tendency towards E, A impacted on P in a way that their force vectors were not pointing in the same direction and P reached E. If, in contrast, the force vectors of both P and A point towards E and P reaches E, the model predicts that people will say "A enabled (rather than caused) P". Importantly, according to Wolff's account, the core dimensions which underlie the different causal terms, such as P's tendency towards E, are defined in strictly non-counterfactual terms. Hence, "tendency" is defined as the direction of P's force rather than whether P would reach E in the absence of any other forces.

While the force dynamics model has strong intuitive appeal for interactions between physical entities, it is questionable how it can be extended to capture causal attributions in situations involving more abstract entities. For example, one might legitimately assert that the fall of Lehman Brothers caused the financial crisis or that Tom's belief that he forgot his keys caused him to turn around and go back home. While it is unclear how these causal relationships could be expressed in terms of force vectors, they do not pose a problem for the more flexible dependency accounts. For example, according to a counterfactual account, Tom's belief qualifies as cause of his behaviour if it is true that his behavior would have been different had the content of his belief been different. Hence, there appears to be a trade-off between the semantic richness of process accounts on the one hand and the generality and flexibility of dependency accounts on the other hand.

Rather than fostering the divide between process accounts and dependency accounts, we propose a theory of causal attribution that combines the best of both worlds. In the spirit of Pearl (2000), we model causal attributions in terms of counterfactuals defined over probabilistic generative models. However, we agree with Wolff (2007) that people's causal knowledge is often richer than what can be expressed with a causal Bayes net. We aim to unify process and dependency accounts by showing that people have intuitive theories in the form of detailed generative models, and that causal judgements are made by considering counterfactuals over these intuitive theories. Here we demonstrate the superiority of our approach over existing models of causal attribution in a physical domain. We show that people use their intuitive understanding of physics to simulate possible future outcomes and that their causal attributions are a function of what actually happened and their belief about what would have happened had the cause not been present.

## Overview of Experiments and Model Predictions

Before discussing the predictions of our model and the supporting evidence from four experiments, we describe the domain to which we applied our model. In all experiments, participants saw the same 18 video clips which were generated by implementing the physics engine Box2D into Adobe Flash CS5. Figure 1 depicts a selection of the clips.<sup>1</sup> In each clip, there was a single collision event between a grey ball (A) and a red ball (B) which enter the scene from the right. Collisions were elastic and there was no friction. The black bars are solid walls and the red bar on the left is a gate that balls can go through. In some clips B went through the gate (e.g. clip 18) while in others it did not (e.g. clip 5). In the 18 video clips, we crossed whether ball B went through the gate given that it collided with ball A (rows in Figure 1: actual miss/close/hit) with whether B would go through the gate if A was not present in the scene (columns in Figure 1: counterfactual miss/close/hit). Participants viewed two clips for each combination of actual and counterfactual outcome.

In Experiments 1 and 2, the video clips stopped shortly after the collision event. Participants judged whether ball B will go through the gate (Experiment 1) or whether ball B would go through the gate if ball A was not present in the scene (Experiment 2). In Experiment 3, participants saw each clip played until the end and then judged to what extent ball A caused ball B to go through the gate or prevented B from going through the gate. Finally, in Experiment 4 participants chose from a set of sentences which best describes the clip they have just seen. All experiments were run online and participants were recruited via Amazon Mechanical Turk.

In order to model people’s predictions of actual and counterfactual future outcomes, we developed the Physics Simulation Model (PSM) which assumes that people make use of their intuitive understanding of physics to simulate what will or what might have happened. Hamrick, Battaglia, and Tenenbaum (2011) have shown that people’s stability judgments about towers of blocks is closely in line with a noisy model of Newtonian physics. While in their model, the introduced noise captures people’s uncertainty about the exact location of each block, the noise in our model captures the fact that people cannot perfectly predict the trajectory of a moving ball (cf. Figure 1, clip 1). We introduce noise via drawing different degrees of angular perturbation from a Gaussian distribution with  $M = 0$  and  $SD = \{1, 2, \dots, 10\}$  which is then applied to B’s actual velocity vector (given that it collided with A, clip 1 bottom left) or B’s counterfactual velocity vector (given that A was not present in the scene, clip 1 top left) at the time of collision.

We evaluate the probability that B would go through the gate when A was present,  $P(B|A)$ , or absent  $P(B|\neg A)$  by forward sampling from our noisy versions of Newtonian physics.

<sup>1</sup>All clips can be viewed here: <http://www.ucl.ac.uk/lagnado-lab/experiments/demos/physicsdemo.html>

Figure 1: Selection of clips used in the experiment. Solid arrows = actual paths, dashed arrows = counterfactual paths. Clip 1 depicts an illustration of the Physics Simulation Model and clip 7 of the Actual Force Model. *Note:* actual miss = B clearly misses; actual close = B just misses/hits; actual hit = B clearly hits; counterfactual miss = B would have clearly missed; counterfactual close = B would have just missed/hit; counterfactual hit = B would have clearly hit.

For each clip and degree of noise ( $SD$ ), we ran 1000 noisy repetitions of the original clip and counted the worlds in which B goes through the gate given that A was present  $P(B|A)$  or absent  $P(B|\neg A)$ .

## Experiments 1 & 2: Intuitive Physics

The aim of Experiments 1 and 2 was to evaluate how well people make use of their intuitive physical knowledge to predict actual (Experiment 1) or counterfactual (Experiment 2) future states. Participants saw 18 video clips (see Figure 1 for some examples) up to the point shortly after the two balls collided (0.1s). After having seen the clip twice, participants answered the question: “Will the red ball go through the hole?” (Experiment 1,  $N = 21$ ) or “Would the red ball have gone through the goal if the gray ball had not been present?” (Experiment 2,  $N = 20$ ). Participants indicated their answers on a slider that ranged from 0 (“definitely no”) to 100 (“definitely yes”). The midpoint was labeled “uncertain”. After having made their judgment, participants viewed the clip until the end either with both balls being present (Experiment 1) or with ball A being removed from the scene (Experiment 2).

## Results and Discussion

Participants were accurate in judging whether ball B will go through the gate (Experiment 1) or would have gone through the gate (Experiment 2) with a mean absolute difference from the deterministic physics model (which assigns a value of 100 if B goes in and 0 if B does not go in) of 28.6 ( $SD = 29.9$ ) in Experiment 1 and 25.1 ( $SD = 30.5$ ) in Experiment 2. Figure 2 shows the correlation of the PSM with participants’ judgments in Experiment 1 (solid black line) and Experiment 2 (dashed black line) for different degrees of noise. While people’s judgments already correlate quite well with a deterministic Newtonian

Figure 2: Correlation of the Physics Simulation Model with people's judgments in all four experiments for different degrees of noise.

nian physics model (degree of noise = 0°), introducing small degrees of noise results in much higher correlations with a maximum correlation of  $r = .95$  in Experiment 1 and  $r = .98$  in Experiment 2 for  $SD = 5^\circ$ .

The results of Experiments 1 and 2 show that people are capable of mentally simulating what will happen (Experiment 1) or what would have happened (Experiment 2). Given that each clip stopped very shortly after the collision event, participants' accuracy in judging whether ball B will go in or not is quite impressive.

### Experiment 3: Causation and Prevention

In Experiment 3, we wanted to investigate how people use their intuitive understanding of physics to make judgments about the extent to which one event caused or prevented another event from happening. Unlike in Experiments 1 and 2, participants ( $N = 22$ ) saw each clip played until the end. After having seen each clip twice, participants answered the question "What role did ball A play?" by moving a slider whose endpoints were labeled with "it prevented B from going through the hole" and "it caused B to go through the hole". The midpoint was labeled "neither". The slider ranged from -100 (prevented) to 100 (caused). Participants were instructed that they could use intermediate values on the slider to indicate that ball A somewhat caused or prevented B.

### Model Predictions

**Physics Simulation Model** According to the PSM, people arrive at their cause and prevention judgments by comparing what actually happened with what they think would have happened if the cause event had not taken place. More specifically, our model predicts that people compare  $P(B|A)$ , the probability that ball B will go through the gate given that it collided with ball A, with  $P(B|\neg A)$ , the probability that B would have gone through the gate if A had not been present in the scene. Since participants in Experiment 3 watch the clips until the end, the value of  $P(B|A)$  is certain: it is either 1 when B goes through the gate or 0 when B misses the gate.

In order to determine  $P(B|\neg A)$ , the PSM assumes that people use their confidence in the result of their mental simulation of what would have happened had A not been present.

In general, if  $P(B|A) - P(B|\neg A)$  is negative, participants should say that A prevented B from going through the gate. Intuitively, if it was obvious that B would have gone in had A not been present (i.e.  $P(B|\neg A)$  is high) but B misses the gate as a result of colliding with A (i.e.  $P(B|A) = 0$ ), A should be judged to have prevented B from going through the gate. Similarly, if the difference is positive, participants should say that A caused B to go through the gate. If the chance that B would have gone through the goal without A was low but, as a result of colliding with A, B goes through the gate, A should be judged to have caused B to go through the gate. Clip 1 in Figure 1 shows an example for which our model predicts that participants will say that A neither caused nor prevented B.  $P(B|A)$  is 0 since B does not go through the gate. However,  $P(B|\neg A)$  is also close to 0 since it is clear that B would have missed the gate even if A had not been present in the scene.

**Actual Force Model** The Actual Force Model (AFM) is our best attempt to apply Wolff's (2007) force dynamics model to our task.<sup>2</sup> According to the AFM, participants' cause and prevention judgments are a direct result of the physical forces which are present at the time of collision.

Clip 7 in Figure 1 illustrates how the AFM works. First, a goal vector (dotted arrow) is drawn from ball B's location at the time of collision to an end state (E), which we defined to be in the center of the gate. Second, the angle  $\alpha$  between the velocity vector that ball B has shortly *after* the collision with A (solid arrow) and the goal vector as well as the angle  $\beta$  between the velocity vector that ball B has shortly *before* colliding with A (dashed arrow) are determined. Third, the model predicts people's cause and prevention judgments via comparison of  $\alpha$  and  $\beta$ . In general, if ball B goes in and  $\beta - \alpha$  is greater than 0, the model predicts people will say that A caused B. Conversely, if ball B does not go in and  $\beta - \alpha$  is smaller than 0, the model predicts people will say A prevented B. For situations in which  $\beta - \alpha$  is greater than 0 but B does not go in or  $\beta - \alpha$  is smaller than 0 but B does go in, we fix the model prediction to 0. This constraint prevents the model from predicting, for example, that people will say "A caused B" when B missed the gate.

### Results and Discussion

Figure 3 shows participants' mean cause and prevention judgments for the 18 different clips together with the predictions of the PSM and the AFM. For the particular implementation of the PSM depicted in Figure 3, we directly used participants' judgments from Experiment 2 in which they indicated whether ball B would have gone through the gate if ball A had not been present as the values for  $P(B|\neg A)$ . For example, in clip 5 the ball misses the gate (hence  $P(B|A) = 0$ ) and

<sup>2</sup>While the force dynamics model only makes predictions about which out of several sentences participants will choose to describe a situation, the AFM makes quantitative predictions about the extent to which an event is seen as causal/preventive.

Figure 3: Z-scored mean cause (green) and prevention ratings (red) for the different clips denoted on the x-axes.  $\circ$  = predictions of the Physics Simulation Model ( $r = .99$ ),  $\diamond$  = predictions of the Actual Force Model ( $r = .77$ ). Error bars are  $\pm 1$  SEM.

participants' average confidence rating from Experiment 2 of whether B would have gone through in the absence of A is 97% (hence  $P(B|\neg A) = .97$ ). Thus the PSM predicts that participants will indicate that A strongly prevented B in this clip, because  $P(B|A) - P(B|\neg A)$  is close to the minimum of -1.

Overall, the PSM predicts participants' cause and prevention ratings very well with  $r = .99$  and  $RMSE = 0.02$ . A high median correlation across participants of  $r = .88$  with a minimum of  $r = .61$  and a maximum of  $r = .95$  demonstrates that the good performance of the PSM is not due to a mere aggregation effect. The PSM achieves its high predictive accuracy without the need for any free parameters. We directly used participants' judgments from Experiment 2 to determine the value of  $P(B|\neg A)$  for each clip. Figure 2 shows that participants' judgments also correlate highly with the PSM when we generate  $P(B|\neg A)$  through the noisy simulations of Newtonian physics as described above.

The AFM, in contrast, does not predict participants' judgments equally well with a correlation of  $r = .77$  and  $RMSE = 0.44$ . While the AFM predicts people's judgments for many of the clips, there are a number of clips for which its predictions are inaccurate (most notably: clips 2, 5, 9, 11 and 14).

Interestingly, people's cause and prevention judgments were not affected by the closeness of the actual outcome. That is, participants' cause ratings did not differ between situations in which B just went through the gate (clips 8, 10, 12:  $M = .51$ ,  $SD = .40$ ) compared to situations in which B clearly went through (clips 13 - 18:  $M = .49$ ,  $SD = .42$ ). Similarly, prevention judgments were not different between situations in which B just missed (clips 7, 9, 11:  $M = -.41$ ,  $SD = .43$ ) and situations in which B clearly missed (clips 1-6:  $M = -.47$ ,  $SD = .44$ ).

People's cause and prevention judgments were very well predicted by the PSM. In order to judge whether ball A caused or prevented ball B, participants appear to compare what actually happened with what they think would have happened had A not been present. This very high correlation is achieved

without the need for any free parameters in the model.  $P(B|A)$  is determined by the outcome of the clip and  $P(B|\neg A)$  by participants' judgments in Experiment 2. The PSM also correlates highly with participants' causal attributions when  $P(B|\neg A)$  is treated as a free parameter and estimated via the noisy Newtonian physics model with a maximum correlation of  $r = .99$  (cf. Figure 2).

The AFM which assumes that people arrive at their judgments via comparing instantaneous force vectors, rather than a mental simulation of the full physical dynamics cannot capture people's judgments equally well. Clip 14 (see Figure 1) gives an example in which the AFM gets it wrong. While participants indicate that A caused B to go through the gate (see Figure 3), the AFM model cannot predict this. In this situation, the angle between the velocity vector of B shortly after the collision and the goal vector  $\alpha$  is greater than the angle between the velocity vector of B shortly before the collision and the goal vector  $\beta$ . Hence, the model predicts that A is preventing B but since B does in fact go in, the model's prediction is fixed to 0. In defense of the AFM, it could be argued that clip 14 is better thought of as a causal chain in which A causes B to hit the wall which then causes B to go in. Whether participants would count the static wall as a cause of B going through the gate is an empirical question. In any case, the other problematic clips mentioned above remain. Each of these clips only involves a single interaction.

## Experiment 4: Almost Caused/Prevented

The results of Experiment 3 show that people's cause and prevention judgments are only influenced by their degree of belief about whether the event of interest would have happened without the cause being present and not influenced by how close the outcome actually was. However, often the closeness with which something happened clearly matters to us, such as when we almost missed a flight to Japan or only just made it in time for our talk.

As mentioned above, one of the appeals of process accounts is that they acknowledge the semantic richness of the concept of causation by making predictions about which out of several causal verbs people will choose to describe a particular situation. In this experiment, we will demonstrate that our framework is not only capable of capturing the difference between different causal verbs such as *caused* or *helped* but also predicts when people make use of intrinsically counterfactual concepts such as *almost caused* or *almost prevented*. Current process accounts (e.g. Wolff, 2007) cannot make predictions in these situations as they aim to analyze causality without making reference to counterfactuals.

In Experiment 4, participants ( $N = 41$ ) had to select from a set of seven sentences the one that describes the situation best. The sentences were: A caused / helped / almost caused B to go in the hole; A prevented / helped to prevent / almost prevented B from going in the hole; A had no significant effect on whether B went in the hole or not.

Table 1: Predicted probability of choosing different sentences in Experiment 4.

	outcome	probability
(1) caused	hit	$1 - P(B \neg A)$
(2) helped	hit	$1 - \text{abs}(0.5 - \text{caused})^*$
(3) almost caused	miss	$p(\text{almost } B A) - \text{prevented}$
(4) prevented	miss	$p(B \neg A)$
(5) helped to prevent	miss	$1 - \text{abs}(0.5 - \text{prevented})^*$
(6) almost prevented	hit	$p(\text{almost } \neg B A) - \text{caused}$
(7) no effect	hit/miss	$1 - \max((1), \dots, (6))$

\*rescaled to range from 0 to 1

## Model Predictions

Table 1 gives an overview of the model predictions which are a function of the outcome, that is, whether B went in or not, and the probabilities  $P(B|\neg A)$ ,  $P(\text{almost } B|A)$  and  $P(\text{almost } \neg B|A)$ . For  $P(B|\neg A)$  we can again use participants' judgments from Experiment 2 or the predictions of the PSM.

The model's predictions for *caused* and *prevented* are identical to the predictions in Experiment 3. According to our model, the difference between *caused* and *helped* is an epistemic one. People are predicted to select *helped* when B went in and when they were uncertain about what would have happened had A not been present. However, when it was clear that B would have gone in or would have missed, people are predicted to select *no effect* or *caused*, respectively, and not *helped*. Similarly, when B missed and it was uncertain whether B would have gone in, the model predicts that people select *helped to prevent*.

In order to predict when people select *almost caused* or *almost prevented*, we first have to define the probabilities  $P(\text{almost } B|A)$  and  $P(\text{almost } \neg B|A)$ . These probabilities express the closeness of an alternative counterfactual outcome to the actual outcome. One way to get at the probabilities would be to have participants judge how closely B hit or missed the gate. However, here we used a variation of the PSM to generate these probabilities. For each clip we ran a set of  $100 \times 10$  noisy simulations for different noise levels from  $SD = 1^\circ$  to  $5^\circ$ , whereby the noise was again introduced at the time of collision. If the outcome in the noisy simulations was different from the original outcome in *any* of the ten repetitions in each of the 100 simulated worlds, we counted this as a positive instance. If the outcome in all ten repetitions was the same as the original outcome, we counted this as a negative instance. For example, a value of  $P(\text{almost } \neg B|A) = .87$  in a situation in which B goes through the gate in the original clip, means that in 87 out of the 100 generated worlds, the ball did not go through the gate in at least one of the ten repetitions of each of the worlds. For the remaining 13 worlds, the ball did go in for all ten repetitions. Intuitively, in situations in which the outcome was close, the chances that the outcome in the noisy simulation will be different from the outcome in the original clip in at least one out of ten repetitions are high. However, if ball B clearly missed, for example, it is unlikely

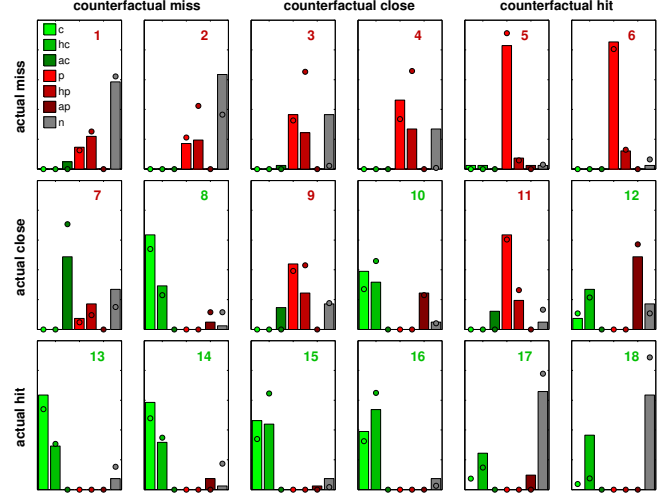

Figure 4: Frequencies with which different sentences were selected in Experiment 4 (bars) and predictions by the Physics Simulation Model (circles),  $r = .86$ . The color of the clip number indicates whether the ball went in (green) or not (red). Note: c = caused, hc = helped (to cause), ac = almost caused, p = prevented, hp = helped to prevent, ap = almost prevented, n = no significant effect.

that there will be a noisy simulation in which the introduced angular perturbation is sufficient to make B go in.

The model predicts that people will select *almost caused* when B just missed (which means that  $P(\text{almost } B|A)$  is high) and the probability that it would have gone in given that A was absent is low. People should select *almost prevented* when B just went in ( $P(\text{almost } \neg B|A)$  is high), and when it was clear that B would have gone in had A been absent ( $P(B|\neg A)$  is high). Finally, if none of these calculations result in a high value, people are predicted to select that A had *no significant effect* on whether B went through the gate.

The model predictions for the 18 different clips can be seen in Figure 4. We used Luce's (1959) choice rule to transform the different probabilities into predictions about the frequencies with which the different sentences will be selected. The model predicts that the modal choice in situations in which B does not go in changes from *prevented* for clips in which it was clear that B would have gone in (clips 5 & 6) to *helped to prevent* in situations in which it was unclear whether B would have gone in (clips 3 & 4). The same switch of the modal response as a function about the certainty of what would have happened is predicted for *caused* (clips 13 & 14) and *helped* (clips 15 & 16). If there was little uncertainty about the counterfactual outcome and it matches the actual outcome, people are predicted to select *had no effect* (clips 1, 2, 17, 18). For clip 7 in which B just misses, people are predicted to select *almost caused* since it was clear that B would have missed but for A. Conversely, for clip 12, the model predicts that people will select *almost prevented*: B just goes in and it was clear that it would have gone in without A being present.

## Results and Discussion

The model predicts the frequencies with which participants select the different sentences very well,  $r = .86$  (cf. Figure 4). Figure 2 shows the correlation when we generate  $P(B|\neg A)$

through noisily perturbing the vector rather than taking participants' ratings from Experiment 2. It predicts the modal choice correctly in 12 out of 18 clips. While participants' modal response does not change between clips 5 & 6 and clips 3 & 4 as predicted by the model, the proportion of *helped to prevent* selections clearly increases. A similar shift is observed between clips 13 & 14 and 15 & 16 for which participants' selection of *helped* increases as a function of the uncertainty over what would have happened.

As predicted by the model, participants' modal response in clip 7 is *almost caused* and in clip 12 *almost prevented*. The variance in responses within a clip is greater for the clips in which the actual outcome was close (middle row) compared to when it clearly missed (top row) or clearly hit (bottom row). For example, in clip 10 in which B just goes in and the counterfactual outcome is close the majority of participants selected *caused* or *helped* while a minority of participants selected *almost prevented*. This pattern closely matches the predictions of our model. Whether a participant is expected to select *caused* or *almost prevented* depends on the participant's subjective belief about the counterfactual outcome. If a participant thought that B would have missed she will say A *caused* or *helped* it. However, if a participant thought that B would have gone in but for A he will select *almost prevented* because B barely goes in.

The close fit between our model prediction and participants' selection of sentences demonstrates that our model is capable of capturing some of the richness of people's causal vocabulary. Our model not only allows to distinguish cases of *causing/preventing* from *helping* but also accurately predicts people's *almost caused/prevented* judgments. Process theories that analyze different causal concepts without the use of counterfactuals (e.g. Wolff, 2007) cannot make predictions about when people will say that something almost happened.

## General Discussion

In this paper, we developed a framework for understanding causal attributions that aims to break the longstanding dichotomy between process accounts and dependency accounts of causation. We showed that people's quantitative cause and prevention judgments (Experiment 3) as well as people's use of different causal verbs (Experiment 4) can be very well predicted by assuming that people compare what actually happened when the cause was present, with what they think would have happened in the absence of the cause. We provided evidence that people use their intuitive understanding of physics to simulate possible outcomes (Experiments 1 & 2). Understanding causal attributions in terms of counterfactuals defined over probabilistic generative models sidesteps the presumed trade-off between flexibility and richness described above. Our model retains the generality of dependency accounts while the use of a generative model based on Newtonian physics allows us to capture some of the richness of people's concept of causation.

According to our account, causal attributions are subjective

and model-dependent. Two observers with a different understanding of the underlying generative model are predicted to reach different causal verdicts for the same clip when their beliefs about what would have happened in the absence of the cause event differ. The noisy Newtonian physics model predicted participants' judgments well in our experiments. However, we are not committed to this particular generative model – indeed, our account predicts that the ways in which people's intuitive understanding of physics is biased will be mirrored in their causal attributions.

While our framework shares some of the key insights of Wolff's (2007) force dynamic account, such as the need for a richer specification of people's causal representations, our proposals are different in critical respects. Most importantly, our accounts differ in the role that counterfactuals play. Wolff (2007) aims to reduce causal attributions to configurations of force vectors and argues that these force representations (which are primary) can then be used for the simulation of counterfactual outcomes (which are secondary). Our account, in contrast, does not try to explain causal attributions in terms of non-causal representations but postulates that causal attributions are intimately linked with the simulation of counterfactuals. Hence, we claim that in order to say whether A caused B, it is necessary to consider what would have happened to B in the absence of A and not sufficient to only consider what forces were present at the time of interaction between A and B.

In future experiments, we will investigate how our account can handle more complex physical interactions and interactions between intentional agents.

## Abstract

Analogical reasoning is commonly recognized as essential to human cognition, but young children often perform poorly in the classical A:B::C:? analogical reasoning task. Previous eye-tracking results have shown that children did not visually explore the A:B pair as much as adults in this task. We hypothesized that this lack of exploration could help account for the low scores of children in comparison to adults. The present study shows that children's performance improves significantly if they are required to look at and process the A:B pair before they are shown the full A:B::C:? problem. This confirms our hypothesis that the A:B pair is insufficiently processed by children during the resolution of such problems.

**Keywords:** Analogical reasoning; development; executive functions; cognition.

## Introduction

Analogical reasoning is a central feature of human cognition (Gentner & Holyoak, 1997; Hofstadter, 2001). It is defined as the transfer of a structured set of relations from a source domain to a target domain from which it is more or less distant. A most classical example is the A:B::C:D analogy (e.g., dog:doghouse::bird: ? solution "Nest", in which the "lives in" relation must be abstracted). In other analogy problems, a solution to a source problem can be used to solve a target problem (e.g. Holyoak et al. 1984).

Many experiments have been devoted to the study of ontogenetic changes in the ability of analogical reasoning (Chen, Sanchez, & Campbell, 1997; Gentner, 1988; Goswami & Brown, 1990; Holyoak, Junn, & Billman, 1984; Richland, Morrison, & Holyoak, 2006; Thibaut, French, & Vezneva, 2010a). Data suggest that analogical reasoning can be found present as early as 10 months in very simple experimental settings (e.g., Chen et al, 1997). Children's analogical reasoning capacities improve as their knowledge of the involved relations, or their abilities to resist irrelevant information increase. Several models have been proposed in order to explain these changes. They fall roughly into two subclasses: models that try to explain development of analogical reasoning by the increase of structured knowledge about the world (Goswami, 1992) and models that suggest that the key lies with the maturation of control processes, such as working memory or executive functions (Halford, Wilson, & Phillips, 1998; Richland et al., 2006).

Richland et al. (2006) and Thibaut and colleagues (Thibaut, French, & Vezneva, 2009, 2010a, 2010b; Thibaut, French, Vezneva, Gérard, & Glady, 2011) posited that while knowledge of relations is necessary to do analogy making, executive functions are also involved in solving analogical problems. Thibaut et al. interpreted their results as showing that younger children's difficulties with analogy making arose because of insufficiently developed executive functions, specifically inhibition. In one experiment involving semantic A:B::C: ? analogies with four possible responses Thibaut, French, and Vezneva, (2010b) compared weak and strong analogies (i.e., analogies in which the items of the A:B and C:D pairs were weakly, or strongly, associated). Results revealed poorer results in weak (e.g., shirt:suitcase::toy:box) analogies than in strong ones, especially when the number of distractor items was high (i.e., three vs. one). Importantly, the authors controlled to ensure that the children knew the semantic relations within the pair (i.e., the semantic relations between A and B, and between C and D). Thus, children's failure to map the A:B pair on the potential C:D target pair could not be explained by a lack of knowledge. They showed that a greater number of distractors led to poorer performance in the case of weak analogies. They suggested that for strongly associated A:B and C:D item pairs, children were not interfered with by the semantic distractors. In contrast, when the problem involved weakly associated items, mapping the A:B pair onto the C:D pair requires more than simply accessing the obvious semantic dimensions of the items.

The authors characterized analogy-making as a search through a space of features and potential relations. The number of relations holding between any A:B pair is potentially large because, depending on the context, any number of different relations might be relevant (Chalmers, French, & Hofstadter, 1992; French, 1995; Hofstadter, 1995; Mitchell, 1993; Murphy & Medin, 1985; Thibaut, 1997). As mentioned above, the structure of the search space and the presence or absence of competing non-analogical solutions have an effect on the search, especially for young children, who have greater difficulty handling the cognitive load associated with a more elaborate search of the space of possible solutions.

The notion of "searching in a semantic space" was directly investigated in an eye-tracking study by Thibaut,

French, Missault, Gérard, and Glady (2011; Thibaut & French, submitted). The authors started with the idea that the search space in an analogy task is dynamically created as the result of comparisons between the items that compose the analogy problem and this requires the integration of the various sources of information that are available during the task. They used an eye-tracker because cognitive monitoring is difficult to assess with the sole performance measures (i.e., error measures and reaction times) that are usually used in the literature (e.g., Rattermann & Gentner, 1998; Richland et al., 2006; Thibaut et al., 2010b). Eye-tracking allowed them to study precisely how the space of potential solutions was explored by both children and adults. The idea was to study what parts of the space were explored and exactly when that exploration took place. By manipulating various aspects of analogical problems of the A:B::C:D type, eye-tracking allowed them to probe the factors affecting the search of solution space.

Compared with adults, children obtained poorer results. There were also key differences between adults and children in the temporal organization of their respective search profiles. First, adults focused on the A and B pair at the beginning of the trial, paying less or no attention to C and to stimuli in the solution set. Later they focused on C and the Target, which they compared with the semantically related distractor. At the end of the trial, the Target was their sole focus of attention. By contrast, children organized their search around C on which they actively focused during the entire trial. At the very beginning of the trial they paid more attention to C and B. They began looking at the Target and the semantic distractor earlier than in the adults' case. Thus the main differences between children and adults were that children focused on B and C at the beginning of a trial, compared to A and B for adults, and that the Target and the semantic distractor were focused on earlier by children than by adults. The comparison between error trials and correct trials in the case of children revealed that errors were characterized by longer looking times on C and shorter looking times on A. Overall, the results showed that children organized their search around C and paid less attention to A and B when necessary.

This pattern of results suggests that one reason children might fail in analogy-making tasks is that they do not pay sufficient attention to A and B or do not include them in their search. Recall that the task explicitly requires "finding the item that goes with C". Thus, in order to successfully comply with the task, children have to focus on stimuli other than the ones which are highlighted by the instructions, i.e. the C item and the set of distractors. Specifically, they have to study A and B and integrate information from these items in their search for the "one that goes with C". The executive function framework predicts that children might find it hard to inhibit the search-for-the-one-that-goes-with-C goal in order, first, to study A and B, and, second to compare what they have discovered for this pair and to integrate it in their search for the Target item that goes with C.

This analysis led us to the central prediction of the present paper. We started with the general hypothesis that young children find it hard to follow the instructions, that is, to integrate A and B in their exploration of C and the solution set. In this context, if the way the analogy task is implemented forces them to study and interpret the A:B pair, then they should obtain better results than in the classical situation in which all the stimuli are introduced simultaneously.

Thus, in the present experiment, we compared two conditions, i.e., the Standard condition and an A:B-first condition. In the latter condition, children first saw the A:B pair alone and were asked to describe the relation holding between A and B before they were shown C and the solution set. We hypothesized that the A:B-first condition would force children to focus on this pair which would help them to integrate it in their search for the correct C:Target pair.

## Experiment

The present study more directly tested the influence of A:B in children's analogy making. The reasoning was as follows. If children do not pay enough attention to A:B while making analogies, they should obtain better results with procedures requiring a preliminary treatment and interpretation of the A:B pair. Children were, first, presented the A:B pair alone. Then, they had to study it and explain the semantic relation holding between A and B, *before* they were presented with the other pictures. We predicted that, in this condition, children would have higher scores than children that would see all the stimuli composing a problem simultaneously. Indeed, as suggested by Thibaut, et al., (2011), young children have difficulties not looking at C and the solution set rather than at A and B. In a similar vein, Thibaut and French (submitted) showed that a distinctive feature of errors, compared to correct trials, is an imbalance between A and C in favor of C.

## Methods

### Participants

Subjects were 42 5-year-old preschool children (M = 67.1 months; range, 57 to 77 months). Their participation to the experiment was submitted to informed consent of their parents.

The subjects were equally divided into two groups: Standard Analogies group (N = 21; M = 67.4 months; range, 56-75 months) and A:B-first group (N = 21; M = 66.8 months; range, 59-77 months).

### Materials

The experiment consisted of 14 trials, with 2 training trials and 12 experimental trials (See Table 1 for the list of trials). Analogies were of the A:B::C:? format composed of 7 items (black and white drawings; see Figure 1). The problem consisted of the A:B pair (the source), the C item (the target), and an empty square. The solution set was

composed of four stimuli: the analogical answer, a distractor that was semantically related to the C item, and 2 items that were not semantically related to C. Positions of the different alternatives were counterbalanced.

The trials were presented to the children on a touch screen controlled by an E-Prime® program used to run the experiment.

### Procedure

Children were individually tested in their school, in a quiet room.

First, participants' knowledge of the stimuli used in the experiment was assessed. Each stimulus was introduced alone and participants were asked to name it or, when they did not know its name, to describe its function or a context in which it could be found. Children recognized 98% of the items correctly. The analogy task followed.

The Standard Analogies group was shown all 7 items defining a problem simultaneously. In the first practice trial, the task was explained to children belonging to the Standard Analogies group as follows: "Let me explain how it works. At first, you have to find why these two pictures [showing A and B] go well together. So, why do you think [A] goes with

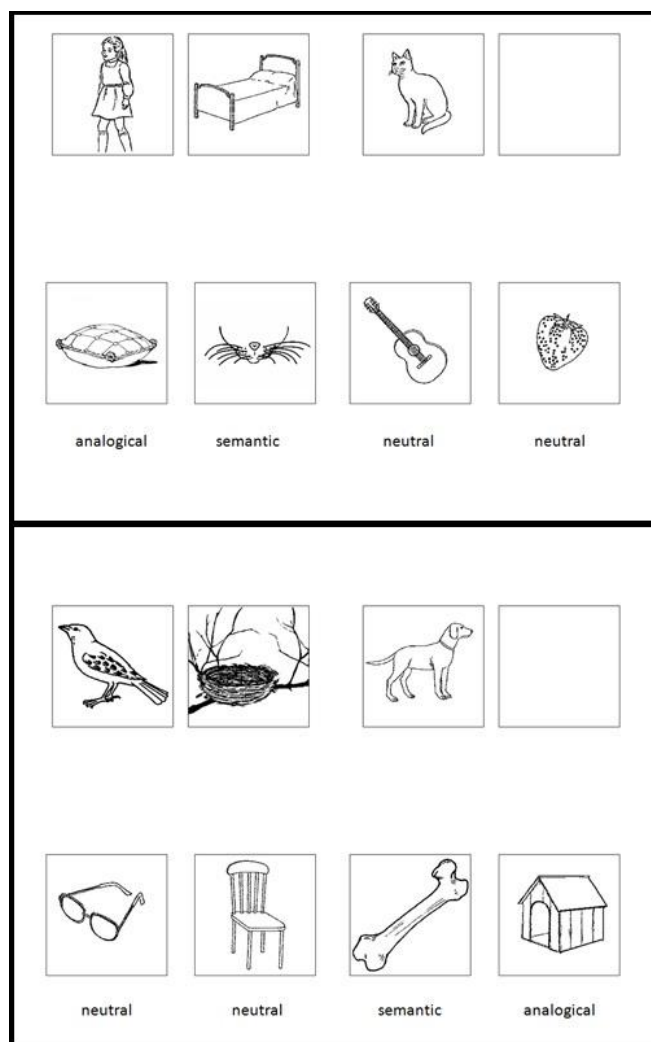

[B]? OK! You see this one [showing C]? It is alone. What you have to do is to find one picture in these four images [showing the four answer options] that goes well with this one [C] in the same way as this one [B] goes with [A] so the two pairs of pictures go together for the same reason. Which picture goes up there [showing the empty slot] with [C] like [B] with [A]? The child gave an answer and justified her choice. Then, the experimenter rephrased the entire trial, explaining and emphasizing why "A and B" and "C and D" go together for the same reason. During the second practice trial, they were asked to do the same. When children did not attend to the A:B pair while explaining their choice, they were asked to do so, and care was taken to ensure that they understood the instructions during the training trials. In the experimental phase, they were asked to do the same thing that was explained to them during the experiment trials and to justify their answer afterward. No feedback was given for the experimental trials.

The A:B-first group was first shown the A:B pair alone and was asked to describe the semantic relation holding between the two drawings: "Why do these two things go together". Once they had given the relation, the

A	B	C	D (Target)	Semantic Distractor	Relation

Table 1: List of stimuli and relations used to build the analogies of the experiment

experimenter displayed the full set of 7 stimuli defining the problem and asked them to complete the second pair as for the other group. Apart from this preliminary question for the A:B pair, the two practice trials were framed in the same way as in the Standard Analogies group. In other words, after they had mentioned the relationship holding between A and B they were shown the set of stimuli defining a trial and the same instructions as in the Standard Analogies group were given.

**Figure 1:** Two examples of analogies used in the experiment. Analogical: Analogical answer; Semantic: Distractor related to the C item; Neutral: unrelated picture

Afterwards, children's understanding of the semantic relation between A and B and between C and D was assessed. They were shown the A:B pairs and were asked *why* the two items of each pair went together. The same was true for the C:D pairs (see Thibaut et al., 2011, for more details).

## Results

We first removed all the trials in which children could not identify one of the semantic relations, either A:B or C:D. As a result, 3% of the trials were removed from subsequent analysis. Note also that in most trials (90% of the cases), children found the target relation that was intended by the experimenter.

We ran a one-way ANOVA on the scores defined as the proportion of correct answers with Condition (Standard Analogies vs. A:B-first) as a between-subject factor.

There was a main effect of condition,  $F(1, 40) = 6.02$ ,  $p < .05$ ,  $\eta^2 = .13$ , with better scores in the A:B-first condition (mean score = .68; see Figure 2) than in the Standard Analogies condition (mean score = .58). These results confirmed our hypothesis that processing the A:B pair first could help children in their search for the analogical answer.

**Figure 2:** Scores of the 5-year-olds in the analogical reasoning test in the two conditions;  $p < .05$ .

When children did not select the analogical match, in 84.5% of the cases, they selected the distractor that was semantically related to C. This result differs significantly from chance (25% of selection, one-sample t test;  $t(41) = 21.31$ ,  $p < .001$ ).

## General discussion

The main purpose of the experiment presented in this paper was to test whether young children's difficulties in analogy-making might result from their difficulties to integrate the A:B pair in the analogy problem. In this study, we conjectured that one source of children's difficulty lies in their search strategy for the task. We suggest that this strategy is, at least in part, induced by the instructions which

require them to find “the item that goes with C.” In the experiment, we directly tested our hypothesis in a condition that required children to first interpret the A:B pair. It was compared with the classical analogy problems. The results confirmed our hypothesis, since children were better in the A:B-first condition.

The experiment is consistent with the idea that children spend less time than adults studying the A:B pair. These data are consistent with Thibaut et al. (2011) eye-tracking data (see also Thibaut & French, submitted) showing that children spend less time on A and B, compared to C, had fewer A:B transitions than adults. The experiment forced them to do what adults do spontaneously and, i.e., inducing the sequential A:B then C:D strategy, which gave rise to higher scores than in the “classical” simultaneous presentation.

Lovett et al. (2009) proposed a two-stage computational model of geometrical A:B::C:? task solving. The program’s performances fitted well with adults performances on Evans’ geometrical problems (Evans, 1968), predicting the different patterns of human answers on each item of the task. This program may also well model children’s pattern of answer observed in this study by modifying some of its processes, like allowing only a shallow first-stage A:B relational description that may result from the lack of treatment of this pair observed in children and/or not allowing the executive to induce another description of the A:B pair.

The increased performance in the A:B-first condition (Thibaut, French, Missault, et al., 2011) are entirely compatible with the executive function view. Given that the instructions prompt them to find a partner for C in the set of solutions, they might find it hard to inhibit the set of stimuli which were explicitly mentioned in the instructions. Another, related interpretation, could involve the representation and maintenance of the sub-goals of the task. This has been suggested for other tasks assessing executive functions (Blaye & Chevalier, 2011; Gruber & Goschke, 2004). Children may represent the main goal of the task, which is to find a picture that is related to the C item, but may have difficulty departing from this goal to achieve a crucial sub-goal – namely, finding which relation has to be used to find the correct answer between the different options related to the C item (analogical answer and distractor). Studying and verbalizing the relation linking the A:B pair may contribute to enhance this sub-goal. In this format, they should not have to generate this sub-goal by themselves. Another interpretation would be that children lack the correct strategy which is to look at the A-B pair first. In this context, our “A:B first” condition provided them with the correct strategy for performing the task. In other words, children would not know how to perform the task or to organize it in order to perform it correctly. This is a plausible hypothesis. However, it is difficult to disentangle what is due to inhibition and/or flexibility mechanisms from what results from an explicit strategy.

The studies in the literature have pointed out two main explanations of children’s failures to do analogies correctly. The first is the role of knowledge (e.g., Gentner, 1988; Goswami & Brown, 1990). The second is related to executive functions. It has been shown that children might have difficulties handling all the information available in the task, such as distractors related to C (see Richland et al., 2006; Thibaut et al., 2010a, b for discussions). The present research demonstrates that the task itself has cognitive constraints which generate a cognitive load that must be coped with by young children. In other words, for adults and most likely children older than 9, the comparison between A:B and C and the potential candidates for a solution is automatically driven by the task instructions (the so-called mapping process). By contrast, for children, temporally leaving aside the instructions “looking for the one that goes with C” in order to compare A with B, generates cognitive load. One might conceive of this as a necessity to temporarily inhibit C and the solution set, or as a necessity to be cognitively flexible, that is to be able to conceive the task under different perspectives (i.e., from an A-B perspective or from a C-solution set perspective and integrate these two perspectives). In sum, the present research has made it clear that the analogy task generates its own demands that cannot be taken for granted, in the case of children.

# Knowledge and implicature: Modeling language understanding as social cognition

Department of Brain and Cognitive Sciences, MIT

## Abstract

Is language understanding a special case of social cognition? To help evaluate this view, we can formalize it as the *rational speech-act* theory: listeners assume that speakers choose their utterances approximately optimally, and listeners interpret an utterance by using Bayesian inference to “invert” this model of the speaker. We apply this framework to model scalar implicature (“some” implies “not all”, and “N” implies “not more than N”). This model predicts an interaction between the speaker’s knowledge state and the listener’s interpretation. We test these predictions in two experiments, and find good fit between model predictions and human judgements. **Keywords:** Language; Bayesian model; Scalar implicature

To what extent does language understanding rely on extralinguistic knowledge and processes? One view of language processing suggests that it consists of largely separate, special-purpose faculties; another view, that it depends critically on domain general inference mechanisms, and even on intuitive theories that are not specific to language. Indeed, many thinkers have viewed speech as an action with communicative goals, such as informing a listener (Grice, 1975; Levinson, 2000; Clark, 1996). A listener making this assumption can make stronger inferences than an utterance would allow from its literal meaning—pragmatic effects can strengthen, or change, the interpreted meaning.

Recent work has aimed to formalize the social inference view of pragmatics using tools of Bayesian statistics and information theory (Frank & Goodman, under review); we refer to this formal framework as the *rational speech-act* theory of language understanding. It views pragmatic competence as following naturally from an intuitive theory of speech production, which in turn is a special case of intuitive theory of mind. More precisely, listeners have an internal model which describes speakers as choosing their utterances approximately optimally on the basis of certain social goals, such as conveying information to the listener; listeners then interpret an utterance by using Bayesian inference to “invert” this model of the speaker, drawing conclusions about the world state and speaker’s intention from the utterance and any other relevant world knowledge. These two rationality assumptions, for listener and speaker, have a role similar to those made in ideal observer models of perception (Geisler, 2003): they provide a starting point for a quantitative understanding of the complex interactions involved in language understanding. Indeed, this view has provided good quantitative models for pragmatic inference in a number of simple settings (Frank, Goodman, Lai, & Tenenbaum, 2009; Frank & Goodman, under review).

Because rational decision making predicts that action selection is related to the *expected* utility—a quantity that de-

Figure 1: How will the listener interpret the speaker’s utterance? How will this change if she knows that he can see only two of the objects?

pends on the actor’s belief distribution—a listener who views the speaker as rational should be sensitive to the speaker’s belief state. The rational speech-act theory thus predicts an interaction between (shared) knowledge about a speaker’s knowledge state and a listener’s interpretation of his utterance. This is a very general prediction of the framework, which could easily prove to be false—if pragmatic inference is a highly modularized computation, for instance, we would not expect such general knowledge to affect it. Deriving and testing precise predictions about this interaction thus provides an important test of the rational speech-act theory.

If you hear “some of the apples are red,” you will infer that not *all* of the apples are. Pragmatic effects of this sort are called scalar implicatures (Horn, 2004), and they provide a window on the interactions between the language faculty and general cognition. Consider Fig. 1: If the speaker has seen all the apples, his utterance would be interpreted as “some, but not all, of the apples are red.” However, if the speaker had only looked at two of the apples, the listener might draw a different conclusion. Indeed, we show below that the implicature “not all” can be canceled by facts about the speaker’s perceptual access. This interaction between language understanding and general knowledge is not predicted by strongly modular theories of scalar implicature, and even moderately modular theories (Chierchia, Fox, & Spector, 2011) predict that such influences can only turn off scalar implicatures. We show that the interaction of knowledge and implicature is more fine grained: the details of a speaker’s belief distribu-

tion affect the details of an implicature.

This paper provides a formal model of the pragmatic inference that leads to scalar implicatures, building on the rational speech-act framework. We directly model the possibility that the speaker may have incomplete knowledge and the effects this has on the listener’s interpretation. We derive predictions of this model for interpretation of the quantifier “some” and the number words (“one”, “two”, etc.). The model both explains the standard implicatures for these words, and predicts that these implicatures can be canceled, completely or partially, when the speaker has incomplete knowledge. We test these predictions in two experiments and find good fits to human judgements, both qualitatively and quantitatively.

### A rational speech-act model

We view language comprehension as a rational inference based on an intuitive theory of language production. Our setting is illustrated in Fig. 1. The listener infers the world state,  $s$ , given the speaker’s utterance,  $w$ , and shared information about the speaker’s (possibly incomplete) information access,  $a$ . By Bayes’ rule:

$$P_{\text{listener}}(s|w, a) \propto P_{\text{speaker}}(w|s, a)P(s). \quad (1)$$

Where  $P(s)$  captures the listener’s prior beliefs about the world state, and  $P_{\text{speaker}}(w|s, a)$  describes the listener’s intuitive theory of how the speaker chooses words.

The speaker chooses an utterance in accord with Bayesian decision theory (Berger, 1985): she acts to approximately optimize expected utility. Imagine a speaker who makes observation  $o$  about the true state of the world. (For instance, in Fig. 1, the speaker has perceptual access to two of three apples, and observes that those two are red). The speaker selects an utterance  $w$  to convey information about the world state to a listener, and does so by soft-max optimizing expected utility:

$$P_{\text{speaker}}(w|o, a) \propto \exp(\alpha \mathbb{E}_{P(s|o, a)}[U(w; s)]) \quad (2)$$

The speaker’s utility function,  $U(w; s)$ , captures the value of saying  $w$  if the world is actually  $s$ . The expectation is taken over the speaker’s belief state,  $P(s|o, a)$ , because the speaker may still be uncertain about the state of the world. The parameter  $\alpha$  controls the deviation from optimality.

So far, nothing in the model is unique to language—indeed, similar models have been used to model social cognition more generally (Baker, Saxe, & Tenenbaum, 2009; Goodman, Baker, & Tenenbaum, 2009; Ullman et al., 2009). To capture a motivation to be informative, utility must be related to the information conveyed in the utterance.<sup>1</sup> More specifically, utility is related to the amount of information that a *literal* listener would not yet know about state  $s$  after hearing it described by utterance  $w$ —this is the negative *surprisal* (Cover & Thomas, 1991):

$$U(w; s) = \ln(P_{\text{lex}}(s|w)), \quad (3)$$

<sup>1</sup>Other communicative motivations could be added to this utility, such as a complexity term influencing the manner of expression.

where the *literal interpretation* probability  $P_{\text{lex}}(s|w)$  is determined by the lexicon—here we will assume that each utterance has a truth function,  $F_w : s \mapsto \{0, 1\}$ , and the distribution is otherwise uninformative:  $P_{\text{lex}}(s|w) \propto \delta_{F_w(s)}$ .

We assume that the speaker’s access  $a$  is common knowledge of speaker and listener, but the listener still does not know what observation the speaker made, hence:

$$P_{\text{speaker}}(w|s, a) = \sum_o P_{\text{speaker}}(w|o, a)P(o|a, s) \quad (4)$$

In the experiments below (as in Fig. 1), the state of the world is always a set of objects that may have a given property and observations consist of looking at a subset of the objects. Thus the observation probability  $P(o|a, s)$  is a hypergeometric distribution (i.e. the probability of drawing  $N$  balls of a given color, without replacement, from an urn containing a given set of colored balls). In this setting, it is also reasonable to assume that the prior probability,  $P(s)$ , is a binomial distribution (i.e. draws *with* replacement); we will initially assume so, and will later measure the distribution empirically.

Overall, the above equations describe the inferences that a rational listener will make to comprehend a speaker that she believes to be approximately rational and have a goal to be informative. Importantly, these inferences depend on shared knowledge about the aspects of the world to which the speaker has access. Thus the rational speech-act theory predicts that the speaker’s access affects utterance interpretation; we test this prediction below. To derive more specific predictions we must describe the set of alternative utterances.

### The alternatives

We have assumed that the interpretation of an utterance is made with respect to a set of alternative utterances. These alternatives could be all possible utterances, or could be a limited set generated by replacing key words in the actual utterance with related words. The alternatives may, for instance, be generated by a grammatical mechanism as in Fox and Katzir (2011). For our results the details of this process are unimportant; what is important is that there exists a set of alternative expressions and a (truth-functional) literal meaning for each. We make standard assumptions in both respects.

Consider the case of the quantifier words “some” and “all”. Under the standard semantics, “all the balls are red” is true exactly when  $N$  of the  $N$  balls are red, while “some of the balls are red” is true when  $M \geq 1$  of the  $N$  balls are red. In particular, the literal meaning of “some” allows the state where all  $N$  balls are red. We use a lexicon that consists of the standard meanings for “none”, “some”, and “all”. Model predictions are shown in Fig. 2a for the listener’s interpretation of “some of the balls are red” when there are 3 objects, under varying conditions of speaker access.

When the speaker has perceptual access to 3 of the 3 objects (hence complete knowledge) and says “some”, there is a lower probability on 3 than 2—this is the standard “some but not all” implicature. To understand why the model predicts this implicature, we can first simplify the speaker model: in

Figure 2: (a,b) Model prediction for probability of each world state (number of objects with property), varying the word the speaker used and the speaker’s perceptual access. The prior is assumed to be binomial with base rate 0.62, and the speaker optimality parameter is set to  $\alpha = 3.4$ . (c,d) Mean participant bet on each world state, varying the word the speaker used and the speaker’s perceptual access. Data have been filtered to include only trials where the participant’s bet that the speaker had complete knowledge was greater than 70 in the expected direction. Error bars are standard error of the mean.

a complete knowledge situation the speaker’s belief distribution is concentrated on the true state, so Eqs. 2, 3, and 4 become:

$$P_{speaker}(w|s,a) \propto \exp(\alpha \ln(P_{lex}(s|w))) \propto (P_{lex}(s|w))^\alpha. \quad (5)$$

Using the standard meanings described above, we see that if the state were 3 the speaker would be more likely to say “all” ( $P_{lex}(s|w)=1$ ) than “some” ( $P_{lex}(s|w)=\frac{1}{3}$ ); conversely, if the state were 2, the speaker would say “some”, since the probability for “all” is now  $P_{lex}(s|w)=0$ . Now consider Eq. 1 and imagine for the moment a uniform prior over states. In this case the listener will infer each state  $s$  in proportion to how likely the speaker was to say “some” given this state. Overall, this leads to the implicature that “some” is unlikely to be interpreted as 3—“some but not all”.

In contrast, when the speaker has only partial access the calculation is more complex, involving the inferred belief distribution of the speaker. Comparing across the three panels of Fig. 2a, we see the probability of 3 is much higher when access is 1 or 2 than when it is 3. When access is 1, no implicature is predicted (the probability of 3 is approximately the same as the probability of 2); when access is 2, only a very slight implicature. Overall, we predict that incomplete speaker knowledge can *cancel* the standard “some but not all” implicature.

The case of numerals (“one”, “two”, ...) is similar but more subtle. It has been argued that number words have a lower-bound meaning (Horn, 1972) (e.g. “two balls are red” means  $M \geq 2$  of the balls are red), and the intuitive, exact, meanings arise as a pragmatic implicature—“one but not two, three, etc.”. In Fig. 2b we show model predictions based on the

lower-bound semantics for number words, varying speaker's access. We see that exact meanings do arise as an inference when the speaker has complete access, but there is an interaction: number words do not receive an exact interpretation when the speaker has incomplete knowledge. Of particular interest is the case where the speaker has seen 2 out of 3 objects and says "one": here a *partial* implicature is predicted, with the probability of 3 low, but 1 and 2 high.

## Experiment 1

Because a rational speaker chooses actions based on *expected* utility, the rational speech-act model predicts an effect of speaker's knowledge on the listener's interpretation of "some" statements. We tested the predictions of the model by putting participants in the role of the listener and asking them to judge the state of the world in scenarios where perceptual access (and hence knowledgeability) of the speaker varied.

### Participants, Materials, and Methods

50 participants were recruited through Amazon's Mechanical Turk crowd-sourcing service and completed the experiment for a small payment.

We constructed six scenarios in which a speaker had three objects that could have (or not) a given property. The speaker then made a statement indicating the number of objects they had looked at and a quantified ("some") statement. We split each scenario into setup and speech act phases. The setup phase named the speaker and described the objects and the relevant property. For example:

Letters to Laura's company almost always have checks inside. Today Laura received 3 letters.

Because our model predicts greater effects when the *a priori* base rate of the property is high (otherwise it is difficult to tell an implicature from an *a priori* belief that it is unlikely for all objects to have the property), we describe all properties as "almost always" holding. To make sure participants attended to the setup, we asked them to report the *a priori* probability that 0, 1, 2, or 3 objects had the property:

How many of the 3 letters do you think have checks inside?

The speech-act phase introduced a speech act in which the speaker both declared how many of the objects they had observed and stated that some objects had the property:

Laura tells you on the phone: "I have looked at 2 of the 3 letters. Some of the letters have checks inside."

We then again elicited judgements about how many objects had the property:

Now how many of the 3 letters do you think have checks inside?

Finally, because the speech act might not be a perfect manipulation of speaker's knowledgeability (for instance, the speaker

may have gained knowledge by another route), we elicited this directly:

Do you think Laura knows exactly how many of the 3 letters have checks inside?

Each response was given by a betting measure: participants were instructed to divide "\$100" among the options, betting to indicate their confidence in each option. For the first two questions there were four options (0–3 of the objects have the property) and for the final question there were two options (the speaker does/doesn't have complete knowledge). Before the experiment began, participants were given a brief warm-up, using unrelated questions, to familiarize them with the betting measure.

Each scenario existed in forms varying speaker access (the number of objects the speakers had looked at) from 1 to 3. Each participant saw each access condition once, in random order, presented using randomly chosen scenarios (with no duplicate scenarios). In terms of our predictions, we have two partial-knowledge conditions (where we expect cancellation of the implicature) and one complete-knowledge "control" (where we expect the standard implicature).<sup>2</sup>

### Qualitative Results

There was no effect of scenario, so we collapse across this factor in all analyses. As expected based related work (Goodman et al., 2009), the speaker's access statement (e.g. "I have looked at 2 of the 3 letters") was not a perfect manipulation of knowledgeability: in the partial access conditions some participants judged that the speaker was likely to know exactly how many objects had the property. (The bet that the speaker had complete knowledge when access=1 was  $M = 27.1$ ,  $SD = 4.9$ ; when access=2,  $M = 34.8$ ,  $SD = 5.7$ ; when access=3,  $M = 93.0$ ,  $SD = 2.7$ .) Since we were interested in the effects of varying knowledgeability, we initially exclude trials in which the knowledge judgement was less than 70 in the expected direction (we come back to the full data set in the quantitative analysis below). Fig. 2c shows the mean of bets on each option, as access varied. As predicted, there was an effect of speaker's access on listener's interpretation (one-way ANOVA with bets on 3 as dependent variable,  $F(2, 102) = 10.18$ ,  $p < 0.001$ ).

We next performed our pre-planned comparisons to check that an implicature was drawn when the speaker had complete knowledge, but not when the speaker had partial knowledge. In the complete access condition bets on 3 were less than bets on 2 (paired, directional t-test,  $t(43) = -10.2$ ,  $p < 0.001$ ). In the partial access conditions the implicature was canceled: bets on 2 did not exceed bets on 3 when speaker had access to 1 object (paired, directional t-test,  $t(31) = 0.77$ ,  $p = 0.78$ ) or when access was 2 (paired, directional t-test,  $t(28) = -0.82$ ,  $p = 0.21$ ). If we look at just bets on 3, we see significantly lower bets in the complete access condition than the

<sup>2</sup>Expt. 1 may be viewed at <http://goo.gl/3S5zz>, Expt. 2 at <http://goo.gl/iSc6o>.

access 1 condition (unpaired, directional t-test,  $t(47) = -4.0$ ,  $p < 0.001$ ) or the access 2 condition (unpaired, directional t-test,  $t(43) = -3.5$ ,  $p < 0.001$ ). While there was no significant implicature in either partial-access condition, there is a slightly greater tendency toward implicature in the access 2 condition than the access 1 condition, as predicted by the model (two-way ANOVA with bet as dependent variable, and access (1 or 2) and state (2 or 3) as independent variables,  $F(2, 294) = 3.77$ ,  $p < 0.05$ ).

Thus, the knowledge of the speaker affected listener's interpretation of "some" in the way predicted by the rational speech-act model. We examine the quantitative fit of the model below.

## Experiment 2

In Expt. 2 we tested the predictions of the rational speech-act model for interpretation of numerals. We again expect to find an effect of speaker's knowledge, but in this case there is a more detailed interaction: the implicature should be canceled when the speaker says "one" after seeing only one object and when the speaker says "two" after seeing two objects, but it should only be partially canceled when the speaker says "one" after seeing two objects—this implies a fine-grained interplay between the speaker's knowledge state and the interpretation of her utterance.

### Participants, Materials, and Methods

50 participants were recruited through Amazon's Mechanical Turk crowd-sourcing service and completed the experiment for a small payment.

We used the same stimuli as in Expt. 1, modifying the scenarios only in the speech act: the speaker now made a statement indicating the number of objects they had looked at and the number that had the property. For instance:

Laura tells you on the phone: "I have looked at 2 of the 3 letters. 1 of the letters has checks inside."

Each scenario existed in forms varying the speaker's access, from 1 to 3, and the number word the speaker used, from 1 to 3; we limited to sensible situations where the word used was no greater than the number of objects seen. Hence we had six conditions, with access/word: 1/1, 2/1, 2/2, 3/1, 3/2, 3/3. In terms of our predictions, we have three partial-knowledge conditions (where we expect partial or complete cancellation of the implicature) and three complete-knowledge "controls" (where we expect the standard implicatures). The order of scenarios and the order of conditions were randomized between participants.

### Qualitative Results

There was again no effect of scenario, so we collapse across this factor. As in Expt. 1, the speaker's access statement was not a perfect manipulation of knowledgeability (bets that speaker had complete knowledge in partial-access conditions:  $M = 42.0$ ,  $SD = 3.4$ , in complete access conditions:  $M = 92.1$ ,  $SD = 1.6$ ). We once again limit to trials with the expected

judgements of knowledgeability (with a threshold of 70). The mean of participants' bets are shown in Fig. 2d. To evaluate the overall effect of access, we performed an ANOVA with access and word as independent measures and bet on 3 as dependent measure. We find a main effect of access ( $F(2, 205) = 6.57$ ,  $p < 0.01$ ), an interaction between word and access ( $F(1, 205) = 34.7$ ,  $p < 0.001$ ), and a main effect of word ( $F(2, 205) = 269.8$ ,  $p < 0.001$ ).

We then explored the results in more detail using planned comparisons to test whether implicatures were drawn (only) when predicted. We found an implicature in the complete access conditions: when the speaker said "two", bets on state 3 were less than on state 2 (paired, directional t-test,  $t(43) = -10.2$ ,  $p < 0.001$ ). When the speaker said "one", bets on state 1 were greater than on state 3 (paired, directional t-test,  $t(42) = -13.1$ ,  $p < 0.001$ ) or state 2 (paired, directional t-test,  $t(42) = -17.1$ ,  $p < 0.001$ ). In contrast, there was no implicature when access was 1 and the speaker says "one"—bets on 1 were not greater than on 2 (paired, directional t-test,  $t(24) = 1.9$ ,  $p = 0.96$ ) or on 3 (paired, directional t-test,  $t(24) = 3.2$ ,  $p = 1.0$ )—and no implicature when access is 2 and the speaker says "two"—bets on 2 were not greater than on 3 (paired, directional t-test,  $t(24) = 1.1$ ,  $p = 0.87$ ). When access is 2 and the speaker says "one" we found the predicted *partial implicature*: bets on state 1 were significantly greater than on state 3 (paired, directional t-test,  $t(25) = -3.9$ ,  $p < 0.001$ ), but not on state 2 (paired, directional t-test,  $t(25) = 1.5$ ,  $p = 0.92$ ).

These results again support the predictions of the rational speech-act model, showing not merely an interaction between the speaker's knowledge and the listener's tendency to draw an implicature, but a fine-grained interaction that is unlikely to result from a modular process of language understanding. In addition, these results support the standard, but controversial (Huang, Snedeker, & Spelke, 2004; Barner & Bachrach, 2010), view that number words have a "lower-bound" semantics which is only strengthened into an exact meaning by pragmatic inference.

### Quantitative model comparison

To evaluate the quantitative model predictions, we first compare model predictions with mean human ratings for the subset of trials in which participants gave knowledgeability ratings in the expected direction (greater than 70, as above). As in the model description, we assume a binomial prior distribution. We fit the prior base rate parameter and the  $\alpha$  parameter by minimizing the root mean squared error (RMSE) of the model predictions and mean data for both experiments. The resulting model fit is  $RMSE = 9.01$  and  $r = 0.96$ . The model predictions with the best-fitting parameters are shown in Fig. 2a,b and show striking correspondence with the human data in Fig. 2c,d.

To consider all responses, including those previously removed due to unexpected knowledge judgements, we extend the model by including an additional knowledge parameter: the probability that the speaker did in fact have complete

knowledge (regardless of perceptual access). Since we measured prior expectations and knowledgeability in each trial, we compute model predictions, trial by trial, using these values. Because the betting interface encouraged participants to round small bets to 0, but probability 0 is very different than a non-zero small probability to the model, we changed 0 and 100 bets to 1 and 99. In addition, we assumed a simple power-law relationship between subjective probability and bets (equivalent to the soft-max used to model the speaker, Eq. 2). The parameter of this power law and the speaker optimality,  $\alpha$ , were then fit by minimizing the RMSE of mean model predictions to mean human judgements in both experiments. The resulting fit was again good: RMSE=8.36,  $r=0.95$ . Looking at individual participants, we find median correlation of  $r = 0.75$  between a participant's judgements and the model predictions based on their prior and knowledge scores. These results suggest that the rational speech-act model is able to capture the quantitative pattern of people's judgements both across the population and within individual participants.

## Conclusion

We have described a rational speech-act model of scalar implicatures and their interaction with speaker knowledge. This model formalizes language understanding as social cognition, with language-specific goals and actions, using the tools of Bayesian statistics. In addition to predicting the standard implicatures ("some but not all", etc) as an inference that depends on the alternative utterances, this model predicted that these implicatures could be canceled, completely or in part, when it was common knowledge that the speaker had incomplete knowledge. Expts. 1 and 2 verified these qualitative predictions, and showed tight quantitative fits with the model.

The predicted interaction between interpretation and speaker's knowledge was not a peculiarity of this set of words or of scalar lexical items, instead it follows from the general fact that rational decision makers must choose actions based on their expected utility. In contrast, a strongly modular of implicatures would predict no such interactions. One could amend these theories (Chierchia et al., 2011) to allow a speaker's ignorance to gate the implicature mechanism, but this still would not predict the fine-grained interactions demonstrated for number words: the details of a speaker's knowledge state influence a listener's interpretation.

Our results support the rational speech-act framework for modeling pragmatics. More generally, they further boost the momentum building for quantitative models of language as a branch of rational social cognition. In the words of Grice (1975): "One of [our] avowed aims is to see talking as a special case or variety of purposive, indeed rational, behavior..."

## Abstract

Problem solving is a complex cognitive activity that involves the construction of sequences of actions to reach a given goal. One powerful strategy is to identify analogies between the problem at hand and previously encountered ones. Relevant similarities between problems can be detected more easily if there is a high resemblance on the surface or with respect to structure. Earlier theoretical observations and performance data have pointed to two distinct kinds of analogical reasoning, direct solution transfer (transformational analogy) and the creation of a new solution based on adapted past reasoning processes (derivational analogy). In order to gain insights about the cognitive processes involved, we extend this work by an analysis of different kinds of verbal data. Planning protocols were collected prior to problem solving, and retrospective reports, evaluations, and instructions were elicited after the task was completed. Results show that the different kinds of analogical reasoning involved different degrees of analogy awareness, as reflected by the verbalizations. Derivational analogy involved problem solving on a more detailed and structured step-by-step basis than the more superficial transformational strategy, in which a simple matching procedure was employed.

**Keywords:** analogical problem solving, verbal reports, cognitive discourse analysis

## Introduction

People frequently encounter problem situations in their daily lives. Most of these are instantly solved, as humans are well equipped with numerous problem solving strategies. One powerful strategy is the adaptation of previous experiences to solve the newly encountered problem. Analogical reasoning is not only involved in problem solving but also in a number of other human activities, such as use of metaphor, scientific reasoning, humor, and empathy. Gentner, Holyoak & Kokinov (2001) therefore argue that analogical reasoning is at the core of cognition. Hofstadter (2001) supports this view by arguing that all concepts that are used to understand recurrent and new situations are packages of analogies.

Even though analogical reasoning is assumed to be a

ubiquitous and efficient problem solving strategy, participants seldom apply it in experimental settings, unless the analogous nature is directly salient (Gick & Holyoak, 1980; Schmid, Wirth & Polkehn, 1999). If analogies are used in problem solving the transfer can be on different levels of specificity, leading to different cognitive solution steps and strategies. In this paper, we pursue these issues by an analysis of verbal data collected while solving an analogy problem. In the following, we will first discuss previous work on analogical problem solving, with a brief look at the role of language. Next, we introduce a previous study by Schelhorn, Griego, and Schmid (2007) that served as our starting point. Our current study is then presented and discussed in the remainder of this paper.

## Analogical Problem Solving

Analogies are based on shared relations between base and target problem (Gentner, 1983; Clement & Gentner, 1991). By highlighting shared relational structures, analogies connect domains and problems that may appear only marginally similar on the surface. This process involves structural alignment as a crucial component of analogical reasoning. While similarity centers on shared attributes, analogy concerns the alignment of relational structures at a deeper level. According to the *systematicity principle*, the structural relations are connected by one-to-one correspondences (Gentner & Markman, 1997).

As proposed by Carbonell (1986), analogical problem solving can be performed on different levels of abstraction. *Transformational analogy* is based on direct solution transfer, i.e. the solution to a previous problem is slightly altered in a transformation process to solve the new problem. The solution transfer process contains three basic processes. First, the *initial partial matching process* determines if two problems share similar aspects based on state information and operator sequences. Second, the sequence of actions from the retrieved solution is transferred to the new situation in an *analogical mapping process*. Third, the retrieved solution is copied and altered in a

heuristically guided manner to finally satisfy the given constraints (Carbonell, 1986).

*Derivational analogy* follows the same processes of analogical thinking. However, the accessed information is different, since it is based on the preservation and reconstruction of past reasoning processes. In the *initial partial matching process*, significant aspects are considered analogous if they share the same reasoning steps, i.e. the same issues are considered and equivalent decisions are made. Second, in *transfer of earlier derivation*, significant aspects of the reasoning process are recreated. Finally, the retrieved derivation is applied to the current situation “by ‘replaying’ the problem solving episode, checking for each step if the derivation is still applicable in the new problem solving context” (Schmid & Carbonell, 1999: 116). To summarize, in transformational analogy the solution is slightly altered to fit the new problem. In derivational analogy, in contrast, previous reasoning processes are applied and adapted to find a solution. As a result, new solutions are likely to be different from previous ones.

While Carbonell introduced derivational analogy as an artificial intelligence model, humans have also been shown to use this strategy (Schmid & Carbonell, 1999). Experiments showed that a high saliency of analogous elements fosters the use of transformational analogy (Schelhorn et al., 2007). Furthermore, participants were more successful in solving novel problems when they studied examples by using instructions fostering derivational analogy (Kleinbeck et al., 2001).

### Verbal Reports in Studying Problem Solving

Measuring solution times is common in problem solving research (e.g. Funke & Spering, 2006); the analysis is based on assumptions about the time which different processes take. However, solution times do not contribute information about cognitive processes at work during problem solving. A combination with other measures such as verbal or behavioral data can lead to more detailed insights.

The elicitation and analysis of verbal reports is an established method to study the processes involved in human problem solving (e.g. Newell & Simon, 1972; Gick & Holyoak, 1980; Ericsson & Simon, 1984). Ericsson & Simon (1984) outline the different processes that can be accessed by different kinds of verbal reports. They argue that think-aloud protocols and retrospective reports do not modify cognitive processes; the task-oriented processes determine what information is heeded and verbalized. Most information in these reports is still held in short term memory. If information is retrieved from long-term memory in retrospective reports, some information might already be missing or erroneous, for instance with regard to difficulties encountered while solving the problem.

Most studies investigating verbal data along with problem solving focus on the content level, identifying the explicit statements elicited from participants during (or following) a problem solving process. Few studies analyze verbal reports on a deeper linguistic level, identifying more precisely *how*

the different processes are described (Caron & Caron-Pargue, 1987; Wedman, Wedman & Folger, 1996), or which linguistic differences can be found between reports of successful and unsuccessful problem solvers (Roth, 1985).

In this study, the analysis of performance data is supplemented by a content and linguistic analysis of different kinds of verbal reports. By combining those measures we aim to

- identify the processes described in the verbal reports and match those to the different processes proposed for transformational and derivational analogy,
- explore how transformational and derivational analogy can be linguistically distinguished in verbal reports, and
- confirm that a high saliency of analogous elements fosters transformational analogy.

### The Effect of High vs. Low Guidance on the Selected Analogical Transfer

Our experiment is based on a study by Schelhorn et al. (2007) in which the saliency of the correspondences between entities in base and target problem was varied. These authors used the following design to address the influence of saliency on the selected analogical strategy.

First, in order to prime participants for analogical reasoning, they were given two example problems (‘The Fortress’ and ‘Radiation’, cf. Gick & Holyoak, 1980) and their solutions, where the second was solved analogously to the first. While those two problems were purely conceptual, the base and target tasks in the study by Schelhorn et al. concerned a type of path-finding problem called “Eulerian Trail” where a path needs to be found that visits every edge of the graph exactly once. After participants were presented with the *base problem* (Boat; see Schelhorn et al., 2007: Appendix), the solution was explained step-by-step (visually supplemented by a graph). Then participants were given the *target problem* (Birthday) and asked to find a solution. In the *high guidance* condition, the initial letters of the five objects that represented the edges of the graph were identical (cities in the base problem and peoples’ names in the target problem). This was not the case in the *low guidance* condition. After giving the solution, participants were asked to map objects from the base to those of the target. Mapping times were recorded. Participants then completed a *Strategy Assessment Questionnaire* (SAQ), which contained 16 statements that participants should agree or disagree with (see Schelhorn et al., 2007: Appendix). Five statements corresponded to the derivational strategy (e.g. *The “boat” and the “birthday” problem seemed similar but I could not figure out how the solutions were related*), and five corresponded to the transformational strategy (e.g. *It was simple to use the “boat” solution to solve the “birthday” problem by replacing the names of the towns with the names of the people*). The remaining statements were fillers. Finally, biographical information was collected.

Schelhorn et al. (2007) found that participants transferred knowledge from the base to the target problem even in the

absence of surface and structural correspondences, namely by using derivational analogy. Since the derivation process takes longer than direct solution transfer, participants in the *high guidance version* should be faster. However, as participants may solve the problem while reading the task instructions, or take time to re-read parts of the instruction when facing difficulties, solution times as such did not seem to be an accurate measure. Mapping times seemed more informative since participants in the *low guidance* condition needed to map the entities from the base problem to those of the target problem in a separate step to solve the mapping task. Results showed that, as expected, mapping times were significantly longer in the *low guidance* condition. Furthermore, participants in the *low guidance* condition agreed with more SAQ questions that corresponded to the derivational strategy than participants in the *high guidance* condition, indicating that low correspondence hampers direct solution transfer.

In a comparable study, Schmid & Carbonell (1999) report similar performance results. Additionally, they briefly report how the two analogical strategies were expressed in think aloud protocols. In preparation for the analysis of verbal reports in our current study, we revisited the set of 14 think aloud protocols to identify linguistic markers of cognitive processes. This analysis revealed the following general structure in 10 of the protocols:

1. construct the graphs representing cities and locks,
2. connect cities satisfying the given constraints, and
3. check the solution during a final evaluation.

The final stage of evaluation was missing in the remaining four protocols. An analysis of the verbs occurring in the protocols revealed that participants were engaged in a number of mental activities: satisfying constraints (*have to*, *need to*), forming hypotheses (*should*, *could*), gaining insight (*I see*), planning (*want to*, *going to*), and recalling (*seen before*). In those data, the distribution of verbs (categorized following Halliday & Matthiessen, 1999) could to some extent be associated with use of derivational and transformational strategies. For instance, participants using derivational analogy used more verbs of ‘doing’ (*go*, *start*) than participants using transformational analogy.

## The Eulerian Trail: Empirical Study

### Hypotheses

The current study supplements the quantitative analysis of performance data by a qualitative analysis of verbal data. We expected protocols to show transformational and derivational strategies, reflecting the processes proposed by Carbonell (1986). In particular:

- Participants in the high guidance version were expected to state explicitly that they noticed the analogy.
- We assumed that participants using the transformational strategy would explicitly state that they used the base solution for solving the target problem. On a linguistic level, they might use explicit markers of

correspondence, such as “the same as”, “similar”, and “analogous”.

- Reports by participants using derivational analogy should include descriptions of different stages of the problem solving process, such as visualizing the different connections (relationships) between the different points (people). Furthermore, unspecific terms (in general) and structuring devices, i.e. ordinal numbers and temporal connectors were expected to be more frequent.

### Design

In addition to replicating the study by Schelhorn et al. (2007) (*original* condition), we collected different kinds of verbal reports in two further conditions, yielding a 2x3 design (high vs. low guidance, original vs. planning vs. retrospective). In the *planning condition*, participants were asked to write down how they would solve the problem (*planning protocol*) after going through the example problem and viewing the target problem for the first time. Furthermore, they were asked to *evaluate* their plans after completing the mapping task. Participants in the *retrospective condition* were asked to write a *report* on how they solved the target problem, and subsequently to write an *instruction* for a friend to solve this problem. Since these verbal reports were collected at different times relative to the problem solving process, different kinds of information were gathered. We expected that planning protocols and retrospective reports would be most likely to include descriptions of the actual problem solving process. Planning protocols were expected to contain information on spontaneous transfer from base to target problem. Retrospective reports may further include memories of detours and fresh starts, and possibly information on the mapping task and meta-information on the study or the problem solving process. This kind of meta-information may also be reported in evaluation protocols. Instructions, on the other hand, would be highly structured and include generalized steps to solve the given problem.

### Procedure

Participants were recruited by various means, e.g. by a call for participation on LinguistList.org and among students at the University of Bremen. As a consequence, the age range was very wide (22 to 73 years, mean 38,1 years). Participants were randomly assigned to conditions. Performance was analyzed with regard to solution and mapping correctness, mapping times, and the answers given in the SAQ. The elicited verbal reports were analyzed qualitatively with regard to their content, the overall structure, and linguistic markers such as verbs, nouns, structuring devices, and other keywords.

### Results

69 participants (35 female and 34 male) took part in the web-based study. 33 of these were given the *high guidance* condition by the system, and 36 saw the *low guidance*

condition. We collected 20 planning protocols, 21 evaluations, 22 retrospective reports, and 21 instructions (evenly distributed between the two guidance conditions).

**Performance and Strategy Assessment.** Solutions to the target problem did not differ significantly between the *high* (57,6%) and *low guidance version* (66,7%). However, the mapping task was solved significantly better in the *high* (90,9%) than the *low guidance version* (63,9%),  $\chi^2 = 7.01$ ;  $p < .01$ . Also, mapping times in the *high guidance* condition ( $n = 33$ ;  $M = 76.9$  s;  $SD = 64.5$ ) were significantly shorter ( $W = 947$ ,  $p < .001$ ) than in the *low guidance* condition ( $n = 36$ ;  $M = 217.0$  s;  $SD = 206.7$ ).

The answers to the SAQ were analyzed using Mann-Whitney U tests to compare the amount of positively ranked questions belonging to the derivational strategy to those that belong to the transformational analogy. Participants with *high guidance* ( $n = 33$ ) agreed with significantly more statements corresponding to transformational analogy than participants with *low guidance* ( $W = 854.4$ ,  $p < .001$ ). Statements that corresponded to derivational analogy were significantly more often confirmed by participants in the *low guidance* ( $n = 35$ ) than by those in the *high guidance* condition ( $W = 771.5$ ,  $p < .01$ ) (Figure 1). One participant in the *low guidance* condition did not complete the SAQ.

Figure 1: Mean number of agreed SAQ questions.

Running a Kruskal-Wallis test no interaction was found between the verbal elicitation task and mapping times ( $H = 2.8207$ ,  $p = .244$ ). For this reason, and because the results of the performance measures confirmed the findings by Schelhorn et al. (2007), we assume that the elicited verbal data did not affect performance in any substantial way and can therefore contribute to the study of differences in derivational and transformational analogy.

**Verbal Data Analysis.** First we investigated the general structure of the collected 21 planning protocols. In 12 of these, participants stated *noticing the analogy* between base and target problem in the beginning. In 7 protocols this insight was followed by a *description of the graph* and a subsequent description of the *problem solving process*. 17 participants stated the *solution* at the end of the protocol. Similar structures were also found in the retrospective reports, which additionally contained meta-information such as remarks on the study design, the problem solving process, and background knowledge. 7 participants (2 *high guidance*, 5 *low guidance*) furthermore reported how they

solved the mapping task. They reported different strategies, viz. redrawing the graph (4 cases), aligning the entities (once), or matching functions of entities (twice).

88% of all planning protocols in the *high guidance* condition contained statements of *noticing the analogy*, as compared to 40% in the *low guidance* condition. A similar trend emerged in the retrospective reports; 73% of the *high guidance* reports explicitly mentioned noticing the analogies, as compared to 27% in the *low guidance* version. With regard to success, it could be observed that those participants who reported noticing the analogy in their planning protocols succeeded in finding the solution three times more often than those who did not mention the analogy. In retrospective reports no such effect of *noticing the analogy* could be found. A closer analysis showed that some participants reported solving the example problem themselves; if they came up with a wrong solution there, noticing the analogy and transferring the solution to the target would result in a wrong solution.

A closer look at the nature of the descriptions of the analogies revealed a systematic difference. In the *high guidance version* they reflected abstract, general observations of the following kind: “When I read the *birthday problem*, I recognized that it was the *exact same problem* as the *boat problem*”. Here, no alignment of structures or entities is provided. Only protocols collected in the *low guidance version* contained more detailed representations such as: “I recognized right away that the *messages* were analogous to the *locks*.” Here, the entities of the target problem are matched to those of the base problem.

The descriptions of the problem solving processes could be divided into four subcategories. Descriptions of abstract, generalized steps were classified as *general strategy*. If the solution of the base problem was directly transferred to the target problem, this was called *direct solution transfer*. If the strategy (rather than the solution) was described as being transferred, this was categorized as *direct strategy transfer*. If instances of the solution process were specified, the description was classified as *step-by-step*. These categories showed different linguistic markers as illustrated by the following examples:

1. I worked counterclockwise and *connected* as many of the *people* along the edges as possible before working on the *connections* that cut across the middle of my shape. (general strategy)
2. I simply *copied and pasted* the solution from the third problem onto the forth. (direct solution transfer)
3. I *solved* it the *same way*. (direct strategy transfer)
4. Starting from *S*, I *first* connected the group of 3 persons that know each other (*S, B, E*), coming back to *S*. Then from *S* to *R*, and from *R* to the other group of 3 persons that know each other (*R, M, B*), coming back to *R*. Finally from *R* to *E*. (step-by-step)

In detail, the category *general strategy* included

- general statements of the kind ‘find pattern/ mapping’,
- the generalized strategy ‘go through the graph’, and

- the verbs ‘connect’ and ‘draw’ (6 occurrences as compared to 3 in step-by-step descriptions).

The two categories that described direct transfer both contained the markers ‘same’ and ‘again’ (6 times) and the verb ‘solve’ (5 occurrences). But the verb ‘copy’ was solely used in two protocols to describe *direct solution transfer*. And the nouns ‘strategy’ and ‘template’ only occurred in protocols displaying *direct strategy transfer*. Protocols in the category *step-by-step* contained

- first letters or names of entities,
- references to connections drawn by the participants (5 out of 7 cases), and
- a detailed description of the process of drawing the graph, listing the connections and finding a way to satisfy the task constraints (2 cases).

Structuring devices were most frequent in *general strategy* or *step-by-step* descriptions, viz. temporal connectors (13 compared to 3 occurrences in the two *transfer* categories) and the conjunction ‘and’ (27 compared to 2 occurrences).

26 out of 33 *planning protocols* and *retrospective reports* contained strategy descriptions. Of these, 15 were categorized as *general strategy* descriptions and 7 occurrences were found for each of the other three categories respectively. *Step-by-step* descriptions were most frequently used in the *low guidance* version (5 as compared to 2 times). *Direct solution transfer* was more often described in the *high guidance* version (6 as compared to 1 occurrence).

*Instructions* were found to be more structured (structuring devices were used in 50% of the instructions) and more general in describing the steps to be taken (12 out of 20 protocols). Those steps can be summarized as ‘draw the graph & find a pattern by satisfying the given constraints’. Eight instructions included references to task-specific entities (e.g. *lock*, *messenger puzzle*). One participant refused to write an instruction. 16 instructions contained an advice for a specific strategy. The same strategy categories as outlined before could be used for the analysis. A comparison between the strategy described in the instruction and (by the same participant) in the *retrospective report* revealed that people advised a more general strategy (6 cases) or the same strategy (9). No differences with regard to *high* or *low guidance* was found. 15 out of 21 *evaluations* stated if the planned strategy was used; this was mostly the case (10 of 15).

## Discussion

We set out in our study to extend findings previously published by Schelhorn et al. (2007) concerning the use of transformational and derivational strategies in analogical problem solving. Our performance results successfully replicate the earlier findings in that participants given *high guidance* were more likely to use transformational analogy, while participants given *low guidance* could be associated with derivational analogy. The assumption that participants would have to map base and target entities in a separate step

in order to solve the mapping task was confirmed by the descriptions found in 8 protocols.

The analysis of verbal data furthermore provides a range of insights about the cognitive processes involved in analogical problem solving. As a tendency, participants reported recognizing the analogy more often when it was highly salient. Equally unsurprisingly, those recognizing the analogy appeared more likely to succeed in giving the right solution. However, as the *retrospective reports* revealed, participants working their way through the example problem by themselves may give the wrong solution although they noticed the analogy. This observation might explain the low performance in solution correctness of the target problem. The distinctively better performance of participants in the high guidance version on the mapping task supports this view. This interesting possibility could not be detected by performance data alone.

Our qualitative analysis of strategy categories suggested that participants in the *high guidance* version described *direct solution transfer* more often than participants in the *low guidance* version, as opposed to more detailed *step-by-step* descriptions that were associated with *low guidance*. Together these tendencies support the idea that high guidance fosters a transformational strategy involving more superficial and less intricate cognitive processes.

A comparison of the processes identified in our verbal data with the processes hypothesized for transformational and derivational analogy by Carbonell (1986) reveals the following. For transformational analogy, which is associated with *high guidance*, the *initial partial matching process* is expressed in descriptions of *noticing the analogy*. Since the descriptions exhibit a very abstract level of representation, no conclusions can be drawn about the nature of the aspects that are considered analogous. Quite possibly, participants did not need to consider the matter in any more depth (leading to the lack of more detailed alignment descriptions), since a superficial transformation was sufficient. The *analogical matching process* in which knowledge from the base problem is transferred to the target problem is evident in the descriptions of *graph representation*. The following example is representative for the transfer of the sequence of actions: “making nodes for each person and drawing lines between acquaintances”. The process of *alteration of the retrieved solution* is straightforwardly expressed in descriptions of *direct solution transfer*.

In *low guidance* protocols that are associated with the use of derivational analogy, the initial step of matching reasoning processes of base and target problem is also verbally expressed by *noticing the analogy*. These descriptions show a more detailed representation (matching base and target entities), but do not contain information on individual reasoning steps. The transfer of significant aspects of the reasoning process and traces of replaying the problem solving episode can be observed in *step-by-step* descriptions.

Our analysis of verbal reports thus enabled the identification of different cognitive processes involved in analogical problem solving, along with linguistic markers, depending on the degree of guidance which led to the different problem solving strategies previously described as transformational and derivational (Carbonell, 1986). These findings illustrate that the analysis of verbal data contributes to a more detailed understanding of the processes at work during analogical problem solving.

Our elicitation of written data can be regarded as a first broad exploration of the kinds of verbalizations that might be expected along with complex analogical problem solving tasks. Quite typically for free production tasks and low participant numbers that allow for a more or less complete comprehension of the descriptions (rather than performing quantitative computations), the resulting numbers of occurrences of specific phenomena (as reported in this paper) were too small for statistical validation. Nevertheless, the distribution of contents and linguistic markings were both inspiring and suggestive in light of the theoretical background of this study, and thus open up some avenues for further research. In particular, we suggest the following:

- Of the four types of elicited verbalization the planning protocols seemed to be the most informative. Quite unexpectedly, participants seemed to already solve the task while writing up how they would do this, rendering the descriptions rather similar to think aloud data (elicited during, rather than before, problem solving). If this observation can be supported by further studies, it would open up interesting ways of collecting verbal data much more efficiently than possible with think aloud recording.
- The tendency for *low-guidance* participants to produce more detailed procedural descriptions of a derivational problem solving process calls for further exploration. Focusing on this particular aspect, a more controlled elicitation of a larger amount of verbal data should highlight how these matching processes develop over time, as well as the extent to which the two proposed analogical reasoning strategies (transformational and derivational) are systematically distinct. The linguistic markers identified in the present study can serve as a first indication of the ways in which language represents these distinctions.

## Abstract

Understanding the relationship between connectionist and probabilistic models is important for evaluating the compatibility of these approaches. We use mathematical analyses and computer simulations to show that a linear neural network can approximate the generalization performance of a probabilistic model of property induction, and that training this network by gradient descent with early stopping results in similar performance to Bayesian inference with a particular prior. However, this prior differs from distributions defined using discrete structure, suggesting that neural networks have inductive biases that can be differentiated from probabilistic models with structured representations.

**Keywords:** Bayesian modeling, connectionism, inductive biases, property induction

## Introduction

Cognitive scientists use different mathematical formalisms to model human cognition. Understanding the relationships between these approaches is critical to resolving questions about the nature of the mind. Recently, researchers have debated whether probabilistic or connectionist models of cognition provide better prospects for making progress in cognitive science (Griffiths, Chater, Kemp, Perfors, & Tenenbaum, 2010; McClelland et al., 2010). One of the key issues in this debate is that many probabilistic models are defined in terms of structured, discrete representations, while connectionist models use continuous, graded representations that can mimic discrete structure when needed. A possible resolution would be to view probabilistic and connectionist models as lying at different levels of analysis (Marr, 1982), with neural networks a continuous approximation to Bayesian inference over discrete representations. However, this requires establishing whether such an approximation is possible.

To explore this issue, we use the problem of property induction as a case study for investigating the relationship between probabilistic models of cognition and neural networks. Property induction – inferring the properties of a novel object based on the properties of other objects – has played a key role in the debate between probabilistic and connectionist models. An influential probabilistic model explains human property induction in terms of Bayesian inference over discrete representations such as graphs and trees (Kemp & Tenenbaum, 2009), whereas a successful connectionist model explains people’s inferences via continuous representations learned by gradient descent (Rogers & McClelland, 2004).

We use a combination of mathematical analysis and computer simulations to address three questions. First, can a probabilistic model with a discrete representation for a set of objects be approximated by a neural network model with continuous representations? Second, are the solutions that tend

to be found by training neural networks by gradient descent comparable to those produced by Bayesian inference (that is, are the *inductive biases* of these approaches related)? Finally, how compatible are the inductive biases of neural networks with those of structured probabilistic models? We provide positive answers to the first two questions, showing that a simple neural network can always approximate a probabilistic model of property induction, and that training this network using a gradient descent algorithm is similar to Bayesian inference with a particular prior distribution. However, we also show that there remains a significant difference between this prior and distributions based on discrete representations.

## Mathematical analysis

Our mathematical analysis focuses on comparing the model of property induction used by Kemp and Tenenbaum (2009; henceforth KT09) with a linear neural network.

### Setting up the problem

The KT09 model assumes that we want to capture the joint distribution of the elements of continuous  $N$ -dimensional vectors  $\mathbf{x}$  indicating the value of a single property for  $N$  objects.<sup>1</sup> This distribution,  $p(\mathbf{x})$ , results from a diffusion process on a graph. The diffusion process induces a multivariate Gaussian distribution on  $\mathbf{x}$  with mean zero and covariance

$$\Sigma_{\text{discrete}} = \left( \Delta + \frac{1}{\sigma^2} \mathbf{I} \right)^{-1} \quad (1)$$

where  $\Delta$  is the Laplacian of the graph, being  $\mathbf{G} - \mathbf{I}$  for a graph with adjacency matrix  $\mathbf{G}$ , and  $\mathbf{I}$  is the identity matrix.

Now consider a linear neural network model.<sup>2</sup> This model represents an observed  $N \times M$  matrix (the values of  $M$  properties for  $N$  objects) as the product

$$\mathbf{X} = \mathbf{Y}\mathbf{Z} \quad (2)$$

where  $\mathbf{X}$  is the  $N \times M$  matrix of observed objects,  $\mathbf{Y}$  is an  $N \times K$  matrix, and  $\mathbf{Z}$  is a  $K \times M$  matrix. In this model,  $\mathbf{Z}$  is the representation of the set of properties on a hidden layer with  $K$  units (as might be encoded in the weights from an

<sup>1</sup>This formulation is a little counter-intuitive, as the set of objects is fixed but the set of properties is left open (ie. new properties tend to be observed, rather than new objects). This differs from the most intuitive way of thinking about the problem for a neural network, in which the network is trained to predict the properties that objects have, with the set of properties fixed and the set of objects left open.

<sup>2</sup>Neural network models typically use non-linear activation functions at the hidden layer. This complicates the analysis, but we hope to explore the consequences of such non-linearities in future work. We return to this point in the Discussion.

input layer to the hidden layer, with localist coding of properties at the input layer) and  $\mathbf{Y}$  encodes the relation of properties over objects on the hidden layer.<sup>3</sup> A single property vector is generated by multiplying the weight matrix,  $\mathbf{Y}$ , by the vector representing the property,  $\mathbf{z}$ , to obtain  $\mathbf{x} = \mathbf{Y}\mathbf{z}$ . The model is trained by finding weights  $\mathbf{Y}$  and representations  $\mathbf{Z}$  that minimize the error in reconstructing  $\mathbf{X}$ .

### Approximating generalization

It should be clear that the linear neural network can perfectly reproduce any observed matrix  $\mathbf{X}$ , provided  $K$  is greater than or equal to the rank of  $\mathbf{X}$ . This follows simply by thinking about Equation 2 as a set of equations for the entries in  $\mathbf{X}$  where the entries in  $\mathbf{Y}$  and  $\mathbf{Z}$  are free parameters – we can reproduce  $\mathbf{X}$  if we have enough free parameters to construct its linearly independent columns. The more interesting question is thus how the network will generalize. That is, what does it predict for a new property based on what it has learned from the observed properties?

Analyzing generalization requires making assumptions about the nature of the  $\mathbf{z}$  vector for a novel property. If we assume that  $\mathbf{z}$  follows a multivariate Gaussian distribution with mean zero and covariance  $\sigma_z^2 \mathbf{I}$ , we can obtain some results that provide connections between the neural network and Bayesian approaches. This is a reasonable assumption if the weights from the localist node from an unobserved property to the hidden layer are assumed to be independently drawn from a Gaussian distribution. This will be true if the initial weights are drawn from a Gaussian, but as we show below it is also consistent with the implicit prior assumed by gradient descent algorithms.

We can determine the prediction the neural network will make for a new property by asking how  $\mathbf{x}$  is distributed given  $\mathbf{Y}$ . Using standard Gaussian identities,  $\mathbf{x}$  will be multivariate Gaussian with mean zero and covariance

$$\Sigma_{\text{continuous}} = \sigma_z^2 \mathbf{Y}\mathbf{Y}^T \quad (3)$$

since  $\mathbf{x}$  is a linear function of a Gaussian random variable.

Characterizing the distribution on  $\mathbf{x}$  implied by this model makes it straightforward to construct a condition under which the model produces the same joint distribution as a probabilistic model based on any discrete graph structure: This will occur when  $\Sigma_{\text{discrete}} = \Sigma_{\text{continuous}}$ . This can be used to establish a direct connection between the neural network's representations for the objects and the graph Laplacian  $\Delta$ . In particular,  $\mathbf{Y}$  can be obtained from the eigenvectors of  $\Delta$ . If the network is trained from a matrix  $\mathbf{X}$  of property values sampled from  $p(\mathbf{x})$ , then any learning algorithm that produces a representation corresponding to the principal components of  $\mathbf{X}$  will

<sup>3</sup>Since the model is linear, this interpretation can be “transposed” to give another interpretation, where  $\mathbf{Y}$  is the hidden layer representation of the objects and  $\mathbf{Z}$  the weights for the properties. This is a more intuitive way of formulating the model and is also more consistent with connectionist models of these phenomena, as advocated by Rogers and McClelland (2004). However, this interpretation is a little harder to use to get intuitions about the results shown below.

approximate this outcome, with the approximation improving as the number of samples  $M$  increases. Thus, the answer to our first question is that the probabilistic model can be approximated arbitrarily well by a neural network.

Establishing that our simple neural network with continuous representations can potentially approximate the generalization performance of a probabilistic model using a discrete representation raises a different question: Will these models also perform similarly when learning those representations from data? That is, if we train a neural network model on a finite number of samples from  $p(\mathbf{x})$ , will it behave similarly to a probabilistic model that infers a discrete representation from the same data via Bayesian inference? This is a question about the inductive biases of these two different approaches to learning – those factors that lead a learning algorithm to favor one solution over another. In the context of the property induction problem, this question reduces to whether the predictions produced by the neural network after training will be similar to those resulting from Bayesian inference with a particular prior distribution.

### Gradient descent and Bayesian inference

Gradient descent is a standard approach to training a neural network, where the weights are assigned small random values and then modified in the direction indicated by the gradient of the error repeatedly for a fixed number of training iterations. In this section, we summarize results showing that this learning algorithm behaves similarly to Bayesian inference with a Wishart prior on covariance matrices.

For simplicity, we start by considering the problem of updating  $\mathbf{z}$  for a single property, keeping  $\mathbf{Y}$  fixed. In this case the goal is to find the  $\mathbf{z}$  such that  $\mathbf{Y}\mathbf{z}$  minimizes the squared error in reconstructing the corresponding property vector  $\mathbf{x}$ . We can write the objective function as  $(\mathbf{x} - \mathbf{Y}\mathbf{z})^T(\mathbf{x} - \mathbf{Y}\mathbf{z})$ . Differentiating, we obtain the weight update rule

$$\Delta \mathbf{z} = \eta \mathbf{Y}^T (\mathbf{x} - \mathbf{Y}\mathbf{z}) \quad (4)$$

where  $\eta$  is a learning rate (assuming simultaneous updates).

For comparison with performing Bayesian inference, we can derive the estimate for  $\mathbf{z}$  that we would obtain by assuming a Gaussian prior and finding the posterior mean (or the maximum a posteriori value, as they are the same in this case). The Bayesian estimate is

$$\hat{\mathbf{z}} = (\mathbf{Y}^T \mathbf{Y} + \frac{\sigma_x^2}{\sigma_z^2} \mathbf{I})^{-1} \mathbf{Y}^T \mathbf{x} \quad (5)$$

where  $\sigma_x^2$  is the assumed noise variance in  $\mathbf{x}$ .

Inspecting these two equations, we can see that they use two different forms of *regularization* – approaches to controlling the complexity of the solution found by learning. Neural network training typically starts with weights close to zero, so weights grow over successive passes through the data. Stopping early keeps weights smaller. In the Bayesian solution, the ratio of  $\sigma_x^2$  to  $\sigma_z^2$  controls the size of the weights: If  $\sigma_z^2$  is small relative to  $\sigma_x^2$  (i.e., we are more confident in our prior

beliefs than the observed data), the corresponding term can dominate the matrix that is inverted, reducing the weights proportionally. Despite this difference in regularization style, there are cases where they will produce similar results: If  $\mathbf{z}$  is close to zero and  $\mathbf{Y}^T \mathbf{Y}$  is close to  $c\mathbf{I}$ , then  $\hat{\mathbf{z}}$  will equal  $\mathbf{z}$  after one pass of gradient descent with  $\eta = 1/(c + \frac{\sigma_z^2}{\sigma_x^2})$ .

More generally, it is possible to show that the solution produced by a linear neural network trained by gradient descent with early stopping is equivalent to generating a Bayesian estimate with a Gaussian prior (Fleming, 1990; Santos, 1996). When applied to Equation 4, these results indicate that following this learning rule is equivalent to assuming a Gaussian prior on  $\mathbf{z}$  with mean zero and a covariance determined by  $\mathbf{Y}$  and the number of iterations of learning.

While the analysis presented so far has focused on  $\mathbf{Z}$ , the linearity of the network means that learning  $\mathbf{Y}$  can be analyzed in the same way. A Gaussian prior on  $\mathbf{Y}$  implies that the implicit prior on  $\mathbf{Y}\mathbf{Y}^T$  assumed by a neural network trained by gradient descent with early stopping is a Wishart distribution, the distribution obtained by taking the product of two matrices drawn from a multivariate Gaussian (Muirhead, 1982).

## Summary of mathematical results

The key results of the mathematical analyses presented in this section are that the generalization performance of the KT09 model can be approximated by a linear neural network model with continuous representations, and that the inductive bias induced by training the neural network by gradient descent with early stopping should be similar to that of Bayesian inference with a Wishart prior on covariance matrices. These results make two clear predictions: Neural networks should perform best when learning from data whose covariance matrices are Wishart distributed, and we should expect them to perform more similarly to Bayesian models that use a Wishart prior than to models with other priors.

These results also raise a question: How similar is the Wishart distribution to distributions that are based on discrete representations? If the distributions are similar, then the inductive biases of neural networks and probabilistic models with discrete representations will also be similar, meaning that these approaches need not be seen as lying in opposition to one another. If the distributions are different, then there are opportunities to empirically separate these accounts and we cannot view simple neural networks as a scheme for approximating the solutions identified by probabilistic models.

## Simulations

We explored the issues raised by our mathematical analyses through simulations comparing the performance of neural networks and Bayesian models with different prior distributions. The set of priors that we used included the Wishart distribution as well as several distributions based on discrete structures. Following the KT09 model, we included distributions on covariance matrices by defining a distribution on graphs  $\mathbf{G}$  and then deriving a covariance matrix for

each graph. The distributions on graphs we considered were stochastic graph grammars that generate trees, chains, grids, and partitions (Nagl, 1986; Kemp & Tenenbaum, 2008) and Erdős-Rényi random graphs (Erdős & Rényi, 1959).

Our analysis proceeded as follows. For each prior distribution over covariance matrices, we generated  $T$  samples of  $N \times N$  covariance matrices  $\Sigma_1, \dots, \Sigma_T$ . From each covariance matrix, we sampled a  $N \times M$  matrix  $\mathbf{X}$  containing the values of  $M$  features for each of the  $N$  objects ( $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_M]$ ,  $\mathbf{x}_i \sim N(\mathbf{0}, \Sigma)$ ). We then computed the marginal probability of these samples under a Wishart distribution, integrating over its parameters. This let us determine how closely different priors relate to the Wishart distribution.

To compare the different approaches to learning, we applied the neural network and Bayesian models to all of the samples of  $\mathbf{X}$  we had produced. We found  $\mathbf{Y}\mathbf{Y}^T$  at different stopping points and compared this to the true covariance matrix for data generated from each of the different priors. The goal of this first analysis was to evaluate whether the neural network performed best with data whose covariance matrix was Wishart distributed. For the second analysis, we also obtained an estimate of the covariance matrix from each sample using Bayesian inference with each of the different prior distributions and calculated the distance between these covariance matrices and  $\mathbf{Y}\mathbf{Y}^T$ . This allowed us to examine how the distance between the solutions produced by the neural network and Bayesian inference was related to the extent to which the priors were similar to a Wishart distribution.

## Calculating marginal Wishart probabilities

To perform our analysis, we must be able to calculate how close a distribution is to a Wishart. We did this using the marginal probability of a set of covariance matrices under a Wishart, integrating over the parameters of the distribution. The result is a measure of the “Wishartiness” of the covariance matrices, which can be applied to samples from different distributions in order to evaluate their similarity to a Wishart.

Assume we have a Wishart distribution with degrees of freedom  $b$  and covariance center  $\mathbf{S}$ , and that  $\mathbf{S}$  is drawn from an inverse-Wishart distribution with parameters  $a$  and  $\Psi$ . We draw covariance matrices  $\Sigma_1, \dots, \Sigma_T$  from this distribution. The marginal probability of  $\Sigma_1, \dots, \Sigma_T$  given  $a$ ,  $b$ , and  $\Psi$  is

$$p(\Sigma_1, \dots, \Sigma_T) = \int d\mathbf{S} p(\mathbf{S}|a, \Psi) \prod_{t=1}^T p(\Sigma_t|b, \mathbf{S})$$

which yields

$$p(\Sigma_1, \dots, \Sigma_T) = \frac{\Gamma_N(\frac{1}{2}(a + bT)) |\Psi|^{a/2} \prod_{t=1}^T |\Sigma_t|^{(b-N-1)/2}}{\Gamma_N(a/2) (\Gamma_N(b/2))^T |\Psi + \sum_{t=1}^T \Sigma_t|^{(a+bT)/2}}$$

where  $\Gamma_N(\cdot)$  is the multivariate gamma function,

$$\Gamma_N(x) = \pi^{N(N-1)/4} \prod_{j=1}^N \Gamma(x + (1-j)/2)$$

Figure 1: Average distance between the true covariance matrix and the covariance matrix learned by the neural network.

and  $\Gamma(x)$  is the generalized factorial function (Boas, 1983). This is the ratio of the normalization constants for a Wishart and an inverse-Wishart distribution, due to conjugacy.

### Neural network learning

The linear neural network is defined by two matrices: a  $N \times K$  matrix  $\mathbf{Y}$  that maps the properties into the latent space and a  $K \times M$  matrix  $\mathbf{Z}$  that maps the latent space to the objects. We trained the neural network by gradient descent on error, with

$$\Delta \mathbf{y} = \eta (\mathbf{x} - \mathbf{y}\mathbf{Z})\mathbf{Z}^T \quad (6)$$

and Equation 4 as the weight update rules.  $K$  was set to one more than the rank of the object matrix  $\mathbf{X}$ . The weights were initialized to normally distributed random values with mean 0 and variance 0.05. We used a learning rate  $\eta$  of 0.0025 and 2000 training epochs (full passes through the data), which were determined by pilot simulations. At each possible stopping point (epoch), we recorded  $\mathbf{Y}\mathbf{Y}^T$ . Figure 1 shows the average distance between  $\mathbf{Y}\mathbf{Y}^T$  and the true covariance matrix as a function of epoch, which initially decreases and then rises again due to overfitting.

### Priors and Bayesian inference

We considered eight different prior distributions, requiring us to use three different algorithms for Bayesian inference.

**Wishart prior.** The first Bayesian model used a Wishart prior with covariance center  $\mathbf{I}$  and degrees of freedom  $b = 1000$ . Unfortunately the Wishart is not conjugate to the multivariate Gaussian, so we found an estimate of the covariance matrix under this prior using stochastic search with simulated annealing. The state of the search (a covariance matrix) was initialized to a random draw from the posterior distribution using an inverse-Wishart prior (for details, see Gelman, Carlin, Stern, & Rubin, 1995). A new proposed state was then drawn from a Wishart distribution centered at the current state with  $b + N$  degrees of freedom. A Metropolis-Hastings acceptance rule was used to decide whether to replace the current state with the proposed state, based on the product of two ratios of their (unnormalized) posterior probabilities

and the probability of generating the proposed state from the current state and vice versa (Metropolis, Rosenbluth, Rosenbluth, Teller, & Teller, 1953). This probability was annealed by raising the probability to the power  $1/\tau$ , with  $\tau$  decreasing according to a logarithmic schedule.

**Graph grammar priors.** We used four priors based on graph grammars, defining distributions on graphs that correspond to trees, grids, chains, and partitions (Nagl, 1986; Kemp & Tenenbaum, 2008). These random graph grammars are generative processes that start with a single node and then replace a random node in the current graph with two nodes  $J$  times, where  $J \sim \text{Geom}(\theta)$ . Different graph structures result from using different rules for connecting the parents and children of the old node to the new nodes (for the tree grammar, there is also a latent node that cannot contain any objects), and different rules for connecting the new nodes result in different generated graph structures.<sup>4</sup> Afterwards, the objects are assigned to nodes uniformly at random (except not to latent nodes). For example, if the rule for node replacement does not create any edges, then the random graph grammar generates random partitions of the objects.

To convert the graph to a covariance matrix, we follow Kemp and Tenenbaum (2008) by first forming an “entity” graph containing  $N + L$  nodes, where the first  $N$  nodes represent each object and are only directly connected with an edge to their assigned node. Second, we complete the “entity” graph by connecting the last  $L$  nodes to each other according to the result of the previous graph replacement process. Next, we form a  $(N + L) \times (N + L)$  adjacency matrix  $\mathbf{W}$ , where  $1/w_{ij} \sim \text{Exp}(\beta)$  if there is an edge between nodes  $i$  and  $j$  (representing how close nodes  $i$  and  $j$  are). Otherwise,  $w_{ij} = 0$ . This specifies a  $(N + L) \times (N + L)$  covariance matrix for the multivariate Gaussian distribution over the latent and observed variables,  $(\mathbf{E} - \mathbf{W} + \frac{1}{\sigma^2}\mathbf{I})^{-1}$  where  $\mathbf{E}$  is a  $(N + K) \times (N + K)$  diagonal matrix with  $e_{ii} = \sum_j w_{ij}$  and  $\mathbf{I}$  is the  $(N + K) \times (N + K)$  identity matrix. The hidden nodes can be marginalized out analytically, resulting in the  $N$  objects being normally distributed with covariance matrix given by the first  $N \times N$  elements of the original covariance matrix.<sup>5</sup> Bayesian inference was performed with code from <http://charleskemp.com>, which uses stochastic search to find an estimated maximum *a posteriori* covariance matrix for a given set of data.<sup>6</sup>

**Erdős-Rényi priors.** In addition to the four random graph generators from Kemp and Tenenbaum (2008), we used a standard random graph generator: the Erdős-Rényi random graph (Erdős & Rényi, 1959). Each object is represented by a node. Unlike the node replacement grammars, we gener-

<sup>4</sup>For simplicity, we assumed the graph structures are undirected.

<sup>5</sup>It is important to note that this is not equivalent to the first  $N \times N$  elements of the inverse covariance matrix.

<sup>6</sup>The parameters were set to  $\beta = 0.4$  (edge length parameter),  $\sigma^2 = 0.4$  (covariance matrix regularization parameter), and  $\theta = 1 - e^{-3}$  (simplicity bias), which are similar to the values used by Kemp and Tenenbaum (2008). We used the “45” speed setting.

ate random graphs by directly connect pairs of objects with an edge with probability  $p$ . Once the graph is generated, the implied covariance matrix is found by the same procedure as before (except we do not need to perform the additional marginalization step as the initial covariance matrix is already  $N \times N$ ). We considered priors corresponding to  $p \in \{0.1, 0.5, 0.9\}$ . Covariance matrices with these priors were estimated using stochastic search by simulated annealing. The covariance matrix was initialized to a random Erdős-Rényi covariance matrix and proposals were generated from the current state by removing or deleting a random number of edges (such that the number of edges in the proposals were binomially distributed). The search procedure and annealing schedule were otherwise the same as for the Wishart prior.

### The distance between covariance matrices

To analyze the results produced by the neural network and Bayesian models, we needed a measure of the similarity of two matrices. We used a distance metric between positive definite matrices (valid covariance matrices) defined by Förstner and Moonen (1999)

$$d(\Sigma_1, \Sigma_2) = \sqrt{\sum_{i=1}^n \ln^2 \lambda_i(\Sigma_1, \Sigma_2)}, \quad (7)$$

where  $\lambda_i(\Sigma_1, \Sigma_2)$  are the generalized eigenvalues of  $\Sigma_1$  and  $\Sigma_2$ , being the roots of  $|\lambda \Sigma_1 - \Sigma_2| = 0$ . When computing these distances, we used the best stopping point for the neural network (the one resulting in minimal distance). Looking across epochs, we found the value of  $\mathbf{Y}\mathbf{Y}^T$  with the minimal distance to the true covariance matrix and to the eight covariance matrices estimated by Bayesian models with different priors.

### Simulation procedure and results

For each prior, we generated 101 data sets that each consisted of  $T = 100$  covariance matrices. From each matrix, we sampled the values of  $M = 100$  features for  $N = 10$  objects. We then computed the marginal probability of the covariance matrices generated by each prior under the assumption they were drawn from a Wishart distribution, with the median result shown in the top row of Table 1. As expected, the Wishart prior was the most compatible with a Wishart distribution. The discrete priors produced results that were reasonably consistent with the Wishart distribution, while the the Erdős-Rényi generative processes produced results that were poorly characterized as Wishart. We used the data set with the median Wishart value for the subsequent analyses.

Next, we trained neural networks on the object set  $\mathbf{X}$  generated from each covariance matrix sampled from each of the eight priors, and computed the distance between  $\mathbf{Y}\mathbf{Y}^T$  and the true covariance matrix. The results are shown in the second row of Table 1. Performance was statistically significantly better when the true covariance matrices were drawn from the Wishart, consistent with our mathematical analysis.

Finally, we found Bayesian estimates of the covariance matrix for each object set  $\mathbf{X}$  using all eight priors. Stochastic search was run for 20000 iterations in each case. We

Figure 2: Average (smallest possible) distance of  $\mathbf{Y}\mathbf{Y}^T$  from the Bayesian estimates of the covariance matrix, plotted as a function of the logarithm of the Wishart marginal likelihood for the corresponding prior.

computed the distance between  $\mathbf{Y}\mathbf{Y}^T$  and the Bayesian estimates for each object set, then averaged this quantity across all object sets. The results are shown in the third row of Table 1. As predicted, we found a negative correlation between the distance between estimates and the extent to which the corresponding prior is consistent with a Wishart distribution (as reflected by the marginal probabilities in the first row of Table 1) with  $r = -0.92$  and  $r = -0.83$  for Pearson’s product-moment and Spearman’s rank-order correlation, respectively.<sup>7</sup> A scatterplot showing the relationship between these two quantities is shown in Figure 2.

The variation in how well the neural network approximated the Bayesian estimates with different prior distributions is informative about the inductive biases of neural networks and structured probabilistic models. The neural network was closest in performance to Bayesian inference with a Wishart prior, which is purely continuous. All priors based on discrete structure, in the form of an underlying graph, resulted in statistically significantly worse performance. Within these discrete priors, those based on graph grammars were better approximated than the Erdős-Rényi priors. This pattern of results is interesting from the perspective of the debate between probabilistic and connectionist accounts of property induction, which has focused on discriminating the predictions of probabilistic models using representations based on graph grammars from neural networks. Our results suggest that this may be harder than discriminating probabilistic models that assume arbitrary discrete structure, as in the Erdős-Rényi priors, from neural networks.

<sup>7</sup>We confirmed that this correlation could not be fully explained by the norm of the matrices, but plan on running further simulations to rule out other possible alternative explanations for our results.

Table 1: Properties of different priors and comparison of gradient descent and Bayesian learning

	Wishart	Graph grammar priors				Erdős-Rényi priors		
		Grid	Chain	Tree	Partition	$p = 0.1$	$p = 0.5$	$p = 0.9$
Marginal probability under Wishart	-567.87	-867.68	-884.95	-946.22	-1073.10	-2678.04	-2940.98	-2919.44
Distance of $\mathbf{Y}\mathbf{Y}^T$ from true covariance	14.15 <sup>a</sup>	33.31 <sup>b</sup>	34.18 <sup>b</sup>	32.36 <sup>b</sup>	33.97 <sup>b</sup>	33.93 <sup>b</sup>	31.73 <sup>b</sup>	33.35 <sup>b</sup>
Distance of $\mathbf{Y}\mathbf{Y}^T$ from Bayesian estimate	23.53 <sup>a</sup>	36.04 <sup>b</sup>	36.07 <sup>b</sup>	36.03 <sup>b</sup>	36.19 <sup>b</sup>	50.21 <sup>c</sup>	46.29 <sup>d</sup>	53.23 <sup>e</sup>

Note: In each row, different superscripts indicate statistically significant differences in scores (Bonferroni  $p < .05$ ).

## Discussion

Our analysis of the relationship between probabilistic and connectionist models in the context of property induction has produced several interesting results. First, the generalization performance of a probabilistic model with a discrete representation can be approximated by an appropriately configured linear neural network with continuous representations. Second, training such a network by gradient descent with early stopping is similar to performing Bayesian inference over covariance matrices with a Wishart prior. Finally, prior distributions that assume discrete structure vary in the extent to which they resemble a Wishart prior, and this variation predicts how well Bayesian inference using those prior distributions is approximated by a neural network. However, all prior distributions using discrete structure that we considered resulted in worse approximations than that given with a Wishart prior.

There are limitations in the analyses presented here that we hope to address in future work. As noted earlier, the assumption of linearity in the neural network deviates from standard practice in connectionist modeling. While we do not expect that this will substantially change our results (given that early stopping enforces small weights, effects of the non-linearity should be minimized), further simulations should be conducted to confirm that this is the case. We would also like to explore more sophisticated learning algorithms, such as cascade correlation (Fahlman & Lebiere, 1990), which may result in different inductive biases.

Returning to the questions that motivated our investigation, our results provide a mixed set of answers as to the potential for neural networks to be viewed as a continuous approximation to Bayesian inference over discrete representations. While specific neural networks can always be constructed that emulate the generalization performance of probabilistic models using discrete representations and the inductive biases of neural networks can be expressed in a form that is consistent with Bayesian inference, these inductive biases are quite different from those of Bayesian models using priors defined on discrete objects. Our results suggest that there is room to empirically separate these two approaches, and that identifying neural systems that can approximate arbitrary Bayesian mod-

els may require going beyond simple neural networks that use general-purpose learning algorithms.

## Abstract

The paper explores the influence of the type of relations among players on cooperation in the Prisoner's dilemma game. The relations between players are operationalized according to Fiske's relational models theory (Fiske, 1991): communal sharing, authority ranking, equality matching, and market pricing. This is achieved by using various ways of distributing the total payoff gained by a dyad of players in a series of Prisoner's dilemma games: each player receives the total payoff (*unity*), one of the players receives more than the other (*hierarchy*), each player receives half of the total payoff (*equality*), each player receives a portion of the total payoff proportional to his/hers individual payoffs (*proportionality*). For these four conditions, the cooperation rates, the mutual cooperation, the mutual defection, and the payoffs gained are analyzed and compared for a series of forty games. The results show that in the *proportionality* condition there is less cooperation, less mutual cooperation, more mutual defection and less total payoff than in the other three conditions.

## Introduction

### Prisoner's Dilemma Game

The Prisoner's dilemma (PD) game is one of the most extensively studied social dilemmas. PD is a two-person game. The interest in studying PD game arises from the idea that many social situations and problems such as overpopulation, pollution, energy savings, participation in a battle, etc. have such a dilemma structure (Dawes, 1980). The payoff table for this game is presented in Figure 1. In the PD game the players simultaneously choose their moves – C (cooperate) or D (defect), without knowing their opponent's choice.

In order to be a Prisoner's dilemma game, the payoffs (see Figure 1) should satisfy the inequalities  $T > R > P > S$  and  $2R > T + S$ . Because of this game structure a dilemma appears – there is no obvious best move. On one hand, the D choice is dominant for both players – each player gets larger payoff by choosing D (defection) than by choosing C (cooperation) no matter what the other player chooses. On the other hand, the payoff for mutual defection (P) is lower than the payoff if both players choose their dominated C strategies (R for each player).

As PD game is used as a model for describing social dilemmas and studying the phenomenon of cooperation, there is a great interest in the conditions that could promote or diminish cooperation.

		Player II	
		C	D
Player I	C	R, R	S, T
	D	T, S	P, P

		Player II	
		C	D
Player I	C	3, 3	1, 4
	D	4, 1	2, 2

Figure 1: Payoff tables for the PD game – with standard notation for the payoffs and an example. In each cell the comma separated payoffs are the Player I's and Player II's payoffs, respectively.

In game theory several assumptions about the game and the players are made. The agents are assumed to be perfectly rational and to have perfect information about the game. Under these conditions, they are supposed to try to maximize their payoffs in a completely selfish manner (Colman, 2003). From this point of view the dominant strategy in the game is defection (in one-shot or in repeated PD games with a fixed and known number). This prediction is in contrast with the behavior of the players observed in laboratory settings or in real life situations.

In human societies, people cooperate all the time and often cooperation is seen as one of the foundations of human civilization (see e.g. Gärdenfors, 2003). Sally (1995) provides a meta-review of the experiments involving PD games published between 1958 and 1995 and shows that in its iterated version (the game is played many times), cooperation choices are made in 20-50 % of the games (mean 47.4 %) and even in one-shot games many players cooperate although much less than in the iterated version.

Several studies have shown how cooperation can emerge from expected utility or anticipatory reinforcement models without any specific relations between the players (Grinberg, Hristova, & Lalev, 2010; and the references there in).

However, it is clear that the deeper understanding of how people make decisions while playing PD games should account for the role of the social relations involved in the interactions. Moreover, as the PD game is central in the

modeling of social interactions it can be used to explore the existence and limits of the relational social types as posited by relational social models (see e.g. Haslam, 2004). Exploring the potential of games like the PD game as modeling relational types is one of the goals of this paper.

### Social Interactions and Cooperation

How decision-making in PD games is influenced by social interactions has been explored in many studies that try to account for the contradiction between the normative predictions and the experimental results in PD games.

Several studies have established the influence of social interaction on cooperation. For instance, Durkin, Frost, Aronov & Breslow (1967) found that cooperative moves double when participants have visual contact with each other compared to the condition where they don't have such contact. Sally (2001) investigated the behavioural changes in participants who know each other or are psychologically or socially close and discussed the importance of such closeness in game strategy building. According to this account, participants play differently depending on how they perceive their opponent – as a friend or a stranger. In both cases, according to Sally (2001), the social interaction is essential and the social dilemmas like PD need to be investigated from the perspective of a general relational theory.

There are several theories that account for the cooperative behavior in PD games in terms of socially established values and stress the importance of social interaction and relationships as tools for achieving cooperation. Among them are theories that explain cooperation by altruism, reciprocity or reputation building.

*Reputation building theory* (Kreps et al., 1982; Andreoni & Miller, 1993) is one of the main theories aimed to explain cooperation in iterated PD game. This theory assumes that players are self-interested (not altruists), but the repetition in iterated PD games creates incentives to cooperate. According to this model, the player is building himself a reputation of a cooperative player and expects that the other player will also cooperate.

*Reciprocity*, according to many researchers, is a widespread norm and is the basis of many relationships and societies (Trivers, 1972). People reciprocate cooperation with cooperation. One of the most studied strategies that are based on reciprocity is the tit-for-tat strategy. A player using this strategy cooperates initially, and then plays the same as his/her opponent did in the previous game. It has been demonstrated in computer tournaments that in the long run the tit-for-tat strategy results in higher payoffs compared to other strategies (Axelrod & Hamilton, 1984; Komorita, Hilty, & Parks, 1991).

Another influential theory about cooperation in PD game is based on the concept of *altruism*. In contrast to reputation building theory, this theory assumes that some players are not strictly self-interested and view more benefit in cooperation than the actual payoffs they receive (Cooper et

al., 1996). From an altruistic perspective, cooperation can yield higher payoffs than defection.

Although these social theories of cooperation have been proposed to explain cooperative behavior unexpected by normative game theory, it is interesting to consider more general social theories that are more closely related to the game theoretic analysis of social relations. In our opinion such a theory is the relational models theory proposed by Alan Fiske (Fiske, 1991).

### Relational Models Theory

Relational models theory (Fiske, 1992; Fiske & Haslam, 1996; McGraw, Tetlock, & Kristel, 2003; Rai & Fiske, 2011) states that there are four basic schemas that are used to build, organize and maintain relationships and interactions among individuals in a society. These models are supposed to be universal and all relations could be described by these models or by combination of them. The four types of relations generate four modes for every aspect of the interactions between people – resource allocation, moral judgments, decision-making, etc.

These four relation models are the following (Fiske, 1992):

- **Communal Sharing** – relations in an undifferentiated group of people with equivalent status. Everyone in a community - which could consist of two members or could be very large – has some rights and some duties. The focus is on commonalities and not on distinctions;
- **Authority Ranking** – implies an ordinal ranking in society and this ranking scheme determines one's relative status. For instance, military hierarchy can be considered a prototype of such relations;
- **Equality Matching** – relations are based on a model of one-to-one correspondence as in turn-taking, tit-for-tat strategies, etc. The social prototype would be friendship networks, in which reciprocity is a norm which rules the distribution of wealth;
- **Market Pricing** – based on a model of proportionality in social relations in which people reduce their interaction to some ratios of utility measures. Examples of relations of this type are the ones governed by prices, rational calculations, expected utilities, etc.

### Payoff Distribution in PD and Fiske's Relational Model Types

Fiske's relational model theory (Fiske, 1992) claims that different relational models influence and are manifested in a lot of domains and activities, e.g. reciprocal exchange, distribution, contribution, work, significance of time, social influence, constitution of groups, motivation, moral judgments, etc.

Here, we focus on the type of distribution of group resources using one and the same game, namely the PD

game. We focus on social interaction related to social exchange as instantiated by contribution and distribution of a common resource. We share the opinion that situations involving exchange are the most appropriate to study the four types of relational models in isolation (Haslam, 2004).

In the classical PD game experiments each player is rewarded according to his/hers personal payoffs. However, Fiske's relational model theory states that in real-life situations the distribution of payoffs and resources depends on the type of the relational model behind the social interaction. There are **four types of distributions**, corresponding to the four relational types described above (Fiske, 1992, Table 1, p. 694):

- **communal sharing** – 'corporate use of resources regarded as common, everything belongs to all together';
- **authority ranking** – 'the higher the person's rank, the more he or she gets';
- **equality matching** – 'to each the same, everyone gets identical shares';
- **market pricing** – 'to each in due proportion'.

## Goals of the Study

The main goal of the present study is to make a first step in the mapping of Fiske's relational models theory to games from game theory. More specifically, we want to study how the four relational types, implemented as distinct payoff distributional models, influence cooperation in PD games. As relational models are complex and encompass various domains, in the present study the focus is on the different **distribution schemas** within the same type of games (the PD game).

We aim to explore what is the influence of the type of relation among players on a set of game outcomes that characterize the playing of a PD game – cooperation, mutual cooperation, and mutual defection. It is also important to check the influence of the distribution model on the overall payoffs that are received – e.g. what type of model is more beneficial in terms of total payoff earned in interactions with the strategic structure of the PD game.

Cooperation is expected to be the highest if the payoff distribution is in accordance with the communal sharing model. Cooperation is expected to be lowest if the distribution follows the rules of market pricing model, e.g. when everyone is rewarded depending on his/her personal contribution – in this scenario we expect more individualistic orientation of the players.

## Method

### Stimuli

A sequence of 40 Prisoner's dilemma games is used in the experiment. All of the games used had the payoff matrix given in Figure 2. At the beginning of the series there were

5 training games (results from these games are not included in the analysis) thus the total sequence comprised 45 games.

		Player II	
		C	D
Player I	C	40, 40	10, 50
	D	50, 10	15, 15

Figure 2: Payoff table for the PD game used in the experiment.

## Experimental Conditions

The **distribution of the total payoff** is varied in accordance with the four relational models described above in a between-subjects design. There are four experimental conditions that differ in the way that the total payoff of a pair is divided between the players in that pair:

- **Unity condition** – each player receives the total payoff earned by the pair (*communal sharing* relational model);
- **Hierarchy condition** – one of the players receives more than the other – 2/3 vs. 1/3 of the total payoff of the pair (*authority ranking* relational model);
- **Equality condition** – each player receives equal portion of the total payoff (*equality matching* relational model);
- **Proportionality condition** – each player receives a share of the total payoff proportional to his/hers individual payoffs (*market pricing* relational model).

## Procedure

Subjects were tested in pairs. After receiving the appropriate instructions for the experimental condition they were in, each dyad played 5 training games, followed by 40 games that were analyzed. The experimenters secured that the participants will not have visual, verbal and any kind of other contact before and during the experiment. Therefore, no player knew who the other player was before the end of the experiment.

Instructions for the experiment explained in details the rules of the game and included several test questions to make sure that the participants understood correctly the rules. There were four instructions that varied only in the explanation for the total monetary payoff distribution. They are quoted below because they define the relational models in the four conditions:

- *Unity condition* – 'Each of you will receive the amount of money you have earned together';
- *Hierarchy condition* – 'You will get 2/3 of the total amount of money of the pair, and the other player will get 1/3 of it (for one of the players). You will get 1/3 of

the total amount of money of the pair, and the other player will get 2/3 of it (for the second player)';

- *Equality condition* – ‘The total amount of money of the pair will be split equally between you and the other player’;
- *Proportionality condition* – ‘The total amount of money of the pair will be split between you and the other player in accordance with the number of points each of you has earned’.

The game was presented in a formal and a neutral formulation. On the interface, the cooperation move was labeled ‘1’ and the defection move was labeled ‘2’. However, further in the paper, for convenience, we will continue to use *cooperation* instead of move ‘1’ and *defection* instead of move ‘2’. Matlab 7.6.0 (R2008a) was used for presenting the game and recording the choices of the players.

After each game the subjects got feedback about their own and the other player’s choice and payoffs in the current game. They could also constantly monitor their own total payoff; the total payoff of the other player; the total payoff for the pair, and the monetary equivalent of the total payoff of the pair (that is to be distributed among them).

Participants were instructed to try to *maximize* the amount of money they will get. Subjects were paid real money accordingly to the final payoff in the game. Players in the *unity* condition received the same amount of money for 1000 points as participants in the other 3 conditions received for 500 points. Thus we tried to equate the absolute magnitude of the monetary payoff that the participants could receive during the experiment.

Each session lasted about 20 minutes.

## Participants

80 participants (47 female, 33 male) took part in the experiment. All of them were university students, mean age 23.3 years.

They were tested in 40 pairs – 10 pairs in each experimental condition. Participants were randomly assigned to the experimental condition. In the *hierarchy condition*, it was randomly determined which player will get 1/3 and which player – 2/3 of the total payoff of the pair.

Subjects who have previously played the Prisoner’s dilemma game were not allowed to participate in the study.

## Results

To explore the influence of payoff distribution model on choices and cooperation in the PD games, the following dependent variables are analyzed: number of **cooperative choices for each player**; number of games with **mutual cooperation in a pair**; number of games with **mutual defection in a pair**. In the figures results are presented in percentages for clarity. However, the analysis is performed using the specified dependent variables.

Average **total payoff for a dyad (in points)** is analyzed to assess which type of payoff distribution led to higher profits.

Each dependent variable is analyzed in ANOVA with distribution model as between-subject factor with 4 levels (*unity* vs. *hierarchy* vs. *equality* vs. *proportionality*).

## Cooperation

The cooperative choices (%) for each distribution type are presented in Figure 3. The analysis shows a significant influence of the distribution type on the number of cooperative moves ( $F(3, 76) = 4.49, p = 0.006$ ).

Figure 3: Average percentage of cooperative choices in each distribution condition (\* means  $p < 0.05$ ; \*\* – marginally significant difference).

Post-hoc LSD test shows that the cooperation rate in the *proportionality condition* is significantly lower than the cooperation rate in the *unity condition* ( $p = 0.003$ ) and in the *equality condition* ( $p = 0.002$ ). The difference between cooperation rates in *proportionality condition* and *hierarchy condition* is marginally significant ( $p = 0.065$ ). All other differences are non-significant.

It seems that the type of distributional model influences the cooperation rate. Cooperation is lower when each player gets a portion of the total payoff that is proportional to his/her payoffs during the game. In the terminology of the Fiske’s theory, the market pricing relational model leads to diminished cooperation in comparison to the other three relational models. When the final payoff for the player depends on his/her individual results, the choices are more non-cooperative in comparison to the cases in which the total payoff of the pair is divided between players (no matter in what predefined proportions) and when each player received the total amount earned by both of them.

## Mutual Cooperation

Average percentage of games in which there is mutual cooperation (both players have chosen to cooperate) is presented in Figure 4.

The ANOVA does not identify a statistically significant influence of the distribution type on the number of mutual cooperative game outcomes ( $F(3, 36) = 1.94, p = 0.141$ ). However, a further conducted Post-hoc LSD test shows that difference exists between the *proportionality* and *equality condition* ( $p = 0.038$ ). A marginally significant difference is observed between the *proportionality* and *unity condition* ( $p = 0.079$ ).

Figure 4: Average percentage of mutual cooperation in a pair in each distribution condition (\* means  $p < 0.05$ ; (\*) – marginally significant difference).

It turns out that mutual cooperation is lower when the payoff of each player depends on his individual contribution compared to the situations in which players divide their joint winnings in equal shares or receive the total amount earned. This is a rather logical result in line with the assumption of the current study that the distribution type representing communal sharing or equality matching will promote collectivistic orientation; while money pricing relationship will most probably trigger an individualistic behavior among subject.

### Mutual Defection

Average percentage of games with mutual defection (both players have chosen to defect) is presented in Figure 5.

For the number of games with mutual defection the ANOVA shows a significant influence of the distribution type ( $F(3, 36) = 3.943, p = 0.016$ ). Post-hoc LSD test identifies differences between the *proportionality condition* and every other condition in the experiment – *unity* ( $p = 0.006$ ), *hierarchy* ( $p = 0.032$ ), and *equality* ( $p = 0.005$ ).

Therefore, it can be concluded that when distribution of payoff is conducted according to individual results, mutual defection is a much more typical choice in comparison to all other distribution cases. In all other conditions this outcome (mutual defection) is relatively low. It should be noted that mutual defection leads to the lowest possible payoff for the pair. As noted in the introduction, the defection is dominant strategy for each individual player; however, mutual defection leads to the worst possible payoff for the society –

thus the dilemma structure of the game arises as the opposition between individual and collective rationality.

Figure 5: Average percentage of mutual defection in a pair in each distribution condition (\* means  $p < 0.05$ ).

### Average Payoff

The payoff analysis was conducted on the basis of the average payoff per pair (in points) for the sequence of 40 games (Figure 6). The ANOVA shows a significant influence of the distribution type on the payoff ( $F(3, 76) = 3.271, p = 0.026$ ).

Figure 6: Average payoff per sequence of 40 games for a pair in each distribution condition (\* means  $p < 0.05$ ; (\*) – marginally significant difference).

Significant differences were established through post-hoc LSD test between the *proportionality* and *unity condition* ( $p = 0.011$ ) and between the *proportionality* and *equality condition* ( $p = 0.006$ ). Marginally significant is the difference between the *proportionality* and *hierarchy condition* ( $p = 0.093$ ).

The total payoff of a pair is lower when its distribution among the players depends on the individual contribution and points earned. This is a rather paradoxical result taking

into account that such a distribution is representing the market pricing relational model, which is mostly related to individualistic attitude and profit orientation. However, taking into account that in the *proportionality condition* there is the highest number of games with mutual defection, the result is not surprising and could be explained by the lower payoff that the players get when both are non-cooperative.

## Conclusions and Discussion

The current paper presents an experimental study on the phenomenon of cooperation in Prisoner's dilemma game in the light of Fiske's Relational models theory. The experiment was designed to explore the influence of the different distribution types of the total payoff (thus reflecting the four elementary human relations according to Fiske's theory) on the level of individual and mutual cooperative and non-cooperative behavior.

The results show that the distribution type corresponding to the individualistic Market Pricing relational model is characterized by a lower cooperation, lower mutual cooperation, higher mutual defection and lower total payoff of the participating subjects in comparison to the other distribution situations. When players are rewarded based on their individual results, they cooperate less and receive lower payoffs (for each player and for the dyad of players). This is an interesting result taking into account the fact that in formal game theory, in many experiments, in many real life situations, the players are perceived as individualistic beings. And there are attempts to apply policies aimed at achieving higher collective payoff by profit distribution accordingly to the contribution of each individual. Current results demonstrate that such distribution in fact leads to significantly lower total collective earnings.

An interesting topic for reflections and further research is whether a behavioral model representing competitiveness and profit-orientation might actually be effective in achieving its goals within the Prisoner's dilemma game model, respectfully within real life situations depicting this model.

Another related direction for exploration is *hierarchy condition*. Generally speaking, this condition could lead to higher cooperation despite the difference in received payoffs if the relation between the players is perceived as an in-team relation. This could be achieved by justifying the role attribution in this condition with some game related advantage (e.g. a better strategy in the test games).

A broader implications of these results might be applicable not only to studies of decision making in games, but also to socio-economical policies employed by organizations, governments, etc.

## Abstract

The last 2 decades have produced a vast literature describing relationships between cognitive performance and neuropsychological data. This literature has provided the foundation for countless theories about the neural correlates of cognitive processing and specific theories regarding the role of different cortical areas in human cognition. In this paper, we examine a particular theory – the error likelihood model (Brown & Braver, 2005) – that attempts to account for the function of a particular brain area (the anterior cingulate cortex). A careful evaluation of behavioral data from humans raises questions about the error likelihood model and the implications of neuropsychological data for understanding cognitive performance.

**Keywords:** Neural Correlates; Anterior Cingulate; Error Likelihood; Cognitive Performance; Change Signal.

## Introduction

The last 2 decades have produced a vast literature describing relationships between cognitive performance and neuropsychological data. This literature has provided the foundation for countless theories about the neurological correlates of cognitive processing and specific theories regarding the role of different cortical areas in human cognition. These theories have had a tremendous impact on cognitive science, as well as the perceptions of the general public about the relationship between neural activity and cognitive processing.

The debate surrounding the role and utility of neuropsychological data in understanding human cognition has been ongoing (e.g., Cacioppo, Berntson, Lorig, Norris, Rickett, & Nusbaum, 2003; Coltheart, 2006; Henson, 2006; Uttal, 2001). Whereas evidence of neural correlates have been found in a variety of contexts (e.g., Cabeza & Nyberg, 1997; 2000), direct mappings of information processing activity to particular brain areas may be too simplistic (c.f., Horgan, 1999; Hubbard, 2003; Sohrabi & Brook, 2005). Instead, we argue that it is necessary to understand in detail both the cognitive behavior and the neuropsychological evidence to accurately understand the relationships between neural activity and cognitive processing.

In this paper, we consider a particular example of this complex relationship. We begin with a description of a task – the *change signal task* – which has been used in research attempting to understand the function of the anterior cingulate cortex (ACC) in humans (Brown & Braver, 2005).

Brown and Braver (2005) used fMRI data from participants performing this task to support a model of ACC function they refer to as the *error likelihood model*.

We conducted an extension of Brown and Braver's study using the same task and present the empirical data from human participants here. A detailed analysis of the change signal task and the human performance data provides alternative explanations for most of the human data captured by the error likelihood model, and raises some cautions for those attempting to interpret the significance of neuropsychological data for understanding the underlying cognitive processes of human cognition.

## The Change Signal Task

The change signal task is a modification of the stop signal task from Logan and Cowan (1984), which Brown and Braver (2005) used in an fMRI study to examine the function of the ACC in responding to potential errors. In the task, participants are presented with an arrow on each trial, which points either to the left or the right. This is the *go signal*. Critically, on 33% of the trials, a second arrow facing in the opposite direction (the *change signal*) is presented at a carefully controlled delay (the *change signal delay*) relative to the onset of the first arrow. In trials where this arrow appears, participants are instructed to withhold their initial response, and make the response associated with the change signal instead.

The change signal delay is manipulated throughout the task to ensure a relatively constant error rate, however, this characteristic of the task is not revealed to the participants. In Brown and Braver (2005), two stimulus colors were used, and the change signal delay was manipulated independently for each of the color conditions to produce different error rates (error likelihood conditions). In one, the change signal delay tended to be longer, leading to a higher error likelihood, while the other condition tended to have shorter change signal delays with a correspondingly lower error likelihood.

The change signal delay was 250ms in both conditions at the start of the study for all participants. Correct responses led to an increase in the change signal delay; 2ms for the low error likelihood condition, and 50 ms for the high error likelihood condition. In both conditions, errors led to a 50 ms decrease in the change signal delay. These parameters were intended to produce error rates of 4% and 50% in the

low and high error likelihood conditions, respectively. Finally, the change signal delay was constrained to be between 20ms and 800ms, and responses taking longer than 1000ms after the go stimulus presentation were identified as lapses and treated as errors. This last manipulation prevented people from waiting for arbitrarily long periods before making their responses.

### Experiment in Brown and Braver (2005)

Brown and Braver (2005) conducted an empirical study to assess the role of the ACC in performing the change signal task. In it, participants completed an average of 535 trials of the task in a single session. While doing the task, fMRI data was collected. Brown and Braver (2005) did not consider in detail the performance data from the study, instead focusing on the fMRI results and their error likelihood model. They did, however, provide supplementary materials that include some additional consideration of the behavioral results.

The change signal task offers interesting challenges for human cognition, and the results presented in Brown and Braver (2005) show that the ACC is sensitive to the differences between go and change trials as well as the error likelihood conditions. Our analysis of the task and data from a replication, however, suggest that many of the findings may reflect artifacts of the task, rather than revealing critical differences in the underlying cognitive processing across conditions by the participants in the study. Before describing this in detail, we provide an overview of Brown and Braver's (2005) error likelihood model, and the relationships between the mechanisms in the model and the fMRI data they presented.

### The Error Likelihood Model

The Brown and Braver (2005) error likelihood model presents a theory of ACC function embodied in a neural network-based computational model. The model posits that the ACC functions to detect the likelihood of an error, given a particular task and stimulus context. As they put it, "[the] ACC learns to signal, via the magnitude of its activity, the predicted likelihood of an error occurring in response to a given task condition" (Brown & Braver, 2005, p 1120). They also describe how this conceptualization of ACC function can account for conflict and error detection phenomena that have been shown in ACC activation patterns (e.g., Botvinick, Braver, Barch, Carter, & Cohen, 2001; Cohen, Botvinick, & Carter, 2000).

Brown and Braver suggest that detecting the likelihood of error plays a key role in cognitive control by serving as an "early warning signal" that can be used to recruit resources for performing the task. Thus, a central claim in their theory and model is that ACC activation is used by higher-level cognitive processes to guide adaptive behavior in the task and improve cognitive performance.

The details of the model are beyond the scope of this paper. However, it makes several important predictions in the context of the change signal task. Most intuitively, it predicts that ACC activation should be higher for the high

error likelihood condition than for the low error likelihood condition. The authors discuss this effect in their model as a consequence of learned associations between the stimulus color and the likelihood of an error.

In addition to the predicted differences in cortical activation for the error likelihood conditions, the model also predicts differences between *change trials* (where a change signal is presented) and *go trials* (where no change signal is presented), with higher activation for change trials due to the signal these trials provide for reinforcement learning processes in the ACC. The fMRI data from humans show the same qualitative trends, providing support for the model.

A critical finding in support of the error likelihood model was that ACC activation was higher for go trials in the high error likelihood condition than it was for go trials for the low error likelihood condition. It is argued that sensitivity to the stimulus color is responsible for this effect, since these trials are equivalent in all other respects. This is also the primary finding that differentiates the error likelihood model from an alternative account, the response conflict model (Botvinick et al., 2001).

### Empirical Study

To better understand human performance in the change signal task, we conducted our own empirical study to obtain detailed data on task performance. In addition to the change signal task, participants performed a two-alternative forced choice (2AFC) task that matched the change signal task, only without any change signals. One motivation for this design was to investigate the role of within task fatigue on changes in response time in the change signal task (see Moore, Gunzelmann, & Brown, 2010).

### Methodology

There were 33 participants in the study (18 female and 15 male; ages between 18 and 50). Each participant performed both tasks in a single session lasting approximately 1 hour (task order was counterbalanced). The design of the change signal task replicated the study described in Brown and Braver (2005), except that our participants performed more trials. Specifically, participants completed 6 blocks of 107 trials for a total of 642 trials in our study.

In Brown and Braver's experiment, the association between stimulus color and error likelihood condition was swapped after participants had completed approximately 80% of the trials. This occurred in our experiment at the midway point. Just as in Brown and Braver (2005), this switch in associations between color and error likelihood condition was not signaled to participants. Only one participant in our study reported noticing this manipulation. In fact, only 9 participants were able to accurately articulate the significance of the stimulus colors in the experiment at all.

### Results

We collected accuracy and response time data from participants performing the task. Unless noted otherwise, the

results presented here only include data from trials where correct responses were made. Furthermore, the data from two participants were excluded from the analyses because one failed to complete the 2AFC task, and the other exhibited an unusually long string of incorrect responses during the change signal task. As in Brown and Braver (2005), trials where no response was made within 1000ms of the onset of the go stimulus were aborted and treated as errors, with change signal delays adjusted accordingly.

Figure 1 shows median participant response times relative to the presentation of the initial go stimulus across each of the 6 blocks of trials. Firstly, response times for the 2AFC task are stable across all blocks, showing no evidence of within-task fatigue during the course of the experiment,  $F(1,19723)=3.144$ ,  $p=.076$ .

Beyond the 2AFC, the results for the change signal task are generally consistent with those obtained in the Brown and Braver (2005) experiment, and there are several features that will be relevant for the rest of the analyses and discussion that follows. First, note that the response times for the change signal task are consistently much longer than for the 2AFC, and that there is a wide disparity between the change high and change low conditions. We will demonstrate how these phenomena are related to the dynamics of the task. The closely coupled go low and go high conditions will also be discussed, and it will be shown that participant behavior was indistinguishable between the two.

Figure 1: Median reaction times measured from the go signal for the four conditions of the change signal task as well as the 2AFC.

Figure 2 shows a significant ( $F_{Low}(1,3180)=444.4$ ,  $p < .001$ ,  $F_{High}(1,1643)=374$ ,  $p < .001$ ) correlation ( $r = .77$ ) between the change signal delay and the participant reaction time in the change trials. These data illustrate the impact of the change signal delay on overall response times shown in

Figure 1. In fact, if the change signal delay is subtracted from the response times on change trials, the disparity between these conditions nearly disappears (Figure 3).

Figure 2: Reaction time as a function of change signal delay in correct change signal trials. Regression lines overlay the lighter scatter plots of each condition.

Figure 3: Median reaction times measured from the final stimulus for the four conditions of the change signal task as well as the 2AFC (i.e. the change signal delay has been subtracted from the high error condition reaction times).

One clear consequence of factoring out the change signal delay on change trials is that response times are significantly faster for change trials than for go trials ( $t(10836.23) = -17.2995$ ,  $p < .0001$ ). This effect can be explained in context as a strategic adaptation to the characteristics of the change signal task. Specifically, it is our hypothesis that participants

are intentionally delaying their responses to go signals in hopes of correctly responding to the change signals (Moore, Gunzelmann, & Daigle, 2012).

This perspective accounts for the slower reaction times in the go trials, because it suggests that participants would respond to the go signal only after their strategic delay, or hedge, was complete. It also explains the large difference in response times for the go trials in the change signal task versus response times for the 2AFC task (Figures 1 & 3).

Although we hypothesize that participants also hedge their response in the change conditions, there is no reason for them to delay making a response once a change signal is presented. In change trials, therefore, responses can be initiated as soon as the change signal appears. Moore et al. (2012) present a computational model demonstrating the plausibility of this account.

Another interesting feature in Figure 3 is that median response times for change trials are faster in the high error likelihood condition than in the low error likelihood condition. To understand this average difference, it is necessary to examine the details of human performance in these cases and the characteristics of the task that give rise to the observed results. Figure 4 shows the distribution of response times for the change high and change low conditions (left side), as well as the proportion of lapses in each of the conditions (right side).

Figure 4 illustrates that the difference in response times between the two change conditions in Figure 3 is likely a function of the 1000 ms lapse threshold. In the high error likelihood condition, 15 % of the trials resulted in lapses (see the right half of Figure 4), while only 1% of trials in the low error likelihood condition resulted in lapses. The right side of Figure 4 gives clear evidence that the response time distribution is truncated at the lapse threshold, which has the effect of reducing the median response time for correct responses (lapses are treated as errors).

Figure 4: Response distribution for the high and low change conditions, and the proportion of lapses for each.

Lastly Figure 5 shows the distributions for the two go conditions. They align extremely well, and Kolmogorov-Smirnov test shows no statistical difference ( $p=.36$ ). As discussed below, this is an important result, as it generates questions regarding the extent to which people are aware of the significance of the stimulus colors in the task, or the degree to which they are able to use the colors in a meaningful way to adapt to the characteristics and demands of the task. In the next section we compare and contrast the results of our study with the fMRI data described in Brown and Braver (2005).

Figure 5: Distribution of response times for go trials in the two error likelihood conditions (accumulated into 25ms bins).

## ACC Activation and Error Likelihood

Evidence for the error likelihood model in Brown and Braver (2005) came from fMRI data. However, to fully evaluate the validity and significance of the model, careful analysis of the task and consideration of human performance data are necessary. Based on the analyses of the response time data presented above, we discuss the fMRI findings in this section, showing that nearly all of the critical phenomena in the fMRI data from the task can be accounted for by simply assuming that longer trials (including the change signal delay) lead to more ACC activation (though this may be too simplistic in general; see Mulert, Gallinat, Dorn, Herrmann, & Winterer, 2003; Winterer, Adams, Jones, & Knutson, 2002).

## Task Artifacts in Performance and ACC Activation

Brown and Braver (2005) cited several findings in their fMRI data to support the error likelihood model of ACC function. Most of these can be related directly to task-driven differences in response time we found in our study. One

example of this is the finding in Brown and Braver (2005) that activation in the ACC was higher for change trials than for go trials. We did find longer response times for change trials, but the evidence suggests that this difference is an artifact of the task-driven change signal delay (Figure 3).

In addition to the main effect of trial type (change versus go), Brown and Braver (2005) also found greater ACC activation for change trials in the high error likelihood condition than in the low error likelihood condition. Once again, this is associated with a significant difference in response time (Figure 1). The response time difference, in turn, is driven by the difference in the change signal delay between the two conditions. When those delays are factored out of the response times, the difference between those conditions disappears (Figure 3).

### The Critical Phenomenon

The only phenomenon that is not captured well by the timing of the presentation of stimuli in the task is the difference in ACC activation between go trials in the two error likelihood conditions that is predicted by the error likelihood model and supported by the fMRI data in Brown and Braver (2005). In this case, the behavioral data diverge from those trends. In fact, our data show essentially equivalent performance, with no significant difference in behavior across conditions (Figure 5).

This result creates an interesting circumstance with regard to assessing the significance of the fMRI data and the implications of the error likelihood model for understanding human cognition. On the one hand, the fMRI data show a significant difference in ACC activation between go trials from the two error likelihood conditions. Importantly, the error likelihood model predicts the fMRI data well, providing a consistent account of neuropsychological data. This is an interesting capacity of the model, and one that adds support to the proposed mechanisms.

On the other hand, while the fMRI data and the model both suggest that the error likelihood conditions are differentiated at a neuropsychological level, there is no evidence that they are differentiated at a behavioral level in our data. Brown and Braver (2005) take the position that the ACC is critical in the recruitment of cognitive control during task performance when the likelihood of making errors is greater. In this case, color provides a cue to differences in difficulty, albeit a cue that is not explicitly described to participants. Importantly, others have failed to replicate the fMRI findings reported by Brown and Braver, even with more explicit cues regarding the error likelihood cues and their significance (Nieuwenhuis, Schweizer, Mars, Botvinick, & Hajcak, 2007).

The critical question is, if the ACC is sensitive to the color of the stimulus as an indication of the likelihood of making an error, why is there no evidence in the behavioral data? The answer to this question is essential to understanding the relationship between cognitive processing and neuropsychological data in the change signal task. We conclude the paper with a discussion of this issue, and more

generally the challenges associated with using neuropsychological findings to inform our understanding of cognitive processes.

### Conclusions and Implications

Brown and Braver (2005) presented provocative neuropsychological data from a novel task, which they used to validate a computational theory of ACC function. As our results and analyses show, however, questions remain about whether it is task artifacts or cognitive phenomena that are responsible for many trends in the fMRI data, and about the implications of the data and the error likelihood model for understanding human cognitive performance and behavior.

Importantly, the model accounts for what appears to be a critical phenomenon in the empirical study – higher ACC activation for go trials in the high error likelihood condition than in the low error likelihood condition. This is, in fact, the only phenomenon predicted by their model that cannot be explained by the timing of the presentation of stimuli in the task, which directly impacts response times as well. Unfortunately, others have failed to replicate that finding (Nieuwenhuis et al., 2007).

Even if the effect is real, questions remain about what these results mean with regard to the underlying cognitive processes. According to Brown and Braver (2005), the ACC is an “early warning system that recruits cognitive control to match its predicted demand” (p.1120). In the context of the change signal task, however, one would expect that recruiting cognitive control would (1) increase explicit awareness about features in the environment related to error likelihood and/or (2) impact human behavior in a manner consistent with the implications of the likelihood of error.

In support of these expectations, Dehaene et al. (2003) found evidence for elevated ACC activation only in circumstances where stimuli creating conflict in a priming task were “consciously detected” (p. 13726). Based upon our results, however, the manipulation of error likelihood was not obvious to participants, and there was no impact on task performance. This creates some challenges that must be addressed to better understand the cognitive processing involved and the significance of ACC activation in the task.

There is evidence in the change signal task that participants adapt to the change signal delay. As they gain experience with the task, average response times increase, reflecting strategic adaptation to the task. However, there is *no* evidence that their adaptation is sensitive to the distinction between error likelihoods signaled by the two stimulus colors. Instead, reaction times for go trials are virtually identical, regardless of the error likelihood condition (Figure 5). This is also true of change trials, when the change signal delay and truncated response distribution in the high error likelihood condition are taken into account (Figures 3 & 4). An interesting follow-up would be to examine human performance if the role of the colors was explicitly explained to participants before the study began (see Nieuwenhuis et al., 2007 for an experiment along these lines).

Of course, this leaves the incongruity between ACC activation and participant performance in these two conditions begging for a theoretical explanation, in addition to questions regarding the replicability of the phenomena (Nieuwenhuis et al., 2007). Our findings expose the discrepancy and reveal the importance of understanding this finding. And, we hasten to add that our empirical findings do not provide evidence to directly contradict the error likelihood model of Brown and Braver (2005). Taken with the failure to replicate the fMRI findings (Nieuwenhuis et al., 2007), however, there is an indication that further research is warranted to understand human performance on the task and the role of the ACC.

Finally, our results suggest in general that fMRI data, like the results presented in support of the error likelihood model, must be interpreted with caution and considered in the context of the performance of participants as well as the context of the task environment that is the focus of study. We have shown that these factors can add important information to inform theories regarding the relationship of neuropsychological data to cognitive processes. It is only by considering multiple sources of evidence that we will be able to arrive at comprehensive theories of human information processing and cognition and how those functions are realized in the brain.

## Abstract

What is the role of feedback information in different visual category learning (VCL) scenarios? To address this question we tested participants' performance in VCL tasks in which stimuli varied in three feature dimensions, one of which was relevant for the task and the other two were irrelevant. The relevant feature could be identified based on trial-by-trial feedback. In one condition the task relevant and irrelevant features were highly-salient. In the second condition all features had low-visual-saliency. Feedback information was also manipulated: In the high-information condition the task relevant feature could be identified by the information provided in each trial whereas in the mid-information condition the feedback was ambiguous and information from several learning trials was required in order to confidently identify the relevant feature. Surprisingly, our data shows that mid- and high-information feedback are similarly effective in high-saliency VCL tasks. In contrast, in low-saliency VCL tasks, mid-information feedback impairs learning. We suggest that VCL can be done effectively either when feedback is ambiguous or in low-saliency conditions, but not in scenarios when both challenges occur concurrently.

## Introduction

Humans are capable of effectively managing a vast amount of sensory information, rapidly rendering it into a coherent, reliable and meaningful representation of objects and events. This capability depends on two fundamental learning processes: One is perceptual learning which allows identifying subtle, initially hard to detect, differences between stimuli (Goldstone & Barsalou, 1998; Kourtzi, 2010). The other is attentional learning which requires shifting attention to relevant attributes while at the same time filtering out irrelevant, even if salient, visual attributes (Blair, Watson & Meier, 2009; Kalish & Kruschke, 2000; Rehder & Hoffman, 2005). It is known that these two forms of learning allow reducing the probability of future decision errors by improving discriminability among similar objects from different categories, and allowing effective generalization to novel stimuli. To date, it is not clear how these processes interact in different learning scenarios.

Difficulty in perceptual learning tasks is determined by feature-saliency. Difficulty in attentional learning tasks is determined by the numbers of simultaneous perceptual features one has to process when categorizing objects.

Learning trajectories in both attentional and perceptual learning tasks are also determined by the availability of informative feedback. In this study we examine the interaction between perceptual and attentional learning by testing the interaction between feature-saliency and feedback information in visual category learning (VCL) tasks of complex visual stimuli.

We define feature-saliency as the physical dissimilarity between stimuli in a given feature dimension. When objects are perceived as highly dissimilar across a feature dimension, this feature is perceived as more diagnostic than lower-saliency feature dimensions (Chin-Parker & Ross, 2004). In each VCL task in our experiment stimuli differed from one another in three feature dimensions, yet only one was relevant for correctly categorizing the stimuli. In each task we kept the relative feature saliency (low or high) similar across all three feature dimensions making them equal candidates for being perceived as task relevant. Therefore, the diagnostic value of each feature could be determined only by the information provided by feedback.

We define the feedback information level based on its ambiguity. In each learning trial we presented a pair of stimuli and the participant had to determine if these stimuli belong to the same category or different categories. We used two levels of feedback information: 1) In the *high-information* learning condition the feedback in each and every trial provided sufficient information for learning the rule as *same-category pairs* were identical only in the task relevant feature and differed in the two irrelevant ones, whereas *different-categories pairs* were different only in the task relevant feature (and identical in the two irrelevant ones). If  $A$  denotes the relevant feature,  $B$  and  $C$  the irrelevant features, and  $X$  is the outcome of a categorization decision, the only possible trial-by-trial inferred causality (a feasible feature-decision association) in the high-information condition was  $A \rightarrow X \cap A \rightarrow X \cap A \rightarrow X \dots$  2) In the *mid-information* condition each trial was ambiguous as *same-category pairs* were identical in the task relevant feature and one of the two irrelevant features (randomly alternating between the two), whereas *different-categories pair* were different in the task relevant feature and one of the irrelevant features. The causality here was  $(A \cup B \rightarrow X) \cap (A \cup C \rightarrow X) \cap (A \cup C \rightarrow X) \cap (A \cup B \rightarrow X) \dots$  This learning scenario is more likely to require distributing attention between features and integrating information across more trials in order to learn the categorization rule.

We expect VCL efficiency to depend both on feature-saliency and the level of feedback information. Specifically, we hypothesize that when differences across visual feature dimensions are hard to detect, shifting attention from one feature to the other will not be effective due to the poor representation of features. This will become a greater challenge when feedback is ambiguous, making it harder to associate a feature representation with the corresponding decision outcome (Nosofsky & Palmeri, 1996). In contrast, when feature-saliency is high, relevant visual information is readily available, enabling to rapidly shift attention away from irrelevant features. This may allow effective learning even in the face of ambiguous feedback. Therefore, we expect an interactive effect of feature-saliency and feedback information. Nevertheless, based on current knowledge, we cannot predict whether this interaction will manifest as an additive effect or as an augmented interference in which the effect of feedback ambiguity on learning efficiency will be more profound in low-saliency learning conditions.

## Methods

### Participants

Sixty paid adults (36 females), with normal or corrected to normal vision, participated in the experiment. The experiment was approved by the Stanford University IRB.

### Materials and setting

We ran the experiment using Psychtoolbox (MATLAB®) on 1920X1200 pixels computer display. Participants' head was located about 70 cm (~2 feet) from the computer screen such that each one of the two simultaneously presented stimuli occupied approximately 14° of the visual field.

### Stimuli

We used four distinct sets of novel creature-like stimuli. In each set the stimuli varied in three feature dimensions (see examples in Figure 1). Exemplars for each stimulus set were produced from one standard object and three morph targets, each differed from the standard in one feature dimension. For VCL tasks with high-feature-saliency we used high morph values (at least 77%). Low-saliency exemplar pairs differed by small morph values (22-33%). The morphing values we used were determined based on pilot tests such that within each stimulus set differences in all feature dimensions were similarly likely to be detected. We also ensured that in the low-saliency condition differences within each feature dimension will be not detected easily without feedback. For each stimulus set we determined two categories. Members of each category varied in the two irrelevant feature dimensions and were identical in the third. This third feature-dimension was the diagnostic feature-dimension differentiating between the two categories.

### Design

Tasks differed in feature saliency (high-saliency vs. low-saliency), and three levels of feedback information. In high-saliency VCL tasks both within-category and between-

categories differences had high-saliency. In low-saliency VCL tasks both within-category and between-categories differences had low-saliency. In each VCL task participants were trained with one of three levels of feedback information: 1) High-level information feedback that potentially enabled identifying the diagnostic feature within each learning trial; 2) mid-level information feedback, in which each learning trial provided ambiguous information regarding which feature was the relevant one; 3) In addition to these two feedback-based learning conditions, we also tested participants in a control condition in which no feedback was provided to the participants. This provided a useful benchmark for assessing the contribution of feedback information to learning.

Each VCL task was based on a different stimulus set and a unique combination of feature-saliency and feedback information level. In order to prevent cross-conditions differences in categorization performances that derive from differences between stimulus sets, we counterbalanced the tasks across participants such that each one of the four stimulus sets was used in each one of the six experimental conditions the same number of times.

Figure 1: Examples of pairs of creatures from the four stimulus sets. Each row shows examples from a different stimulus set. *Left*: high-saliency pairs; *Right*: low-saliency pairs. Green arrows indicate high-saliency differences in the three feature dimensions in which the paired creatures differ (e.g., in the upper row the two creatures differ in horns, limbs and body-width). In each stimulus set, the same diagnostic feature was used for both the low- and high-saliency tasks. From top to bottom, the task relevant feature was body-width, head-spikes, horns and body curvature.

Each VCL task included seven blocks: four test blocks (denoted as T1-T4) that alternated with three learning blocks (L1-L3). Each block consisted of 24 trials. In each

trial two creatures were presented simultaneously on a computer screen for 2.2 seconds during which the participant had to decide if they belonged to the same or different categories by pressing one of two keyboard keys. Feedback was given during the 0.8 seconds inter-trial interval: In the mid- and high-information feedback conditions, a green square indicated a correct answer and red square an incorrect one. In the control, no feedback, learning blocks and in the test blocks, a yellow square indicated that the response was recorded (Figure 2a).

During test blocks, creature pairs always differed in two feature dimensions. *Same-category pairs* differed in the two irrelevant feature dimensions and were identical in the relevant one (as the right upper pair in Figure 2b). *Different categories pairs* differed in the relevant feature dimension and in one of the irrelevant feature dimensions, but were identical in the other irrelevant dimension (see left lower pair in Figure 2b). This design prevents participants from making the same/different categorization decision based on the overall similarity between stimuli. It also allowed us to keep the statistics of the three features and their pair-wise covariance identical.

For feedback-based learning blocks, pairs of creatures were selected in the following way: 1) In the high-information feedback condition *same-category pairs* were identical in the relevant feature dimension and differed in the two irrelevant feature dimensions. *Different-categories pairs* differed in the relevant feature dimension and were identical in the two irrelevant ones. Thus, each trial indicates either all the within-category variability (*same-category pairs*), or only the diagnostic feature dimension discriminating between categories (*different categories pairs*). 2) For mid-information feedback, *same-category pairs* were identical in the relevant dimension and in one of the two irrelevant dimensions (alternating between the two across different trials). *Different-category pairs* differed in two features: the relevant one and an irrelevant one (again, randomly alternating across trials between the irrelevant two). Although in this case each trial was ambiguous, it was still possible to learn the categorization rule based on the information provided across several trials. Such ambiguity in the feedback keeps the attentional learning aspect of the task more challenging by increasing the probability that participants will divide attention, in each trial, between two feature dimensions that are equally perceived as relevant. 3) The composition of the trials in the learning blocks with no feedback was similar to the one used in the test blocks.

## Procedure

To keep the duration of the experimental session short (~ 75 minutes), each participant performed a combination of three out of six conditions; [2 feature-saliency] X [3 feedback information]. Participants were informed that in each VCL task they have to learn to classify unfamiliar creatures from two distinct subspecies based on one attribute (feature dimension). Participants were also told that any variability in other attributes should be considered as irrelevant and

ignored. Before starting the experimental tasks, participants performed a warm-up VCL task (with a different stimulus set). This enabled the participant to become familiarized with the experimental tasks.

Figure 2: Experimental design. (a) An illustration of an experimental trial. A pair of stimuli presented for 2.2 seconds during which the participant had to judge if the creatures are from same or different categories. This was followed by 0.8 seconds of feedback presentation (e.g., green square indicates a correct answer) after which the next trial started. (b) Examples of different-categories (left) and same-category (right) pairs, high-information (top) and mid-information (bottom) condition. In each of the feedback based learning blocks, the category relation between the paired stimuli could be derived from the feedback. In High-information trials different-categories pairs differ only in the relevant feature, and same-category pairs are identical only in this feature. Such a trial enables effectively pinpointing the relevant feature dimension by eliminating 2 out of three possible hypotheses. Mid-informative trials provide less information since such a trial always leaves two options (out of three). (c) A table describing all possible hypotheses for a given VCL task. When all feature dimensions are salient the participant is only required to decide which feature is relevant (H1 – H3). When features are not salient, VCL requires shifting from H0 (represent a case in which the participant is unaware of either one of the potentially relevant feature dimensions) to the correct hypothesis signaling the relevant feature dimension.

## Performance measurements

We define a “Hit” as correctly deciding that two creatures are members of the same category, and a “False-Alarm” as

incorrectly deciding that creatures of different categories are members of the same category. Based on the Hit and False-Alarm rate we calculated participants' sensitivity using the non-parametric measure A-prime (Grier, 1971; Formula 1).  $A' = 1$  indicates perfect performance and  $A' = 0.5$  indicates chance level.  $0 \leq A' < 0.5$  represent a response confusion.

Formula 1: A-prime calculation.  $H$  denotes the Hit rate, and  $F$  the False-Alarm rate (Hit and False-Alarm rates are calculated based on the 24 trials in each test/learning block).

$$A' = 0.5 + \left[ \text{sign}(H - F) \times \frac{(H - F)^2 + |H - F|}{4 \times \max(H, F) - 4 \times H \times F} \right]$$

### Benchmarks

We evaluated participant performances according to the following benchmarks: Chance performance,  $A' = 0.5$ ; Perfect performance,  $A' = 1$ ; Performance based on systematically referring to an irrelevant feature during a test block or during a no-feedback "learning" block,  $A' = 0.12$ ; Performance based on systematically referring to an irrelevant feature during a learning block with mid-information feedback,  $A' = 0.5$ ; Performance based on systematically referring to an irrelevant feature during a learning block with high-information feedback,  $A' = 0$ .

## Results

Reported data is based on 24 participants in each condition. Excluded from this analysis are cases in which performance level was inconsistent between the test vs. the learning trials within a given VCL task (evident as high performance in the learning blocks, where feedback was available, contrasted with near-chance performance in the following test blocks, where feedback was not available).

### Pre-learning performance

First, we confirmed that the initial performance level, in each of the two feature-saliency conditions, is similar. A two-way analysis of variance (ANOVA) with feature-saliency and feedback information as independent variables, and participants' sensitivity ( $A'$ ) in the first, pre-learning, test block (T-1) as the dependent variable shows no significant interaction  $F(2, 144) = 0.93$ , no main effect of feedback information  $F(2, 144) = 0.91$ , and no main effect of feature-saliency  $F(1, 144) = 2.12, p = 0.15$ .

### Trial-by-trial, feedback-based, learning dynamics

We assessed categorization improvement in the mid- and high-feedback information conditions based on learning trajectories across 72 learning trials (across the three learning blocks, L1 to L3). We calculated performance based on a moving average with a window of six trials. Figure 3 shows rapid learning, with almost identical trajectories, both with mid- and high-information feedback in the high-saliency condition. In contrast, in the low-saliency condition mid-information feedback resulted with significantly lower improvement compared with high-information feedback. Note that high-information feedback

ended with similarly high performance level in both saliency conditions, yet in the low-saliency condition it required more learning trials.

Separate two-way ANOVAs, one for the high-saliency condition and one for the low-saliency condition, with feedback information (mid/high) as the between participants independent variable, learning trial number (1-72) as a within participant independent variable, and participants' percent correct as the dependent variable, show a significant difference in the linear contrast between mid- and high-information feedback learning conditions in the low-saliency condition,  $F(1, 46) = 4.73, p < 0.04$ , but not in the high-saliency condition,  $F(1, 46) = 0.29$ .

Indeed, a three-way ANOVA with feature-saliency, feedback information and learning trial number as independent variables, and participants' percent correct as the dependent variable, confirm that the interaction between feature-saliency and feedback information is significant,  $F(3, 92) = 2.73, p < 0.02$ , partial  $\eta^2 = 0.029$  (Figure 3).

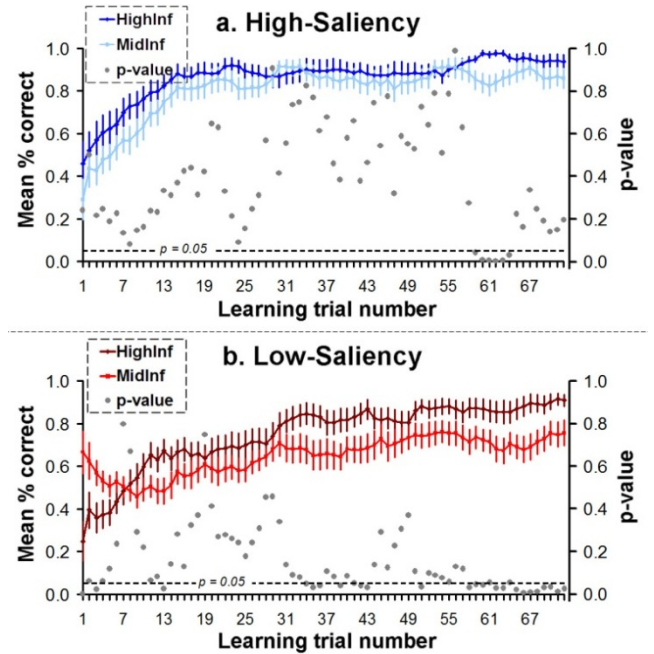

Figure 3: Participants' mean percent correct in the high-saliency (a) and low-saliency (b) conditions in each of the 72 learning trials. The value in each bin is based on moving average with a window of 6 trials (error bars represent standard error of the mean across 24 participants). Gray dots represent the significance level ( $p$ -value) of the difference between mid- and high-information learning in each trial (based on independent sample t-tests; Dashed line marks a significance level of  $p = 0.05$ ). This illustrates a consistent significant difference between the mid- and high-information conditions, particularly in the second half of the learning process, only in the low feature-saliency condition.

### Between test blocks dynamics

To further assess participants learning, we examined their performance in the test blocks where no feedback was given

and all trials had the same composition irrespective of the feedback information condition (paired creatures always differed in 2 features; see Methods). Results are shown in Figure 4. Our analysis shows significant improvement in all learning conditions (all  $p < 0.01$ ). Importantly, we found a significant difference in the learning trajectories between the mid- and high-information feedback conditions in the low-saliency condition but not in the high-saliency condition.

Figure 4: Participants' mean sensitivity (error bars represent standard error of the mean) in the (a) high-saliency and (b) low-saliency conditions. Feedback information levels are marked by different colors. T-1 to T-4: Performance in the test blocks (data points connected with lines); L-1 to L-3: Performance in the learning blocks. When feature-saliency is high, there are no significant differences in VCL efficiency between the mid- and high-information conditions. On the other hand, when the feature-saliency is low and participants were provided with mid-information feedback, performance was lower as compared with the high-information feedback condition.

*High-feature-saliency VCL:* A two-way ANOVA for the high-saliency condition, with feedback information and test block order (T-1 to T-4) as independent variables and participants' sensitivity ( $A'$ ) as a dependent variable shows no significant linear contrast between the mid- and high-information conditions,  $F(1, 46) = 0.04$  (Figure 4a).

*Low-feature-saliency VCL:* In contrast to the above, in the low-saliency condition there was a significant linear contrast between the mid- and high-information feedback conditions,  $F(1, 46) = 6.09$ ,  $p < 0.02$  (Figure 4b).

*Comparing high-feature-saliency and low-feature-saliency VCL:* A three-way ANOVA with feature-saliency

(low/high), feedback information (mid/high) and test block order (T1 to T4) as independent variables, and participants' sensitivity ( $A'$ ) as a dependent variable, confirm that the interaction between feature-saliency and feedback information is close to significant,  $F(3, 92) = 2.84$ ,  $p = 0.06$ , partial  $\eta^2 = 0.030$ .

Next, we examined if differences in sensitivity between the high- and low-saliency conditions are driven mostly by participants' Hit rate or by their False-Alarm rate. We found no significant effect in the False-Alarm rate and a trend in Hit rate: Two-way ANOVAs, one for the high-saliency and one for the low-saliency condition, with feedback information and test block order as independent variables and participants' Hit rate (in the test blocks) as the dependent variable, show a close to significant difference between the mid- and high-information feedback conditions in the low-feature-saliency condition,  $F(1, 46) = 3.65$ ,  $p = 0.06$ , but not in the high-feature-saliency condition,  $F(1, 46) = 0.57$ . A similar analysis with False-Alarm rate as the dependent variable, shows no significant difference between mid- and high-information learning, neither in the low-saliency condition,  $F(1, 46) = 1.49$ ,  $p = 0.23$ , or in the high-saliency condition,  $F(1, 46) = 1.94$ ,  $p = 0.17$ .

These findings are surprising since the main challenge in low-saliency tasks is to learn to identify subtle important differences between similar categories (i.e. avoiding False Alarms) rather than deciding correctly that two apparently similar objects are from the same category (i.e. avoiding Misses). Nevertheless, our findings shows that higher information feedback in low-saliency conditions is mostly helpful in assisting participants performing better by avoiding Misses. We suggest that the lack of significant differences in False-Alarms rate represent, in fact, a response bias exhibited by participants in low saliency conditions – instead of discriminating between categories based on the relevant feature dimension, in the low-saliency tasks participants are more likely to react to any apparent subtle difference among paired creatures as if it is relevant, perhaps due to poor capacity in pinpointing the relevant one.

This interpretation is consistent with the apparent “superior” performance in the first few learning trials in the low-saliency mid-information condition (Figure 3b) where the participants seem to perform better than in the low-saliency high-information condition. In mid-information tasks, a strategy based on deciding “different categories” whenever identifying any difference, is with advantage since the task diagnostic feature is always coupled with an irrelevant one (whereas same-category pairs differ in only one, irrelevant, feature-dimension). That is, in low-saliency mid-information learning conditions people are likely to effectively avoid False-Alarms but for the wrong reason.

#### Performance in the control, no feedback, tasks

Finally, we confirmed that without feedback there is no significant learning in our VCL tasks: A two-way ANOVA conducted for the no feedback VCL tasks with feature-saliency (high/low) and test block order (T1 to T4) as

independent variable, and participants' sensitivity ( $A'$ ) as the dependent variable, shows no significant interaction between feature-saliency and test block  $F(3, 46) = 1.73, p = 0.20$ , and no test block order learning effect  $F(3, 46) = 0.36$ . Note that mean performance in the no-feedback tasks never significantly exceeded values of  $A' = 0.5$ .

## Discussion

We tested the interaction between feature-saliency and feedback information in visual category learning (VCL) tasks as a mean to explore the nature of the interaction between perceptual learning and attentional learning. Simply speaking, perceptual learning is a process that involves improvement in the ability to identify important fine differences between categories, whereas attentional learning improves the ability to filter out irrelevant (even if salient) within category differences (Hammer et al., 2009). Here we show that the interaction between these two processes is more complex than this simplistic view.

We report two important findings: First, perhaps surprisingly, we show that mid-information and high-information feedback are equally effective for learning when stimuli have marked visual differences as in the high-saliency condition. This suggests that when diagnostic visual information is readily accessible, ambiguity in feedback (which is associated with higher attention load) can be resolved with no apparent effort (at least in simple rule learning tasks and when testing typical adults). Second, importantly, there are substantial differences between mid-information and high-information feedback when stimuli are only subtly different. This suggests that low-saliency VCL depends more on informative feedback that serves to orient attention to the relevant feature. Unlike in high-information learning trials, in mid-information learning trials with low-saliency features, participants may not only face difficulties in noticing the relevant feature, but also have difficulties in disassociating it from irrelevant ones. Therefore, participants may have been unaware of the relationship between the feedback and the relevant feature-dimension, which consequently lowered learning effectiveness.

These findings are relevant to the developing debate on the role of attention in perceptual learning: Most findings suggest that perceptual learning requires attention to a target visual feature (Ahissar & Hochstein, 1993; Schoups et al., 2001), or the presence of informative feedback associated with an attended visual feature (Herzog & Fahle, 2002). In contrast, recent findings show that "accidental" perceptual learning can occur (Seitz, Kim & Watanabe, 2009). Nevertheless, this seems to be restricted to learning scenarios with informative feedback where unattended features are strongly correlated with an attended one.

Here we show that when there is only a partial positive correlation between the presentation of a task relevant feature and the presentation of irrelevant features (as it is inherently the case in mid-information feedback conditions), together with lack of explicit information regarding which feature is relevant, there is significant interference with the

learning process. This is evident as significantly less effective learning compared with cases where the relevant feature and irrelevant features are consistently anticorrelated (as in high-feedback-information learning scenarios).

We conclude that the role of attention in visual learning tasks depends on the correlations between relevant and irrelevant features, the nature of information provided by available feedback, and feature-saliency. This suggests that in everyday life scenarios, when making judgments on complex objects in cluttered scenes, the relative contribution of attentional learning and perceptual learning can change quite substantially from one learning scenario to the other. Thus, perceptual learning and attentional learning should not be construed as mutually exclusive processes but rather as complementary processes, and visual learning tasks should be considered as a mixture of these two processes.

## Abstract

In most free-recall experiments, participants are given a preset amount of time to search memory. Recently, several studies have examined retrieval in an open-interval design in which the participant, not the experimenter, determines when to terminate memory search. The present study performs the first direct comparison between participant-terminated and experimenter-terminated retrieval. No difference was found in the number of items retrieved from memory; however, inter-retrieval times (IRTs) did differ, such that the participant-terminated paradigm did not show the hyperbolic function typically found when using the experimenter-determined, closed-interval design. We were able to account for this result by equipping a simple relative sampling model with a memory search stopping rule that assumes that giving participants a pre-set retrieval interval causes them to search longer (and tolerate more search failures) than they would in the open-interval design.

**Keywords:** memory; free-recall; stopping rules.

## Terminating Memory Search

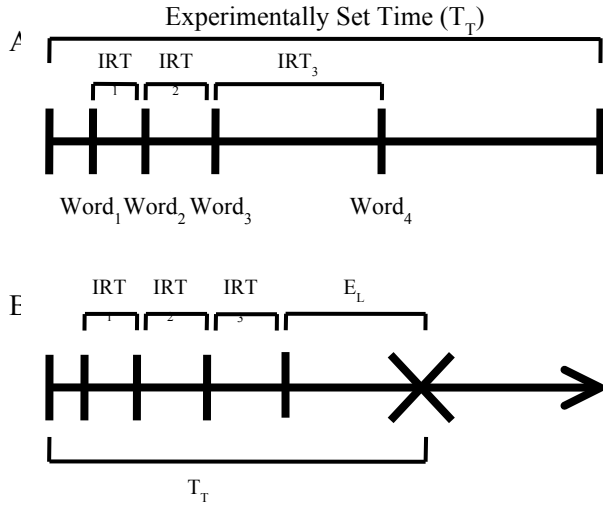

At some point, any search of memory must end. Several recent studies have begun to examine how this decision is made in free recall tasks, where search is often terminated while there remain potentially retrievable items unreported (Dougherty & Harbison, 2007; Harbison, Dougherty, Davelaar, & Fayyad, 2009; Unsworth, Brewer, & Spillers, 2011). These studies used a slightly modified version of the standard list recall paradigm; the only difference is that participants terminate their own memory search. This open-retrieval interval design (henceforth, open-interval design) is in contrast to the standard, closed-retrieval-interval design (closed-interval design) that gives participants a pre-determined retrieval interval. Both the open-interval and closed-interval designs have strengths and weaknesses, but to date, they have not been directly compared. The goal of the present study is to perform this comparison and evaluate how allowing or not allowing participants to terminate their own search influences the variables used to describe memory retrieval.

## Open- and Closed-Interval Designs

The difference between the open-interval and closed-interval recall design is illustrated in Figure 1. The closed-interval design, shown in Panel A, is restricted, in that the retrieval interval participants are given is pre-determined by the experimenter. After the interval has expired, search is terminated for the participant by the experimenter or by the software program used for the experiment. One reason this design has been used is that it allows greater focus on basic processes of memory retrieval, attempting to eliminate individual differences in how long participants spend searching memory. However, it is not necessarily the case that participants search during the entire pre-determined interval. In fact, many process models that have been proposed to account for the retrieval results from the closed-interval design have assumed a stopping decision to be part of the memory search process (e.g., Raaijmakers & Shiffrin, 1981). Moreover, the closed-interval design might induce participants to search memory longer than they normally would, potentially leading to results that do not replicate when participants are free to retrieve and self-terminate memory search.

The open-interval design (panel B of Figure 1) gives participants an unlimited amount of time to retrieve. The principle strength of this design is that it allows for the measurement of memory search termination decisions, including the total time spent in search—determined by the participant—and the exit latency, or the time between the final retrieval and the decision to terminate search. Both measures have proven diagnostic for evaluating memory search stopping rules (Harbison et al., 2009). The design also, arguably, has greater ecological validity: Individuals are unlikely to have a fixed external time limit when searching memory during most everyday tasks outside the lab (for an examination of termination decision in response to external demands, see Davelaar, Yu, Harbison, Hussey, & Dougherty, 2012). However, the open-interval design too has potential weaknesses: Self-termination might prime participants to put less effort into retrieval and therefore provide inadequate data for the purposes of theory testing. If

participants lacked sufficient motivation to adequately search memory, they might recall fewer items in the open-interval paradigm. However, to the best of our knowledge, this account has not been evaluated. Moreover, as far as we are aware, there has been no comparison between open- and closed-interval designs more generally. In what ways do retrieval data obtained from an open-interval design differ from those obtained in the closed-interval design? And, what can the open-interval design tell us about memory retrieval that cannot be discerned from the close-interval design?

**Figure 1.** (A) Closed-interval and (B) open-interval retrieval designs, adapted from Harbison & Dougherty (2007). X indicates the time when a participant decides to terminate memory search; hash marks indicate the time associated with the latency onset of words recalled.  $T_T$  = Total Time Searching;  $E_L$  = Exit Latency; IRT = Inter-Retrieval Time.

## Previous Results

As no experiment has yet directly compared the open- and closed-interval designs, it is not possible to draw firm conclusions from existing data. However, there is a wealth of data from closed-interval experiments suggesting specific patterns in the temporal dynamics of recall. For our purposes, we focus on the inter-retrieval times (IRTs), or the time between successive retrievals. IRTs have played an important role in constraining theories of memory retrieval (Rohrer, 1996; Wixted & Rohrer, 1994), and they are generally well described by the equation:

$$IRT_i = \frac{\tau}{N - i} \quad (1)$$

for  $i=1,2,\dots,N-1$ , where  $i$  is the inter-response interval starting with the interval between the first and second retrieval,  $\tau$  is the estimated mean retrieval latency, and  $N$  is the total number of items retrieved. Equation 1 captures the key empirical result that IRTs typically follow a hyperbolic function, such that the time between successive retrievals

increases as the number of items retrieved increases (Murdock & Okada, 1970; Polyn, Norman, & Kahana, 2009; Raaijmakers & Shiffrin, 1980; Wixted & Rohrer, 1994).

**Figure 2.** 1/IRT data from (A) Dougherty and Harbison, 2007 and (B) Harbison et al., 2009. The x-axis is the retrieval interval in reverse order, with 1 representing the final interval. The legend indicates the number of items recalled.

A particularly informative way of looking at IRT data is by inverting the IRT (1/IRT) and plotting the results in reverse order along the x-axis, such that the final IRT is in the first position. When plotted this way, Equation 1 predicts that the intercept should be zero. Rohrer (1996) found support for this prediction using the closed-interval design. However, a reanalysis of data from two open-interval experiments (Dougherty & Harbison, 2007; Exp. 1, Harbison et al., 2009) revealed a different pattern: Instead of an intercept of zero, the data from these experiments were best fit by lines with intercepts greater than zero (ranging from .103 to .210), as shown in Figure 2.

What does this result mean for the comparison of open- and closed-interval designs? In particular, could this indicate that something differs in the search process when participants make their own stopping decisions? To answer these questions, we conducted a simulation evaluating the predictions of the relative-strength model of retrieval when stopping decisions were included.

## Simulation

For simplicity and ease of comparison with previous research examining IRT results from the closed-interval design, we followed the same simulation procedure as Rohrer (1996). We used the same relative-strength model, which is nearly identical to the sample and recovery processes of the search of associative memory (SAM) model (Raaijmakers & Shiffrin, 1981). We also used the same activation patterns tested by Rohrer (1996). The model randomly sampled items based on their relative activation and attempted to recover the sampled item based on its absolute activation. An iteration of random sampling and attempted recovery is referred to as a retrieval attempt and each retrieval attempt could either succeed or fail. For the

current simulations, potential retrieval failures are (1) re-sampling an already-outputted item or (2) failing to recover a sampled item due to its absolute activation not meeting the recovery threshold. As we used the same activation patterns as Rohrer (1996), we also used the same recovery threshold, .5.

The one difference between the model tested here and the model used by Rohrer was our use of a stopping rule that terminated the search process. Our model included a stopping rule based on the number of retrieval failures. This stopping rule, native to the SAM model, is the only rule tested so far that has been able to account for both the total time and exit latency data from open-interval experiments (Harbison et al., 2009).

Other than the recovery threshold, the only parameter in the model was the stopping threshold, the number of retrieval failures the model allowed before memory search was terminated. The stopping threshold was varied between 10 and 40 in steps of 10. Each activation pattern was run with each stopping threshold 10,000 times. The dependent variables of interest included the number of items retrieved, the IRTs, and the intercept of the best fitting line for the 1/IRT data.

**Table 1.** Mean Simulation Results by Activation Pattern.

Act. Pattern	Variable	Stopping Threshold			
		10	20	30	40
1,1,1,1,1,1	Num Ret	5.60	5.94	5.99	6.00
	Last IRT	3.30	5.17	5.80	6.00
	Intercept	.16	.03	0	0
.5,.6,1,1.2,1.2,1.5	Num Ret	5.35	5.79	5.92	5.97
	Last IRT	3.35	5.54	7.03	8.12
	Intercept	.14	0	-.05	-.06
.4,.5,.6,1,1.5,2	Num Ret	4.35	4.78	4.92	4.97
	Last IRT	3.37	5.73	7.43	8.42
	Intercept	.13	-.02	-.07	-.09

## Results and Discussion

The results are reported in Table 1 and a representative sample of the model's behavior over various activation patterns. The results of the second activation pattern in Table 1 are shown in Figure 3. First, it should be noted that the variation in stopping threshold did not have a large impact on the mean number of items retrieved (see Figure 3a). However, Figure 3c illustrates that the intercept of the inter-retrieval rates did show substantial variation. Consistent with Rohrer (1996), when the stopping threshold was larger (e.g., 40 failures), the intercept was indeed near zero. However, there was a negative correlation between stopping threshold and the intercept, such that at smaller stopping thresholds the intercept was greater than zero. Therefore, the 1/IRT predictions of the relative-strength model appear to be consistent with closed-interval experiments at greater stopping thresholds and open-interval experiments at smaller stopping thresholds.

Investigating the IRT data more closely, Figure 3b shows the last (or K) IRT, the second to last (K-1) IRT, the third to last (K-2) IRT, and so forth for each stopping threshold value tested. The last IRT showed the greatest variation due to changes in the stopping threshold. Weaker relationships between IRT and stopping threshold were observed the further the IRT was from the final IRT. Importantly, there were large variations in the last IRT even when there were only minute changes in the number of items retrieved. For example, while the mean final IRT more than doubled in size when going from a stopping threshold of 10 to 40, the mean number retrieved varied by only ten percent.

**Figure 3.** Simulation results for (A) number of items retrieved, (B) IRT, and (C) 1/IRT functions for 4 stopping thresholds (10, 20, 30, or 40 failures).

What is the source of the relationship between IRTs and the stopping threshold? When using the total failures

stopping rule, the lower the stopping threshold, the fewer the number of possible attempts for retrieving each item, on average. If an item is not retrieved with a minimal number of failures, it will not be retrieved. For example, if the fifth item is not retrieved before 10 retrieval failures have occurred, then search will terminate with only four items retrieved. Since the probability of retrieval failure increases with each item retrieved, the limit on the number of allowable retrieval failures plays a larger role towards the end of retrieval and particularly for the final item retrieved.

Note that these predictions are particular to the total failure stopping rule. Although not presented here, of the four stopping rules tested in Harbison et al. (2009) the only other stopping rule that correctly predicts the general form of the IRTs is the total time rule, though this rule *cannot* account for the systematic variation in total time spent in search. When equipped with the time-since-last-success or the last-IRT stopping rules, the relative-strength model produces IRT predictions that vary substantially from the results of both open- and closed-interval experiments.

The apparent difference in IRT data between the open- and closed-interval designs are accounted for by the relative-strength model as long as the model includes a stopping rule based on total retrieval failures. According to the model, the difference between the open- and closed-interval designs is expected if the designs induce subjects to use different stopping thresholds. What is left to determine is if the pattern is indeed real. Testing this requires a direct comparison between the designs.

## Experiment

Forty-nine participants were randomly assigned into one of two counterbalancing conditions: open-then-closed or closed-then-open. List length was also varied within participant, resulting in a 2 (retrieval block: open vs. closed) x 4 (list length: 5, 7, 9, vs. 11 words) within-subjects design. List length was varied randomly such that all participants were given four study lists of each of four lengths evenly and randomly within each block. List length was systematically varied primarily to prevent participants from learning exactly how many items were on each list and using that information to determine stopping decisions.

**Stimuli** Thirty-six word lists were randomly generated for each participant from a list of 280 high-imagability ( $M = 577/700$ ), high-concreteness ( $578/700$ ), moderate-to-high-frequency (Kucera-Francis frequency = 54), single-syllable nouns drawn from the MRC psycholinguistic database (Wilson, 1988).

**Procedure** For both the open- and closed-interval blocks, participants were given a total of 18 lists consisting of 2 practice trials followed by 16 test trials. During the list presentation of each trial, words were presented sequentially at a rate of 3 seconds per word. Following the list, participants were given a distracter task that consisted of two simple, timed math problems. Each problem contained

three digits and two operands (e.g.,  $3 * 2 + 1$ ). Each component of the problem was presented sequentially at a rate of one second per item. After viewing the final digit of the problem, participants saw an equal sign with a question mark, prompting them to respond with the correct answer.

Participants were then given the opportunity to verbally recall items from the most recent word list. During open-interval trials, participants were told to press the spacebar when they could no longer retrieve additional items from the current memory list; hence, they were given control over when to end the retrieval interval. During closed-interval blocks, participants were given 45 seconds to retrieve the study list items. Based on prior research, we anticipated that a 45-second retrieval interval would provide ample time for most participants to complete the recall task.

All participants were presented with both block types to ensure a proper comparison of IRTs between the open and closed intervals, and the order of block presentation was counterbalanced across participants. All retrievals were made verbally by speaking into a microphone and were digitally recorded for later scoring. The responses for each list were recorded in an audio file and hand coded to extract the time-to-word for each item recalled.

## Results and Discussion

We conducted Jeffreys-Zellner-Siow (JZS) Bayes-factor (BF) tests to verify the results of each significance test. Moreover, some comparisons reported below are expected to support the null hypothesis, and JZS BFs provide a means to assess the degree to which this is indeed the case. Bayes-factor tests reflect the likelihood of support for the null hypothesis over support for the alternative hypothesis, such that coefficients less than 0.3 index strong support for the alternative hypothesis and those greater than 3 index strong support for the null hypothesis (Rouder, Speckman, Sun, Morey, & Iverson, 2009).

**Block Order** We first conducted a manipulation check to determine whether there was an effect associated with block order (open-interval first vs. closed-interval first). A repeated-measures analysis of variance (ANOVA) revealed no effect of Block Order x Block Type for average number of items recalled ( $F(1,47)=0.002$ ,  $p>0.96$ ,  $BF=4.68$ ) or total number of intrusions ( $F(1,47)=0.442$ ,  $p>0.50$ ,  $BF=3.84$ ). Because exit latency cannot be computed for trials in the closed-interval block, we examined the effect of Block Order on exit latency only on open-interval trials, and found no main effect ( $F(1,47)=2.30$ ,  $p>0.13$ ,  $BF=1.70$ ). Finally, there were no reliable effects of Block Order for IRTs at any level of number recalled ( $p's>0.56$ ). Because these early analyses suggest that there are no effects of Block Order, all subsequent analyses will be collapsed across this factor to increase statistical power.

**List Length** We next examined the effect of list length on number recalled. Replicating earlier work, we showed a main effect of number recalled ( $F(3,291)=60.39$ ,  $p<0.0001$ ).

Scheffé post hoc analyses revealed that longer study lists resulted in the retrieval of additional items ( $M_5=4.14$ ,  $M_7=4.75$ ,  $M_9=5.16$ ,  $M_{11}=5.92$ ;  $p's < 0.05$ ). Thus, all subsequent analyses will be collapsed across list length.

**Number Recalled** There was not a significant difference in the number of items retrieved between the closed- ( $M=5.11$ ) and open-interval trials ( $M=4.89$ ;  $t(48)=0.947$ ,  $p>0.33$ ,  $BF=5.78$ ), indicating that people's decisions to terminate retrieval did not impact recall rates. Analyses of intrusion and repetition errors are also consistent with this conclusion: The average number of intrusions did not differ as a function of Block Type ( $M_{closed}=0.351$ ;  $M_{open}=0.441$ ;  $t(48)=-0.972$ ,  $p>0.33$ ,  $BF=5.64$ ). An effect of Block Type did not emerge when intrusions were split into 3 types: a) repetitions ( $t(48)=0.467$ ,  $p>0.64$ ,  $BF=8.04$ ); b) extra-list false alarms, or items recalled that were not presented in any prior study lists ( $t(48)=0.502$ ,  $p>0.61$ ,  $BF=7.91$ ); and, c) intra-list false alarms, or items that were incorrectly output that occurred on previous lists ( $t(48)=1.642$ ,  $p>0.10$ ,  $BF=2.47$ ). Also, intrusion rates did not change as a function of time spent in the experiment ( $p>0.47$ , but see Unsworth et al., 2011). Given these results, we are comfortable concluding that the open-interval design does not differ from the closed-interval design in terms of number and type recalled.

**Exit Latency and Total Time** We found that the current exit latency and total time data were consistent with previous results using an open-interval paradigm. Exit latency decreased as a function of number recalled (Dougherty & Harbison, 2007): Mean within-subject gamma ( $\gamma$ ) correlation coefficients for exit latency and number recalled (mean  $\gamma = -0.139$ ) indicate that participants spend more time deciding to terminate search after the final item is recalled when fewer words are output in a trial (one-sample t-test of  $\gamma$ :  $t(48)=-3.719$ ,  $p<0.001$ ). Also consistent with previous data, the total time spent in search was positively correlated with the number recalled (mean  $\gamma = 0.268$ ;  $t(48)=5.775$ ,  $p<0.0001$ ).

**Inter-Retrieval Times** IRTs were computed by taking the difference between the verbal onset times for each subsequent item recalled in a trial. We conducted these irrespective of the identity of the item recalled (i.e., IRTs were computed to incorporate trials containing intrusions). We first examined IRTs as a function of Block Type (open- vs. closed-interval) for each level of Number Recalled for each participant. Since many participants did not output a full range of Number Recalled levels across both open- and closed-interval blocks, pairwise comparisons were only conducted for subjects that could contribute data to both levels of Block Type for a given Number Recalled level. For example, it was possible that a participant recalled three items in two separate trials of the open-interval block and never recalled three items in any trials of the closed-interval block. Because of this variation in observations, we only

report IRT averages when at least 15 subjects contributed data to both open- and closed-intervals.

**Figure 4.** Mean IRTs as a function of Number Recalled for (A) Closed- and (B) Open-interval retrieval trials.

Figure 4 illustrates the  $1/IRT$ s for open- and closed blocks as a function of Number Recalled. Closed-interval intercepts were less than the open-interval intercepts for 6 of the 7 different total number of items retrieved. Especially important to this functional relationship is the final, or K, IRT (see Figure 5); there was a main effect of Block Type on the K IRT ( $F(1,47)=28.48$ ,  $p<0.0001$ ,  $BF=1.53 \times 10^{-4}$ ), such that closed-interval trials ( $M=4.462s$ ) led to longer final IRTs than open-interval trials ( $M=2.792s$ ). In fact, the mean K IRT on closed-interval trials was significantly larger than that on open trials for all but two levels of Number Recalled (i.e., 3 and 8,  $p's > 0.38$ ). A sign test of the binomial relationships for the number recalled of all final IRTs reveals that six of the six comparisons favor closed-retrieval intervals to have longer IRTs than open-interval intervals; a one-tailed test assessing the probability of this pattern occurring yielded a p-value of 0.016. Thus, despite the fact that there were no significant differences in overall number recalled, there do appear to be differences in the temporal dynamics between open- and closed-interval results.

## General Discussion

The present experiment directly compared the closed-interval design, in which the experimenter determines the length of the retrieval interval, to the open-interval design, in which participants are allowed to terminate their own

memory search. The IRT functions differed between these designs: Compared to their closed-interval counterparts, open-interval trials resulted in overall shorter final average IRTs.

**Figure 5.** Mean retrieval times for the final (K) IRT, second-to-last (K-1) IRT, third-to-last (K-2) IRT, and fourth-to-last (K-3) IRT.

What do these differences in the IRTs mean? According to the present simulations, these results suggest a difference in the stopping threshold between open- and closed-interval retrieval. As shown in Figure 3B, the relative-strength model, when equipped with the stopping rule supported by the existing data (Harbison et al, 2009), predicts a positive correlation between the final IRT and the stopping threshold. When the stopping threshold is sufficiently large, the final IRT is also large and the IRT predictions are consistent with Equation 1; specifically, the intercept of the inverse of the IRTs is 0 when plotted in reverse order (Rohrer, 1996). However, when the stopping threshold is set to smaller values, the final IRT is also smaller. This decreases the predicted slope (or mean retrieval latency,  $\tau$ ) and increases the intercept, producing results similar to those observed under the open-interval design and inconsistent with Equation 1.

The present research finds systematic differences in the temporal characteristics of memory retrieval between open- and closed-interval designs. These differences are predicted by the relative strength sampling model when equipped with a memory search stopping rule if it can be assumed that the type of retrieval interval influences memory search stopping decisions. In the terms of the model, participants appear to use the same stopping rule but set a higher stopping threshold for closed-interval retrieval than for open-interval retrieval. Participants persist in search longer; however, they do not retrieve more items in the closed-interval design than in the open-interval design. The temporal differences were predicted by the model and observed in the data despite no appreciable differences in the number of items retrieved. These results indicate that participants do not in fact terminate search over-quickly in open- relative to closed-interval designs. Furthermore, as participants were able to retrieve the same amount of items in less time, the results suggest that the open-interval design might provide a

method to measure not only how memory is searched, but also how efficiently memory can be searched.

## Abstract

Driving a car is obviously a complex task and the construction of an ACT-R model of human attention while performing this task is similarly complex along multiple dimensions and presents a challenge to architecture and modeler. This work is a first attempt to develop an integrated driver model of attention in the cognitive architecture ACT-R. The model is able to keep a traffic lane, identifies traffic signs and crossroads in a sparse, simulated environment.

**Keywords:** Driver behavior model; cognitive architecture; ACT-R; Attention

## Introduction

For most of us, driving a car is one of our everyday tasks. But even for experienced drivers, just the task itself it is a cognitive challenging task involving a big range of human senses like sight, hearing, touch and acceleration. And this is not yet considering secondary tasks like talking on the phone or visual distractions like city illuminations. Luckily, most driving task are not as challenging as the Traffic Light Tree in Fig. 1, an artificial scenario by the French sculptor Pierre Vivant.

Fig. 1: The (thankfully not on a crossroad) installed traffic light sculpture by Pierre Vivant.

Current attempts to model human attention while driving a car are realized in a quite more simple environment, yet they are quite an important first step towards the modeling

of these highly complex tasks. Vice versa, it also can provide an indication for the future development of a cognitive architecture by showing what cannot be realized yet.

Fig. 2: Screenshot of the environment interaction with ACT-R. The red circle indicates the current visual focus of attention of the model.

The simulation environment for this model was restricted to the components the cognitive architecture can recognize. Nevertheless, basic driving scenarios simulating human visual attention and driver behavior could be implemented.

The screenshot from the driving environment, which was separately implemented in Lisp for this work, shows from top-down another (blue) vehicle, the focus of attention (red circle) and the navigation point (N) to keep the vehicle in the center of the road. This model focuses on basic reference points like the horizon, a leading car, the border and the center line of the road, crossroads and traffic signs. For example, the model of a driver in the screenshot in Fig. 2 sets the focus of visual attention on the outer border of the road which enables it to reevaluate the center for the N point. In the next step, it will shift the focus of attention to the front and (hopefully) detect the car in front. If so, possible next steps could be the comparison of the distance to a (here fixed) safety distance or an overtaking procedure.

The here presented cognitive model should simulate through ACT-R human attention while driving in a simplified environment and produces the behavior for scenarios with other cars, crossroads and traffic signs.

## The cognitive architecture

The ACT-R (Anderson, 1993; Anderson 2007) cognitive architecture proposes artificial, computational processes that aim to act like a human cognitive system. Most of its basic

assumptions are inspired by the progress of cognitive neuroscience. The tasks that humans can perform should, in theory, consist of a series of discrete operations. ACT-R is primarily used to model experimental psychological data. ACT-R comprises theories about the operation mode of human information processing and describes a comprehensive computer model of human cognition. The architecture is not only a proposed unified theory of cognition, it is also a programming environment, a production system with a development environment where it is for example possible to set parameters or run simulations. ACT-R is a framework in which the researcher can create models (programs) for different tasks. Running this model produces a simulation of human behavior.

As many cognitive architectures, ACT-R contains a number of modules which can be accessed through their limited-size buffers. For each module, a dedicated buffer serves as an interface with that module. The state of ACT-R at a given time is the content of the buffers at that time. Buffers are connected to the modules and are changed by production rules. Every buffer and (nearly) every module can be allocated to a cortex region. This enables an interesting mapping between buffers and neural processes (Anderson 2007).

Fig. 3: ACT-R system diagram (Byrne, 2001). The Cognitive Layer and each of the Perceptual-Motor modules run in parallel, but each component is itself serial.

The main assumption of ACT-R is the representation of knowledge as either declarative or procedural knowledge. Declarative knowledge, consisting of facts, is represented in form of *chunks*, or small logical units which encode simple facts (e.g. the fact: “Sapporo is in Japan”). Procedural knowledge, representing knowledge about how we do things, is represented in form of *production rules*, condition-action rules that generate a specific action (e.g. manipulate declarative knowledge) if the conditions of this rule are fulfilled. In other words, ACT-R’s knowledge representation is split in two kind of memory modules, perceptual-motor modules and memory modules.

The diagram in Fig. 3 shows the ACT-R in action. For the visual attention, the environment provides screen objects to the vision module. The target of attention is put into the declarative memory in form of a chunk.

We decided to choose ACT-R for this task because it has a visual search, is a well-accepted cognitive architecture, and was already used in the past to evaluate the attention during a driving task. A crucial advantage of the ACT-R architecture is that the three main components used in this model (control, monitoring and decision-making) can be implemented directly. This takes into account human constraints and results in a cognitive adequate model of human attention.

## Previous work

Most developed approaches can be distinguished into two categories: task specific and generic approaches. *Task specific approaches* such as Cosmodrive (Bellet et al., 2007) and Pelops (Benmimoun, 2004) reproduce the cognitive functions of a car driver. In contrast to task specific approaches, *generic approaches* can model various aspects of human behavior. Therefore, it is necessary for these architectures to include a theory of human information processing. Examples for such architectures in which driver models have been implemented are ACT-R (Anderson, 1993; Salvucci, 2006), SOAR (Aasman, 1995) and QN-MHP (Liu et al., 2006).

Driver models were described by Aasman (1995) in the cognitive architecture SOAR and by Liu (1996) in Queuing Network-Model Human Processor (QN-MHP). Although these models already exist in other cognitive architectures and the central ideas remain the same in any architecture, the ACT-R model of a driver shows a broader spectrum of application (Salvucci 2001; 2006).

Salvucci (2006) developed a first integrated cognitive model of human driving behavior in ACT-R. He showed in his work the generality and the applicability using the cognitive architecture ACT-R for the specific task of driving. His model is designed to keep a standard vehicle on a multi-lane highway with moderate traffic. The model is also able to recognize the distance to a vehicle ahead and to make the decision for overtaking. As driving is a highly complex task and not readily implementable, this model has some limitations. The model solely was meant to interact with a highway environment without recognition of traffic signs, crossings or slip roads. An implementation limitation was the use of the previous version ACT-R 5.0 and its incompatibility to newer versions. It was also not possible to make the ACT-R model interact directly with a driving simulator.

Regardless the challenges, Salvucci proposed to develop a driver model in the context of embodied cognition, task and artifact (ETA) framework (Byrne, 2001), an idea which was adopted in this work.

## Cognitive model

A driver model can be a powerful instrument with several possible fields of application, such as the development of intelligent driver assistant systems. Our model is implemented the newest version ACT-R 6 (Anderson, 2007) and using the standard ACT-R development environment

running on an open source LISP, which not only guarantees support and accountability, but also enables the research community to use the developed model for further research.

## Driver Modeling

We introduce a computational model of human attention in a car driving task implemented in the ACT-R architecture. As described previously, this model aims to account for the embodied cognition, task and artifact (ETA) framework.

The complex task of driving a car can be divided into basic subtasks. These must be integrated and interleaved to achieve the continuously changing parent task. Michon (1985) identified three levels of skills and control for the driving task: operational (control), tactical (maneuvering), and strategical (planning). He claims that a comprehensive model should take into account the various levels.

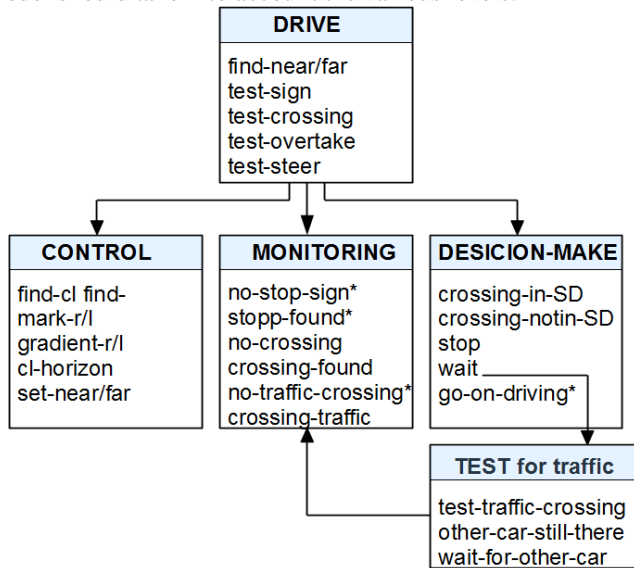

Fig. 4: Schematic representation of the production rules of the driver model in a simple crossroad scenario. The title of a box indicates the current goal and the corresponding production rules. The arrows show the flow of control and the asteriks the return to the parent-goal.

The independent subtasks of the (simplified) parent task *drive* (see Fig. 4) were implemented as *control*, the operational process controlling the input, *monitoring*, the tactical process interacting with the environment, and *decision making*, also analogous to the tactical level of Michon (1985), managing maneuvers like overtaking. These subtasks are processed serially. Every production of the top level goal *drive* has sub-goals, which incorporate the three components.

**Development Environment** The theory of ACT-R is embedded in the ACT-R software in form of Common Lisp functions. This model is implemented in the open source Clozure CommonLisp 1.3 and the current version of ACT-R 6.0 under the operating system Ubuntu 9.04. In order to

make the simulation environment interact with the ACT-R system, it was directly implemented in LISP with simple graphics and the extension with the LTK Lisp Toolkit. As it was not possible to make ACT-R directly interact with a driving simulator, we decided to use a Lisp-implementation of a driving environment.

## Model Specification

As mentioned earlier, human attention during a driving task is quite complex along multiple dimensions. It is not yet possible to model every aspect of human attention within a cognitive architecture for such a complex task. To limit the scope of the project, model is hold quite simple. The model focusses on simple visual perception and attention shifts how they might occur in a sparse, artificial environment.

The first issue to address was to implement the three components control, monitoring and decision making as a loop of cognitive operations in the serial processor of the ACT-R architecture. The UML diagram in Fig. 5 shows the behavior of the cognitive model. This diagram identifies one primary loop, which corresponds largely to the control component in Fig. 4. The primary loop implements the identification of the near and the far point, in other words, the points responsible for the stable navigation in the middle of the road. From the initial state, the model finds the road marks and sets the near point for stable navigation on the road. The model then fires a production rule screening for a traffic sign, changes the state according to the result and sets the far point. In our model, the near and far point are used as control components and explained in detail in the next paragraph. If the model reaches the state *find far* it will continuously repeat the primary control loop.

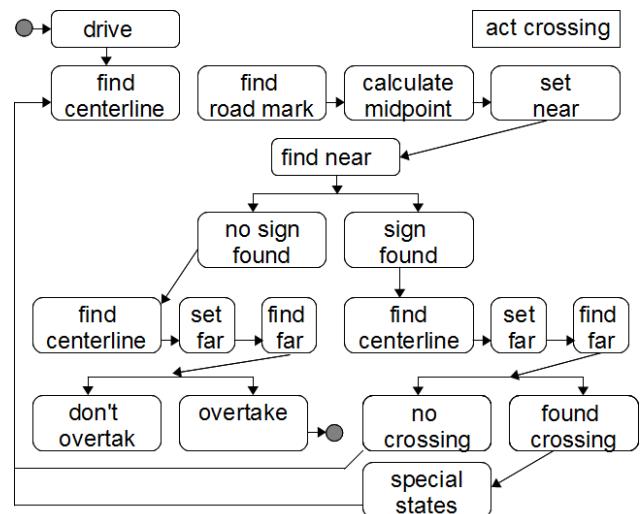

Fig. 5: UML-Diagram of the driver model. To execute the task drive, the model runs through several states.

This primary loop can be extended in case the monitoring component finds a special state like an intersection, that is, the condition part of a production rule investigating the right road marks on the right detects a crossing and the action part of this rule changes the state of the model, testing for other

given constraints. According to the result, the model might change the state or repeat the primary control loop updating the near and the far point for stable navigation.

## Control

The control component of attention while performing a driving task manages the perception of lower level visual cues and the control over the vehicle (e.g., stopping). The model uses the simple concept of two salient visual attributes, based on earlier findings on locomotion (Llewellyn, 1971). Steering is described (Land & Horwood, 1995) as divided in two levels, guidance and stabilization, by using a „far“ and a „near“ region. Models of steering developed under this assumption have been proven to be consistent with empirical evidence.

This task specific information was required to construct the model. An issue to be addressed was what kind of strategies might be used by a human in a driving environment. Salvucci & Gray (2004) base the perception of a cognitive model on a near and a far point for guidance and stabilization. This model extends the idea of two levels to the extend, that with the far point, also other salient attributes are encoded. The visual attention of the model does not only switch in between the near point in the middle of the road and the horizon (or any other straight point ahead), but also encodes crossings, traffic signs or other cars coming from the right hand side on a crossing. For the here created artificial road environment, these two points account to capture the relevant aspects of the environment. The idea behind this wider use of the far point is the possible extension in further implementations. The far point could be used to determine other attributes relevant or irrelevant for the driving task and give an account, how errors while driving (e.g. overlooking of a traffic light before a noisy background during monitoring).

Fig. 6: Near and far points for a straight road with a vanishing point and a road segment with a lead car.

Fig. 6 illustrates the near and far points and how they are set in some possible situations during the driving task. The near point determines the position in the middle of the road. The far point is used to identify the direction of driving and other non-control points like vehicles, crossroads and traffic signs. If there is a lead vehicle, the distance between the two

points is determined, and in case it falls below a certain safety distance, the model can react according to that. At a crossroad the model will set the far point on the border of the crossing or on the vehicle approaching from the right. If the model decides to continue driving, it will not look again for another car at the crossroad, which is surely an issue for future implementations. Stopping is implemented by setting the far point onto the near point. The model will continue a loop until the other vehicle is not on the crossroad anymore and out of the safety distance.

## Monitoring

The monitoring component captures the environment continuously and updates the declarative memory. In the here implemented driving environment, the situation awareness mainly focuses on other vehicles around or traffic signs. The model shifts the focus of visual attention towards a certain object which is then encoded as visual attribute in the declarative memory. This shift is achieved through three different methods of shifting attention: First by specific locations or directions, second by specific characteristics, and third by objects, that have not been in the focus of attention yet. The combination of these methods of attention shift enables the model to create complex search strategies through the production rules. As ACT-R has a build-in memory decay mechanism, it might be possible to predict driver errors because the chunks encoding the current environment decay and can be forgotten if not updated continuously. Another source of possible driver errors could be the potential failure in encoding relevant information (e.g. to overlook a traffic sign or a vehicle).

## Decision Making

The information provided by the control and monitoring component is used to determine if and what decisions must be made on the tactical level concerning the maneuvering (e.g. stopping or overtaking). Our focus on decision making assumes that the attributes in the environment are encoded correctly. The decision how to proceed (in what state of the model) is based on a pattern matching with the knowledge about the environment. If there is no crossing encoded, the corresponding production rule will not fire and the primary loop will continue. The decision whether to stop or to continue driving depends on the encoded traffic sign or on other vehicles. In our environment, the model always recognized these situations correctly, but it would be interesting in future implementations to observe the behavior and decision of the model in case, an error during encoding of attributes occurs.

In order for the model to produce a decision making process similar to humans, encoding a visual attribute and shifting visual attention cannot occur at the same time. For this model, the focus of attention is for example either on the near or far point or encoding a traffic sign.

## Results and Discussion

Obviously, the model presented here does not account for all aspects of human attention during driving, especially not in a naturalistic environment. There are still quite some practical limitations in both, the architecture and the modeling effort itself. This study is an attempt to capture some of the difficult behaviors involved in driving. It also shows some of the limitations of the ACT-R architecture.

This study presents a simple simulation environment and a cognitive model of driver attention during car driving that is able to interact during run-time.

To obtain an integrated driver model of human driving behavior, it is essential to develop models in an architecture which is not task specific and can also model human behavior also in a different context, like ACT-R. This model is a first attempt to recognize, still simplified, traffic signs and crossroads and might make a first step towards the vision of accident-free driving. A majority (over 80%) of the automobile accidents are caused by the driver themselves (Statistisches Bundesamt, 2011). Nearly 16% of the accidents happen while turning and during exit, followed by disregarding the right of way (15%) and not-adapted speed (15%). Theoretically, the cognitive driver model could give a deeper insight for around 30% of the human errors while driving. However, it has to be taken into account that the model is still interacting with a simplified environment and not yet taking into account driver's prior experience, which could be implemented by an increased attention in potentially high accident risk situations. The model and the environment do not present a complete picture of driver behavior yet, but they form a base to extend the ETA framework in any direction.

The ACT-R architecture limits the employment of the three components control, monitoring and decision making by using a serial cognitive processor. The serial processing of the subtasks is typical for the human bottleneck of information processing (Anderson et al, 2004). The resulting model is not an optimal model in a mathematical sense, but approximates human behavior and makes it possible, to mimic human cognitive capacities, simulate the dynamic nature of human driving behavior, and therefore to produce a cognitive adequate model of human driving behavior. If the model is, for example, occupied with an attention shift, it cannot simultaneously update the near point. Also, the model can only fire on production rule at a time and only one visual operation can be executed at a time. These processes take a certain time which are written in an output file. This file contains the time, the active buffer and the according event. This enables the researcher to compare the produced data with human data.

The knowledge representation comprehends declarative knowledge in chunks and procedural knowledge in production rules. For example, the scenario at a crossroad was implemented in 73 explicit production rules, which are highly detailed and is therefore open to future extensions of the model.

This study did not validate the model data so far. Future research could compare the output file data with human data, specially compare the attention shift of the model to human drivers over eye-tracking and the reaction times. But one must remember, that only most critical parts of key scenarios can be validated as no single method is sufficient enough to understand the complex task of human driving behavior yet.

### ACT-R for complex tasks

Modeling such complex tasks in the cognitive architecture ACT-R presents quite some technical challenges to the modeler. For a complex driving task and the validation, the ACT-R model and the participants should interact in the same environment. However, for this validation, it must be possible from the technical side to connect the ACT-R model directly to the simulation environment, which can be technical challenging. Also thinkable is to develop a Lisp version of a driving simulator which can easily interact with ACT-R. If the simulator allows to extract the same information ACT-R does, the output files could be compared, even though the multiple implementation might be a potential source of errors. Also, the current version of ACT-R has some difficulties to directly recognize other components than the already implemented. The attempt to model such complex tasks in generic cognitive architectures show the applicability as well as the still remaining technical limitations.

However, such a complex task might raise the question not only about the limitations of the architecture itself, but also the modeling of human behavior. It might be a good approach to study the key scenarios of human attention during driving in more detail and transfer these results into the model code, breaking down the overall complex task into smaller subtasks in specific situations.

## Conclusion and Outlook

We hope that this research will motivate more members of the computational modeling community to study human attention during driving a car and to overcome the practical limitations. Modeling of such complex tasks holds great promise for meeting the modeling challenges.

The progress to date in the development of cognitive architectures has been impressive, yet scientific gaps, technical challenges and practical issues remain. On one hand, cognitive models help to develop an understanding of driver behavior and aim to provide a theoretical account for human attention while driving. On the other hand, they are powerful and practical tools when implementing human-centered design and real-world applications. First steps towards the examination of the source of human mistakes through distraction from the primary driving task through secondary tasks like dialing a phone haven been taken (Salvucci, 2001) showing the feasibility of the architecture for these task and possible extensions.

The ACT-R architecture enables to elucidate interesting aspects and provides a theory of human attention while

driving. At the same time, human attention during driving is a challenging task for the ACT-R cognitive architecture. It shows the still existing limitations beyond basic laboratory tasks and pushes the research community to expand the architecture towards more complex and finally real-world tasks.

### Acknowledgments

We are grateful for the kind advice and assistance of Prof. Bernhard Nebel, the support of Prof. Wolfram Burgard (University of Freiburg), and for intensive discussions with Dario Salvucci (University of Philadelphia). This work has been partially supported by a grant from the DFG to MR (Project R8-CSPACE in the SFB/TR8 "Spatial Cognition").

## Abstract

Intelligent tutoring systems (ITS) are a successful application of cognitive science theory to the field of education. Data generated by students using an ITS can also be used to test the external validity of cognitive science principles developed largely in laboratory settings. The present paper collected data from high-school students using two versions of *Cognitive Tutor*, an ITS for Geometry, to assess the impact of eliminating the split-attention effect. The two versions differed in the extent to which the interface required split attention during problem solving. One version used integrated diagrams whereas the other used non-integrated tables and diagrams. Results suggested that students needed fewer problems to master skills in the integrated version, and this was particularly true for mastering difficult skills. This study demonstrates the successful use of cognitive science principles to improve learning through empirically and theoretically derived enhancements to an ITS used in a natural educational setting.

**Keywords:** Intelligent tutoring systems, mathematics instruction, split-attention effect, cognitive load theory.

## Introduction

One of the promises of cognitive science is that it informs the design and implementation of effective instruction and educational tasks (Bruer, 1997). Unfortunately, there is often a disconnect between instructional tasks, as they are originally designed, and the actual implementation of those tasks in the classroom (Stein, Smith, Henningsen, & Silver, 2000; p. 4). One way to partially mitigate this danger is to design instructional tasks in software. Ideally, the design of the software is based on a cognitive theory of learning. Several intelligent tutoring systems (ITS) have been designed based on cognitive theories, including constraint-based reasoning (Mitrovic & Ohlsson, 1999), failure-driven learning (VanLehn, 1988), and the ACT-R theory of human cognition (Anderson, Boyle, Corbett, & Lewis, 1990).

The designers of intelligent tutoring systems face at least two challenges. First, they must demonstrate a learning benefit above and beyond traditional classroom materials and activities. More importantly, an ITS should be able to demonstrate continuous improvements to learning as the theories and empirical findings from cognitive and learning sciences advance.

The purpose of the current paper is to evaluate how enhancements to the ITS *Cognitive Tutor: Geometry* affected student learning in real-world, educational settings. The ITS modifications were based on the predictions of

cognitive load theory, which claims that learning is harmed when a student splits his or her attention across interdependent sources of information. The so-called “split-attention effect” inspired an *in vivo* study in which a single unit from *Cognitive Tutor* was heavily revised to reduce split attention caused by the user interface. The goal of this paper is to extend the generalizability of that *in vivo* experiment by conducting a more in-depth analysis of student learning using data collected from real students using two different versions of the commercially available *Cognitive Tutor*.

## Cognitive Tutor

*Cognitive Tutor* is an intelligent tutoring system inspired by the ACT-R theory of human cognition. *Cognitive Tutor* is based on the pedagogical principle that knowledge is decomposed into knowledge components called *skills*, and learning is maximized when the student is responsible for actively taking each problem-solving step. A cognitive model tracks if the student takes a step off the ideal solution path. Student modeling also allows the tutor to provide immediate feedback, as well as help, in the form of hints, at any step during problem solving. The *Cognitive Tutor* operationally defines “mastery” when the probability that a student knows a skill reaches a threshold of 95%.

*Cognitive Tutor* has been evaluated for its efficacy in both the laboratory and the classroom (Anderson, Corbett, Koedinger, & Pelletier, 1995; Koedinger, Anderson, Hadley, & Mark, 1997), as well in randomized field trials (Ritter, Kulikowich, Lei, McGuire, & Morgan, 2007). A majority of the aforementioned studies used traditional learning materials, such as textbooks and paper-and-pencil homework assignments, as the baseline learning condition. Summarizing over several studies, Corbett (2001) estimates the effect size of *Cognitive Tutor* to be around one standard deviation above traditional instructional materials.

Although effective, there is still room for improvement given that one-on-one human tutoring, when combined with mastery learning, produces about a two standard deviation increase in learning (Bloom, 1984). One way to improve an ITS is to go back and reanalyze the design of individual units and ask if there are any opportunities for enhancing the student’s interaction with the target material. One of the pedagogical commitments of *Cognitive Tutor* is to “minimize working memory load” (Anderson et al., 1995; p.

180). Therefore, the next section discusses cognitive load theory as it applies to geometry instruction.

## Cognitive Load Theory and the Split-Attention Effect

According to cognitive load theory, learning is most likely to take place when the learning environment maximizes *germane* load and minimizes *extraneous* load. Germane cognitive load is defined as “load devoted to the processing, construction and automation of schemas;” whereas extraneous load is defined as “load generated by the manner in which information is presented to learners and is under the control of instructional designers” (Chandler & Sweller, 1991).

Solving problems in geometry is most likely to include both types of load. For example, it is often the case that geometry problems are stated verbally, and they are accompanied by a diagram. The student’s first task is to map the given information, stated in the problem scenario, onto the figure. For example, this would require that the student holds an angle name and its measure in working memory (e.g.,  $m\angle ABC = 15^\circ$ ) while locating the relevant angle in the diagram. This is an example of the *split-attention effect* (Kalyuga, Chandler, & Sweller, 1999).

Holding the angle name and its measure in working memory is not directly relevant to learning how to solve these types of problems; therefore, the working memory load imposed on the student is considered an extraneous load. According to cognitive load theory, instructional designers are recommended that they create a learning environment that minimizes extraneous load caused by the split-attention effect.

Based on the hypothesis that splitting one’s attention across multiple sources of information harms learning, Butcher and Aleven (2008) conducted an *in vivo* experiment where they contrasted classroom learning from two different versions of *Cognitive Tutor: Geometry*. The traditional interface included a verbal statement of the given information, a diagram, and a table. The table was the focus of the student interactions and required students to enter the measure of each angle, as well as a reason justifying the calculation. For the experimental interface, all of the inputs were made directly in the diagram. Students entered their measures and reasons by clicking on angles in the diagram. The learning results from that study suggested that the interactive diagram was easier to learn from, especially in terms of a delayed posttest for numerical test items.

Because the study by Butcher and Aleven (2008) was conducted with a relatively restricted sample of students ( $n = 58$ ) and a single unit of instruction, there is an open question as to whether a change to the interface translates to classroom learning. Will the results replicate when they are implemented in the “wild?”

To address this question, we conducted an analysis of log files generated by students using one of two different versions of *Cognitive Tutor: Geometry* that differed in terms of the split attention required by the user interface.

## Method

### Participants

We compared the usage data from two different versions of *Cognitive Tutor: Geometry* software developed by Carnegie Learning, which are described in the section below. User log files generated by the tutor contain detailed information about every action taken in the interface, including latencies, errors, and access to the various forms of help (i.e., requesting hints, accessing the glossary, reading the lesson page, or studying the interactive example).

Two cohorts of students used two different versions of the software. Approximately 10% of the schools that use Carnegie Learning products were randomly selected to collect log files from their students. For the current study, that translates into approximately  $n = 1,577$  students for the 2009 version and  $n = 2,168$  students for the 2010 version.

### Materials

The interface for several units and sections of the *Cognitive Tutor: Geometry* curriculum were revised to reduce the split-attention effect by using interactive diagrams. Those units include: Pythagorean Theorem, Angle Relationships in a Triangle, and Special Right Triangles.

**Table Interface (v.2009).** Previous versions of *Cognitive Tutor: Geometry* included an interface similar to the one described as the control condition from Butcher and Aleven (2008). The interface included a static diagram, a verbal statement (in paragraph form) of the givens and the sought, and a table of angles in which the student is tasked with calculating the measure and providing a rationale for the calculation (see Fig. 1).

Angle	Measure	Reason
m.∠RTS	30.8	Given
m.∠RST	75.4	Given
m.∠RTU	90	Right Angle
m.∠TRU	59.2	Triangle Sum Theorem
m.∠SRU	90	Right Angle
m.∠SRU	14.6	Triangle Sum Theorem
m.∠TRS	73.8	Angle Addition Postulate

Figure 1: Table Interface (v.2009).

**Interactive Diagram Interface (v.2010).** In an effort to reduce the split-attention effect, several units/sections of geometry were modified to use an “interactive diagram.” The design of the interactive diagrams was similar, but not identical, to the design of the circle tutor used in Butcher and Aleven (2008). All student interactions were handled in the diagram itself. Students had the ability to click on individual angles. Once an angle was selected, a *flyout*

(shown with a blue background in Fig. 2) appeared with several input fields, including the angle measure, a reason field where the student justifies her calculation, and drop-down menus to select the other angles that participate in the target angle's calculation. When the tutor determined that each entry was complete, a summary appeared under the "Diagram Notes," and the diagram itself was labeled with the angle measure.

As previously mentioned, the revised design was intended to reduce working memory load by externalizing some of the information. Because students can *see* an angle in the diagram, they are no longer burdened with holding the angle's name and measure in working memory. Theoretically, this should provide students with more cognitive resources to search the problem space (Larkin & Simon, 1987) and generate domain-relevant inferences.

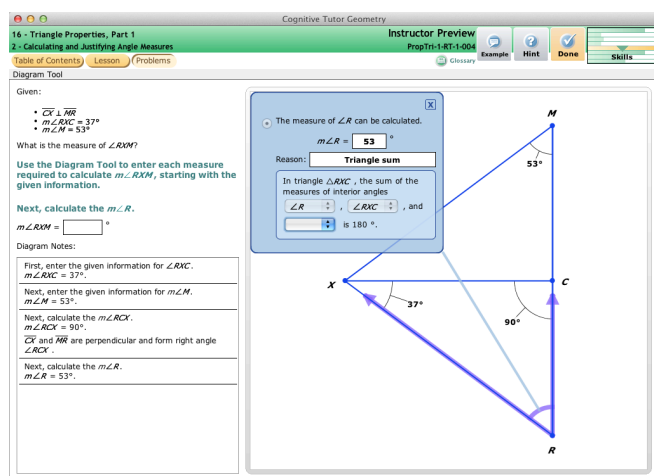

Figure 2: Interactive Diagram Interface (v.2010).

## Results

Due to the large sample sizes, all of the independent, two-sample tests were significant with an alpha level of  $\alpha = .01$ ; thus, instead of reporting  $p$ -values, we relied on Cohen's  $d$  as an effect-size indicator. This allows for a better estimate of the practical significance of the differences.

The results are broken down into two sections. The first section analyzes learning at the unit level. Given that units from v.2009 were reorganized in v.2010, this made one-to-one comparisons at the unit level difficult. We therefore analyzed learning at a finer level of granularity by focusing on the learning of individual skills, regardless of the unit in which the skill appeared.

To control for school-related differences, we replicated all skill-level analyses by restricting our sample to students from the same school. There were small numeric differences in the magnitude of the effect sizes, but they were all in the same direction and interpretation category (e.g., small [ $d = .20$ ], medium [ $d = .50$ ], & large [ $d = .80$ ]); therefore, we collapsed across schools in all subsequent analyses.

## Learning Measured at the Unit Level

The software organizes the learning material hierarchically. Units form the highest level of organization, which are subdivided into sections. Sections are further broken down into problems, which can be further subdivided into individual skills.

We used two different measures to evaluate learning at the unit level. The first was the median number of *Problems* the students solved before graduating the unit. Graduation was defined as mastering all skills. Second, we measured the total amount of *Time* (in minutes) spent in the unit. The results for unit-level measures are summarized in Table 1.

For the problem metric, students using the table interface generally needed to solve more problems in the tutoring system than students using the interactive diagram interface. This was true for Special Right Triangles (5+33 vs. 27 in v.2009 and v.2010, respectively) and Angle Relationships (39 vs. 9+7). The results were reversed, however, for the Pythagorean Theorem unit (5 vs. 9).

The results for the total amount of time spent in the tutor were largely consistent (and correlated with) the number of problems the students solved. The biggest time saving was observed for Angle Relationships (220.01 vs. 70.67+32.22).

Table 1: Unit-level comparisons between the two versions of the software.

Unit	Year	Section Num.	$n$	Problems to Grad.	Time (min.)
Pythagorean Theorem	2009	1	1,577	5	19.34
	2010	1	2,168	9	38.54
Special Right Triangles	2009	1	858	5	9.67
		2	745	33	54.56
	2010	1	1,197	27	67.71
Angle Relationships	2009	1	331	39	220.01
	2010	1	1,213	9	70.67
		2	899	7	32.22

One potential explanation for the results in which the table interface demonstrated better performance than the interactive diagram interface could be due to a difference in the distribution of material across sections. For example, the Special Right Triangles unit originally included two sections: "Finding the Lengths of Sides of a 45-45-90 Triangle" and "Finding the Lengths of Sides of a 30-60-90 Triangle." In the revised version, these sections were combined to form a single section: "Calculating the Lengths of Sides of Special Right Triangles." Combining the sections may have increased the difficulty because students were required to discriminate between the principles necessary to solve two different types of problems.

A similar case could be made for the Pythagorean Theorem unit. The original unit included a section that only required students to solve for the length of the hypotenuse. However, in the revised version, either the hypotenuse or

the leg could be the sought value. Again, students were required to make finer-grained discriminations in the revised version, which could have accounted for the increased time required to graduate from the unit.

### Learning Measured at the Skill Level

As the previous paragraph suggests, the two versions of *Cognitive Tutor* changed in more ways than just the interface. In some cases, the geometry units were rearranged such that the section breakdown was different from one year to the next; therefore, measures of learning could be confounded by section-level changes.

To control for these potentially confounding factors, we measured learning on individual skills, with learning operationally defined as the number of problems the students solved to master each skill. As stated previously, mastery was achieved when the probability of a student knowing a skill reached 95%. To ensure a fair comparison, for this analysis we focused on skills that were consistent between the two versions.

The skills for each unit are presented in separate sections below. The name and id of each skill can be found in the Appendix.

**Special Right Triangles.** Two types of triangles were covered in this section: 45-45-90 and 30-60-90. For the easier triangles (45-45-90), the revised version using interactive diagrams actually led to worse performance in that students needed more problems to master these skills in the revised interface (see Table 2; shaded values). Effect sizes ranged from small ( $d = -0.33$ ) to large ( $d = -2.54$ ).

The reverse, however, was true for the more challenging triangles (30-60-90). The revised interface reduced the number of problems needed to master the associated skills. Effect sizes ranged between ( $d = .33 - .46$ ).

Table 2: Skill comparisons for Special Right Triangles.

Skill ID	2009		2010		$d$
	$n$	$\bar{x}$ ( $SD$ )	$n$	$\bar{x}$ ( $SD$ )	
SR-45_01	871	3.09 (1.9)	991	3.99 (3.41)	-0.33
SR-45_02	785	1.52 (1.06)	1028	6.32 (7.66)	-0.88
SR-45_03	819	3.33 (1.2)	938	16.67 (7.81)	-2.39
SR-45_04	798	2.35 (1.03)	934	16.6 (7.88)	-2.54
SR-30_01	476	21.78 (11.36)	893	17.27 (7.79)	0.46
SR-30_02	558	19.68 (11.8)	991	16.29 (7.65)	0.34
SR-30_03	478	21.56 (12.07)	1000	16.63 (6.96)	0.50
SR-30_04	543	21.08 (12.13)	1009	17.89 (5.93)	0.33
SR-30_05	577	16.29 (10.95)	924	19.5 (5.85)	-0.36
SR-30_06	465	22.31 (12.04)	890	17.57 (7.95)	0.46

Note: Skill IDs refer to Special Right Triangles, followed by the first angle measure (e.g., 45 or 30).

One potential explanation for the inconsistent results is that the previous version was easier than the revised version because it separated the two special right triangles into their own sections (see Table 1). When students solved 45-45-90 problems, they did not have to discriminate between shorter, longer, or equal leg lengths when calculating the non-given side. Restricting our analyses to the 2009 sample, students demonstrated fewer errors while solving 45-45-90 problems ( $M = 5.15$ ,  $SD = 5.93$ ) than 30-60-90 problems ( $M = 39.53$ ,  $SD = 37.35$ ),  $d = 1.29$ . This suggests that, at the section level, the 45-45-90 problems were easier to solve.

**Angle Relationships in a Triangle.** The skills associated with the unit “Angle Relationships in a Triangle” were more consistent. For these skills, the revised interface showed a marked reduction in the average number of problems the students solved before mastering their skills. The effect sizes ranged between medium ( $d = .57$ ) and large ( $d = 2.66$ ), with a majority of the skills falling in the large category (see Table 3).

The lone exception was the first skill, which asks the students to “Enter given value.” It seems that entering the given value was slightly easier in the original table interface that required students to map between the verbal description and entering the given in a table. This might be because the answer of the top row of the table is *always* the given value, whereas a small amount of search is required to enter the given in the interactive diagram.

Table 3: Skill comparisons for Angle Relationships.

Skill ID	2009		2010		$d$
	$n$	$\bar{x}$ ( $SD$ )	$n$	$\bar{x}$ ( $SD$ )	
Ang_Re_01	1140	1.86 (1.27)	901	2.29 (0.98)	-0.38
Ang_Re_02	1244	4.38 (5.83)	891	1.79 (1.56)	0.61
Ang_Re_03 <sup>1</sup>	455	9.86 (5.43)	887	2.19 (2.49)	1.82
Ang_Re_04	455	5.90 (8.8)	887	2.19 (2.49)	0.57
Ang_Re_05	369	24.50 (16.83)	887	2.19 (2.49)	1.85
Ang_Re_06	344	29.80 (16.41)	887	2.19 (2.49)	2.35
Ang_Re_07	344	30.17 (16.35)	887	2.19 (2.49)	2.39
Ang_Re_08	331	31.86 (15.59)	887	2.19 (2.49)	2.66
Ang_Re_09	344	29.79 (16)	887	2.19 (2.49)	2.41
Ang_Re_10	450	10.10 (13.31)	889	3.88 (2.2)	0.65

**Pythagorean Theorem.** The final section in which there were matching skills was the unit on the Pythagorean Theorem. The two skills in this section that fit our criteria both demonstrated an advantage for the interactive diagram. Students using the revised interface needed fewer problems to solve both skills (i.e., calculate the length of the

<sup>1</sup> “Ang\_Re\_03” through “\_09” have the same statistics because the 2010 skill included each of the 2009 variants as sub-skills.

hypotenuse in and out of a contextual scenario). The effect sizes were both considered “large” ( $d > .90$ ; see Table 4).

Table 4: Skill comparisons for Pythagorean Theorem.

Pythag_02	1702	15.38 (8.9)	2338	8.84 (4.42)	0.93

## Discussion

Using data gathered from the use of an intelligent tutoring system (ITS) in natural educational settings, the current study demonstrates how an already effective intelligent tutoring system can be further refined through the application of cognitive and learning theories. The current study draws from research on the “split-attention effect,” which demonstrates that performance on a task is greatly reduced when the student must split her attention across interdependent sources of information. Learning is greatly reduced because working memory is tasked with holding a large number of chunks of information. According to cognitive load theory, when that large burden on working memory is not relevant to abstracting principles from the domain, then this leads to an “extraneous load.” Students are not able to transfer the knowledge that is inferred from problem solving to long-term memory.

The split-attention effect is particularly relevant to solving geometry problems in an ITS, where the student is required to split her attention across a verbal scenario that states given information, a diagram that depicts relationships between segments and angles, and a table that holds information about each angle.

Butcher and Aleven (2008) demonstrated, in an *in vivo* study, that a revised ITS interface can enhance learning both immediately and over the long term. On the basis of their strong results, the *Cognitive Tutor: Geometry* interface was revised to emulate the same type of interaction. With the “interactive diagrams,” students were given the chance to concentrate the focus of their attention on the learning materials.

Although the *in vivo* results were strong, there was a chance that crucial design elements did not get directly translated into the commercial version of the software. A comparison of screenshots between the Butcher and Aleven (2008; Fig. 1) and the current study (Figs. 1 & 2) reveals that there were subtle design differences. For example, the original study modified a unit on circles, whereas the current study mainly concentrated on triangles. There may be subtle content differences that lend themselves more or less well to learning gains through interactive diagrams. Second, the information in the interactive circle diagrams was echoed in a table; whereas, the triangle tutor included a “Diagram Notes” panel with similar, but differently formatted, information.

The current results support the generalization that small design differences can have a measurable impact on learning. At the unit level, there were generally mixed results with some, but not all, units demonstrating a reduced amount of time spend solving problems. Analysis at the more fine-grained level of individual skills yielded more consistent results. Most, but not all, of the skills associated with the interactive diagram showed a positive effect. Some of the skills that showed an increase in the number of problems required to master the skills seemed to fit into one of two categories. Either the skills were very easy (i.e., “enter given”) or they were embedded in a particularly easy unit. In these cases, it might have been better to rely on the old design. For more difficult skills, however, there was a definite advantage to interacting directly with the diagram.

Although the results are encouraging, the current set of analyses could be improved in the following ways. First, this was not an experimental study. Students were not randomly assigned to condition; therefore, the conclusions that we can draw from these analyses are strictly correlational. However, these results are suggestive and point to interesting new research projects. For example, subsequent research should test the hypothesis that interactive diagrams are especially helpful for more difficult topics.

Another improvement on the current analyses would be to assess “robust” learning, which is defined as learning that is retained over a long interval, transfers to new situations, and helps accelerate learning of subsequent material (Koedinger, Corbett, & Perfetti, 2010). Because this was an analysis of the log files generated by student users, we were not privy to the students’ pre- and post-test scores. Future analyses will look at post-requisite materials available in the tutor and evaluate if there is any evidence of transfer or accelerated future learning. Although it may have taken students more problems to master the skills presented in the Special Right Triangles unit, students might be able to transfer their knowledge more accurately when they were required to struggle with deciding which rule applies within the collapsed Special Right Triangle section (e.g., desirable difficulties; Bjork, 1994).

In addition, we would also like to conduct further analyses to determine whether the changes in the design features affected the learning curves of the matched (i.e., comparable) skills.

In conclusion, it is widely acknowledged that learning geometry is challenging. As instructional designers and members of the cognitive science community, it is incumbent upon us to ensure that learning difficult science, technology, engineering, or math (STEM) topics is both efficient and robust. One way to continuously improve our methods of instruction is to keep going back and testing our learning environments against the most recent empirical and theoretical developments. The current study takes an important step in that direction.

## Acknowledgments

The authors would like to thank the schools that allowed us to collect log files from their students. More importantly, we wish to thank all of the anonymous students who used our software to solve their geometry homework problems. Special thanks to Leslie Hausmann for commenting on a previous version of this paper.

# The effect of "Maverick": A study of Group Dynamics on Breakthrough in Collaborative Problem solving

Yugo Hayashi ([yhayashi@fc.ritsumei.ac.jp](mailto:yhayashi@fc.ritsumei.ac.jp))

College of Information Science and Engineering, Ritsumeikan University,  
1-1-1 Nojihigashi, Kusatsu, Japan

## Abstract

The presented study is concerned with one aspect of the effect of a "whistleblower" or a person arousing or informing a different perspective on a collaborative problem-solving task. Its purpose is to find out, through an experiment, how a whistle-blower (which we called "Maverick") affects the facilitation of a breakthrough in a rule-discovery task. In the experiment two hypotheses were tested: 1) Collaborative problem-solving task is facilitated by contribution of member with different perspective. 2) Problem-solving task is facilitated more as the number of participant with a different perspective increases. In the experiment, several sets of figures were presented in three different settings (without a different perspective, with Maverick, three members with a different perspective), where a group of six members (one human and five conversational agents) collaboratively engaged in a rule-discovery task via a text-based chat system. The experiment revealed an interesting result to the effect that while a different perspective, overall, contributed to the facilitation of problem-solving such contribution was not statistically significant when it was presented by half of the members. The implications of the result were discussed by referring to the related literature in psychology.

**Keywords:** Collaborative Problem Solving; Different Perspectives; Conversational Agent.

## Introduction

In Cognitive Science, many studies have been conducted to investigate what contributes most to collaborative problem solving. Several of them found that different perspectives promote an interaction between a pair and lead to collaborative problem solving (Miyake, 1986; Shirouzu, Miyake, & Masukawa, 2002; Hayashi, Miwa, & Morita, 2006). Others reported that asking reflective questions to conversational partners is a useful interaction strategy for gaining a deeper understanding about the problem (Okada & Simon, 1997; Miwa, 2004). They argued that the use of verbal probes such as providing clarification questions and suggestions prompted the problem solvers' reflective thinking and metacognition. A study by Shirouzu, Miyake, & Masukawa (2002) also suggested that taking different roles is an effective way to reconstruct the external representation of problem solvers and stimulate creative thinking.

Unfortunately, most of the findings on collaborative problem solving in the past have been based on the experimental data using a few participants such as a pair. Only few studies investigated the interactional aspects of collaborative process in a group of people and it remains unknown what kind of group dynamics actually operates in the perception and interpretation of different perspectives

during the task of collaborative problem solving among several people. In the present study, the author will look into the nature of such operation through an experimental set-up where a different perspective is presented to illusory members of a conversational group.

## Integrating different perspectives of others during collaborative problem solving

Cognitive operations such as combing and integrating different perspectives during problem solving are effective strategies for generating new ideas (Finke, Ward, & Smith, 1992). They are also considered to play important roles in several cognitive domains. In the model of Hegelian dialectic thinking, different perspective is regarded as a key concept for creativity. Also important in this model is a process called the 'aufheben' whereby contradicting different opinions are integrated and interpreted into a higher level of concept (Hegel, 1874). In group problem solving, it is assumed that this process of integrating different perspectives can play an important role during collaborative problem solving.

Hayashi & Miwa (2009) is one of the few experimental studies that examined the effect of cognitive operations such as combining and integrating different perspectives upon collaborative problem solving. In that study, they investigated the nature of such operations in a rule-discovery task where each of a pair had a different perspective. Results of the experiment showed that establishing a common ground between the two through such operations is a key to success in problem solving.

It can be expected that such operations would become more difficult when more than two people with different perspectives engage in problem solving. The present study will focus on the nature of group dynamics of collaborative problem solving in a group, which very few studies have investigated and still remains an unsolved issue in cognitive science (see Figure 1 for an experimental set-up of this study).

Figure 1. An experimental setting.

## Changing perspectives in group problem solving: Participation of 'whistle blower'

One of the common phenomena observed in problem-solving task is that people are often fixated on or biased in favor of a particular perspective. In such a situation, it is vital that they take a different perspective, but an important question is how we can make that happen.

In the field of organizational study, it has been found that participation by so-called a 'whistle blower' often arouses a different perspective among group members (Elliston, Keenan, Lockhart, & Van Schaick, 1985; Near & Miceli, 1987). In general, a whistle blower is defined as the person who dissents from the laws and systems of the organizations to which she/he belongs. It is said that such person may be perceived as a troublemaker that brings a confusing idea to a group, or, sometimes as a reformer who brings an innovative idea to a group. In either case, whistle blower is known to become a potential provider of an 'anomaly cue' that stimulates reflective thinking. We may predict that participation of whistle blower with a different perspective promote reflective process of collaborative problem solving.

### Aim of this study

Studies discussed above suggest that different perspective provided by whistle blower may provide breakthrough and facilitate their task in collaborative problem solving. The group dynamics of incorporating different perspective may also be affected by several factors such as the number of whistle blower in a group. It may be natural to expect that collaborative problem solving will be facilitated more when a different perspective is suggested by more than one person. The purpose of the present study is to examine these assumptions, by testing the following hypotheses:

- 1) Collaborative problem-solving task is facilitated by contribution of member with different perspective.
- 2) Problem-solving task is facilitated more as the number of participant with a different perspective increases.

### Experiment of design

In this study, we used a modified version of the experimental design in Hayashi et al. (2006), where pairs of participants with different perspectives engaged in a rule-discovery task. The design of the experiment was developed based on the Gestalt theory.

### Controlling the participants' perspective

In the experiment, several sets of random patterns of several figures on a 6 x 6 grid base, each colored black or white, were generated, (see Figure 2). In each set, a pattern consisting of combined square blocks was shown against the background of either black or white background colors. The background color was controlled to derive, through Gestalt effect, the change in problem-solver's perspective (Koffka, 1935).

Figure 2. Example of stimuli with ten components (six in white and four in black).

Each set consists of several "objects" (or patterns) in black or white color, each of which consists of a single block or combined multiple blocks. In one example shown in Figure 2, one of the paired objects has a total of ten "components" comprising four black components and six white components. They were shown on a computer display against either black or white background. When a participant is focusing on white components inside a black background, they become the figure and the six components pop out; on the other hand, when a participant is focusing on a black object, it becomes the ground. The default setting was such that the participants easily see figure component in white color (See Figure 2). The alternative perspective is a perspective that suggests figure component in black.

While only two members engaged in the task in Hayashi et al. (2006), in the present study a group of six problem solvers collaboratively worked on the problem solving task through computer terminals connected via a local network. The six members of the problem solvers consisted of one human participant and five chat partners of computer gents. In this study we call member with a different perspective 'maverick'. It is agent that plays the role of group member and focuses on a background color which is different from that the human participant does. Shown in Figure 3 is an illustration of the setting where all six members except one (or Maverick) see four white components against black background.

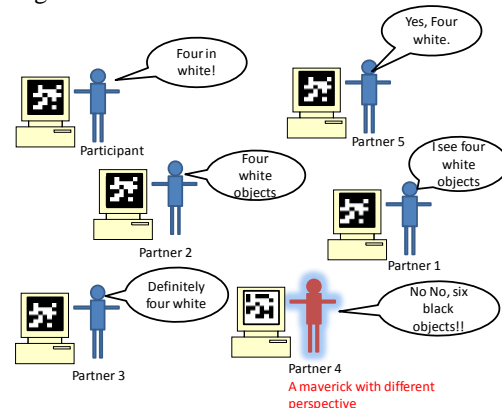

Figure 3. Example of experimental situation.

In the experiment, several types of objects were presented in sequence on a computer display (see Figure 4). For each

object, a square outer-box was shown on the display for one second, which was followed by stimulus picture presented inside the box frame. The number of white components and black components was controlled and the total number of the components presented to the participants was between six and twelve. Sequential pattern of the sums of black components and white components was repeatedly presented (i.e. 6, 8, 10 / 6, 8, 10) (see Table 1).

Figure. 4. Series of presented stimuli.

Table 1. Example of sequences of the presented objects.

White	4	6	4	7	2	4	6	5	3
Black (maverick)	2	2	6	5	4	4	4	7	3
Sum of Black and white	6	8	10	12	6	8	10	12	6

In this experiment, the task of a participant is to discover a rule concerning the regularity of the series of sums of the components. If participants are preoccupied to focus on only one of the two background colors, they cannot find a target rule. To make a breakthrough in the task, problem solvers have to take into consideration the number of components that pop out as figure and that of components hidden in the background. In order for a participant to find a rule, he/she needs to focus on the components hidden in the background. In a setting shown in Figure 3, for example, the maverick (partner 4) keeps suggesting an alternative perspective to call their attention to the presence of the black components.

The task required of the participants in the experiment was to type in the chat exchange when engaging in the task. The participants were assigned to always talk first during the chat exchange. Shown in Figure 5 is an illustration of interface record of a text-based exchange among a participant and five other agents that are discussing the problem. During the task, they were able to use buttons at the bottom of the screen to change objects, send messages, and to terminate the experiment. The participants were allowed to write only one sentence of less than 30 characters for each pair of components and were asked to finish the task within 30 minutes.

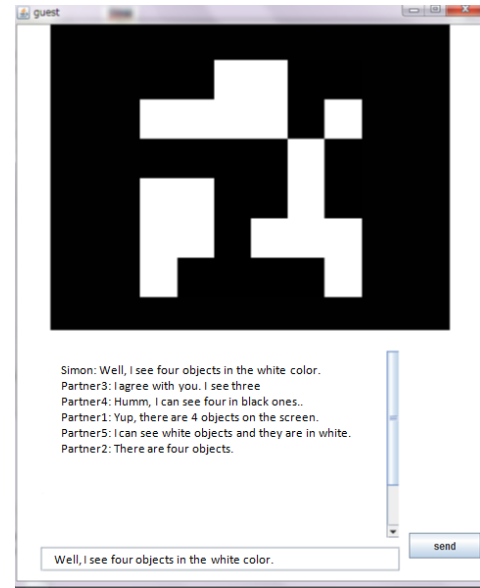

Figure 5. Example of the interface.

## Conversational agents and the experimental system

The system used in the experiment was designed by Java (see Figure 6) and consists of four program modules: (1) Server, (2) Client, (3) Agent, and (4) Problem Generator. Multi-threads, which process all the messages simultaneously, were used for the Server. When messages are sent to the Server, they were re-distributed to all Clients (Agents). The Problem Generator generates the objects that were presented in sequence (see Table 1). This module provided important information about the sequence of the stimuli and the objects presented by GUI, which was used by the agents to generate messages. A simple conversational computer agent used in this study is a typical rule-based system. Based on some pre-defined rules, it can respond meaningfully to sentences that were input by the participants (See Figure 7).

The Semantic Analyzer extracts keywords from input messages and detects keywords relevant to the task. Keywords collected from a previous study were used to build the Dictionary which contained important keywords for the task (Hayashi et al., 2009). Working Memory is created by the Generator, and it consists of two associated database: (a) presented objects (Picture Database), and (b) detected key words (the Semantic Analyzer). Various types of argument statements are stored in Rule Base in the form of 'if-then' format. Definitions from Working Memory are sent to Rule Base to search for matching statements. When there are several overlapping statements, a simple conflict-resolution strategy is utilized. When a matching process ends, selected sentences are sent to the Generator. Then, definitions in Working Memory are updated, and finally, output messages are displayed.

Figure 6. The structure of the system.

The conversational agent described above played the role of partner and produced a virtual experimental environment. The participants of the experiment were instructed that they are interacting with real people, though they were actually interacting with computer agents to solve the task.

Figure 7. Structure of the agent.

## Experimental Setting

To test the hypotheses, the following three conditions were set up: (1) 6:0 condition, (2) 5:1 condition, and (3) 3:3 condition. The third condition was included to test the second hypothesis. In the first 6:0 condition, all of the members had the same perspective; there were no members with different perspectives in this condition. In the second 5:1 condition, one of the collaborating agents had a different perspective. In the third 3:3 condition, half of the six members had a different perspective. In all conditions, a group of six members consisted of one human participant and five computer agents and a different (or an alternative) perspective based on black background color was provided by computer agent to a human participant (See Figure 8). The participants engaged in the task, without being told that they were interacting with computer agents.

101 undergraduate students participated in the experiment (38 males and 63 females; the average age was 20.3). The experiment took place in a computer room where maximum capacity was 60 people. All participants were randomly assigned to each condition and they were instructed that

they will start the task with someone inside the room. Those participants who did not follow the instructions to answer the final questions or who felt suspicious about their partners were excluded from data. Participants who did not begin the experiment by focusing on the objects by figure color were also excluded. After this screening, the total number of participants that provided to the data was 92 (31 participants each for the 6:0 and the 5:1 condition and 30 participants for the 3:3 condition.)

Figure 8. Experimental conditions.

## Dependant variables

After the task, each participant was asked to describe the target rule on an answer sheet. If their answers were in some ways related to the number of black or white components of the objects, they were judged as 'integrated' (e.g. The sums of the black and white components are 6,8,10 and the sequence is repeated in the same order. The difference of the number of the black and white components is between zero to two.) If their answers did not include such information, they were evaluated as 'not integrated'.

All of the answer sheets were also analyzed to evaluate their cognitive process of perspective change. If the conversation data included a description that referred to the background color, it was counted as a token of 'a change of perspective'. (e.g. "I was counting only the white objects, but maybe the black objects have something to do with the target rule...". If their data did not include such information, it was counted as a token of 'no perspective change'. The data was then statistically analyzed for (1) the number of integrated answer, and (2) the process of change in perspective.

## Results

### Problem Solving Performance

The results were analyzed using a 1 x 3 between-subjects factorial design. Figure 9 shows the results of the performance of problem solving. The vertical axis represents the ratio of the problem solving performance, and the horizontal axis represents the experimental condition. The numerals shown on the cylindrical bars indicate the number of participants in each condition.

A Chi square analysis was conducted to verify if the difference of the number of problem solvers who used perspectives of others was statistically significant. An overall analysis suggests that, a group which had a member with a different perspective integrated its perspective into their own perspective more frequently than a group which did not. There were a significant difference among the three conditions ( $\chi^2(2) = 7.189, p < .05$ ). Next, a multiple comparison was conducted on each two conditions using the Fisher's exact test. There was a significant difference between the 6:0 and the 5:1 condition ( $p < .05$ ). On the other hand, the differences between the 6:0 condition and the 3:3 condition were marginal ( $p < .10$ ). There was no significant difference between the conditions of 5:1 and 3:3 ( $p = .41$ ).

Figure 9. Results of the problem solving performance

### Perspective change process

Figure 10 shows the results of the performance of a change of perspective. The vertical axis represents the ratio of the change of perspective, and the horizontal axis represents the experimental condition. The numerals shown on the cylindrical bars indicate the number of participants in each condition.

A Chi square analysis was conducted to check the difference of the number of problem solvers who integrated their perspectives during the task. Results indicate that there were differences among the conditions ( $\chi^2(2) = 15.230, p < .01$ ). Next, a multiple comparison was conducted on each two conditions using the Fisher's exact test. There were differences between the 6:0 and 5:1 condition ( $p < .01$ ). On the other hand, the differences between 6:0 and 3:3 conditions were marginal ( $p < .10$ ). At last, differences were found between the conditions of 5:1 and 3:3 ( $p < .01$ ).

Like the problem solving performance, an over-all analysis suggests that a group which had members with different perspectives were taking into consideration the perspectives of others more frequently than a group which did not. More importantly, the results showed that the problem solvers were incorporating others' perspectives most when a different perspective was proposed by a single partner; the difference was greater than when different perspectives were proposed by more than one person.

Figure 10. Results of the problem solving process

### The effect of 'Marverick' and experimental condition

The statistical analyses above indicated that in both problem solving performance and perspective change process, a group which had member with a different perspective were incorporating their alternative perspective more frequently than a group which did not have such member. In other words, the over-all analysis revealed the results that support the first hypothesis.

Further analysis showed, however, that the participants were not incorporating an alternative perspective when it was proposed by three members; that is, different to the expectation, the effect of an alternative perspective by a single partner was greater than that by three partners (i.e. half of group members). In other words the results of the experiment did not support the second hypothesis; Marverick outperformed the impact of its alternative perspective than multiple members with an alternative perspectives. In other words, it suggests that people are less inclined to integrate a different perspective when it is suggested from several people. Implications of this finding will be presented below.

### Discussion

It has been pointed out that a different perspective in a group may be favored especially when people face a situation which is comprehensible only vaguely or partially. Though people tend to be influenced by a perspective that is dominant in a group, a breakthrough can take place when a member of a group presents a dissenting view. In psychology this type of social influence is called the "minority influence". In one of the classical studies on 'minority effects', Moscovici & Nemeth (1974) argued that a minority of one is more influential than a minority of more than one. They argued that if one person is consistent with the minority view, over time, it may capture more attention from the majority. In the 5:1 condition of the experiment, suggestions of a different perspective from a single member (i.e., Marverik) was not only consistent but persistent in that it gave suggestions more frequently and over longer time compared to those in the 3:3 condition. That may have aroused the participants to think that the suggestion of

alternative perspective from that person must be very helpful if he/she is so sure of it. One of the possible reasons why the facilitation effect from Marverik was higher in the experiment may have to do with the effect of attention and its consistency. Other studies have shown that the influence of a minority perspective is a desirable condition for increasing the diversity of views, prompting reconsideration, processing information and making a decision (Moscovici, Lage & Naffrechoux, 1969; Nemeth, Brown, & Rogers, 2001). While the situations investigated in these studies are somewhat different from the present study, the result of the experiment showed that minority overall can exert a similar desirable effect to the facilitation of the task of collaborative problem solving where a breakthrough is needed.

The experiment also suggested that a different perspective from a single member may be more easily incorporated to facilitate cooperative problem-solving task than that from multiple members. One of the factors that are involved in the rejection of the second hypothesis may be related to the notion called "groupthink". It is a psychological phenomenon that often occurs when the desire for harmony overrides critical evaluation of own perspective and serious appraisal of alternatives. In a more realistic setting, social influence may force people to adapt a perspective a majority of others take. People may ignore the view of a minority, favoring a certain perspective, whether that perspective is ideal or not. This may take place in the process of decision making in a group where its members want to minimize conflict and reach a consensus decision without critical evaluation. This is similar to a negative effect associated with a whistle blower mentioned above. It may be that this negative effect of groupthink was working for the participants in 3:3 condition.

Also, a different perspective with people with the same opposing perspective may have lead to confusion. This type of confusion is pointed out in the literature of organizational psychology (Pondy, 1967). To confirm why the point investigated by the second hypothesis was rejected, these and other factors may need to be taken into account in a further experiment.

## CONCLUSION

This study investigated the influence of different perspective during collaborative problem solving. The results showed that, while a different perspective is more likely to contribute to problem solving, it was more effective when it was presented by only one person than by several people. The discussion suggested that further study is needed to confirm the latter point.

## Acknowledgments

I want to thank my student advisee Shin Takii (Ritsumeikan University) for helping collect the experimental data. I am deeply gratefully to Hitoshi Ogawa (Ritsumeikan University) for giving me suggestions for the experiment system. I appreciate Hajime Shirouzu (Chukyo University) for mentoring me during the writing action. My deepest

application goes to Kazuhisa Miwa (Nagoya University) who always gives me insightful comments.

## Abstract

The paper seeks to tighten up the notion of joke structure in the context of the Ontological Semantic Theory of Humor for computational use. The method is testing the prior hypothesis that a minimalist version of a joke, consisting only of the setup and punch line, is the most effective one. A small ‘human computation’ pilot study casts serious doubt on this hypothesis.

**Keywords:** humor research; (minimalist) joke structure; setup; punch line; joke versions.

## 1. Introduction

The human ability to communicate is incomplete without humor. If a computational system is ever to approximate this human communicative ability and act as a competent partner in a conversation with a human, humor must be accounted for. Over the last decades, humor research has become an intense multidisciplinary effort with significant contributions from linguistics, psychology, sociology, neuro- and cognitive sciences (Raskin 1985, 2008; Ruch 1998, Oring 1992, Davies 1990, Attardo 1994, Morreall 1983). Along with theories and analyses of human-generated and perceived humor, since the early 1990s, there have been more explorations of computational humor as well, starting with attempts at humor generation through humor detection to semantically based systems (see Section 2.1 below).

Part of the difficulty in relating computational humor-generation and, to a lesser degree, humor-detection systems to human appreciation is the question how much information has to be present in the text of a joke to ensure a successful setup and the most effective punch line. This is precisely what has not been addressed yet on the computational front—how much information is enough and not too much to carry a joke without risking the opposite extremes of crypticality or verbosity.

Two related goals of this line of research are a) to create an NLP system capable of understanding the mechanism of a joke at a level sufficient for providing a punch line to a human-generated setup (even if unintentionally) and b), conversely, for the computer to react competently to a human-generated punch line that follows a setup, generated

by either participant. The first scenario enables the computer to generate humor in reaction to a human cue in human-computer interaction, the second scenario lets the computer identify humor in the same scenario and enables it to react competently to it.

Most existing theories available for humor detection or generation fall short of providing the adequate support for this task. These theories are either too fine-grained to be useful or too coarse to correctly classify any given text as a joke or a non-joke. But our ontological-semantic system provides a sufficiently rich and flexible basis because it operates at the level of human text-meaning processing. In the following, we will summarize the state of the art, introduce our approach, and then discuss a pilot study assessing human appreciation of jokes in variants of different length and types of manipulation.

## 2. Background

### 2.1. State of the Art

The usefulness of and motivations for computational humor, along with its feasibility, have been intensely discussed (see Ritchie 2004, Hempelmann 2008, Taylor 2008, Strapparava et al. 2011 and references in all of these sources). The most useful work on computational humor is based on a humor theory and seeks to gain further insights, to validate, and to improve the theory, while taking advantage of its assets. Work on humor theories has a long history, and, to this day, the true multifaceted nature of humor is still being debated (Raskin 1985, Morreall 1983, Oring 1992, Ruch 1998, Davies 1990, Attardo 1994): there is no universally accepted theory of humor that explains “what is funny, why it is funny, how it is funny, when it is funny, and to whom it is funny.” (Raskin 1985: 5).

The linguistic theories of humor (Raskin 1985, Attardo & Raskin 1991) have reached a level of formal representation that is adaptable for the computation of any humorous text (Raskin et al. 2009a,b). But the best-known and most-used linguistic theory of humor remains the early Script-based Semantic Theory of Humor (SSTH: Raskin 1985).

According to the SSTH, there are two conditions for a text to be humorous:

- A text has to be compatible, fully or in part, with two different scripts.
- The two scripts with which the text is compatible are opposite, and the text must overlap fully or partially with them.

The compatibility of the text with two scripts is the necessary condition for humor; the oppositeness of the scripts is the sufficient condition. The former was to be detected in the course of normal semantic analysis; the latter was not included at that point.

The central concept, that of a script, is defined as “an enriched, structured chunk of semantic information, associated with word meaning and evoked by specific words. The script is also a cognitive structure internalized by the native speaker, and it represents the native speaker’s knowledge of a small part of the world. [...] Formally or technically, every script is a graph with lexical nodes and semantic links between the nodes” (Raskin 1985: 81). Scripts were further developed, formally and computationally, in Ontological Semantics (Nirenburg and Raskin 2004, Raskin et al. 2003), and the current, third stage of the theory, the Ontological Semantic Theory of Humor (OSTH), has the functionality both to perform the computational semantic analysis that establishes the necessary compatibility of scripts and encompasses their sufficient oppositeness.

The scripts can be linguistic, general knowledge, restricted, or individual. Linguistic scripts are known to any “average,” “standard” native speaker (adult, reasonably educated, mainstream culture, etc). General knowledge scripts, such as crossing the street or going to a store, are known to a large number of people and are not affected by their use of language. Restricted knowledge scripts are known to a smaller number of people and are not affected by their use of language either. Individual scripts are “owned” by one person: an example of an individual script would be a child’s memory of her first swim.

The General Theory of Verbal Humor (GTVH: Attardo & Raskin 1991), is an extended, second-stage multidisciplinary theory of humor that is also built upon the notion of script overlap and script oppositeness. The theory, empirically verified in Ruch et al (1993), describes jokes in terms of six knowledge resources: *Script Opposition* (SO), informed largely by linguistics, deals with script overlap and oppositeness presented in Script-based Semantic Theory of Humor (SSTH); *Logical Mechanism* (LM), informed by logic and cognitive psychology, accounts for the way in which the two scripts in the joke are brought together in a faulty, but locally valid way; *Situation* (SI), informed by many disciplines, contains the “props” of the joke, the textual materials evoked by the scripts of the joke that are not necessarily funny; *Target* (TA), informed by sociology, represents any individual or group from whom humorous behavior is expected; *Narrative Strategy* (NS) is the rhetorical structure of the text; *Language* (LA) is the actual

lexical, syntactic, phonological, etc., choices at the linguistic level that instantiate all the other choices. According to the GTVH, each joke can be viewed as a 6-parameter vector (Ruch et al. 1993): Joke = {SO, LM, SI, TA, NS, LA}.

## 2.2. Ontological Semantic Theory of Humor

Since Raskin’s (1985) definition of scripts and the general conditions for a text to be humorous, the definition and interpretation of script overlap and oppositeness have been debated (Attardo et al. 2002, Hempelmann 2003, Taylor 2008). Basing the GTVH on Ontological Semantic Technology (OST) allows a crisper definition of the necessary and sufficient conditions for verbal humor (Raskin et al. 2009a,b).

At the core of OST (Raskin et al. 2010, Hempelmann et al. 2010, Taylor and Raskin 2011, Taylor et al. 2010) are repositories of world and linguistic knowledge, acquired semi-automatically (or, rather, in hybrid automatic and human computation—see Law and von Ann 2011) and used to disambiguate the different meanings of words and sentences and to represent them comprehensively. These repositories consist of the ontology, containing language-independent concepts and relationships between them; one lexicon per supported language, containing word senses anchored in the ontology which is used to represent their meaning; and the onomasticon, which contains names of people, countries, organizations, etc., and their descriptions, also anchoring them in ontological concepts and interlinking them with its other entries.

Figure 1: A simplified representation of joke (4)

The lexicon and ontology are used by the OST Processor, a software that produces Text Meaning Representations (TMRs) from the text that it reads. The format of TMRs conforms to the format and interpretation of the ontology. The processed TMRs are entered into the Information Repository, from which information is used for further

processing and reasoning. Recent implementation of components of the system have produced successful results.

OST progress has enabled enhanced meaning representation of all the components of the joke, shedding light even on such less linguistic ones as the Target and Narrative Strategy (see a much simplified graphic representation of Joke 4 below in Figure 1). OSTH is reconsidering the six GTVH knowledge resources with the additional emphasis on providing the ontological support to tighten and straighten their definitions and conditions of usage. However, one troubling, even if expected result, of the formalization in OSTH is the realization that the SO of GTVH and SSTH was defined inadequately. Because SO constitutes the decisive factor in determining whether a text is a joke, and thus dominates other knowledge resources, the current theories have to be modified and revised to an extent for future research, the rationale and pilot study for which we are presenting here, will help to determine.

### 3. Joke Variants

One of the recent discoveries, part of gaining new insights into the Narrative Strategy within OSTH, is the apparent need of some extra material right before the punch line (see Taylor 2010, 2011). More generally, by observing the coexistence of different versions of the same jokes, we realized that some extra parts of jokes, in the setup and punch line, may have specific functionalities, while others are pure ballast contributing nothing but verbosity. To the best of our knowledge, the contribution of seemingly inessential information in jokes has never been systematically studied.

Understanding the seeming importance of extra material is needed to detect the essential and necessary information for a joke to make sense and to be effective. Kuipers (2006: 204), for example, found that both in the United States and the Netherlands, longer jokes are considered generally funnier than shorter ones. Such information cannot be measured in the number of words but rather by the tightness/non-redundancy of the underlying conceptual structures. An initial approach along these lines, proposing “meaning density” as a factor in joke funniness was presented in Hempelmann (2011). What allows for testing this assumption is the fact that the same joke often exists in several attested versions. One attractively simple hypothesis may thus be that the essential information of all versions of the joke is the conceptual structure of the minimalist version of the joke. The rationale for computing the essential information is to understand the proliferation of multiple versions, of widely varying lengths and genres, of the same joke—in conversational practice, in print and on the Internet—and to test whether their “common core” can carry the joke on its own.

To illustrate this point, let us compare two versions of the following blind date joke:

(1) Danny sets up Andy to go on a blind date with Shirley, a friend of a friend of his. But Andy is a little worried about going out with someone he has never seen

before. “What do I do if she’s ugly?” says Andy, “I’ll be stuck with her all night.” “Don’t worry.” Danny says. “Just go up to her door and meet her first. If you like what you see, then everything goes as planned. If you don’t, just shout Aaaaauuggghhh! clutch your chest and fake a heart attack.” So that night, Andy knocks at Shirley’s door, and when she comes out he is awe-struck at how beautiful and sexy she is. Andy’s about to speak when the girl suddenly shouts, “Aaaaauuggghhh!”, clutches her chest and falls to the ground.

(2) Andy is going on a blind date but is worried that she may turn out to be ugly. A friend advises him to fake a heart attack if it turns out to be the case. When Andy arrives, the door is open by a sexy and beautiful woman, who suddenly clutches her chest and falls to the ground.

Both versions contain the same scripts, roughly corresponding to the anticipation of the blind date and the actual event. The second version is minimalistic in that it contains virtually nothing that can be removed from the text without rendering it incomprehensible and useless as a joke. The first version adds much additional detail. The second version is synthesized, and it is possible that it has lost too much, and some supporting detail would actually improve it. This optimality is of crucial significance in generating a joke by a computer. To put it differently, removing information that is redundant for a plain expository text may result in a significant loss for a joke, as demonstrated in (3).

(3) Andy is going on a blind date but is worried that she may turn out to be ugly. A friend advises him to fake a heart attack then. The date turns out to be sexy and beautiful, but she suddenly clutches her chest and falls to the ground.

It has been established in humor theory that the punch line has to be short, and preferably by far to conclude the joke (see, for instance, Attardo et al. 1994). What has not been adequately researched is the punch line parameters, including its boundaries and most effective delivery mode, especially how minimalistic it can and should be. It has been suggested (see, for instance, Giora 2002) that including a familiar element within an innovative stimulus leads to more pleasure for the subjects than a purely innovative stimulus. Our preliminary research seems to indicate that, while, generally, accompanying information can be removed from the setup, some seemingly disposable elements may have to be left in the punch line.

Thus, if we compare (3) above to (4) below, the former reads more like the serious report of a somewhat funny event than as a joke, while the latter is easier to perceive as a joke.

(4) Andy is going on a blind date but is worried that she may turn out to be ugly. A friend advises him to scream and fake a heart attack then. The date turns out to be sexy and beautiful, but she suddenly screams “aaaauuhhh,” clutches her chest and falls to the ground.

The difference between these two versions is presence of the clause *she suddenly screams ‘aaaauuhhh’* in (4). Its precise contribution to the text is something that we are interested in establishing in this pilot.

#### 4. Pilot Study

To test the hypotheses outlined in the previous section and explore general effects between joke variants to generate more hypotheses for more formal future inquiry, we created a small test corpus for a pilot study.

This corpus of fifty stimuli consists of 10 jokes found online in at least two variants differing in length, complemented by another three synthesized variants for each joke: one is the minimalist version, condensing the joke to a summary only mentioning the necessary and, presumably sufficient information for the joke to be operational; another is this minimalist version together with a dialogue element in the Narrative Structure of the joke, since we realized in creating the non-dialogue minimalist version that the joke seemed to us radically decreased in funniness; the third artificial variant was added to be just that, a control version based on the longer real variant of the joke, to see if artificial manipulation in itself affected perceived funniness. The rationale for the final version is based on the fact that jokes are folkloristic creations optimized by iterations of retelling and not owned by individual authors, a characteristic that does not hold for cut-and-paste online joke collections created to generate traffic. In sum, the five variants<sup>1</sup> for each of the ten jokes are:

- long non-manipulated version
- shorter manipulated version
- non-dialogue manipulated minimalist version
- dialogue manipulated minimalist version
- longer manipulated minimalist version with paraphrasing

In this pilot study, we recruited raters for the funniness of these variants using Amazon's Mechanical Turk, a method generally deemed valid (Buhrmester et al. 2011) and now proclaimed to be a form of 'human computation' (Law and von Ann 2011), with an incentive of \$0.10 for participation. The Mechanical Turk aims to filter bots and human responders who don't pay attention to the instructions in several ways. This includes the researcher's ability to block certain countries, including those where non-native English issues might affect the research issue, and to select only participants who have had a certain number of approved assignments in the past. In addition to these controls, in a second pilot study we included as the only difference from the first study reported here one additional stimulus that instead of a punch line had the direction to rate it at a given level of funniness. We then excluded all responses who didn't follow this direction under the assumption that the raters didn't read the instructions and clicked through the responses randomly. Interestingly, there was no significant difference in the results to the initial study.

In both versions of this pilot study, the participants, of whom we aimed for 200, were directed to a survey in

Qualtrics, in which they were presented with a random variant of each of the ten jokes, in random order of joke. Ideally, we would have gathered 40 ratings for each of the 50 variants, but some variation exists because raters who took under 2 minutes for their 10 stimuli or had the same rating for each stimulus were excluded, resulting in a sample of 176 participants for the version without the control stimulus presented here.

Figure 2: Mean funniness for each joke across all variants

An Analyses of Variance (ANOVA) for repeated measurements for the funniness of the ten different jokes across all variants revealed that the jokes were perceived to differ in funniness,  $F(8.38, 1558.03) = 11.38, p < .001$ . Joke 2 ("Matthew Chapter 11") was considered significantly less funny than the other jokes, while joke 10 (cheap parking in New York City) was deemed funnier than all others (see Figure 2). Low numbers did not allow for the exclusion of these two jokes from further analysis homing in on the variants.

Figure 3: Mean funniness of variant type across all jokes

More importantly for the line of inquiry that we are pursuing here, a second ANOVA for repeated measurements for the funniness of the five variants of jokes revealed significant differences,  $F(3.72, 338.48) = 7.43, p <$

<sup>1</sup> For lack of space we can't include all jokes here, but the minimalist versions are in the appendix, while the full text of all variants of all jokes can be found at: [http://web.ics.purdue.edu/~vraskin/joke\\_variants.pdf](http://web.ics.purdue.edu/~vraskin/joke_variants.pdf)

.001. Figure 3 shows that joke variant type 3, the manipulated minimalist version without dialogue, was rated as the least funny and significantly so against all other variant types. This effect is most interesting in contrast to the other minimalist manipulated variant type 4 that does include a dialogue in its Narrative Structure. The importance of this result, privileging dialogue over exposition, warrants further investigation in our continued research.

Table 1 shows the levels of significance for the effects summarized in Figure 3.

Table 1. *Within-subjects contrasts for the pairs of joke variant (v) types.*

	v 2	v 3	v 4	v 5
v 1	2.71	25.91***	4.18*	1.69
v 2		12.13**	0.41	0.20
v 3			7.30**	19.68***
v 4				1.06

Note. Cells contain F-statistics for the contrasts,  $F(1, 91)$ .

\*  $p < .05$ , \*\*  $p < .01$ , \*\*\*  $p < .001$ .

Clearly, the minimalist versions fared worst and the longer versions overall were deemed funnier, if not significantly so. But some amount of non-essential information clearly accounts for relevant degrees of funniness of jokes.

## Summary and Outlook

With respect to our initial hypotheses, our results confirm that condensing jokes so they only contain the SO-relevant information is not optimizing their funniness. Something is lost in the process and the difference between the dialogue and non-dialogue manipulated variants seems to point at the importance of that NS factor. A further speculation that should be explored based on these results is that the faultiness of the logical mechanism might no longer be sufficiently hinted at to make it retrievable, rendering the oppositeness of those variants too blunt. In terms of a classic linguistic distinction, these initial findings are pointing at the importance of performance-related factors in jokes, in contrast to purely competence-based relation of information. In other words, joke texts have an aesthetic dimension that has yet to be allocated more clearly to a part of the OSTH model in future follow-up studies with further careful manipulations of joke variants.

## Acknowledgments

The authors are grateful to Ursula Beermann, Department of Psychology, University of California at Berkeley, for her help with the pilot study. They would also like to thank the IRB of Purdue University for the prompt granting of the exemption.

## Abstract

In the present study we propose a context wherein the endorsement rate of the scalar inference from ‘some’ to ‘not all’ either increases or decreases. It is known that people tend to interpret the quantifier ‘some’ as ‘not all’, though logically some means ‘some and possibly all’. However, we argue that this tendency to derive the scalar inference is variable and depends on the attitude of the reader or listener. When the ‘not all’ interpretation implies a confirmation of one’s attitude, we expect a higher endorsement rate of the inference. On the other hand when the ‘some and possibly all’ interpretation contains pro-attitudinal information, we expect a decrease in endorsement rate. These predictions are derived from Kunda’s theory of motivated reasoning (1990) and are supported by the data. Theoretical implications and suggestions for further research along this line are discussed.

**Keywords:** Scalar inferences; Motivated reasoning; Attitudes; Relevance theory.

## Introduction

Understanding utterances requires knowledge about grammar and the semantics of words, but also about non-linguistic properties such as the speaker’s intentions and the context in which the utterance is expressed. The interpretation of utterances has been studied extensively and belongs to pragmatics (Sperber & Wilson, 1986). Within the field of pragmatics one can distinguish different topics such as deixis, presupposition, speech acts, implicatures (Levinson, 1983). However, in the present paper we will only focus on the latter. An implicature, a term introduced by Grice (1975), is what is suggested by an utterance though not explicitly stated nor logically deducible. Consider the following classic example:

- (1) They got married and had a baby.

Here, it is suggested that they first got married and then had children (i.e., the implicature), though logically the sequence of events could also be reversed. A lot of research has been devoted to a subclass of implicatures called scalar implicatures. When a weaker term (e.g., ‘some’) is used to imply the negation of a more informative, stronger term

(e.g., ‘all’), it is called a scalar implicature. For instance, when confronted with a sentence like (2), people tend to interpret ‘some countries’ as ‘not all countries’. Although logically, ‘some countries’ could mean ‘all countries’, people rarely take this possibility into account.

- (2) Some countries are poor.

The explanation for this tendency can be found in Grice’s cooperative principle (1975, 1989). According to this principle, people should make their contributions such as it is required, when they interact. For that purpose, he proposed four maxims, enabling people to communicate effectively. One of these maxims, the maxim of quantity, states that any contribution to a conversation should be as informative as possible. Returning to the example, if the speaker knows for a fact that all countries are poor, he would have used the stronger quantifier ‘all’. However, the speaker employed the weaker term ‘some’, which is taken to mean that the stronger term is not appropriate (either because the speaker knows that not all countries are poor or because he is unsure that all countries are poor).

Looking through the literature, one can find two contradicting opinions concerning the mechanism underlying the production of scalar inferences (Noveck & Reboul, 2008). The neo-gricean account (e.g., Levinson, 2000) assumes that the ‘not all’ interpretation (also called the pragmatic interpretation) is derived by default. A logical interpretation of ‘some’ may be possible, but only when the pragmatic interpretation is cancelled in a certain context. Chierchia (2004) has also proposed a default theory in which he argues that scalar inferences are derived by default except when the scalar term occurs in a downward entailing context. These contexts include negations, question forms and antecedents of conditionals (Noveck & Reboul, 2008). On the other hand, there are theorists who argue against the default character of scalar inferences. Instead, they defend a contextualist view, which comprehends that the narrowing from ‘some’ to ‘not all’ is entirely determined by the context. The best known of these theories is probably Relevance theory (Sperber & Wilson, 1986, 1995; Wilson &

Sperber 2003). This theory states that people will only derive a scalar inference when it yields sufficient positive cognitive effects. To interpret an utterance as (2), listeners and readers are thought to follow a path of least effort in computing cognitive effects and to stop when their expectation of relevance is satisfied.

Evidence from different experimental studies seems to favour Relevance theory. Studies involving response time measures showed that a logical interpretation of underinformative utterances like ‘some oaks are trees’ takes less time than a pragmatic interpretation (Bott & Noveck, 2004; Noveck & Posada 2003). Also when participants were instructed to respond quickly, they produced less scalar inferences (Bott & Noveck 2004). Moreover, De Neys and Schaeken (2007) found that people made more logical and fewer pragmatic interpretations under high cognitive load. Breheny, Katsos and Williams (2006) took another approach and manipulated the context wherein the implicature was embedded. They found longer reading times in an upper-bound context (i.e., a context that warrants the scalar inference) than in a lower-bound context (i.e., a context that makes the inference inappropriate). Recently, two studies examined the computation of scalar inferences using a visual world paradigm (Grodner, Klein, Carbary & Tanenhaus, 2010; Huang & Snedeker, 2009). Where Grodner et al. (2010) report that the scalar inference is computed immediately, Huang & Snedeker (2009) found a short delay in the computation of the scalar inference. Since the latter is in line with Relevance theory and other experimental studies (Bott & Noveck, 2004; Noveck & Posada, 2003), we can conclude that most of the experimental evidence favours Relevance theory.

As already mentioned, Relevance theory states that the scalar inference from ‘some’ to ‘not all’ is highly dependent on the context. Some theorists have tried to identify contexts in which the availability of the scalar inference varied (Bonneton, Feeney & Villejoubert, 2009; Breheny et al., 2006). Two of them, the lower-bound and upper-bound contexts, were already discussed above. Furthermore, Bonneton et al. (2009) established that the endorsement of the inference declines in face-threatening contexts. In this paper we propose a different context wherein the occurrence of the scalar inference depends on one’s attitudes. Such a context is more subjective (compared with more objective upper/lower-bound and face-threatening contexts) since scalar inferences here depend on feelings and motives of people.

In the literature, one can find many examples of how reasoning is affected by beliefs and attitudes. Performance on the Wason selection task for instance improved significantly when the task rule was contra-attitudinal because participants were motivated to look for disconfirmation, which leads to the correct solution to the task (Dawson, Gilovich & Regan, 2002). Kunda (1990) developed a theory that explained how reasoning might be influenced by attitudes. The theory of motivated reasoning, as it is called, postulates that when one is motivated to

arrive at a particular conclusion, one applies certain strategies that are considered most likely to yield the desired conclusion. Put differently, if confronted with contra-attitudinal information, one is motivated to reject this information (i.e., disconfirmation bias). On the other hand if the information is consistent with one’s attitude, one is inclined to believe in it (i.e., confirmation bias). With this in mind, it should be possible to design a context where the scalar inference is either appropriate or inappropriate. Consider the following example:

- (3) a. in countries where the death penalty is applied, crime has decreased.
- b. in some countries where the death penalty is applied, crime has decreased.
- c. not all countries applying death penalty experience decreasing crime.
- d. some and possibly all countries applying death penalty experience decreasing crime.

Depending on someone’s attitude towards the death penalty, the utterance (3a) is either pro-or contra-attitudinal. For people in favour of the death penalty (3a) is in line with their attitude whereas for people opposed to death penalty it is contrary to their beliefs. If the utterance were prefaced by the scalar “some” as in (3b), it can be interpreted either pragmatically (3c) or logically (3d). The logical interpretation, which is consistent with (3a), is pro-attitudinal for people in favour of death penalty but contra-attitudinal for people opposed to it. The reverse is true for the pragmatic interpretation. Therefore we predict, based on the theory of motivated reasoning, that people are inclined to interpret the scalar pragmatically when they are against the death penalty and logically when they are sympathetic to it. Note that these predictions apply only to the current example. If the word ‘decreased’ were to be replaced by ‘increased’, we would predict the opposite pattern. Furthermore, it is possible that one holds a neutral attitude towards the death penalty. This neutral condition serves as a baseline against which the effect of the pro-and contra-attitudinal context is evaluated. In general, given that the content of the utterance (i.e., 3a) is pro-attitudinal, we expect more logical interpretations while for contra-attitudinal utterances we expect more pragmatic interpretations compared with neutral utterances. In other words, we expect the endorsement rate of the scalar inference in the neutral condition to lie somewhere in between those of the pro-attitudinal and the contra-attitudinal condition.

## Methodology

### Participants

The study has been carried out in two different groups of participants. One group consisted of 73 12<sup>th</sup> grade students at the Groenendaalcollege in Merksem (34 men, 39 women, mean age 17,2), who participated voluntarily. The other participants were 197 first-year psychology students of the

University of Leuven (26 men, 171 women, mean age 18,5), who participated in return for course credit. In the analysis data from both groups are combined because results for each group were very similar.

## Materials and procedure

We used a self-constructed questionnaire to gauge participants' attitudes towards different issues. We asked them to indicate how they felt about e.g. the death penalty, more police on the streets, legalization of soft drugs,... on a scale from 1 to 5, 1 meaning *strong in favour* and 5 meaning *strong in disavour*. They also had to indicate on a similar scale how certain they felt about their answers, with 1 meaning *not sure at all* and 5 *very sure*. The item assessing one's attitude towards the death penalty was the crucial item of the questionnaire. The other items were merely fillers.

To measure whether or not the subjects derived the scalar inference, we took a similar approach as in Bonnefon et al. (2009). Half of the subjects received the following story:

*A research group of sociologists and criminologists did a large-scale study into the relationship between death penalty and crime. From this research has become clear that in some countries where the death penalty is applied, crime has decreased.*

*Do you think then that it is possible that in all countries where the death penalty is applied, crime has decreased?*

Subjects were then asked to circle the correct answer (yes or no). The other half got a slightly adapted story in which the word 'decreased' each time was replaced by 'increased'. Subjects received the questionnaire in small groups and were randomly assigned to one of these two versions. Since the experiment was conducted in Belgium, all materials were in Dutch.

## Results

Based on their responses to the attitude questionnaire, participants were divided into three groups: in favour of death penalty (4 or 5 on the scale), against the death penalty (1 or 2) and neutral towards death penalty (3). These groups were again divided according to attitude strength.

Table 1: Contingency table of content of the utterance against interpretation of the scalar (percentages are in parentheses).

Interpretation of the scalar	Content of the utterance			Total
	Pro-attitudinal	Neutral	Contra-attitudinal	
Logical	30 (34.5%)	7 (17.5%)	8 (8.2%)	45 (20%)
Pragmatic	57 (65.5%)	33 (82.5%)	90 (91.8%)	180 (80%)

Participants scoring 4 or 5 on this second scale were thought to be sure about their attitude whereas 3 or less indicates a rather uncertain opinion concerning death penalty. Participants were divided in these two categories because people with uncertain attitudes might attach less importance to the pro-or contra-attitudinal utterance. As a consequence, their interpretations of the scalar term might be less affected (or even uninfluenced) by the context. Therefore, participants who felt uncertain about their beliefs were excluded from the analysis<sup>1</sup>.

Crossing the type of story (i.e., crime has decreased versus crime has increased) with attitude towards death penalty yields six combinations which can be arranged in three groups or conditions: a pro-attitudinal condition (i.e., crime decreased and in favour of death penalty + crime increased and against death penalty), a contra-attitudinal condition (i.e., crime decreased and against death penalty + crime has increased and in favour of death penalty) and a neutral condition (i.e., crime decreased and neutral + crime increased and neutral). A chi-square test revealed a significant difference in interpretation of the scalar term between these three conditions ( $\chi^2(2, N=225) = 20.14, p < 0.001$ ). As predicted, subjects in the contra-attitudinal condition made more pragmatic interpretations than those who are neutral regarding the death penalty (Table 1). On the other hand, subjects in the pro-attitudinal condition made more logical interpretations compared with the neutral condition. Nevertheless, the tendency to derive the scalar inference seems to be so natural that still two-third of the subjects interpret 'some' as 'not all'. If we look at the data for pro and contra death penalty attitudes separately, we find similar results. For those opposed to the death penalty, the endorsement rate of the scalar inference is 66% in the pro-attitudinal condition and 93% in the contra-attitudinal condition ( $\chi^2(1, N=158) = 17.71, p < 0.001$ ). Subjects in favour of death penalty derived the scalar inference in 62% of the instances when they received the pro-attitudinal story and 86% when they received the contra-attitudinal story ( $\chi^2(1, N=27) = 2.05, p > 0.1$ ). Although this latter result did not reach significance (due to the small sample size), it is clearly in accordance with the other results.

## Discussion

The present research identifies a new context wherein the occurrence of the scalar inference either increases or

<sup>1</sup> Including all participants in the analysis had little effect on the results, probably due to the low number of uncertain attitudes (45 on a total 270). Still, we decided to preserve the distinction between certain and uncertain attitudes.

decreases. It is the first study to demonstrate the crucial role of attitudes in the interpretation of the scalar term 'some'. Depending on one's attitude, the scalar is more likely to be interpreted pragmatically, in contra-attitudinal utterances, or logically, in pro-attitudinal utterances, compared with a neutral condition.

These findings are in line with Kunda's theory of motivated reasoning (1990), in that people are motivated to reach a conclusion consistent with one's attitudes and beliefs. Furthermore, they complement previous studies demonstrating that context plays a crucial role in the interpretation of scalar terms.

The present study does not only differ in the *kind* of contextual manipulation, also the *position* of the scalar term relative to the context deviates from previous research. Formerly, the crucial context occurred either before or right after the scalar term. Here, the contextual manipulation (i.e., the word 'increased' or 'decreased') is situated nine words after the scalar 'some' and this has important theoretical implications<sup>2</sup>. Recent studies have shown that the computation of scalar inferences occurs relatively fast (Grodner et al., 2010; Huang & Snedeker, 2009). Also, Hartshorne and Snedeker (submitted) report that the interpretation of 'some' manifests itself nine words after encountering the scalar term. Given these findings, the contextual manipulation in the present study can initially have no effect on processing and interpretation of the scalar term. Before being confronted with the pro-or contra-attitudinal context, participants have already adopted either a logical or a pragmatic interpretation of the scalar. Thus from the perspective of Relevance theory, people will stop at the optimally relevant interpretation of 'some' without being influenced by the contextual manipulation. However, the ultimate interpretation of the scalar is affected by this context as evidenced by the varying number of logical interpretations in the different conditions. This suggests that readers (and listeners) do not necessarily stop at the first optimally relevant interpretation but rather keep on searching for a more relevant interpretation. In other words, people may temporarily hold a certain interpretation of 'some' but eventually move to a different one due to the context. Further research should be conducted in order to support this claim, especially because it is inconsistent with an assumption of Relevance theory (i.e., that the reader or listener stops at the first interpretation that satisfies his expectations of relevance).

A recent study of Bonnefon, De Neys and Feeney (2011) regarding face-threatening contexts, actually provides evidence for a "second push towards another equilibrium between effect and effort", as they call it. The authors found that logical interpretations took longer and were more difficult to reach in face-threatening contexts. A possible way to reconcile our findings and those of Bonnefon et al. (2011) with Relevance theory is to allow a reconsideration

of the interpretation of the scalar once the meaning of the sentence is fully grasped. This process would only be triggered in certain situations (i.e., pro-or contra-attitudinal context, face-threatening context) and requires processing time and effort. Thus, when people read the word 'increased' or 'decreased' they might revise their initial interpretation of the scalar term but this comes at a cost. Further research should help to determine whether the suggested modification of Relevance theory is valid.

In sum, this study adds to the existing literature in two ways. First, it provides evidence for the existence of a new context wherein the interpretation of the scalar term varies. Second, through the position of the contextual manipulation it challenges the assumption made by Relevance theory that people stop at the first optimally relevant interpretation of the scalar.

## Acknowledgments

## Abstract

Previous research has shown that repeated references are often reduced compared to initial references. The present study looks at the production of repeated references by signers of Sign Language of the Netherlands (NGT). Participants had to describe figures to an addressee, who had to pick the correct figure from a large group of figures. Several figures had to be described several times. The question was whether there would be reduction in the signed repeated references, as has been found previously for speech and gesture. We found systematic effects of repetition, in that repeated references are shorter, contain fewer signs, and shorter signs than initial references. Moreover, a perception experiment showed that signs produced during repeated references were also considered to be less precise than the signs produced during initial references.

**Keywords** sign language; repeated reference; reduction

## Introduction

Variability is ubiquitous in speech production, with words never pronounced the exact same way more than once. For example, someone might first pronounce the word 'of course' slowly and precisely, followed by an instance where it is pronounced quickly, less precise and more like 'fcourse'. This example of language variability shows that language can be reduced (in this case by shortening and merging words). While various studies have looked at reduction in speech, reduction in signs remains largely unexplored. The present study addresses this point.

## Reduction in spoken repeated references

In conversation, people often produce referring expressions to describe objects in the world around us. The production of repeated references occurs when people refer to the same object more than once in the conversation. Research has found that in speech, these repeated references are often reduced in at least two ways (Aylett & Turk, 2004; Bard, et al., 2000; Brennan & Clark, 1996; Clark & Wilkes-Gibbs, 1986; Fowler, 1988; Fowler & Housum, 1987; Galati & Brennan, 2010; Lam & Watson, 2010). Firstly, repeated references to the same target object usually contain fewer words than initial references (Clark & Wilkes-Gibbs, 1986; Galati & Brennan, 2010). Brennan and Clark (1996) claim that this is due to the fact that people establish so-called

conceptual pacts as more common ground is established over the course of the conversation (debated in e.g. Horton & Gerrig, 2005). Secondly, repeated references are often also reduced acoustically (Aylett & Turk, 2004; Bard, et al., 2000; Fowler, 1988; Fowler & Housum, 1987; Lam & Watson, 2010). Repeated references, when taken out of context and presented to a listener, have been found to be less recognisable for the addressee because their pronunciation is less clear in repeated references than in initial references (Bard, et al., 2000; Galati & Brennan, 2010). Lieberman (1963) found similar acoustic reduction for redundant words, which were shorter and perceived as less intelligible when taken out of context.

There are two dominant views on the reason why referring expressions may be reduced. On the one hand, reduction in referring expressions may be due to speaker oriented causes, such as production and planning processes (Arnold, 2008; Arnold, Kahn, & Pancani, 2012; Bard, et al., 2000; Bard & Aylett, 2005; Ferreira, 2008). On the other hand, reduction in referring expressions may be due to listener oriented causes, such as communicative strategies (e.g. Aylett & Turk, 2004; Fenk-Oczlon, 2001; Lieberman, 1963; Lindblom, 1990; Zipf, 1949). The use of communicative strategies, with speakers as efficient language users, has been shown by a range of studies (for an overview, see Jaeger & Tily, 2011), including Zipf's (1949) Principle of Least Effort, and Shannon's noisy channel model (1948). More recently, Lindblom (1990), in his H&H theory, claims that speakers adapt to the listener's needs, meaning that redundant speech is reduced as long as 'sufficient discriminability' remains. Jaeger (2010) proposed the hypothesis of Uniform Information Density (UID), which states that 'speakers prefer utterances that distribute information uniformly across the signal (information density)' (Jaeger, 2010:25). What this means is that the interaction between speaker and addressee is optimized by the speaker's lengthening or shortening of an utterance, such that the utterance becomes more uniform and optimal for both speaker and addressee.

It can be argued that the reduction in repeated references that previous studies have found is due to the abovementioned processes: when speakers produce repeated references, they fully reproduce those (auditory) aspects of the referring expression that contain important or new

information and are necessary for quick target identification. The less informative aspects of the referring expression may be reduced or omitted, leading to reduced references.

### **Reduction in visual repeated references: gesture and sign language**

Taking into account that communication does not only consist of 'spoken' aspects of speech, but can also contain or consist of visual aspects such as gestures (Kendon, 2004; McNeill, 1992) or signs (Stokoe, 2005), we may wonder whether a reduction process such as described above for spoken repeated references also occurs in the visual domain.

Relevant previous research on gesture has looked at the effect of common ground (Gerwing & Bavelas, 2004; Holler & Wilkin, 2009) and repeated references (de Ruiter, Bangerter, & Dings, 2012; Hoetjes, Koolen, Goudbeek, Krahmer, & Swerts, 2011) on gesture production, albeit with inconclusive results. For example, when we look at repeated references, on the one hand, de Ruiter et al. (2012), when testing their tradeoff hypothesis, found that repetition did not affect gesture rate. On the other hand, Hoetjes et al. (2011) found that both speech and gesture were reduced in repeated references.

There has been a range of research on phonological and phonetic aspects of sign language (Crasborn, 2001; Sandler, 1989; Sandler & Lillo-Martin, 2006; Schembri, et al., 2009; Tyrone & Mauk, 2010), starting with Stokoe (2005) in 1960 proposing that signs in sign languages consist of three main parameters (handshape, location and movement). However, hardly any studies have looked at sign language from the perspective of efficient language use. In this light, it is interesting to see how signs behave with regard to reduction in repeated references. We may wonder what the role of signs is compared to speech and to co-speech gesture. On the one hand, considering that signs, like words, usually convey lexical meaning, it might be the case that reduction in sign is similar to reduction in speech, for example with regard to the semantics that are expressed. On the other hand, signs, unlike words but like co-speech gestures, are a means of communication in the visual domain, and there may be aspects of reduction that are modality specific and thus alike between signs and co-speech gestures. Of course, it could also be the case that signs are not reduced in a way comparable to speech or to co-speech gestures, but that signs, if they are reduced, are reduced in a sign-specific manner.

The only experimental study on sign language we are aware of that can be related to the idea of efficiency of language users in the production of repeated references is the work by Tyrone and Mauk (2010) on phonetic reduction in American Sign Language. In their study, Tyrone and Mauk looked at the production of the sign WONDER in two phonetic contexts and at three signing rates. Their results show that sign lowering occurs with increasing signing rate and can, but not necessarily does, occur in specific phonetic contexts. Another study on variation in sign language, by Schembri and colleagues (2009), looked at naturalistic data

and also found that sign location can vary with signs produced at lower locations than their citation form. However, neither of these studies takes repetition into account as one of the factors influencing sign production.

In the present study we will look at signs of Sign Language of the Netherlands (NGT), to see whether reduction in repeated references, as previously found for speech and gesture, also occurs in sign language. Considering that NGT is a fully fledged sign language and presumably behaves in many respects as a spoken language, we hypothesize that, as in speech, reduction in repeated references will occur. The question is of course how reduction in signs can be measured. In the present study we have decided to measure reduction by combining methods that have been used previously in studies on speech and on gesture. We will look at sign characteristics that we consider comparable with some of the aspects of speech that have been studied previously when looking at reduction, namely number of words, utterance duration and word duration. We will also take precision into account, which has been done in previous studies on gesture. Therefore, in the present study on sign language we will look at the number of signs, utterance and sign duration and at sign precision. We conducted a production task to analyse the first three attributes. Following Hoetjes et al. (2011), we conducted a perception task to analyse the last attribute, sign precision.

### **Production experiment**

To study reduction in repeated references in Sign Language of the Netherlands (NGT), a data set was created consisting of recordings of participants taking part in a director-matcher task. In this task, the director had to describe an object in such a way that the matcher could identify the object from a range of similar looking figures. In the stimuli, there were several figures that had to be described more than once, leading to repeated references to the same item.

### **Participants**

The director-matcher task was done by a total of 14 signers of NGT. The group of participants consisted of 5 male and 9 female speakers, with an average age of 46 years old (range 26-60 years old). The average length of time that the participants had been signing NGT was 23.5 years (range 2-50 years). Participants would take part twice in the experiment; first they were randomly assigned the role of either director or matcher and they would switch roles after doing the experiment once.

### **Stimuli**

Two picture grids, each containing 16 pictures, were used by each director. Each picture grid showed either pictures of people, or pictures of furniture items. The two different domains (people and furniture) were used since previous studies on referring expressions had shown them to be efficient domains for making people produce referring expressions (Koolen, Gatt, Goudbeek, & Krahmer, 2011;

Van Deemter, Gatt, van der Sluis, & Power, in press; Van der Sluis & Krahmer, 2007).

Each picture grid was used for 15 trials, adding up to a total of 30 trials. For the first 15 trials, a people picture grid was used, for the last 15 trials a furniture picture grid was used. Since the participants would do the experiment twice, once in the role of director and once in the role of matcher, two sets of picture grids were used, with different pictures on each picture grid, making sure that the same picture never had to be described across roles. In each trial, there was one target object (marked by a red square around the object), surrounded by 15 distractor objects, which had to be described by the director. The crucial manipulation in the task was that several pictures had to be described repeatedly: in each of the picture grids there were two pictures that had to be described three times. Repeated references to the same object were never one straight after the other. This means that descriptions of other objects were given in between the initial and repeated descriptions of the critical objects. An example of a trial with object description can be seen below in figure 1.

“CHAIR, RED, NOT LEFT, SIDEWAYS TO THE RIGHT, LITTLE BIT BIGGER.”

Figure 1. Picture grid showing a trial, followed by gloss of example initial description of the target object.

## Procedure

The director and the matcher were seated at a table opposite each other. A camera was positioned behind the matcher filming the upper body and hands of the director. The director had a laptop screen to her side and the matcher had a picture card in front of her. The director and matcher could see each other directly, but could not see each other's screen or card. The director was presented with a trial on the computer screen and was asked to provide a description of the target object in such a way that the matcher could distinguish it from the 15 distractor objects. The matcher had a picture card filled with the same 16 objects in front of her, which was not visible to the director. The matcher's card showed the same objects as on the director's screen, but these objects were ordered differently for the director and the matcher. This means that the director could not use

the location of the target object on the grid as part of the description. This was explicitly communicated to the directors. Once the correct object was found, the director went on to the next trial. The entire task took the participants about 20 minutes. After conducting 15 trials from the people domain and 15 trials from the furniture domain, the director and matcher would switch roles to conduct the experiment again, using the other set of picture grids.

## Data analysis

For the purpose of the current analyses, the first and third (hence initial and repeated) descriptions of the four objects that had to be described three times were annotated and analysed. These four objects were never described in the first or last trial. The focus on the initial and repeated descriptions means that the current analyses are based on a data set which consists of eight descriptions (two initial and two repeated descriptions for each of the two picture grids) for each of the 14 participants, leading to a total of 112 object descriptions. We used the multimodal annotation programme ELAN (Wittenburg, Brugman, Russel, Klassmann, & Sloetjes, 2006) to annotate the signs. We looked at the duration of the complete descriptions, the number of lexical signs that were produced in the descriptions and the duration of the signs. A separate perception experiment was used to measure sign precision, which will be discussed below under Perception experiment.

The experiment consisted of a 2 x 2 x 2 design with factors Domain (levels: people, furniture), Repetition (levels: initial, repeated), and Picture (levels: one, two). We tested for significance using repeated measures ANOVAs by participants ( $F_1$ ) and by items ( $F_2$ ).

## Results

Firstly, it was found that speakers take significantly less time (in seconds) to describe repeated references ( $M = 14.46$ ,  $SD = 1.46$ ) compared to initial references ( $M = 24.24$ ,  $SD = 2.25$ ),  $F_1(1, 13) = 35.15$ ;  $p < .001$ ,  $F_2(1, 4) = 22.30$ ,  $p < .01$ . For the mean number of signs it was found that speakers produce significantly fewer signs in repeated references ( $M = 5.57$ ,  $SD = .32$ ) compared to initial references ( $M = 8.16$ ,  $SD = .56$ ),  $F_1(1, 13) = 42.5$ ;  $p < .001$ ,  $F_2(1, 4) = 16.59$ ,  $p < .05$ . Moreover, the average duration (in seconds) of signs is shorter in repeated references ( $M = 1.2$ ,  $SD = .054$ ) than in initial references ( $M = 1.47$ ,  $SD = .074$ ),  $F_1(1, 13) = 15.1$ ;  $p < .01$ ,  $F_2(1, 4) = 20.17$ ,  $p < .05$ . In sum: we find systematic effects of repetition, in that repeated references are shorter, contain fewer signs, and shorter signs than initial references. These effects were the same for both domains (furniture and people) and for all pictures; in particular, we found no significant interaction between the factors repetition and domain or repetition and picture. To illustrate, figures 2 and 3 below show a case of reduction in the description of a target object from the furniture domain. In the initial description, the participant takes longer and uses more signs and more precise signs (to

be discussed in the perception experiment below) than in the repeated description.

“SOFA, THREE SEATS, ASKEW, BIG, TO THE RIGHT, TO THE SIDE”

Figure 2. Still and gloss of initial description of a sofa, lasting 48 seconds. Sign depicted in still is SOFA, with a fairly large extension and well defined edges (see arrows).

“SOFA, GREEN, TURNED AROUND, THREE SEATS”

Figure 3. Still and gloss of repeated description of the same sofa as in figure 2, lasting 17 seconds. Sign depicted in still is SOFA, with smaller extension than in figure 2 and without well defined edges (see arrows).

### Conclusion production experiment

The results show that several aspects of NGT were reduced in repeated references. Repeated references produced by signers of NGT were shorter than initial references, and repeated references in NGT contained fewer and shorter signs than initial references. This means that, at least for the aspects taken into account here, repeated references in NGT behaved as previous studies found for repeated references in speech. Repeated references by signers of NGT, containing predictable information, were produced in a more efficient way than initial references.

### Perception experiment

Since it is difficult to define objective measures with which to measure sign precision, a perception experiment was set up in which participants had to judge, in a forced choice

task, which sign they considered to be the most precise, looking at pairs of video clips with signs produced in either initial or repeated references.

### Participants

Twenty-seven first year university students, who had no knowledge of NGT, took part as partial fulfillment of course credits. Non-NGT speaking participants were used on purpose, so that the participants would not know the lexical meaning of the signs but would only judge the signs on their perceived precision.

### Stimuli

The participants were presented with a PowerPoint presentation in which they saw 40 pairs of video clips. Each pair of video clips was presented on one slide. Both video clips showed the same sign, produced by the same signer of NGT, about the same object, as described in the director-matcher task, except in one video clip the sign was produced in an initial reference and in the other video clip the sign was produced in a repeated reference. The order in which the participants were presented with initial versus repeated signs in the video clip pairs was counterbalanced over pairs of video clips (so it was not the case that for each pair the first video clip they saw was always the sign produced in an initial reference).

### Procedure

The participants had to watch the pairs of video clips, one video clip at a time, and were allowed to watch a video clip more than once if they wanted to. The task was to choose for each pair of video clips which sign they considered to be the most precise (the sign in video clip A or B). The task was a self-paced forced choice task and even though the participants were allowed to watch the video clips more than once, they were encouraged to go with their first intuition. The only instruction they were given was to choose which sign they considered to be the “most precise”. No details were given to suggest what the participants should base this judgment on.

### Data analysis

For each pair of video clips, each sign that was considered to be the most precise received a point from each participant. Statistical analyses consisted of repeated measures ANOVAs over proportions, by participants ( $F_1$ ) and by items ( $F_2$ ).

### Results

In line with our earlier results, we find that signs produced during repeated references ( $M = .33$ ,  $SD = .04$ ) were considered to be less precise than the signs produced during initial references ( $M = .67$ ,  $SD = .04$ ),  $F_1(1, 26) = 121.29$ ,  $p < .001$ ,  $F_2(1, 78) = 41.21$ ,  $p < .001$ . The effect was the same for both domains (furniture and people).

## Conclusion perception experiment

The results show that signs produced in repeated references were considered to be less precise than signs produced in initial references. Therefore, it can be concluded that there was also reduction in repeated references when it comes to sign precision.

## Discussion and conclusion

Summarizing the results from the production and perception experiments, we found reduction in repeated references in sign language. We found that repeated references were shorter, contained fewer and shorter signs, and that signs produced in repeated references were considered to be less precise than signs in initial references.

The present results on sign language can be tied in with previous findings, both on speech and on gesture, that language users tend to be efficient by reducing predictable information (e.g. Jaeger, 2010). Relating the results to previous work on speech, we showed that repeated references were shorter and contained fewer signs than initial references, in line with work by Clark and Wilkes-Gibbs (1986) and Galati and Brennan (2010). The result that signs in repeated references were shorter can be related to previous work on speech by Aylett and Turk (2004) and by Lam and Watson (2010) where it was found that predictable speech (through redundancy or repetition) had a shorter duration than unpredictable speech. Our finding that signs in repeated references were considered to be less precise can be viewed to be an extension of the work by Bard et al. (2000), who found that repeated references had a less clear pronunciation than initial references.

When we compare the results from the present study with previous work on co-speech gestures, we can also see clear links. It has been found that gestures with common ground are less precise (Gerwing & Bavelas, 2004) and contain less semantic information (Holler & Wilkin, 2009) than gestures without common ground. This can be related to our findings that signs in repeated references were considered to be less precise and that repeated references in NGT contained fewer signs than initial references. Work on the effect of repeated references on gestures (Hoetjes, et al., 2011) found that repeated references may cause reduction in the number of gestures, as was found in the present study for the number of signs. Moreover, their finding that gestures in repeated references were considered to be less precise than gestures in initial references, can be directly mapped onto the present results for signs. Importantly, the reduction found in the current study can be tied in with work on language efficiency and cannot be explained through a general reduction of descriptions over time (with participants becoming more 'sloppy' in the course of the experiment). In short, the present study is the first study on sign language that shows that signers of NGT behave similarly when describing repeated references as to what previous studies have found for speech and gesture by speakers of spoken languages.

Due to the fact that hardly any previous work has been done on reduction in sign language, the method used in the current study was inspired by relevant previous work on speech and gesture. We looked at fairly rough and modality independent (i.e. applicable to speech, gesture and sign) measures such as duration of the description and number of signs and not at more sign-specific aspects such as exact sign location (as has been done by e.g. Tyrone & Mauk, 2010). Despite the fact that our measures were not based on sign characteristics per se, we were still able to find that reduction in sign language occurred. This shows that it is possible to use such modality independent methods to study reduction in repeated references.

Naturally, the current study leaves room for some discussion. In the perception experiment, we used participants with no knowledge of NGT to judge the precision of signs produced in the production experiment. This was done purposefully, so that the participants were not in any way influenced by the lexical meaning of the signs and could focus only on the precision judgment task. There are reasons to assume that the use of non-NGT signers is indeed a reasonable approach. Research has shown (Brentari, Gonzalez, Seidl, & Wilbur, 2011) that non-signers have a high degree of sensitivity to visual prosodic cues of a sign language. However, future work could include NGT signing participants in the perception experiment. Also, if using NGT signing participants in future work, another possibility would be to set up the task slightly differently by asking participants to judge a sign's intelligibility, as in Bard et al.'s (2000) work on speech, instead of judging its precision.

In sum, the analyses done presently are the first of its kind to show us not only that we can use analyses from related work on speech and gesture and adapt them to analyse signs in repeated references, but also that signers of NGT reduced their repeated references. In fact, the ways in which these repeated references were reduced in NGT are quite similar to what has been found previously for speech and gesture. It is well known that speakers of non-signed languages are communicatively efficient by reducing repeated information, both in speech and in co-speech gestures. This study has shown, for the first time, that signers can design their utterances to be efficient in the same ways.

## Acknowledgments

We would like to thank Axelle Schmit and Manon Yassa for help in collecting and annotating the data, Onno Crasborn and Karin van Nispen for helpful discussions and comments and Martijn Goudbeek for help with the statistics. We received financial support from The Netherlands Organization for Scientific Research, via a Vici grant (NWO grant 27770007), which is gratefully acknowledged.

## Abstract

Co-speech gestures are an integral part of human face-to-face communication, but little is known about how pragmatic factors influence our comprehension of those gestures. The present study investigates how different types of recipients process iconic gestures in a triadic communicative situation. Participants (N = 32) took on the role of one of two recipients in a triad and were presented with 160 video clips of an actor speaking, or speaking and gesturing. Crucially, the actor's eye gaze was manipulated in that she alternated her gaze between the two recipients. Participants thus perceived some messages in the role of addressed recipient and some in the role of unaddressed recipient. In these roles, participants were asked to make judgements concerning the speaker's messages. Their reaction times showed that unaddressed recipients did comprehend speaker's gestures differently to addressees. The findings are discussed with respect to automatic and controlled processes involved in gesture comprehension.

**Keywords:** co-speech iconic gesture; eye gaze; recipient status; communicative intent; multi-party communication.

## Introduction

When we speak, we frequently move our bodies to supplement what we say with co-speech gestures. A large proportion of these gestures are iconic in nature. Importantly, iconic gestures bear a close link with the speech that they accompany on semantic and temporal levels and have therefore been argued to constitute an integral part of human language (McNeill, 1992; Kendon, 2004) and thus of speaker's utterances (i.e., 'composite utterances', Kendon, 2004). While iconic gestures have been shown to fulfill a variety of cognitive functions which appear to benefit the speaker him or herself (e.g., Chawla & Krauss, 1994; Hostetter, Alibali & Kita, 2007), there is a growing body of evidence that their production is also linked to the speaker's communicative intent (Gerwing & Bavelas, 2004; Holler & Stevens, 2007; Kelly, Byrne & Holler, 2011; Özyürek, 2002).

The comprehension of iconic gestures, especially with respect to the attribution of communicative intentions, has been considerably less well researched. What we do know is that iconic gestures successfully communicate semantic information and that recipients integrate this information

with that contained in the accompanying speech (e.g., Holle & Gunter, 2007; Holler, Shovelton & Beattie, 2009; Kelly, Barr, Church & Lynch, 1999; Kelly, Kravitz & Hopkins, 2004; Willems, Özyürek & Hagoort, 2007). However, one limitation of studies on the comprehension of gestures is that many of them have presented stimuli in isolation, that is, video clips showing iconic gestures (and sometimes a torso) but, crucially, no head or facial information, and those studies that have included the face have tended to focus on the lips. In face-to-face communication, however, gestures are not only accompanied by speech and mouth movements, but also by a multitude of additional nonverbal social cues. Instead of focusing our attention solely on speech and gesture when listening to someone speaking we are required to divide our cognitive resources in such a way that allows us to take in and combine all of those cues. How we process and comprehend iconic gestures in more situated contexts that are much closer to real life situations therefore remains a wide-open issue.

Of particular interest in this respect is the influence of eye gaze, one of the most powerful nonverbal social cues (Pelphrey & Perlman, 2009; Senju & Johnson, 2009). Eye gaze is not only an omnipresent contextual cue when observing co-speech gestures, it is also inherently linked to the perception of communicative intent (Kampe, Frith & Frith, 2003; Schilbach et al., 2006) and the regulation of social interaction (Argyle & Cook, 1976; Goodwin 1981; Kendon, 1967). This begs the question of how the co-occurrence of gaze and gesture influences recipients' comprehension. The present study addresses this very question.

To do so, it builds on a couple of recent studies that have begun to focus on the issue of perceived communicative intent in conjunction with gesture comprehension. Kelly et al. (2007, 2010) showed that participants integrated co-occurring information from speech and gesture less strongly when the two modalities were perceived as not intentionally coupled (e.g., male hands gesturing accompanied by a female voice speaking) than when they were perceived as intended to form a composite utterance (e.g., male hands gesturing accompanied by a male voice speaking). This is the first empirical evidence that the perceived intentional

stance of a communicator influences recipients' processing of iconic gesture and speech.

However, as many previous studies in this field, these two studies did not present gestures in their natural context but, instead, in isolation of any facial cues (including eye gaze) with the aim to control for the influence of lip movements. In addition, and in line with the predominant gesture comprehension paradigm at the time, both of the studies used mismatching speech-gesture stimuli, that is, stimuli in which the information provided by speech conflicted with that depicted by the accompanying iconic gestures. Whilst this was an ideal test bed for first enquiries into the semantic integration of speech and gesture, it compromises the generalisability of such findings to more natural speech-gesture utterances, something the present study aims to overcome.

Another recent study that has addressed the topic of communicative intent and gesture comprehension was conducted by Straube et al. (2010). In their study, participants watched video clips of a speaker who looked directly at them or who was oriented away from the camera. In contrast to previous studies on co-speech gesture comprehension, Straube et al.'s paradigm did include the speaker's head and eye gaze, and, furthermore, they avoided the use of mismatching gestures. However, the authors manipulated multiple nonverbal social cues simultaneously (body/torso orientation, gesture orientation, as well as gaze direction), preventing us to draw conclusions about the effect of gaze direction specifically on participants' comprehension. In addition, the information depicted by the gestures used as stimuli was redundant with that in speech (e.g., the speaker referred to a 'round bowl' in speech accompanied by a gesture depicting a round, bowl-like shape). It is therefore not possible to identify whether the differences in participants' comprehension (measured in the form of their neural response and memory performance for the stimuli) between the two conditions (frontal/averted) was due to differences in their perception of speech, gesture, or a combination of the two.

The studies by Kelly et al. (2007, 2010) and Straube et al. (2011) are laudable first attempts tapping the issue of communicative intent and gesture comprehension and useful stepping stones for further investigations on this topic. The present study aims to build on this work by investigating the effect of perceived communicative intent, as signaled through the speaker's eye gaze direction, on the comprehension of iconic gestures. Importantly, this study will be presenting gestures in a more natural context (including the head), manipulating social eye gaze as the only social cue of interest, and it will be based on gestures that match the speech but which are complementary in nature. This, in conjunction with the particular experimental paradigm employed in this study, will allow us to tap into the processing of gesture directly, and to zoom into recipients' processing of the verbal and the gestural components of the speaker's messages separately. We will do so by creating a set-up simulating a triadic

communicative situation involving one speaker and two recipients, combined with a manipulation of the speaker's eye gaze direction which will indicate to participants when they are an addressed and when they are an unaddressed recipient. Thus, it is the first experimental study looking specifically on the effect of social eye gaze on speech and iconic co-speech gestures.

## Method

### Participants

Thirty-two female, right-handed German native speakers participated in the experiment (mean age = 21.6yrs) and were compensated with 8€ payment.

### Design

The study employed an experimental paradigm simulating multi-party communication involving one speaker-gesturer and two recipients, only one of which was a 'real' participant (the other one was fictive). Participants were made to believe that the other participant taking on the role of the second recipient was located in a different room.

A confederate acted as the speaker-gesturer and produced scripted utterances to a video camera (we used pre-recorded instead of live stimuli to ensure that all participants were presented with identical stimuli). These pre-recorded video clips were presented to participants while making them believe that they were engaging in a live communication with the speaker, who they thought was located in yet a different room to themselves but connected to them via a live camera link. (The second recipient was, allegedly, also connected to the person acting as speaker via a live-camera link, in the same way as they were.)

To prevent participants from realising that the speaker was pre-recorded, they were told that the camera link was a one-way connection in that the two recipients were able to hear and see the speaker but that the speaker was not able to hear or see them (and the two recipients were, of course, not able to see or hear each other). They were also told that the speaker had been asked to stand in front of two different cameras, that she knew of the two recipients' presence, and that she had been told that each camera was hooked up to one of the recipients' computer monitors, allowing them to hear and see what she was communicating. In order to create a more plausible situation and convince subjects that the speaker did not memorise the entire set of scripted sentences by heart, the video clips showed the speaker looking down before each sentence was spoken; participants were told that a laptop had been positioned on a table in front of the speaker displaying a black and white drawing accompanied by a couple of words before each trial, and that the speaker had been instructed to communicate the contents of the information displayed on the screen spontaneously and in a way that felt natural to them (no explicit mention of gesture was made). They (the actual participants) were then informed that the speaker would sometimes address them by looking into the camera linked

to their own on monitor, and sometimes the other, second recipient, by looking into the respective other camera. This created two different views for the actual participant, one in which they were directly gazed at, and one in which they observed the speaker's gaze being averted (see Fig 1). Gaze direction, as implemented through this manipulation, constituted our main IV (within-participants). In addition, as a second IV (modality), we manipulated the occurrence of gesture in association with the sentences spoken by the speaker in the video clips (within-participants).

## Stimuli

The experiment set-up described in the preceding section required the creation of four types of video stimuli: a) Direct gaze (speech only), b) Averted gaze (speech only), c) Direct gaze (speech + gesture), d) Averted gaze (speech + gesture) (Fig. 1). In each video vignette, the actor spoke a short sentence (canonical SVO structure), e.g. 'she goes through the list' ('*sie geht durch die Liste*'). Crucially, the verb included in the sentence was always manner *unspecific*, i.e., 'to go through' (*durchgehen*). The iconic gestures accompanying these verbs always specified the manner of action, e.g., to tick items on the list (*abhaken*). This manipulation allowed us to measure participants' comprehension of the gestures independently of speech, without using mismatching gestures (see Introduction). Participants watched the videos on a computer screen in a soundproof experimental test booth; the audio signal was presented via closed-back headphones. Materials were presented with Presentation® software (www.neurobs.com).

Figure 1: Examples of the four types of video stimuli used, A = Direct gaze (S only), B = Averted gaze (S only), C = Direct gaze (S + G), D = Averted gaze (S + G).

## Procedure

First, participants completed six practice trials (showing a different actor). Before the start of the experiment proper, the experimenter made a fake phone call to check whether 'the other participants' were ready to start.

Participants then watched 160 videos (40 stimuli per condition). Each video clip was followed by a written word (presented in capital letters, centre of screen) that matched either the verb contained in the preceding spoken sentence (*speech-related targets* [20 items per condition]; designed to tap into the processing of the verbal component of the

speaker's message) or the content of the gesture performed by the speaker in the video (*gesture-related targets* [20 items per condition]; designed to tap into the processing of the gestural component of the speaker's message).

## Task

Participants were asked to judge "whether the word displayed on the screen had been mentioned by the speaker in the preceding video", thus requiring 'yes' answers for all speech-related targets, and 'no' answers for all gesture-related targets. Reaction times (RTs) to participants' yes/no answers (delivered via a button box; yes = dominant hand) as well as errors<sup>1</sup> were recorded.

## Results

RTs for gesture and speech-related targets were entered into two separate 2 (gaze: direct vs. averted) x 2 (modality: speech only vs. speech+gesture) repeated measures ANOVA, excluding errors (constituting 2% of the total number of trials) and outliers (2 SD).

### Speech-related targets

Our first comparison concerned participants' responses to the speech-related targets (e.g., 'to go through' (*durchgehen*)) designed to tap primarily into the processing of the verbal component of the speaker's composite utterances. This analysis revealed a significant main effect of modality ( $p = .0001$ ), with slower response times in the speech + gesture conditions than in the speech only conditions. The main effect of gaze was not significant ( $p = .090$ ), and neither was the interaction between gaze and modality ( $p = .870$ ).

Figure 2: Addressed and unaddressed recipients' (AR/UR) RTs (ms) in the speech-only and speech + gesture conditions for speech-related targets (error bars = SE).

### Gesture-related targets

Our main comparison focused on participants' responses to the gesture-related targets (e.g., 'to tick' (*abhaken*)) intended to tap primarily into the processing of the gestural

<sup>1</sup> Due to restrictions on space, we only report our RT results here. Note, however, that the error rate analysis revealed very few significant differences, and those that did emerge did not relate to the relevant differences in RTs in a meaningful way.

component of the speaker's composite utterances. This analysis revealed no main effect of modality ( $p = .216$ ) and no main effect of gaze ( $p = .087$ ). However, the interaction between gaze and modality was significant ( $p = .045$ ). Independently from the omnibus interaction effect, we carried out two a priori contrasts (UR S+G vs. AR S+G; UR S-only vs. AR S-only). These showed that the interaction is driven by unaddressed recipients taking significantly longer to respond in the S+G condition than addressed recipients in the S+G condition ( $p = .026$ ). The comparison of unaddressed and addressed recipients' RTs in the speech-only conditions was not significant.

Figure 3: Addressed and unaddressed recipients' (AR/UR) RTs (ms) in the speech-only and speech + gesture conditions for gesture-related targets (error bars = *SE*).

## Discussion

The present study has investigated co-speech gesture comprehension in the presence of eye gaze, a powerful social cue integral to human face-to-face communication. Our findings reveal that recipients' gesture comprehension is indeed influenced by the speaker's eye gaze direction. More specifically, we have shown that, when a speaker's eye gaze is used to signal communicative intent in the sense of address, recipients who are currently unaddressed (but ratified participants in a communication, Goffmann, 1981) do process speech-accompanying iconic gestures differently to addressed recipients. This finding advances our understanding of human communication by pointing to an important way in which pragmatic processes shape and influence the comprehension of co-speech gestures, which, to date, has been addressed by only a very small number of studies (Kelly et al., 1999, 2007, 2010; Straube et al., 2011).

There are at least two competing interpretations of our effects of eye gaze direction on gesture comprehension. One is what we have termed the 'Fuzzy Representation Hypothesis'. According to this hypothesis, due to unaddressed recipients perceiving the speaker's gestures as not intended for them (but for the other, gazed at recipient instead), they interpret the gesture to a lesser degree. As a consequence, they take longer to respond to the gesture-related targets because they have constructed merely a partial, or fuzzy, mental representation of the gestural meaning. They are aware that something relating to the meaning of the word displayed on the screen may have been presented to them, but they have a hard time making a quick

decision on the modality in which this information was presented (since the gestural component of their mental representation is 'incomplete' or 'fuzzy'). Further, we would argue that the underlying mechanism leading to this fuzzy representation would not simply be one of reduced attention. The reason for this is that, first, addressed and unaddressed recipients do not differ in the number of errors they made, and, second, the modality effect we found for the speech-related targets is as strong for unaddressed as for addressed recipients. Thus, our data suggest that unaddressed recipients do process the gestural information but less strongly so, and that the reason for this is a modulation of perceived communicative intent rather than a pure decrease in attention.

An alternative possibility is what we have called the 'Competing Modalities Hypothesis'. The rationale underlying this account is that, while addressed recipients (in both dyadic and multi-party interactions) are expected to engage in mutual gaze with a speaker (Argyle & Dean, 1976; Kendon, 1967), unaddressed recipients are free to disengage from the process of gazing at the speaker. This means that the default situation requires recipients who are directly addressed through a speaker's gaze to split their attention between information coming from multiple modalities including speech, gesture, and gaze (and additional facial cues). Unaddressed recipients, on the other hand, have fewer visual social cues to process since the speaker's gaze is averted from them. They may therefore zoom in on gesture, instead of processing gesture and gaze simultaneously, and may thus have more cognitive resources available to focus on the processing of gesture. As a consequence, in the current paradigm, unaddressed recipients are taking longer than addressed recipients to respond to the gesture-related targets (requiring a 'no' answer) because the gestural component of the speaker's utterance constitutes a more prominent component of their mental representation of the event described (since they focused on gesture more). To declare something as not having been mentioned by the speaker despite the stronger memory trace of the gesture being at the forefront of their mind appears to be a difficult task.

The present study was a fruitful undertaking as it has shown that recipient status can influence gesture processing, but also because it allowed us to formulate two possible accounts of a potential process model explaining those effects. Currently, we are unable to unequivocally declare one of them as the more appropriate one, but further studies are currently underway tackling this issue (this on-going research will also add further insights into participants' visual fixations in the two recipient roles, and it tests recipients' gesture comprehension avoiding the suppression of gestural information/no responses). That said, we believe that the Competing Modalities Hypothesis provides the more intuitive account, and some additional data we have collected speak to this preliminary conclusion, too: as a follow-up analysis, we obtained ratings for all of our stimuli from an independent set of participants which gave us an

insight into the degree of ambiguity/clarity of the individual gesture stimuli in the absence of speech. If the Fuzzy Representation Hypothesis should hold, gestures that are more ambiguous in the absence of speech (i.e., less pantomimic) should cause unaddressed recipients particular problems of interpretation (since they require more interpretation effort and more integration work). Unaddressed recipients should therefore have taken especially long to respond to those iconic gestures. However, when we correlated unaddressed recipients' RTs with the ambiguity ratings of the individual gestures, no relationship of this sort was found. One could argue, of course, that more pantomimic gestures should slow unaddressed recipients down also if we assume that the Competing Modalities Hypothesis holds, since they might 'stick' particularly well in the participant's mind; that is, the gestural components of utterances accompanied by more pantomimic gestures might become particularly prominent parts of unaddressed recipients' mental representations. However, this argument only holds if we assume that unaddressed recipients also integrate the verbal and the gestural information less than addressed recipients. According to the Fuzzy Representation Hypothesis, this would be the case, since processing the gestural information less well will also affect the integration of this information with speech. According to the Competing Modalities Hypothesis, however, unaddressed recipients may integrate speech and gesture to the same extent as addressed recipients, with the addition that they process the gestural information more strongly than them. Therefore, our favoured interpretation is the Competing Modalities Hypothesis, but further research is needed before we can draw firm conclusions.

### **Automatic and controlled processes in gesture comprehension**

With regard to the difference in response patterns for the speech-related and gesture-related targets, our results also relate to the distinction between automatic and controlled processes in co-speech gesture comprehension (Kelly et al., 2010). Bear in mind that these two sets of targets were designed to tap the processing of the speaker's information in different ways. What is striking is that, in the case of speech-related targets - a comparatively easy task - we observed a clear modality effect, as has been demonstrated by previous comprehension studies. The semantic integration of gesture and speech has been argued to be automatic in the sense of a low-level, fast and obligatory process (Kelly et al., 2010; see also Kelly, Özyürek & Maris, 2010). This explanation would account for the intrusion of the gestural information (longer RTs in the speech + gesture conditions) despite participants here having been asked to judge the content of speech only. At the same time, the results show a lack of an effect of our gaze manipulation, indicating that this task (saying 'yes' in response to a visually presented word that was presented auditorily immediately prior to this) might have been so

easily and quickly accomplished that higher-order processes involved in the processing of pragmatic information, and judgements of speaker-intentions in particular, may not have come into play.

Responses to the gesture-related targets tell a different story, however. Here, participants were slower in general, indicating that this task might have been perceived as more difficult (i.e., saying 'no' to indicate that a certain meaning had *not* been mentioned by the speaker, despite the meaning of the word displayed on screen being related to the meaning in the speaker's gesture). This seems plausible since participants here had to consult their mental representation more carefully by actively teasing apart what they heard and what they saw to arrive at a decision. In order to answer accurately, they were essentially required to suppress the gestural information they had received. This contrasts with the speech-target situation where intrusion of the gestural information may have slowed participants down since there was more information to process, but the gestural information did not interfere as such; after all, 'ticking' items on a list is part of the event of 'going through' a list. To answer 'yes', which participants were required to do for speech-related targets, is still correct, even if the gestural information is taken into account. Answering 'no' to the gesture-related targets involved a very different process, as it required the temporary suppression of the gestural information. Consequently, slower and more difficult information processing may have led to the involvement of more controlled, higher-order cognitive operations, which do take into consideration the intentional stance of a speaker.

### **Effects of eye gaze direction on speech processing**

Our results reveal that speech comprehension was not different for addressed and unaddressed recipients<sup>2</sup>. One possibility therefore is that gesture comprehension processes are more sensitive to perceived communicative intent as signalled through a speaker's gaze than the processing of speech is. However, we have to remain cautious with drawing such a conclusion from the present data. This is because the current paradigm required participants to judge speech (i.e., whether a certain word had been *mentioned* in the preceding clip). As a consequence, participants will have devoted much attention to the processing of speech, irrespective of their recipient status, since they were always required to respond. In other words, a paradigm that does not ask participants to explicitly devote attention to the verbal modality might reveal a modulation of eye gaze direction for the processing of speech only utterances also. In fact, based upon the Competing Modalities Hypothesis,

<sup>2</sup> The lack of an effect of recipient status on the processing of speech stands, at first sight, in slight contrast to a study by Schober & Clark (1989) who found overhearers to be slower and less accurate in their understanding of verbal references than addressees. However, in their study, overhearers were not official recipients of the communication, which distinguishes them from unaddressed recipients (Goffman, 1981).

one might expect to see such a modulation, since unaddressed recipients have more cognitive resources available that they are able to devote to the processing of speech. The present study was designed to mainly measure the processing of gesture, and future research is needed to provide more conclusive answers to the question of how speakers' eye gaze direction influences the comprehension of speech.

## Conclusion

In sum, our study suggests that recipients keep an eye on where speakers are looking, and this subtle piece of information has a significant impact on the extent to which co-speech gestures are processed.

## Acknowledgments

We thank four anonymous reviewers for their helpful feedback on an earlier version of this paper. We also thank the European Commission for funding this research (Marie Curie Fellowship, EU Project number: 255569), Manuela Schuetze and Nick Wood for extensive help with creating the experimental materials, Ronald Fischer and Idil Kokal for their help with programming, the participants who took part in our study, as well as the NBL and GSL lab groups, Ivan Toni, Natalie Sebanz and Guenther Knoblich, for valuable feedback in discussions of the design of our study.

# Learning from speaker word choice by assuming adjectives are informative

## Abstract

Pragmatic abilities are not only a component of efficient communication; they can also be an important learning mechanism for young children. We discuss four experiments and a corpus analysis to investigate whether children and adults can infer information about a speaker's knowledge based on the choice of an adjective. In Experiments 1 – 3, we found that adults are sensitive to adjective use as an indicator of intended contrast dimension (e.g. that people say “red” if an object could have been blue, but “tall” if it could have been short). In Experiment 4, we found developmental differences between older and younger 4-year-olds: older children were above chance at selecting the referential dimension of interest, while younger children exhibited some contrast inference but a strong color bias. This suggests that by preschool, children are beginning to make inferences from a speaker's word choices, but that there are differences between adjective types. We conducted an exploratory corpus analysis to investigate possible causes for this developmental difference.

Keywords: Pragmatics; adjectives; language development.

## Introduction

A key feature of human language is its ability to convey information efficiently in context. For adults, the ability to make pragmatic inferences—extrapolations about meaning in context—can dramatically facilitate the exchange of information between conversational partners. For example, from “I can't find my left shoe,” we can make the inference that the speaker probably knows where her right shoe is, or else she would have mentioned that both of her shoes were lost. For children, sensitivity to word choice information is instrumental in early word learning; pragmatic inference helps guide both language acquisition and comprehension. In general, recognizing that speakers have chosen to say something in a particular way *because of some communicative goal* is an integral part of understanding language (H. Clark, 1996).

In addition to aiding in the acquisition and comprehension of language, inferences about the pragmatic implications of speakers' wording decisions might also be an important learning mechanism for children. Following our shoe example further: Children who learn to infer implied information embedded in word choices can incorporate implicit knowledge (we are talking about one specific shoe) and move on to acquire additional information (“where was it last seen?”) rather than spending time repeating and confirming implied details (“only one shoe is lost?”). Using speakers' word choices to make broader inferences allows children to learn from both what is stated and what are implied alternatives. The earlier and faster children can recognize implicit contrasts from word choice, the greater their opportunities to make use of this information.

The goal in our studies was thus to investigate whether children can learn from how speakers choose to express themselves. We focused on adjective use as a case study because adjectives are optional and may signify cues to contrast and noteworthy features. As an extension of the principle of contrast—that a contrast in form signifies a contrast in meaning (E. Clark, 1987)—children should interpret that referential expressions modified with adjectives convey different types of information than expressions with bare nouns. This makes adjective interpretation a useful domain for examining how children form implicit inferences from a speaker's word choices. We began by looking at color and size terms because they are some of the earliest-learned and most commonly-used adjectives.

Adults perceive adjective use as marking contrast, but there are differences between their comprehension and production. Grice's maxim of quantity—that speakers should be only as informative as is necessary—predicts that modifiers should be used selectively to disambiguate target referents from contrast sets (Grice, 1975). Indeed, in comprehension, visual search findings reveal that adults process color and size information as it comes online and are faster to locate a modified referent (e.g. “big comb”) when a contrasting competitor item is present (e.g. a small comb) than when a distractor item is present (e.g. a spoon) (Sedivy, Tanenhaus, Chambers, & Carlson, 1999). This indicates that prenominal modified expressions may evoke a contrast set with the referent; adults are sensitive to implied contrast information embedded in adjective use and process prenominal modifiers incrementally to locate and disambiguate a speaker's intended referent. However, adults are not always Gricean in their production; although they rarely produce scalar modifiers without a size contrast set present, they frequently over-modify with color terms (Grodner & Sedivy, 2005; Sedivy, 2003). In all, adults are sensitive to the implications of adjective use, but they are not always maximally informative.

Children seem to be developing similar skills in their preschool-age years. By kindergarten, children can recognize the informativeness of adjective use in both comprehension and production; children are more likely to use an adjective to uniquely identify a big cup from a small cup than when only a single cup is present (Nadig & Sedivy, 2002), suggesting that they are able to consider what level of description is most useful to the perspective of an interlocutor. Preschoolers can also learn to produce unambiguous references for more complex scenes with feedback (Deutsch & Pechmann, 1982). In processing speech, 3-year-olds make use of adjective information as soon as it becomes available; they correctly look to

the bigger of two cars upon hearing “big”, even before they hear the word “car” (Fernald, Thorpe, & Marchman, 2010).

In sum, preschoolers actively process adjective information in production and comprehension as cues for uniquely identifying referents. But can children apply this knowledge to make inferences about what implicit information is conveyed by a speaker’s choice of adjective use? To our knowledge, this is the first investigation of children’s abilities to use referential expressions to make inferences about the broader context.

In this paper, we outline four experiments and a corpus analysis investigating pragmatic inferences from information contained in speaker word choice. In Experiment 1, we used a novel task to examine whether adults use adjective information to infer referential contrast, and found that they performed equally strongly with color and size terms. We slightly modified the language in Experiment 2 to make implied contrast less salient, and found that performance only decreased slightly. In Experiment 3, we examined performance with other context-dependent and context-independent features, and found no differences across modifier types. In Experiment 4, we extended our task to 4-year-olds, and found a developmental change between children younger and older than 4-and-a-half: while older 4s performed above chance, younger 4s showed a strong color bias. We conducted an exploratory corpus analysis to examine possible causes for this developmental difference.

## Experiment 1

Our goal was to examine what information listeners can infer about why a speaker chose to form an utterance in a particular way. Before studying behavior in children, we wanted to confirm our intuitions that adults interpret adjective information contrastively when more than one possible visual contrast is available. In Experiment 1, we used a novel task in which adjective choice was the only informative cue to referential contrast (Figure 1). If adults are able make inferences about a speaker’s intended contrast set from adjective information, then they will be more likely to infer contrast along the referenced dimension rather than another visible but unstated dimension. This is precisely what we found.

## Methods

**Participants** Seventy-two adult participants were recruited from Amazon’s Mechanical Turk (MTurk). They were informed that the task was designed for children. All reported that they were native speakers of English.

**Stimuli** Participants viewed an online storybook with cartoon images of aliens, with one test trial. The test featured a set of three aliens: a training exemplar, and a test set consisting of an alien identical to the training exemplar except for size and an alien identical to the training exemplar except for color (Figure 1). We used the height dimension to reflect size because piloting revealed that scaling total size was construed as reflecting age rather than size.

Figure 1: Participants saw a set of three aliens: a training exemplar (e.g. tall red) followed by a test set containing one alien that differed only by color (e.g. tall blue), and one that differed only by size (e.g. short red). Participants were told that a character uttered an expression modified by an adjective (color or size), and asked to predict which test exemplar represented what that kind of alien usually looked like.

**Procedures** Participants were introduced to a character named Allen the Alien. Allen presented the training exemplar, and said something about it, e.g. “This is a special kind of glorp. This is a red glorp.” For a third of participants the reference was about color, and for another third the reference was about size. Participants then saw the test set and were asked, “What do you think glorps usually look like?”, and prompted to select one of the two images. We measured whether adults used the adjective information to infer a contrast along the referenced dimension. For the remaining third of participants, we measured responses to a bare noun baseline in order to detect any response biases unrelated to adjective information.

## Results and Discussion

The baseline control revealed that when adults had no access to adjective information, they were exactly at chance for the image they selected. Of the 24 baseline participants, they selected the size contrast half of the time ( $n=12$ ) and the color contrast equally as often ( $n=12$ ). Additionally, participants were equally likely to select an image on either the left ( $n=12$ ) or right ( $n=12$ ) side regardless of counterbalancing ( $n=6$  for each combination of contrast type and side presentation). These results indicate that adults showed no selection bias with our stimuli when only visual cues were available.

For the experimental trials, responses were coded as correct if participants selected the alien that differed along the referenced dimension (i.e. chose the alien that differed by size

in size trials, and color in color trials). Participants selected the contrasting dimension more often than chance ( $p < .01$  in an exact binomial test for both conditions) and performance did not differ across the two conditions ( $\chi^2(1) = 0.10$ ,  $p = .75$ , Figure 2).

Adjective information was used informatively to denote contrast along a specified dimension; adults interpreted color or size reference as conveying a noteworthy or contrastive feature that distinguished different aliens. Although adults often have access to prosody and emphatic stress on prenominal adjectives as additional cues to contrastive focus in speech (Ito & Speer, 2008), they were sensitive to the implications of adjective use even in our written task. The overall high level of performance suggests that adults are attuned to the subtle informativeness of word choice information. Though the only difference across all conditions was the use of a size term vs. a color term to describe the training exemplar, adults were able to detect and apply this information when making generalizations about the broader populations. They effectively interpreted the single difference in word choice across trials as signaling either a color or size contrast.

## Experiment 2

In Experiment 1, we tried to make cues to contrast highly salient by drawing attention to the unique referent (i.e., “this is a special kind of alien”). In Experiment 2, we ran the same procedure but used a more neutral introduction (“this is a glorp”) in order to determine whether adults would still use adjective information to infer a contrast dimension. Performance decreased only slightly from Experiment 1.

### Methods

**Participants** Forty-eight MTurk workers were recruited.

**Stimuli and procedure** Stimuli were identical to Experiment 1. The only change to the procedure was a modification of the referential expression. Instead of Allen saying, “This is a special kind of glorp. This is a red glorp,” we changed the wording to, “This is a glorp. This is a red glorp.”

### Results and Discussion

Again, adult participants performed significantly above chance ( $p < .05$  in an exact binomial test for both conditions) with no difference between conditions ( $\chi^2(1) = 0.11$ ,  $p = .74$ , Figure 2). Adults used adjective information to infer a referential contrast dimension even when more overt cues to contrast were removed.

## Experiment 3

In our next experiment, we tested whether inferences about contrast from adjective use would generalize to other properties that are less ubiquitous than color and size. We re-ran the procedure keeping color constant, but used the dimensions of texture (which, like color, remains constant across contexts) and width (which, like size, is relative to context).

## Methods

**Participants** Ninety-six MTurk workers were recruited.

**Stimuli and procedure** Stimuli were similar to Experiment 1, but color was held constant and other contrasts were added. Participants either saw aliens that differed by height and texture (spiky vs. smooth), or by height and width (fat vs. thin). We again used language to highlight contrast salience, e.g. “This is a special kind of glorp. This is a [spiky] glorp.” A height, texture, or width adjective was used.

### Results and Discussion

Responses were coded as correct if participants selected the alien that differed along the referenced dimension. Adult participants performed significantly above chance in exact binomial tests ( $p < .05$ ) for all conditions, and with no differences between conditions ( $\chi^2(2) = 0.55$ ,  $p = .76$ , Figure 2). This result suggests that adults are able to infer relevant contrast information from adjective use across a variety of context-dependent and -independent dimensions. Our findings thus show that adults are sensitive to pragmatic inference from adjective use across a variety of adjective types. Our next experiment tests children’s sensitivity.

## Experiment 4

To assess children’s ability to use adjective choice to infer contrast, we used a similar paradigm. We focused on color and size contrasts with 4 – 5 year-old children because this has been found to be an age of pragmatic development in other studies (Barner, Brooks, & Bale, 2011). If young children infer the potential informativeness of adjective use to convey cues to contrast, then they should be more likely to select the image that differs along the referenced dimension (i.e. color or size). If they are not sensitive to this information, then they should select an image at random or according to a baseline bias for one dimension or the other.

### Methods

**Participants** We recruited 46 four-year-old children from the Bing Nursery School at Stanford University. Pilot testing suggested response differences by older and younger 4-year-olds, so we recruited two age groups: twenty-four children age 4.0 – 4.5 (mean age 4 years 2 months) and 22 children age 4.5 – 5.0 (mean age 4 years 10 months).

**Stimuli** We used a similar task design to the previous experiments, but printed a physical book that the experimenter read with children. Each child received two training and six test trials. Each test trial used a unique set of three aliens: a training exemplar alien and two test exemplar aliens that differed from the training alien each by only color or only size.

**Procedures** The experimenter read the book to each child individually in a quiet room at the Bing Nursery School. Children were introduced to Allen the Alien, and then completed two training trials with familiar items to get them used to the study design (e.g., “This is a special kind of milk. This is

Figure 2: Mean percent correct performance across all conditions of Experiments 1-4. The dashed line represents chance (50%). Error bars represent 95% confidence intervals.

chocolate milk. What does milk usually look like?”). Training trials featured adjectives other than color and size and only one relevant contrast choice (e.g. plain milk vs. orange juice). If children did not select the correct training image, they were prompted until the correct image was chosen.

Training was followed by six test trials. For each test trial, the child was shown a picture of a single exemplar alien and told something about it, e.g. “This is a special kind of glorp. This is a tall glorp.” Children were then shown two pictures, one of an alien that differed from the exemplar by size, and one that differed by color. They were asked, “What do you think glorps usually look like?” Children received six test trials: two trials using size adjectives (e.g. “this is a tall glorp”), two trials using color adjectives (e.g., “this is a red glorp”), and two trials with no adjective to serve as a baseline (e.g., “this is a glorp”). Adjectives were focused with contrastive stress. The experimenter averted her gaze while children pointed to their response. The sessions were video-recorded. Trial types and test pictures were counterbalanced across children, and alien sets were presented in one of two orders. The task took about 10 minutes to complete.

## Results and Discussion

Preschool-aged children did show sensitivity to the implications of adjective use. Overall, preschoolers could pick out adjective information as marking an implied contrast dimension. Nevertheless, we saw an interesting developmental trend in the data (Figure 2).

We analyzed our results using a logit mixed model, predicting correct responses as an interaction between age (older vs. younger) and contrast type with random effects of participant and alien type. There was a significant effect of age, such that older children performed better than younger children ( $\beta = -2.06$ ,  $p < .001$ ). There was also a significant

interaction between age and contrast (color or size) such that older children performed above chance for both color and size trials, and younger children responded above chance for size trials but were only at chance for color trials ( $\beta = -3.25$ ,  $p < .01$ ). Overall, this analysis suggested weak responding by the younger 4s with successes by the older 4s.

To ensure that performance differences were not due to unfamiliarity with the color and size terms, we ran a posttest with a subset of children for each age group ( $n=13$  younger,  $n=12$  older). Younger children produced the correct size term over 80% and color terms 95% of the time. Older children’s production was 94% for size and 99% for color. These data suggest that younger children’s lower performance on color trials was not a result of not knowing their color words.

Baseline responses also indicated a significant developmental change. While younger 4s chose color-matching targets 71% of the time on the baseline trials, older 4s chose color-matching targets 38% of the time. In fact, nearly half ( $n=10$ ) of the younger children selected a color match for all trials in the study, while only one of the older children did. To examine this effect, we replotted our data by proportion of trials on which the color-matching target was chosen (Figure 3). A correct pattern of responding for a color trial would be choosing the size match (hence success on a color trial would be below 50% in Figure 3), while a correct response on a size trial would be choosing the color match (above 50%). Replotted in this manner, we can see that younger 4s are modifying their responses only slightly for color trials and not at all for size trials, while older 4s modify their responding slightly for color trials and considerably for size trials.

We captured this pattern with a second logit mixed model, this time predicting choice of color-matching target as a function of trial type (including baseline), age group, and their interaction. In this analysis, we saw that younger children had

Figure 3: Mean percent color choices for all trials in the three trial types by the children in Experiment 4. Error bars show 95% confidence intervals.

a significant bias for color ( $\beta = 1.32$ ,  $p = .004$ ), and a trend towards differential responding in color trials ( $\beta = -.83$ ,  $p = .09$ ). There was a significant coefficient on older children's bias, indicating more size responding ( $\beta = -2.02$ ,  $p = .002$ ), as well as a significant interaction for size trials, indicating success in overcoming this baseline effect ( $\beta = 1.76$ ,  $p = .04$ ), but only for size trials. Thus, both groups showed some bias in their responding, but older 4s were better able to overcome that bias—at least for size—and make inferences about why a particular adjective was produced.

To summarize: Even within the narrow age range of our sample, there was a developmental difference between performance on color and size adjective trials. Although children at both ages were sometimes able to make contrast inferences, the ability to make these inferences clearly depended on the category of the adjective being used. Our next study looks to children's input to investigate one potential source for this developmental change.

### Corpus Analysis

There are a number of possible reasons for developmental differences in color and size responding. One factor raised by Sandhofer and Smith (2001) was that distinctions in the ways color and size terms are used may promote production for color terms and comprehension for size terms. We conducted a corpus study to investigate how color and size terms are presented in natural speech to children, and whether there are differences in the types of contexts and contrasts in which these terms are typically used.

**Materials** Fourteen full speech files from the Providence corpus of CHILDES (Demuth, Culbertson, & Alter, 2006) were analyzed for adult-to-child speech containing color and

Figure 4: Percent of color and size corpus samples that were categorized by informative use, being in the context of a visible contrast, and exhibiting stress on the adjective.

size use. We used the last two or three samples for five children to most closely match the ages we used in Experiment 4 (age range 3;5.16 – 4;0.02, mean 3;8.06). A second coder blind to the hypotheses coded a random 40% of the samples. Inter-rater agreement was substantial (Cohen's  $\kappa = 0.70$ ).

**Procedures** For each file, all uses of color and size adjectives throughout the written transcript were analyzed along with the video context. For each adjective use, we marked the category (color or size), adjective (e.g. red), position (prenominal, postnominal, or adjective used as noun), stress (whether or not the adjective was marked with emphatic stress), whether a visual contrast was present (e.g. whether a big and small item were both physically available during a reference to size), and whether the term was used in a contrastive or informative context (e.g. did the adjective convey a clear possible learning opportunity for the child).

### Results and Discussion

We analyzed 330 speech instances of adjective use: 228 for size and 102 for color. The majority of the utterances used the adjective in the prenominal position (66% for color and 77% for size), but while 20% of size uses appeared in the postnominal, we only found 2 instances for color. The remaining third of color examples were used for naming or without a noun.

Emphatic stress was placed on color terms more often than size terms (83% for color, 48% for size). Color terms were also used more often with a visual contrast present than were size terms (59% color samples and 27% size samples). Results are plotted in Figure 4. It may be that adult speakers are selecting informative opportunities to use color labels with children at this age. Children may have a firmer grasp on size terms and infer contrast without a visible contrast set present.

For each of the samples, we examined whether or not the adjective was used in an informative context. Contexts were coded as informative if there was verbal reference to contrast, visual contrast, or marked salience to evoke an implied contrast with the prototype. Adjective use was considered uninformative when it did not provide qualifiable information to the child. In our samples, we found that 25% of size term use was uninformative, but this was almost never the case for color, suggesting that color and size terms are produced in different types of contexts. Color terms were nearly always used in instances that provided some type of information to the child (97%), whereas size was used informatively in 70% of instances. In addition, color was used to reference a visible contrast that was present in the immediate scene—as opposed to a reference to an unseen or implicit contrast item—44% of the time but only 16% for size.

It may be the case that children expect color terms to highlight the salience of a particular item in a visible contrast set instead of selecting an implied contrast set. In addition, perhaps the greater information contained in color utterances for children at this age may lead children to be biased to pair items on the basis of color, as in baseline performance in Experiment 4. Although more work is needed to understand the links between corpus distribution and behavior, the differences in use we observed might lead children to interpret color and size information in different ways.

## General Discussion

Can adults and children learn from speakers' choice of a particular adjective? Our results suggest that adults are able to infer the general structure of a category based on the words chosen to describe a specific, anomalous example. Children also showed sensitivity to word choice, though we saw developmental differences between ages four and five. Children older than four-and-a-half sometimes succeeded in making inferences based on word choice, while younger children primarily exhibited a color bias. Our corpus analysis suggests that the language adults use with children around this age may mark color as implying a salient, immediate dimension, whereas size was used for a wider variety of functions.

The ability to make inferences from speakers' word choices may not only reflect more adult-like comprehension, but may also be an important learning mechanism for children. The earlier and faster children can go beyond what is stated at face value, the more opportunities they have to gain further knowledge through pragmatic cues. This kind of inference is consistent with work suggesting that pragmatic mechanisms can be used in a variety of different kinds of inferences: for inferring speaker meaning, learning words, and in this case, inferring facts about the world (Frank, Goodman, Lai, & Tenenbaum, 2009).

Children who are able to recognize that word choices can convey broader information will have greater opportunities for learning about the world because they can recognize both what is explicitly stated and implicitly implied. This abil-

ity allows children both to learn more from each utterance and to increase learning opportunities. Although pragmatic inferences are not always easy for children, our results suggest that these inferences may become an important source of background knowledge about the world.

## Abstract

A distinguishing feature of dialogue is that contributions can be fragmentary or incomplete. Such incomplete utterances may be later completed by another interlocutor. These cross-person *compound contributions* (CCs) have been hypothesised to be more likely in predictable contexts but the contributions of different sources of predictability has not been systematically investigated. In this paper we present an experiment which artificially truncates genuine contributions in ongoing text-based dialogues, to investigate the effects of lexical, syntactic and pragmatic predictability of the truncation point on the likelihood of one's interlocutor supplying a continuation. We show that what is critical is the actual and presumed accessibility of common ground, and that while people are sensitive to syntactic predictability, this alone is insufficient to prompt a completion.

**Keywords:** Dialogue; compound contributions; common ground.

## Introduction

It is well known that contributions to dialogue are often fragmentary or in some sense unfinished Fernández and Ginzburg (2002). These incomplete utterances may be subsequently completed, either by the original speaker following some response or interruption from an interlocutor, or, by another person (Purver et al., 2009).

These *compound contributions* (CCs) are a paradigmatic feature of dialogue, and cross-person CCs in particular are a key indicator of coordination between interlocutors. Although naturally occurring cross-person CCs and their interpretations have been studied (Lerner, 1996; Purver et al., 2009), there has not previously been a systematic, experimental, attempt to investigate the factors that influence how a completion for an incomplete utterance may be produced. Intuitively, people's willingness to finish another person's incomplete utterance will depend (at least) on how predictable the rest of the utterance is. There are several sources of possible predictability.

*Expansions* are CCs which add material (e.g. an adjunct) to an already complete syntactic element; *completions* are CCs which complete an incomplete element. Conversation analytic (CA) discussions of CCs suggest that they should preferably occur at *transition relevance places* (TRPs), points that are foreseeable by the participants. *Expansions* are CCs with split points at TRPs, and are more common in spoken dialogue (Howes et al., 2011) so ought to be more likely than completions.

**Hypothesis 1** *Cross-person completions are more likely at transition relevance places*

Second, *completions* should tend to occur at syntactically projectable points (e.g. compound turn constructional units Lerner, 1991).

**Hypothesis 2** *Cross-person completions are more likely when they are syntactically predictable.*

A third source of predictability comes from the degree to which the speaker and hearer share, or can be assumed to share, common ground relevant to the CC. If the topic of the utterance is already in the common ground then the content of the completion is more predictable.

**Hypothesis 3** *Cross-person completions are more likely when they address topics that are part of the common ground.*

The effects of these different forms of predictability are directly tested here for the first time using a text chat experiment performed with the DiET experimental platform. The evidence points towards shared knowledge being a key factor with other sources of predictability also contributing.

## Method

In this experiment, to see what factors influence how people respond to unfinished turns and their likelihood of producing a continuation, a number of genuine single contributions in dyadic text-based conversations were artificially split into two parts, using the DiET chat tool.

## The DiET chat tool

The Dialogue Experimental Toolkit (DiET) chat tool is a text-based chat interface into which interventions can be introduced into a dialogue in real time. These interventions can take a number of forms; turns may not be relayed, additional turns may be added, as in Healey et al. (2003), in which spoof clarification requests are added to the dialogue, or turns may be altered prior to transmission. As these manipulations occur as the dialogue progresses, they cause a minimum of disruption to the 'flow' of the conversation.

The DiET chat tool is a custom built Java application, consisting of two main components: the server console and the user interface. The server time-stamps and

stores each key press, and acts as an intermediary between what participants type and what they see. All turns are passed to the server, from where it is relayed to the other participants. Prior to being relayed, real turns can therefore be automatically altered by the server or not relayed, or fake turns can be introduced.

**Character-by-character interface** In the character-by-character version of the DiET chat tool, the user interface consists of a single chat window. Below this, there is a status bar, which indicates if any participants are actively typing (see figure 1).

Figure 1: The DiET chat window (as viewed by *Jen*)

Unlike traditional chat interfaces (such as MSN Messenger), users type directly into the same window in which they see their interlocutors' contributions. This means that each character that any of the participants type is displayed in the window at the time it is entered – i.e. users see both their own and their interlocutors' contributions unfold in a character-by-character fashion. Consequently, only one participant may type at a time.

## The intervention

For this experiment, single contributions were artificially split into two parts. The first part was transmitted to the other participant as it was typed, with the turn truncated according to various factors as discussed below. Following a pilot study, which showed that people were more likely to supply a response after a filler “...” or “...?” than if there were no filler (after a filler: 18/26, 69%, no filler: 12/45, 27%;  $\chi^2_{(1)} = 12.24, p < 0.001$ ), the truncated first part of the genuine turn was followed by a text filler. Subsequently, there was a delay of 12 seconds, during which the other person could respond if they wished. Any response was trapped by the server and not relayed to the original sender, before the rest of the original (interrupted) contribution was transmitted.

Split points are manipulated according to measures of a) syntactic and b) lexical predictability calculated as each turn is produced.

## Entropy

Entropy is a measure of uncertainty: the higher the entropy, the higher the uncertainty; and the lower the entropy, the higher the predictability. Here we used two

measures: part-of-speech entropy, to capture the “syntactic” predictability of one part-of-speech (POS) following another; and lexical entropy, to capture the predictability of a particular lexical item following a specific POS. To illustrate the difference: although determiners are predictably followed by nouns, there are lots of different nouns: determiners therefore have a relatively low POS entropy, and a relatively high lexical entropy.

Since predictability depends on dialogue context and topic, entropy values were calculated from a corpus of prior dialogues (53663 word tokens) collected using the same tool and domain (the balloon task – see below).<sup>1</sup> POS tags were generated using the Stanford POS tagger (Toutanova et al., 2003) with a misspellings map for common chat abbreviations and typos. For each POS, entropy was calculated as follows over the observed types of the following POS  $S$  or lexical item  $L$ :

$$H_{pos} = - \sum_S p_S \log(p_S) \quad H_{lex} = - \sum_L p_L \log(p_L)$$

During the experiment, a POS-tagger analysed the strings in real time and triggered an intervention based on these entropy values, and a minimum requirement of 9 words (based on the mean length of all contributions). This manipulation produced a range of interventions with high, medium and low POS entropy, and, independently, high, medium and low lexical entropy.

## Subjects and materials

The experiment was carried out on 16 pairs of students from Queen Mary University of London who were each paid £7.00 or given course credit for providing an hour of their time. The task was the *balloon task* – an ethical dilemma requiring agreement on which of three passengers should be thrown out of a hot air balloon that will crash, killing all the passengers, if one is not sacrificed. The choice is between a scientist, who believes he is on the brink of discovering a cure for cancer, a woman who is 7 months pregnant, and her husband, the pilot. This task was chosen on the basis that it is known to stimulate discussion, leading to dialogues of a sufficient length to enable an adequate number of interventions.

Subjects were seated at desktop computers in separate rooms, asked to input their e-mail address and username and given the task description. They were told that the experiment was investigating the differences in communication when conducted using a text-only interface as opposed to face-to-face, that the experiment would last approximately 45 minutes, and that all turns would be recorded anonymously for later analysis.

## Analysis

Each intervention was annotated according to a number of factors. Firstly, whether or not there was a response

<sup>1</sup>This corpus is small, but extremely domain specific.

to the intervention during the timeout period. If there had been, the type of response was coded according to whether it was a compound contribution (CC), a clarification request (CR) or a yes/no response.<sup>2</sup> These are not mutually exclusive – example (1) is a CR constructed as a CC, and example (2) is a CC and a yes/no answer. The minimum POS entropy was 1.44, maximum 4.16, mean 3.27 (standard deviation 0.87); for lexical entropy those values are 5.59–8.14, mean 7.03 (s.d. 0.60).

**J:** firstim with nick qne wuwi and susie - tom can explain how toise use the hot air balloon before he jumps [DiET CCInd13 2048-51]

The intervened turn was also annotated for whether it was potentially end-complete and could therefore be responded to as if it were a complete contribution. Antecedent end-completeness can be used as a proxy measure for pragmatic completeness, with 40 of the 241 truncated contributions appearing to end in a complete way.

The other major factor predicted to increase production of CCs was whether the subject under discussion was known to be shared. Lexical entropy gives us a measure of the predictability of the local context, with entities and concepts more or less predictable in certain sentential contexts because of the limited domain. However, it does not capture the potential effect on the predictability of local upcoming material of the *shared* context established in the course of any particular conversation between a specific pair of individuals. Each intervened contribution was therefore classified as either contributing to an ongoing topic of discussion, or introducing a new topic, as a loose measure of common ground.

## Results

Of the 241 interventions, 171 elicited a response (71%). A GEE analysis with whether or not there was a response to the intervention as dependent variable<sup>3</sup> with POS and lexical entropy values as covariates, antecedent end-completeness as a fixed factor and participant as subject effect (goodness of fit QIC = 294.562; see table 1) showed a main effect of antecedent end-completeness such that responses were more likely in cases that could be considered complete on their own, showing that people are sensitive to TRPs.

<sup>2</sup>These response types were chosen on the basis of an examination of the response data.

<sup>3</sup>All models in this paper use a binary model with a logit link function and an independent correlation structure unless otherwise stated.

There was also an interaction effect of POS entropy by lexical entropy ( $B = 0.237$ , Wald- $\chi^2 = 5.893$ ,  $p = 0.015$ ). This effect is illustrated in figure 2. Simple slopes analysis (Aiken et al., 1991) showed that responses are more likely in cases where both POS and lexical entropy were high (the highly unpredictable cases) than in cases where one or both levels of entropy were low.

IV	Model effects	
	Wald $\chi^2$	p
Antecedent end-complete (Ant)	4.286	0.038*
Lexical entropy (Lex)	0.148	0.700
POS entropy (POS)	0.593	0.441
Ant $\times$ Lex	3.251	0.071
Ant $\times$ POS	2.546	0.111
Lex $\times$ POS	6.460	0.011*
Lex $\times$ POS $\times$ Ant	0.287	0.592

Table 1: GEE of response or not by lexical entropy, POS entropy and antecedent end-completeness

Figure 2: Marginal means of probability of a response by POS entropy  $\times$  lexical entropy

## Type of response

The results outlined above may conflate different effects which are specifically associated with different kinds of response. Analyses were therefore carried out separately on the different types of responses.

Response type		Antecedent end-complete			
		N	%	Y	%
Yes/No	Y	20	15	12	36
	N	118	85	21	64
CR	Y	39	28	2	6
	N	99	72	31	94
CC	Y	62	45	10	30
	N	76	55	23	70
Total		138	69	33	83

Table 2: Response type

The breakdown of the 171 responses is shown in table 2.<sup>4</sup>

<sup>4</sup>Note that there were no differences in types of response according to which filler type was used ('...' or '...?').

Participants were more likely to produce a Yes/No response if the antecedent is end-complete ( $\chi^2_{(1)} = 8.374, p = 0.004$ ), and they are also less likely to respond with a clarification request ( $\chi^2_{(1)} = 7.201, p = 0.007$ ). There is no difference in the proportion of responses constructed as CCs based on whether the antecedent was end-complete or not, which is unexpected given the preference for expansions over completions in corpus studies (Purver et al., 2009).

### CR responses

With the data filtered to responses only, GEE analyses on whether or not the response was formulated as a CR, with the POS and lexical entropy values as covariates and participant as subject effect (goodness of fit = 186.828) showed a main effect of POS entropy (see table 3). Greater syntactic predictability (lower POS entropy) increased the probability of the response being a clarification request.

IV	Model effects	
	Wald $\chi^2$	p
Lexical entropy	2.207	0.137
POS entropy	5.135	0.023*
Lex $\times$ POS entropy	0.176	0.674

Table 3: GEEs CRs by lexical entropy, POS entropy and antecedent end-completeness

CRs are often formulated as CCs, as in (3) which is particularly true where the syntactic category of the next word was highly predictable (independently of lexical entropy). Of the 72 CCs, 21 occurred in syntactically predictable (low POS entropy) conditions with 12 of these also being CRs. Of the other 51 CCs, only 13 were also CRs (57% vs. 25%;  $\chi^2_{(1)} = 6.575, p = 0.010$ ).

- (3) **N:** i think susie because she is t ...

**N:** ehe least important out of the three if you think about it ... dr nick is a doctor and could be really useful in the world [DiET CCInd9 1214-7]

### CC responses

IV	Model effects	
	Wald $\chi^2$	p
Antecedent end-complete (Ant)	1.951	0.162
Lexical entropy (Lex)	3.586	0.058
POS entropy (POS)	0.235	0.627
Ant $\times$ Lex	15.835	<0.001**
Ant $\times$ POS	0.018	0.894
Lex $\times$ POS	0.344	0.558
Ant $\times$ Lex $\times$ POS	0.005	0.945

Table 4: GEE of CCs by lexical entropy, POS entropy and antecedent end-completeness

GEE analyses on whether or not the response was formulated as a CC, with the POS and lexical entropy val-

ues as covariates, participant as subject effect and antecedent end-completeness as a fixed effect (goodness of fit = 234.351) showed an interaction between antecedent end-completeness  $\times$  lexical entropy (table 4).

Simple slopes analysis shows that if the next lexical item is unpredictable then you are more likely to formulate your response as a CC if the antecedent is not end-complete. When the antecedent is end-complete (the solid line in figure 3), responses are more likely to be continuations in more highly predictable contexts (as in e.g. (4)), but when it is not end-complete CCs are more likely in the lexically unpredictable cases (as in e.g. (5)).

[DiET CCInd6 929-32]

Figure 3: Marginal means of probability of a CC response by lexical entropy  $\times$  antecedent end-completeness

### Context

To test the hypothesis that CCs are more common where participants share information or common ground about the subject under discussion, planned post hoc analyses were carried out using the topic under discussion. Of the 241 intervened contributions, 170 were about an existing topic under discussion, whilst 71 introduced some new topic.

Participants were no more likely to respond if the turn was about the current topic or not; nor were they more likely to respond with a yes/no answer, or a clarification request. However, they were more likely to construct their response as a CC if it was about the current topic than if it was about something else (topic 59/121, 49% vs. Off-topic 13/50, 26%;  $\chi^2_{(1)} = 7.519, p = 0.006$ ).

Adding topic to the GEE model with CC response as dependent variable (QIC = 227.895, table 5)<sup>5</sup> resulted in a three-way interaction effect of lexical entropy  $\times$  POS entropy  $\times$  topic.

IV	Model effects	
	Wald $\chi^2$	p
Antecedent end-complete (Ant)	0.046	0.830
Topic	0.276	0.600
Lexical entropy (Lex)	2.545	0.111
POS entropy (POS)	0.018	0.892
Line number	2.361	0.124
Ant $\times$ Topic	0.381	0.537
Ant $\times$ Lex	3.435	0.064
Ant $\times$ POS	0.183	0.669
Topic $\times$ Lex	2.103	0.147
Topic $\times$ POS	0.281	0.596
Lex $\times$ POS	0.034	0.853
Ant $\times$ Topic $\times$ Lex	0.091	0.763
Ant $\times$ Topic $\times$ POS	0.005	0.946
Ant $\times$ Lex $\times$ POS	0.133	0.716
Topic $\times$ Lex $\times$ POS	8.635	0.003**

Table 5: GEE of type of CC responses by lexical entropy, POS entropy, antecedent end-completeness and topic

Exploring the interaction effect (figure 4) shows that in lexically unpredictable cases, which were syntactically predictable, participants were more likely to construct their response as a CC if they were talking about some topic which they had already been discussing, and which was therefore contextually salient.

Figure 4: Marginal means of probability of a CC response by lexical entropy  $\times$  POS entropy  $\times$  topic

## Discussion

These results offer some insights regarding the conditions influencing whether and how conversational partners respond to an incomplete utterance, and when they can and do construct those responses as continuations.

There is a response to 71% of the interventions, with this proportion affected by the predictability of the upcoming material. Perhaps counterintuitively, people are

<sup>5</sup>The model also included line number as an additional covariate as it was found that participants were more likely to introduce a new topic later on in the conversation.

more likely to respond to unfinished contributions<sup>6</sup> if both syntactic and lexical items were unpredictable. This is not what we would expect if a simple model of levels of predictability were correct, as intuitively the most predictable cases ought to elicit the most responses. However, it is what we would expect if one of the drivers of human communication is in locally managing and resolving potential sources of misunderstanding (as in the interactive misalignment of Healey, 2008).

The main effect of potential completeness also demonstrates that people are more comfortable responding at all if the other person has reached a potential TRP – backing up findings from corpus studies (Purver et al., 2009) and conversation analysts assertion that people are sensitive to possible endings (Schegloff, 1996).

## Compound contributions

Contrary to Hypotheses 1 and 2, continuations are not more likely at TRPs or syntactically predictable points. What is critical seems to be the actual and presumed accessibility of common ground. If the local content of what comes next is salient from the (presumed shared) context then people will produce completions. They do this by taking advantage of the syntactic structure of the antecedent, but syntactic predictability alone is not sufficient to prompt a completion.

A continuation response is more likely if the antecedent is complete but the next word is predictable (as in e.g. (4)) or if the antecedent is incomplete, suggesting that people complete where they can.

For the cases in which the antecedent is not end-complete, responses were more likely to be constructed as CCs in lexically unpredictable cases. However, if the next lexical item is highly predictable, then it can be interpreted as if it had actually been produced, as in (6). This result is not as surprising as it first appears as in a BNC corpus study (Howes et al., 2011), only 64% of end-incomplete contributions get continued, meaning that 36% never do. These are cases in which the local context is so predictable that it can be taken to be shared without the words themselves being produced.

(6) **T:** its not that fair on the girl doing th ...

**H:** exactly, you need to think of others and not be so selfish :P

**T:** study we should do lots of chatting although i doubt she'll read past the exercise what with it not being standardised etc [DiET CCInd4 685-8]

## Context

The three-way interaction of POS entropy by lexical entropy by topic adds weight to the notion that what is critical to the production of a continuation in response

<sup>6</sup>This could be a genuine difference in text chat because of the availability of other cues in spoken dialogue, but we leave a discussion of this to one side.

to an incomplete utterance is the actual and presumed accessibility of common ground.

If the lexical item is unpredictable then syntactic predictability aids production of CCs in cases where the topic of the truncated contribution is shared, thus acting as a resource which helps frame the offered continuation as such. Syntax does not however help at all in cases where the topic is new so the gist of the contribution cannot be predicted and the predictability of the next word also offers no clues as to a plausible continuation.

This pattern of predictability corresponds to cases in which the high lexical entropy equates to lots of different words of a single type, as in the determiner case, rather than the high lexical entropy being associated with lots of different words of many different types (as with e.g. adverbs). This means that the syntactic category is highly constrained and the additional information associated with contextual salience can significantly narrow down an appropriate continuation.

### Summary

This experiment, to the best of our knowledge the first to ever systematically attempt to induce continuations in an ongoing dialogue, shows that different types of predictability have different effects on what type of response participants produce to incomplete contributions, if any.

It shows that although syntax can be mobilised in constructing a response, it is not the crucial determinant of whether people construct their responses as continuations to the immediately preceding contribution. Participants make use of syntactic predictability only if the context is sufficiently constrained. Though people respect the constraints of the syntax, different points in the sentence do not cause greater difficulty in producing something that syntactically builds off a prior turn. However, that the grammar is a mutually available resource does not mean that it is used in the same way by all interlocutors, as evidenced by the finding that clarification requests are more likely, and more likely to be formulated as continuations, when the syntactic category of the upcoming material is more predictable, as these are cases where the syntax may be exploited to localise the source of a potential misunderstanding.

Another of the main findings is that people are sensitive to potential turn endings. These may be syntactic (in the antecedent end-complete cases) but they are not necessarily so. Some cases which appear to be syntactically incomplete can be responded to as if they are complete, provided that the continuation is highly predictable. If there are indeed cases which are interpreted as complete when they are not – as if the hearer is supplying the missing material internally, but does not necessarily produce it, this has implications for any grammatical or dialogue model. Incomplete syntactic strings must be not only successfully analysed, but also assigned

potentially complete semantic representations.

The evidence from this experiment shows that when people are likely to produce CCs (or produce more CCs) is principally driven by common ground. They are possible (or more likely) when it is shared. How this is cashed out remains to be seen, however, it is apparent that some formal notion of context is crucial for a thorough understanding of CCs, especially if we are to ever hope to model them appropriately in a dialogue system.

## Abstract

Identifying the structure of mental representations is a basic problem for cognitive science. We present a method for identifying people's representations of categories that are defined over a set of discrete items, such as a collection of images. This method builds on previous work using Markov chain Monte Carlo algorithms as the basis for designing behavioral experiments, and we thus call it discrete Markov chain Monte Carlo with People (d-MCMCP). We illustrate how this approach can be used to identify the structure of visual categories using real images drawn from large databases.

**Keywords:** category representation; Markov chain Monte Carlo; image databases

## Introduction

Humans outperform the most sophisticated computers in their ability to process complex stimuli, such as recognizing faces or comprehending ambiguous linguistic input. These abilities are facilitated by organizing stimuli into categories. People's representations of categories directly affect their behavior: Recognizing scenes, parsing language, and making decisions, for example, are all influenced by people's category representations. Therefore, understanding the structure of these representations is an important goal for cognitive science. Most research on computational models of categorization has tended to use artificial stimuli, because such stimuli lend themselves to controlled experiments and yield results which are easily quantified (e.g., Nosofsky, 1986; Ashby, 1992; Nosofsky, 1987). However, the stimuli constituting real-life categories – such as images or words – are often characterized by complex features that vary along a large number of dimensions that are hard to quantify. In this paper, we present a method for estimating the structure of categories using an arbitrary discrete set of stimuli, making it possible to investigate real-life categories using complex stimuli such as images drawn from large online databases.

Many computational models of categorization can be interpreted as representing a category as a probability distribution over stimuli (Ashby & Alfonso-Reese, 1995). For example, a category  $c$  might be represented by the probability distribution over images  $x$  associated with that category,  $p(x|c)$ .

Using this insight, new experimental methods have been developed for estimating these subjective probability distributions. These methods are based on implementing Markov chain Monte Carlo (MCMC) algorithms, which are widely used in computer science and statistics for sampling from complex probability distributions. The Markov chain Monte Carlo with People (MCMCP) method (Sanborn & Griffiths, 2008; Sanborn, Griffiths, & Shiffrin, 2010) adapts MCMC algorithms so as to sample from subjective probability distributions, such as the distributions over stimuli associated with categories. The MCMCP method has been used to estimate the structure of categories defined on continuous, easily parameterized stimuli, such as stick-figure animals and basic fruit shapes (Sanborn et al., 2010) or computer-generated faces (McDuff, 2010; Martin, Griffiths, & Sanborn, 2012).

While the introduction of MCMCP made it easier to explore complex, high-dimensional representations, the original method could only be used with stimuli that vary along a fixed set of parameterized dimensions. This is a serious limitation for exploring real-life categories. For example, it is difficult to quantify the difference between faces with genuine smiles vs. disingenuous smiles. Here, we present an extension of MCMCP that removes this limitation. Our method, which we call discrete Markov chain Monte Carlo with People (d-MCMCP), allows estimation of probability distributions over arbitrary discrete sets of stimuli. This supports the exploration of categories relating to real-life stimuli such as photographic images, every-day objects, real commercial products, and linguistic materials such as documents and words. Because we no longer need to explicitly parameterize the stimuli being examined, d-MCMCP allows us to exploit the vast array of natural stimuli available from the internet.

The outline of this paper is as follows. The next section introduces the key ideas behind MCMCP. We then present our extension of this method to discrete sets of stimuli. The remainder of the paper focuses on two experiments that demonstrate the utility of this method. The first experiment explores the categories of *happy* and *sad* faces using photographic images, allowing us to compare against previous results obtained using the original MCMCP algorithm applied

to parameterized images of faces (Martin et al., 2012). The second experiment explores people’s concepts of the seasons *Spring*, *Summer*, *Autumn* and *Winter* using a set of 4000 images drawn from online databases.

### Markov chain Monte Carlo with People

Markov chain Monte Carlo algorithms are a class of methods for generating samples from complex probability distributions by constructing Markov chains that converge to those distributions over time (see Gilks, Richardson, & Spiegelhalter, 1996). If we want to draw a sample from the probability distribution  $p(x)$ , we define a Markov chain such that the stationary distribution of that chain is  $p(x)$ , and sample a sequence of states from that chain. If the sequence is long enough, the states of the chain can be treated similarly to samples from  $p(x)$ . The Metropolis algorithm (Metropolis, Rosenbluth, Rosenbluth, Teller, & Teller, 1953) is one of the most popular methods for constructing such a Markov chain. The sequence of states is initialized with an arbitrary value,  $x$ . The next value in the sequence is generated via a two step process. First, a candidate for the next value,  $x'$ , is chosen by sampling from an arbitrary proposal distribution conditioned on  $x$  that is specified by the designer of the algorithm,  $q(x';x)$ . Second, a decision is made as to whether that proposed value will be accepted using a valid acceptance function which is a function of the relative probability of  $x$  and  $x'$  under the target distribution  $p(x)$ . While the original Metropolis algorithm used a different acceptance function, an example of a valid acceptance function is the Barker function (Barker, 1965) which specifies the acceptance probability to be

$$A(x^*;x) = \frac{p(x')}{p(x') + p(x)} \quad (1)$$

and defines a Markov chain that converges to  $p(x)$  provided  $q(x';x)$  is symmetric, with  $q(x';x) = q(x;x')$ .

The Markov chain Monte Carlo with People method uses the idea that categories can be represented as probability distributions over stimuli (Ashby & Alfonso-Reese, 1995). The distribution over stimuli  $x$  for category  $c$ ,  $p(x|c)$  indicates the degree to which a stimulus item  $x$  is perceived to represent a given category  $c$ . In theory, the simplest approach to measuring human categories would be to ask people to rate the degree of category membership for all possible stimuli. However, this has two serious limitations. First, categories span such a large number of possible items that collecting individual ratings of each are not practical. Second, a question such as “How good is this example of a *happy face*?” is difficult to answer, and there is no obvious scale to use for the answer. A solution to the second limitation would be to ask people to make pairwise judgments, i.e. “Which example is a better example of a *happy face*?”. However, this only exacerbates the first limitation because the number of judgments required for all possible pairs of  $n$  items is now on the order of  $n^2$ .

Markov chain Monte Carlo with People addresses the challenge of estimating the distribution associated with a category

by constructing a Markov chain that produces samples from that distribution. The method is based on a correspondence between human choice behavior and the Barker acceptance function. If a task can be constructed in which people are offered a choice between  $x$  and  $x'$  and choose  $x'$  with probability

$$P_{\text{choice}}(x';x|c) = \frac{p(x'|c)}{p(x'|c) + p(x|c)} \quad (2)$$

then this provides a valid acceptance function for a Markov chain that will converge to  $p(x|c)$ . Equation 2 has a long history as a model of human choice probabilities, where it is known as the Luce choice rule or the ratio rule (Luce, 1963; Shepard, 1957). This rule has been shown to provide a good fit to human data when people choose between two stimuli based on a particular property (Bradley, 1954; Clarke, 1957; Hopkins, 1954). The Luce choice rule has also been used to convert psychological response magnitudes into response probabilities in many models of cognition (Nosofsky, 1986; Ashby, 1992; Nosofsky, 1987; McClelland & Elman, 1986).

Based on this correspondence, the MCMCP method implements the Metropolis algorithm, using people’s choices to determine which proposals are accepted (Sanborn et al., 2010). In a standard experiment, people would be asked to make a series of pairwise decisions in which they are asked to choose the best category member from two proposed stimuli. The stimuli that are presented in each decision correspond to the values  $x$  and  $x'$  in the Metropolis algorithm, and the choices that people make determine which proposals are accepted. With enough decisions, MCMCP will converge to samples from the probability distribution associated with that category, and individual stimuli will be encountered with probability given by  $p(x|c)$ . The proposal distribution can be selected by the experimenter, provided it is symmetric in the way required by the Barker acceptance rule.

### Estimating categories for discrete sets of stimuli

The MCMCP method requires defining a proposal distribution  $q(x';x)$  for choosing the next stimulus to present on each trial based on the current stimulus. When stimuli are described by a fixed set of parameters, this is easy – previous work has used Gaussian or uniform distributions to generate proposals for continuous parameters, and a multinomial distribution can be used to propose new values for discrete features. However, real-life categories are not made up of easily parameterized items: Real-life categories apply to stimuli that are difficult to parameterize such as real objects, images, sounds, and words. The lack of parameterization makes it unclear how to propose a reasonable stimulus based on the current stimulus, which is central to the MCMCP algorithm’s efficiency. Hence, in order for MCMCP to measure representations of a wide range of real-life categories, we need to a method for making reasonable proposals when exploring stimuli that are not easily parameterized. In this section, we introduce such a method, which we call discrete Markov Chain Monte Carlo with People (d-MCMCP).

The d-MCMCP procedure adds three steps to MCMCP. The first step is to create a database of stimulus items over which the probability distribution associated with a category is to be estimated. The second step is computing a rough measure of the similarity between all possible item pairs, giving a symmetric similarity matrix,  $S$ . The similarity metric can be chosen as appropriate for the domain, and need only provide a heuristic guide to the perceived similarity of human participants. For example, similarity between color histograms can be used to quantify similarity for color images. The third step is constructing a graph of the stimulus items based on these similarities. A random walk on this graph is then used to define the proposal distribution used in MCMCP.

A key assumption in using the Barker acceptance function is that the proposals must be symmetric. That is the probability of choosing a proposal value given a current value would be the same if the proposal and current values were reversed. In order for this to be true of a random walk on a graph, the edges must be symmetric (ie. the walk can traverse an edge in each direction), and each node in the graph must have the same degree (ie. each node must have the same number of neighbors). Just choosing the  $b$  nearest neighbors (as given by the similarity metric) for each node does not suffice, because while node  $i$  might be one of  $b$  nearest neighbors to node  $j$  the reverse is not does not have to be true. As a result nodes will have different degrees. Taking the union or intersection of edges resulting from considering the nearest neighbors of each item will also result in unequal degrees.

To address this problem, we instead construct the graph that maximizes the similarity along edges while keeping the degree of each node constant. Formally, we want to find

$$\arg \max_G \sum_{ij} G_{ij} S_{ij} \quad \text{s.t.} \quad \sum_j G_{ij} = b; \quad G_{ii} = 0; \quad G_{ij} = G_{ji}$$

where  $G$  is the adjacency matrix of the graph, with  $G_{ij} = 1$  if there is an edge from  $i$  to  $j$  and  $G_{ij} = 0$  otherwise. This is an instance of the *maximum weight b-matching* problem (Papadimitriou & Steiglitz, 1998). Exact algorithms exist for solving this problem, such as the *blossom* algorithm (Edmonds, 1965), but these are impractical for large-scale applications. Consequently, we use an approximate algorithm based on max-product message passing to find a  $b$ -matching (Jebara & Shchogolev, 2006).

Given a graph on stimuli that is a  $b$ -matching, proposals for the d-MCMCP algorithm can be made in a variety of ways. The selected proposal method is held constant throughout the experiment (as is standard in MCMC and MCMCP). The most straightforward proposal method is to choose a proposal uniformly from all  $b$  neighbors, where the value of  $b$  is chosen at the experimenter's discretion. A second method is to make a geometric proposal. Here, the proposal is generated iteratively using a number of steps,  $n_{\text{geom}}$ , that is chosen from a geometric distribution with a fixed parameter. A random walk of length  $n_{\text{geom}}$  is then performed, choosing the next node uniformly from the  $b$  neighbors of the most recent one. The node at the end of the random walk is the proposal.

For all proposal methods it is prudent to allow for some small probability of choosing uniformly from all possible stimulus items to allow the algorithm to move between local maxima.

## Experiment 1: *happy* and *sad* faces

As a first test of the d-MCMCP method, we examined the categories of *happy* and *sad* faces using a database of images of real faces. Previous work had applied the original MCMCP method to estimating these categories using parameterized face stimuli, where a continuous space was derived from eigenfaces computed from the same set of images (Martin et al., 2012). Use of the same image database allows direct comparison of the results of d-MCMCP and MCMCP with a matched stimulus set, and ratings of the emotional content of the resulting faces provide a way to evaluate these results.

### Method

**Participants.** A total of 60 undergraduates participated in exchange for course credit.

**Stimuli.** A database of 1271 images of faces was assembled from the California Facial Expression (CAFE) database, a collection of 1280 normalized  $40 \times 64$  pixel gray-scale portraits containing 64 individuals (Dailey, Cottrell, & Reilly, 2001), expressing approximately eight distinct "FACS-correct" emotions, which are classified according to the taxonomy of the Facial Action Coding System (Ekman & Friesen, 1978).

**Procedure.** Face images were convolved with Gabor filters at 8 scales and 5 orientations. Principal Components Analysis (PCA) was then applied to the whole set of convolved images and the Euclidean distance between the top 50 components was used as the similarity metric for defining the matrix  $S$ . Two graphs  $G$  were produced using the approximate  $b$ -matching algorithm from Jebara and Shchogolev (2006), one with  $b = 6$  and one with  $b = 16$ . This algorithm gives an approximate solution to the  $b$ -matching problem, so there was still some minor variation in the degree of individual nodes. Our empirical evaluation of the performance of the d-MCMCP procedure will thus also help to indicate whether this residual variation affects the results. There is no guarantee that a maximal  $b$ -matching is connected, so we used the largest connected component as the basis for the d-MCMCP procedure. The largest connected component contained 1216 images with  $b = 6$  and all 1271 images with  $b = 16$ .

We compared three different methods for defining the proposal distributions. For all three proposal methods, we allowed for a 10% chance of proposing a jump to a node chosen uniformly at random. The three methods for choosing the remaining proposals were the uniform random walk on the graph with  $b = 6$  (U6), the uniform random walk on the graph with  $b = 16$  (U16), and the geometric proposal with  $n_{\text{geom}} = 0.5$  on the graph with  $b = 6$  (G6).

Participants were randomly assigned to proposal-type conditions. Trials were presented on three different computers, one for each proposal type. Each participant completed trials corresponding to four d-MCMCP chains (two for *happy*

Figure 1: Results of comparing MCMCP using eigenfaces and d-MCMCP with a variety of proposal methods on the same set of face stimuli. Average faces for each type of proposal. Averages are taken across all trials and all four chains corresponding to *happy* and *sad*.

faces, two for *sad* faces). There were 100 trials for each of the four chains. On a given trial, the participant decided which of a pair of faces was either more *happy* or more *sad*. Twelve trials in the beginning were offered as practice, which were not included in the analysis. There were also 40 catch trials with face pairs for which the more *happy* or *sad* face was clearly obvious (in this case, we used the emotion designations in the CAFE database to select faces that should clearly be happy or sad). Thus each participant responded to  $100 \times 4 + 12 + 40 = 452$  trials, which took approximately 25 minutes. The responses were linked in chains of ten participants each: The last trial of each of the four chains was passed along to the next participant as his/her first non-practice trial to form a linked chain of 1000 trials. Participants who did not correctly answer at least 27 catch trials ( $p < .01$  under random guessing) were not included in the results, or added into a chain. We collected two chains of 10 participants for each proposal type, corresponding to four *happy* and *sad* chains with 1000 trials in each chain.

## Results

The images selected on each trial were averaged together to produce the average faces shown in Figure 1. All three proposal methods produced mean faces that appeared reasonably consistent with the target emotions. Also included in Figure 1 are the results reported in (Martin et al., 2012) using MCMCP in a parameterized space based on the eigenfaces derived from the image database we used for d-MCMCP. Qualitatively, the results from d-MCMCP are at least as good and perhaps better than those produced using eigenfaces.

To quantify the performance of the different variants of the algorithm, we conducted a follow-up experiment in which a group of 40 participants recruited via Amazon Mechanical

Figure 2: Happiness ratings for average faces for three types of d-MCMCP proposals as well as original MCMCP method as a function of trial number (error bars show one standard error). Averages are taken across the 50 most recent trials (or starting from the first trial for trials less than 50) and across all four chains corresponding to the same emotion (*happy* or *sad*). Also included are face ratings for the results of a previous MCMCP experiment that used eigenfaces derived from the same image database (Martin et al., 2012).

Turk provided ratings of the emotions exhibited by faces derived from our chains. For each proposal type (and for the chains based on eigenfaces used in Martin et al. (2012)), cumulative average faces were computed for each of 40 logarithmically spaced numbers of trials, averaging across all four chains that corresponded to each emotion. For trial numbers greater than 50 images were averaged only over the 50 most recent trials, meaning that no more than 200 faces contributed to any single image. Participants rated the emotion exhibited by each of these mean faces on a scale from 1-9, where 1 indicates “very sad” and 9 indicates “very happy”. All participants rated all faces, and received \$1 in compensation for their time.

The results of our follow-up experiment are shown in Figure 2. The d-MCMCP method results in statistically significantly higher ratings for faces derived from *happy* chains regardless of proposal type, perhaps as a consequence of being able to explore a larger space of faces than the eigenface method. Results for *sad* chains are more comparable. There are no systematic differences between the different proposal types, although the U16 proposal appears to produce happier faces faster than the other two proposals. For both *happy* and *sad* chains there is some variation in the emotion ratings of mean faces over time, consistent with the idea that MCMCP should be exploring the distribution of faces associated with the category (and possibly moving between modes of that distribution) rather than finding the most extreme instance of that category.

## Experiment 2: Seasonal images

Our first experiment indicated that d-MCMCP produced comparable or better performance to MCMCP when applied to a set of stimuli where both methods could be used. In our second experiment, we used d-MCMCP to explore categories defined on a set of stimuli for which there is no simple paramet-

ric representation. Specifically, we explored the categories of images associated with the seasons *Spring*, *Summer*, *Autumn*, and *Winter*, using 4000 images obtained from online image databases. By applying the d-MCMCP procedure to these stimuli, we can identify high probability images and compute informative aggregate statistics for each category, allowing us to answer questions such as what distribution of colors is associated with each season.

## Method

**Participants.** A total of 90 participants were recruited using Amazon Mechanical Turk. Each participant was paid \$1 for completing the 25 minute experiment.

**Stimuli.** A set of 4000 colored season-related images was assembled by searching for public domain web images using the phrases “spring season”, “summer season”, “autumn season”, and “winter season” in Google Image Search and on Flickr.com. The top 500 results for searches on Google and Flickr for each season were downloaded using Bulk Image Downloader. All images were resized so that the maximum dimension was 250 pixels, while preserving the original ratio of image height to width.

**Procedure.** The similarity between all possible image pairs (7998000 pairs for 4000 images) was quantified using both the Basic Color Histogram (BCH) descriptor (Griffin, 2006) and the Scale-Invariant Feature Transform (SIFT; Lowe, 1999). BCH classifies and counts pixels as belonging to one or other of the eleven basic colors (black, white, grey, red, orange, yellow, green, blue, purple, pink, and brown). SIFT applies local filters to transform images into collections of local feature vectors which are invariant to scaling, rotation and translation of the image. Similarity results over all pairs of images for both methods were normalized to have unit variance and then added together, thus yielding a similarity measure which combined results of both BCH and SIFT. The similarity between all pairs was represented as a similarity matrix which was fed into the *b*-matching algorithm. A graph was found using  $b = 5$ , which was the smallest value such that all 4000 images remained fully connected. We used a proposal distribution corresponding to a uniform random walk on this graph.

Each participant made pairwise choices between images by answering questions such as *Which image is more representative of Spring?*. There were 100 trials for each of four chains, one for each season. There were also 12 practice trials, and 40 catch trials for which one image of the pair obviously corresponded to a particular season (as judged by the experimenter). Thus each participant completed 452 trials. Participants who did not at least get 27 catch trials correct were not included in the chains or analysis. We collected data by linking three sets of 10 participants forming three chains of 1000 trials for each of the four seasons.

## Results

The top ten images that were chosen most often over all three chains for each season are shown in Figure 3. Clearly, the im-

ages are very indicative of each season. Figure 4 (a) shows, as a function of the number of trials, the L1 distance between 11-bin color histograms calculated for cumulative images, both between chains for the same season and between chains corresponding to different seasons. Within-chain distance decreases over time, and is typically lower than the similarity between chains, supporting the idea that chains are converging towards different parts of the space of images. Figure 4 (b) shows a simple example of the kind of statistical analyses that can be done on the resulting samples. The color histograms for the different seasons are quite different from one another, and each correspond to a palette that seems consistent with our intuitive representation of each season.

## Conclusion

We have presented a new method for estimating the structure of people’s mental representation of categories, showing that it produces performance that is comparable to existing methods, and can be used with rich sets of complex stimuli such as images derived from online databases. By extending the MCMCP algorithm so that it can be applied to any arbitrary set of stimuli, our d-MCMCP method makes it possible to measure people’s representations of a broader range of natural categories, and in a greater variety of real-world settings. Using our approach, MCMCP algorithms can be applied to large databases which contain discrete items, such as images or text. This has the potential to lead to significant advances for cognitive scientists interested in studying categories in a way that goes beyond simple parameterized stimuli. The results of such an investigation are likely to be valuable to machine learning and computer vision researchers interested in training systems to produce and improve on human performance in categorizing images and other complex stimuli. Conducting experiments using d-MCMCP on a large scale will allow us to build up a catalogue of human category representations, taking a step towards understanding how those categories are formed.

## Abstract

Knowledge regarding social information is thought to be derived from many different sources, such as interviews and formal relationships. Social networks can likewise be generated from such external information. Recent work has demonstrated that statistical linguistic data can explain findings thought to be explained by external factors alone, such as perceptual relations. The current study explored whether language implicitly comprises information that allows for extracting social networks, by testing the hypothesis that individuals who are socially related together are linguistically talked about together, as well as the hypothesis that individuals who are socially related more are talked about more. In the first analysis using first-order co-occurrences of names of characters in the *Harry Potter* novels we found that an MDS solution correlated with the actual social network of characters as rated by humans. In a second study using higher-order co-occurrences, a latent semantic analysis (LSA) space was trained on all seven *Harry Potter* novels. LSA cosine values for all character pairs were obtained, marking their semantic similarity. Again, an MDS analysis comparing the LSA data with the actual social relationships yielded a significant bidimensional regression. These results demonstrate that linguistic information indeed encodes social relationship information and show that implicit information within language can generate social networks.

**Keywords:** social relations; social networks; social cognition; statistical linguistic frequencies

## Introduction

What is the nature of social relations and how can such relations be estimated? Social media, such as Facebook, LinkedIn, and Twitter allow us to answer this question, based on individuals choosing their friends. However, when such deliberate decisions are not readily available, how can social relations be measured and social networks be plotted otherwise?

Social relations can be interpreted in three non-mutually exclusive ways (Fischer, 1982). First, they can be formal in socially recognized roles, such as teacher/student, employer/employee, or father/son. Second, they can be sentimental, as when individuals feel close to others. Finally, a relation can be defined in terms of interactions

and exchanges. The formal, sentimental, and interactive nature of the social relationship can be determined by assessing a number of factors. For example, relationships can be predicted in part by the kinship of the individuals. In families, siblings tend to be close friends. Gender especially impacts the nature of relationships such that if a member of the dyad is a female, the relationship is more likely to be successful (Kim, McHale, & Osgood, 2006; Wright & Scanlon, 1991). Environment tends to weigh heavily in terms of whether or not two individuals are likely to build a relationship together. Proximity has also long been established as a strong predictor for relationships of all varieties, with increased proximity leading to increased likelihood of interpersonal relationships (Ebbesen, Kjos, Konecni, 1976). In addition, ties between locations (e.g., commonly trekked routes) also impact social interaction (Takhetev, Gruz, & Wellman, 2011). Similarly, familiarity fosters attraction between individuals (Reis, Manianci, Caprariello, Eastwick, & Finkel, 2011; Zajonc, 1968; 2001). Further, those who share interests, attitudes, and characteristics are more likely to develop friendships. In fact, any similarity between two individuals promotes the formation of a relationship between them (Bryne, 1971), with important matters (e.g., religious views, political attitudes) given more weight (Touhey, 1972). Emotions also impact relationships. When two individuals first encounter one another, a future friendship becomes more likely if the interaction is positive, whereas a friendship is not apt to blossom if the interaction is negative (Farina, Wheeler, & Mehta, 1991). Even physical features, like smell or appearance influence the relationships we form (Li, Moallem, Paller, & Gottfried, 2007).

After social relations are formed, different factors help these relations to solidify. For instance, Berscheid, Snyder, and Omoto (1989) found that closeness was significantly related to satisfaction of established romantic relationships, as was self-disclosure (Sprecher & Henrick, 2004). Feeney and Noller (1992) argued that individual differences like attachment styles impact the duration of social relationships, as does equity (Hatfield, Traupmann, & Walster, 1978). In addition, when it comes to group relationships, predicting

outcomes becomes more complicated, with members constantly joining and leaving the group. In fact, Kariam, Wang, and Leskovec (2012) found that diffusion growth (i.e., the addition of a new members to a group due to current relationships with group members) limits group size. Such findings indicate that the structure of groups is impacted by various factors.

When these social relationships are formed, how do we plot these relationships as social networks? Social scientists typically rely on interviews. For instance, Fischer (1982) asked respondents who they would share personal information with, who they worked with, and who visited their house, etc. in order to plot personal networks in the San Francisco area. But how could such networks be represented when participants cannot be interviewed as in Fischer's study, or when participants otherwise do not voluntarily release personal information as in social media? One answer to this question might lie in language. Perhaps social networks can also be acquired from and represented implicitly through linguistic sources.

In several studies we have demonstrated that perceptual information that is readily available from the world around us is encoded in language. For instance, Louwerse, Cai, Hu, Ventura, and Jeuniaux (2006) and Louwerse and Zwaan (2009) tested whether language encodes geographical information by correlating statistical linguistic frequencies between cities with the actual physical distances between those cities. Louwerse and Zwaan (2009) further tested the hypothesis by correlating computationally generated semantic relationship cosine values with the longitude and latitude of cities in the US. Recently, Louwerse, Hutchinson, and Cai (in press) found evidence for this hypothesis with Chinese texts predicting locations in China and Arabic texts predicting locations in the Middle East. Louwerse and Benesh (in press) have further extended these findings by demonstrating that the longitude and latitude of cities in the fictional Middle Earth can be predicted using the text of the *Lord of the Rings* trilogy. The semantic associations between cities in a corpus accurately estimated the physical distance between cities, supporting the claim that language encodes geographical information. A similar reasoning can perhaps be applied to social relationships. If the physical distance between individuals is small, their semantic association might be high.

In a number of studies we have shown that perceptual and embodied relations are encoded in language (Louwerse, 2011). Perhaps social relations are also encoded in language, such that computational algorithms can extract such relations from text. In the current paper we tested two hypotheses. First, if individuals are socially related together, they are talked about together. That is, if individuals are in social proximity, they are likely to be found in textual proximity. Second, if individuals are socially related more, they are talked about more.

To test these hypotheses we used the seven fantasy fiction *Harry Potter* novels and extracted the semantic relationships

between the characters and compared them with the actual social relationships between the characters.

## The Social Network of Harry Potter

Social networks are structures that map relationships between individuals. They are complex systems that can be used to examine, predict, and measure various features embedded within a network (see Newman, 2003 for an overview). Nodes represent specific individuals with edges connecting those individuals and representing relational information.

There are several ways social networks are produced. Social networks are often generated manually whereby individuals are linked to others if they are friends, colleagues, family members, etc. Individuals are able to generate their own egocentric social networks representing those other individuals with whom they share a relationship. Of course, the individual generating the network will do so based on the existence and strength of relationships that were generated by and subject to the factors enumerated above (Scott, 1988). This is the technique employed by Muckety LLC (2012). Muckety is a news corporation that manually generates maps of relationship influence between relevant individuals in a network. They manually specify networks of influence where each node is related to numerous other nodes via specific types of relationships (e.g., friend, enemy, relative). These relationships are manually researched using a variety of sources, such as government agencies and organizations, news publications, books, organization web sites, and interviews, and are expectedly costly to produce. Although Muckety generally generates networks representing current political, financial, and educational communities they have also constructed a social network representing each of the relationships between characters and organizations from all *Harry Potter* novels (Rowling, 1998; 1999a; 1999b; 2000; 2003; 2005; 2007).

Although Muckety provided a manually generated relationship network, edge weights between nodes were not provided. We thus computed edge weights as follows. Considering that between any two individuals there exists approximately four friendship links (Backstrom, Boldi, Rosa, Uander, & Vigna, 2012), we calculated a value representing higher-order relationships four degrees away. First order relationships were assigned a value of 1, relationships separated by one friendship link (or degree of separation) were assigned a value of .5, relationships separated by two friendship links were assigned a value of .25, relationships separated by three friendship links were assigned a value of .125, and relationships separated by four friendship links were assigned a value of .0625. To illustrate, *Harry Potter – Ron Weasley* received +1 because they are directly related as friends. *Harry Potter – Percy Weasley* received +.5 because they both share a relationship with *Ron Weasley*. *Harry Potter – Igor Karkaroff* would receive +.25 because *Harry* shares a relationship with someone (e.g., *Dumbledore*) who shares a relationship with

another person (e.g. *Snape*) who directly shares a relationship with *Igor Karkaroff*. This process was repeated until four friendship links were reached.

## Computational Study

The current study investigated whether statistical linguistic information encodes social relationships by testing the hypotheses a) if individuals are socially related together, they talked about together, b) if individuals are socially related more, they are talked about more. Two computational algorithms were used to test these hypotheses. First, we relied on first-order co-occurrence frequencies of character names. Although first-order frequencies are easy to compute, they also come at a price. Due to sparsity problems, they can sometimes give a biased result (Louwerse, 2011). We therefore also used a higher-order co-occurrence algorithm, latent semantic analysis (LSA; Landauer, McNamara, Dennis & Kintsch, 2007).

The seven Harry Potter books were converted to one electronic document used for the research purposes described in this study only. The document consisted of a total of 1,277,991 words. The electronic document was then filtered and all stop words (grammatical items) and punctuation marks were removed, resulting in a final file with 517,501 words and 21,423 paragraphs.

### First-order co-occurrences

In order to determine the first-order co-occurrences of character names, we computed the co-occurrence of all combinations of 56 character names in the Harry Potter novels with name pair in a five-word window. To avoid any biases with single word and two-word names (*Harry* versus *Harry Potter*), we selected the names by which each character was most frequently called while keeping the least ambiguous (e.g., *Ron Weasley* and *Arthur Weasley* are both referred to as *Weasley*, we therefore selected the names *Ron* and *Arthur*).

Although Muckety included 263 nodes (including characters, organizations, and locations), we were only interested in character relationships. We selected 56 characters for the analysis to keep the analysis from becoming too computationally expensive, as each character was paired with every other character. Characters were included on the basis of their prominence in the Harry Potter series, i.e., obscure characters were excluded from the analysis as they shared relationships with the fewest other characters.

These 56 x 56 frequency combinations were entered in an MDS analysis using the SMACOF algorithm. The SMACOF algorithm minimizes the sum of squares of the error by optimizing the fit to the distances (as opposed to the squared distances) and is thus preferred to ALSCAL (Young, 1985). We used default criteria for SMACOF, with the maximum iterations = 100, stress convergence = .0001 and the minimum stress value = .0001. Co-occurrence frequencies converged in 10 iterations with stress = .16.

Similarly, the Muckety scores for all 56 x 56 relations

were entered in an MDS analysis, using the same parameters as for the linguistic data. The MDS converged in 25 iterations, with stress = .13.

To do justice to the 2D structure of the Muckety data, we conducted a bidimensional regression to determine the relationship between the human data and the statistical linguistic frequency data. Tobler (1964) and Friedman & Kohler (2003) introduced bidimensional regressions in order to compute the mapping of any two planes under consideration. Whereas in a unidimensional regression each data point is shifted by intercept and slope, each actual and predicted value of the dependent variable are presented by a point in space, whereby vectors represent intercept and slope.

The bidimensional regression for Muckety and co-occurrence values yielded a moderate correlation,  $r = .43$ ,  $p < .001$ ,  $n = 56$ . The moderate correlation can most likely be attributed to the relatively small size of the corpus, as this impacts first order co-occurrences most (Louwerse, 2011). To account for this sparsity problem, it is often recommended to not so much rely on first-order co-occurrences, but on higher-order co-occurrences.

### Higher-order co-occurrences

To compute the higher-order computational relationship strength values we employed Latent semantic analysis (LSA). Latent Semantic Analysis captures semantic relations by mapping initially meaningless words into a continuous high dimensional semantic space (Landauer, McNamara, Dennis & Kintsch, 2007). More specifically, a first-order process associates stimuli (words) and the contexts they occur in (paragraphs). Stimuli are paired based on their contiguity or co-occurrence. These local associations are next transformed by means of Singular Value Decomposition (SVD) into a small number of dimensions (typically 300) yielding more unified knowledge representations by removing noise.

In the current study the input was the electronic version of the Harry Potter novels, segmented into paragraphs, from which a large term-document was created. For example, if there are  $m$  terms in  $n$  paragraphs, a matrix of  $A = (f_{ij} \times G(j) \times L(i, j))_{m \times n}$  is obtained. The value of  $f_{ij}$  is a function of the integer that represents the number of times term  $i$  appears in document  $j$ ,  $L(i, j)$  is a local weighting of term  $i$  in document  $j$ , and  $G(j)$  is the global weighting for term  $j$ . Such a weighting function is used to differentially treat terms and documents to reflect knowledge that is beyond the collection of the documents. The large matrix of  $A$  has, however, much redundant information, for instance because not every word occurs in every paragraph. Singular Value Decomposition reduces this noise by decomposing the matrix  $A$  into three matrices  $A = U\Sigma V^T$ ; where  $U$  is an  $m$  by  $m$  square matrix and  $V$  is an  $n$  by  $n$  square matrix, with  $\Sigma$  being an  $m$  by  $n$  diagonal matrix with singular values on the diagonal. By removing dimensions corresponding to smaller singular values, the representation of each word is reduced as a smaller vector with each word now becomes a weighted

Figure 1: MDS loadings of Muckety scores (x-axis) and LSA higher-order values (y-axis) for the first dimension (Figure 1A) and second dimension (Figure 1B)

vector on 300 dimensions, with only the most important dimensions that correspond to larger singular values being kept (Landauer et al., 2007). The semantic relationship between characters can then be estimated by taking the cosine between two vectors.

As before, the 56 x 56 cosine matrix was submitted to MDS, which converged in 11 iterations with stress = .15. When we compared the two-dimensional loadings of the Muckety scores and the LSA scores in a bidimensional regression, we found, somewhat surprisingly, a weak correlation,  $r = .23$ ,  $p = .08$ ,  $n = 56$ . Yet when LSA values were allowed to populate a three dimensional configuration (stress = .07, convergence in 20 iterations), the bidimensional regression between Muckety scores and the second and third dimension of the LSA MDS yielded a more moderate (and significant) correlation,  $r = .30$ ,  $p = .02$ ,  $n = 56$ .

Upon visual inspection of the MDS plot, the first dimension did not explain social relations, but identified an outlier in the data. The character *Ginny Weasley* had more direct relationships than any of the other characters (except Harry Potter), yet the frequency with which *Ginny* occurred in the text was quite low. To illustrate, the word *Harry* occurred 21,781 times in the text whereas the word *Ginny* only occurred 762 times. After the removal of this outlier we again ran an MDS with two dimensions for both LSA (stress = .13, convergence in 12 iterations) and Muckety values (stress = .09, convergence in 33 iterations) (see Figure 1). The bidimensional regression now yielded a strong correlation between LSA values and Muckety values,  $r = .76$ ,  $p < .001$ ,  $n = 55$ .

The Muckety standard and the LSA estimates are illustrated in Figures 1A and 1B. As both figures show, the correlation between Muckety and LSA loadings are relatively strong. The correlation between Muckety and LSA values for the first dimension is represented in Figure

1A,  $r = .56$ , and the correlation between Muckety and LSA values for the second dimension is represented in Figure 1B,  $r = .76$ .

Both the first-order and the higher-order co-occurrence results demonstrate that it is possible to extract a social network from language using statistical linguistic frequencies of names of individuals.

## Number of Relationships

In this study we also test the hypothesis that characters who were socially related more are talked about more. We therefore computed the frequency of the 56 character used in the previous study. Next, we calculated how many relationships each character had in the Muckety network. For instance, *Harry Potter* shared direct relationships with 37 other characters whereas *Luna Lovegood* only shared direct relationships with 9 other characters (see Table 1).

Name frequency and number of relationships correlated strongly,  $r = .72$ ,  $p < .001$ ,  $n = 56$ , suggesting that individuals who have a large social network appear more in the text.

## Discussion

The current study aimed to determine if language encodes social relationship information. The reported results suggest computationally derived character pair values can explain human relationship strength ratings. If linguistic representations did not encode relationship structures we would have expected our computationally derived relationship strength values not to predict the human scores. They do, however, significantly predict the human Muckety relationship network scores, suggesting that social information is encoded in language, supporting the hypotheses that individuals who are socially related together are talked about together, and those who are socially related more are talked about more.

Table 1: Number of Relationships (Rel) and Frequency (Freq) of Character Names

Character Name	Rel	Freq	Character Name	Rel	Freq	Character Name	Rel	Freq
Aberforth Dumbledore	6	78	Fred Weasley	16	1075	Narcissa Malfoy	8	75
Alastor Moody	6	874	George Weasley	16	898	Neville Longbottom	10	928
Albus Dumbledore	16	3981	Ginny Weasley	19	792	Nymphadora Tonks	9	243
Amos Diggory	4	54	Goyle	3	278	Padma Patil	5	35
Argus Filch	3	335	Harry Potter	37	21781	Parvati Patil	5	168
Arthur Weasley	15	171	Hermione Granger	13	6132	Percy Weasley	7	512
Augusta Longbottom	3	2	Igor Karkaroff	3	321	Peter Pettigrew	8	163
Bellatrix Lestrangle	16	250	James Potter	10	186	Petunia Dursley	5	671
Bill Weasley	13	365	Kingsley Shacklebolt	4	119	Remus Lupin	12	841
Buckbeak	3	131	Kreacher	3	305	Ron Weasley	17	9144
Cedric Diggory	9	813	Lavender Brown	5	286	Rubeus Hagrid	12	2342
Charlie Weasley	12	165	Lily Potter	10	119	Severus Snape	15	2172
Cho Chang	9	261	Lucius Malfoy	10	148	Sirius Black	15	2314
Cornelius Fudge	2	651	Luna Lovegood	9	401	Slughorn	5	425
Dobby	6	613	Madam Hooch	3	52	Trelawney	5	284
Dolores Umbridge	5	663	Madame Maxime	3	201	Vernon Dursley	4	927
Draco Malfoy	16	1719	Mcgonagall	5	818	Viktor Krum	6	561
Dudley Dursley	4	477	Molly Weasley	15	83	Vincent Crabbe	7	268
Fleur Delacour	6	424	Mrs Norris	2	64			

We found evidence supporting both hypotheses. For the first hypothesis we used first-order co-occurrences which yielded an acceptable bidimensional regression coefficient. A higher-order co-occurrence like LSA yielded a high bidimensional regression coefficient, likely because its reduced sensitivity to sparsity problems of the linguistic data.

Even though narrative fictions offers a simulation of the social world around us (Mar & Oatley, 2008), the main conclusion of this study can of course be extended to the non-fictional world. We have already demonstrated this for geographical estimates for cities in the United States using newspapers (Louwerse & Zwaan, 2009), and geographical estimates for cities in the fictional Middle Earth using Lord of the Rings (Louwerse & Benesh, in press). We therefore expect that the method for the fictional Harry Potter novels can be extended to non-fictional texts. For instance, by using newspaper articles social relations among political leaders can be determined. By using blogs and tweets social networks of individuals in these texts can be estimated.

In addition to this application of the conclusion in this study, another important conclusion for the cognitive sciences is that language implicitly encodes information. In other work we have established this for geographical information (Louwerse & Benesh, in press; Louwerse, Hutchinson, & Cai, in press; Louwerse & Zwaan, 2009), bodily information (Tillman, Datla, Hutchinson, & Louwerse, in press) and other perceptual information (Louwerse, 2008; Louwerse & Connell, 2011). The current study shows that this can be extended to social information. Language has evolved such that statistical linguistic frequencies can capture the social relationships in the world

around us, in the fictional world, and even in the wizarding world.

## Abstract

Explaining symptoms by the most likely cause is a process during which hypotheses are activated and updated in memory. By letting participants learn about causes and symptoms in a spatial array, we could apply eye tracking during diagnostic reasoning to trace the activation level of hypotheses across a sequence of symptoms. Fixation proportions on former locations of possible causes reflected the causal strength of initial symptoms, a bias towards focal hypotheses, and the final diagnosis. Looking-at-nothing revealing memory activation consistent with process models of diagnostic reasoning was stable even after one week.

**Keywords:** Diagnostic reasoning, Probabilistic inference, Eye tracking, Order effects, Spatial index

## Introduction

The goal of diagnostic reasoning is to determine the most likely cause of observed symptoms. In routine cases, medical diagnosis may proceed as simple pattern classification. Often, however, symptoms are ambiguous and the clinician has to consider multiple alternative diagnoses. Then, medical diagnosis is a case of hypothesis generation and hypothesis testing (Lange, Thomas, & Davelaar, 2012; Thomas, Dougherty, Sprenger, & Harbison, 2008) as it occurs in science, criminal investigation, or searching for faults in technical systems. Diagnostic reasoning with limited information search, for example, when clinical cases are presented as case histories, requires information integration based on knowledge and multiple probabilistic cues. In the present study, we used the cover story of an accident in a chemical plant, in which workers were affected by one of four chemicals (Mehlhorn, Taatgen, Lebiere, & Krems, 2011). Participants had to decide, which chemical had caused a worker's symptoms. By laying out chemicals and symptoms in a spatial array in a learning phase, we could use eye tracking for process tracing of memory-based diagnostic reasoning to study the updating of diagnostic hypotheses.

In sequential diagnostic reasoning, the first symptom triggers a limited number of candidate hypotheses, which frame the processing of subsequent symptoms. Equally supported alternative hypotheses may be missed or rated less likely than the focal hypothesis. Similar primacy order effects have been documented for judicial decision making and social judgment, for example.

The focal hypothesis or the set of focal hypotheses is held in working memory. If symptoms have to be retained in

working memory as well, capacity limits increase in importance. Cued recall of candidate hypotheses and sequential symptom processing to update the focal hypotheses' degree of support are cognitive processes, which elude observation and are altered if ratings are elicited during reasoning. If external representations of symptoms or knowledge about causes were permanently ready for inspection, patterns of information search could be recorded via behavior records (e.g., Mouselab) or eye tracking. Here, we demonstrate a similar process tracing method (Renkewitz & Jahn, in press) that is suitable for investigating purely memory-based hypothesis generation and symptom processing. It builds on the tendency to direct the gaze to locations where information was presented before when one attempts to retrieve it from memory or reactivates it in working memory (the "looking-at-nothing" phenomenon; Richardson & Spivey, 2000).

Our participants learned about the four chemicals and the symptoms that they could cause in a spatial array. During diagnostic reasoning, symptoms were presented auditorily and the participants' eye movements on the emptied spatial array were tracked. Our goal was to trace the activation, updating, and revision of hypotheses. In particular, we were interested to see whether the activation of initial hypotheses reflected the strength of support by the first symptom, whether focal hypotheses had an advantage over equally supported alternative hypotheses, and whether fixation proportions corresponded to the final diagnosis in trials with ambiguous symptom sequences. Extending previous findings, we demonstrate the stability of looking-at-nothing over an interval of one week.

## Experiment

### Method

**Participants.** Thirty-six students of the University of Greifswald (28 female, 8 male) with a mean age of 22.1 years ( $SD = 2.4$ ) completed the first session. 32 of them returned for the second session 7.3 days later on average ( $SD = 1$ ; range 6 to 10 days).

**Materials.** To prepare for the diagnostic reasoning task, participants learned about four chemicals and possible symptoms. There were six symptom classes each containing two symptoms that are listed in Table 1. The four chemicals and the symptom classes that each could cause were presented in a 2x2 arrangement as shown in Figure 1. The square in the bottom right quadrant measured 9.1° by 9.1° of

visual angle. Symptoms from the symptom class in the top rectangle were “almost always” caused by the respective chemical, those in the middle and bottom rectangles were “occasionally” caused by the respective chemical.

Table 1: Symptom classes and symptoms. The original materials were in German.

Symptom Class	Symptom	Symptom
Eyes	Eyelid swelling	Lacrimation
Respiration	Cough	Difficult breathing
Skin	Acid burn	Rash
Neurological	Paralysis	Speech disorder
Circulatory Pr.	Sweating	Swoon
Pain	Twinge	Sting

As can be seen in Figure 1, each symptom class appeared with two chemicals. For example, “Eyes” symptoms were almost always caused by the top left chemical, but only occasionally by the top right chemical. Such symptoms are denoted “Ab” (frequent for A, occasional for B) or “Ba” (frequent for B, occasional for A) in the following. Furthermore, each chemical shared an occasional symptom class (Circulatory Problems, Pain) with a chemical in the diagonally opposite quadrant. Symptoms from these classes are denoted “ac” in the following.

A single trial in the diagnostic task consisted of a sequence of four symptoms, for example: Eyelid swelling, Cough, Swoon, and Difficult Breathing (Ab\_Ba\_ac\_Ba). Note that in this example, the third symptom (a circulatory problem) disambiguates the symptoms heard up to then and leaves only “A” (the top left chemical in this example) as the final diagnosis.

Ten different item types were constructed that are listed in Table 2. The point in the sequence at which a symptom in combination with foregoing symptoms determined the final diagnosis did vary across item types. In item type 10 the symptom pattern remained ambiguous. The column denoted “Specific symptoms” shows which item types are equivalent regarding the evidence provided by the symptoms irrespective of symptom order.

The symptom orders in Table 2 were used with each of the chemicals in the A-role. This was possible because the chemicals’ symptom patterns were symmetric. Furthermore, all possible assignments of symptoms to item types were constructed with the restriction that no single symptom was repeated in a symptom sequence.

**Procedure.** The experiment consisted of two sessions. In the first session, the participants acquired the knowledge to be used in diagnostic reasoning and then completed two phases of diagnostic reasoning trials. In the first half of diagnostic reasoning trials, the 2x2 arrangement of geometric forms was the same as during learning. In the second half, the arrangement was changed. The bottom pair became the top pair and the top pair became the bottom pair. In the second session, which took place 6 to 10 days later ( $M = 7.1$ ), the participants returned for diagnostic reasoning trials, in which the original arrangement was presented

again. Eye movements were recorded during diagnostic reasoning only.

**Knowledge acquisition.** Participants were instructed that their task would be to determine the cause of a patient’s symptoms. They were told that the patients are workers in a chemical plant, which processes four chemicals. Each patient was affected by exactly one of those chemicals. They should determine, which chemical most likely had caused a patient’s symptoms. Next, they studied Table 1 and worked through test trials until the set of twelve symptoms was once assigned to symptom classes without errors.

Then, participants were told that each chemical could cause three of the six symptom classes and the frequency with which a chemical causes a symptom class would vary. The symptom class shown in line one would be caused “almost always” and the symptom classes shown in lines two and three would be caused “occasionally”. Next, the chemicals with symptom classes were presented as shown in Figure 1. They could be studied until participants felt ready to be tested.

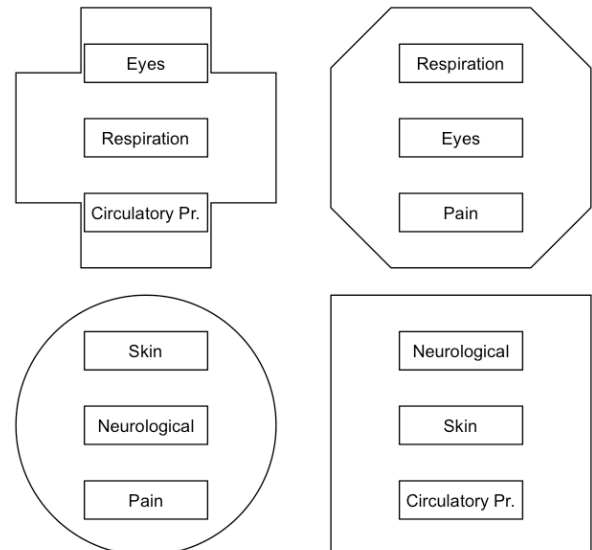

Figure 1: The four chemicals as they were presented in the learning phase. During diagnostic reasoning, the rectangular frames containing the symptom categories were empty.

In each test trial of the learning procedure, the emptied spatial array of geometric forms was shown and a symptom was presented acoustically followed by either “almost always” or “occasionally”. Participants responded by indicating the chemical that causes this symptom with this frequency. The response was given with adjacent keys on a standard keyboard (u, i, j, and k), whose arrangement approximately matched the 2x2 arrangement on the screen. Feedback was provided acoustically with a mellow or an unpleasant tone. After positive feedback, the next trial started automatically. After negative feedback, the filled arrangement was presented until participants hit the space bar to proceed to the next test trial. Testing continued until the set of 20 different testing items presented in random

order was once answered without errors. Learning was completed within 19 min on average ( $SD = 7$ ).

Before diagnostic reasoning in the second session, participants had the opportunity to refresh their knowledge by inspecting the patterns of symptom classes for the four chemicals. These were printed on separate cards within rectangular frames but without the surrounding geometrical forms. There was also one card showing the symptom classes and the single symptoms they contained.

**Diagnostic reasoning.** Each diagnostic reasoning trial started with a fixation cross in the center of the screen for 1000 ms followed by a screen showing the emptied spatial array and the acoustic presentation of the symptom sequence with delays of 3000 ms between symptoms that each lasted 1000 ms. After the fourth symptom, participants indicated their diagnosis with one of the four keys already used during learning. After the response, a confidence rating was collected, which is not reported further in this paper.

In the first session, each participant, worked twice through the 40 possible combinations of chemicals with item types: once viewing the original arrangement and once viewing the flipped arrangement. Participants returning for the second session, worked through the 40 possible

combinations again viewing the original arrangement. In addition, there were four training trials in each session.

The order of the 40 trials in each diagnostic reasoning section was pseudo-random and balanced across participants. For each trial, the actual sequence of symptoms was drawn randomly from the 8 or 4 possible sequences for this combination of item type and chemical in the A-role.

The diagnostic reasoning sections in the first session took approximately 75 min in total. Between sections participants took a rest for about 5 min. The second session took approximately 30 min.

**Apparatus.** The experimental stimuli were presented on a 19" LCD-monitor at a resolution of 800 x 600 pixels, the symptom sequences were presented through headphones. During the diagnostic reasoning phases, eye movements were monitored by a desk-mounted SMI RED eye tracker (Sensomotoric Instruments, Teltow, Germany) with a sampling rate of 60 Hz and an accuracy of approximately 0.5 degrees of visual angle. The eye tracker was calibrated before each diagnostic reasoning phase. Participants sat at a distance of approximately 60 cm to the monitor. Head movements were restrained with a chin rest.

Table 2: The ten item types, the specific symptoms that they contain, the symptom orders, and the chemicals that remain as diagnostic hypotheses after each symptom.

Item type	Specific symptoms	Order	After 1st	After 2nd	After 3rd	After 4th
1	BB	Ba_ac_Ba_ac	B,(A)	A	A	A
2	ABB	Ba_ac_Ba_Ab	B,(A)	A	A	A
3	ABB	ac_Ba_Ba_Ab	A,C	A	A	A
4	AB	ac_Ba_ac_Ab	A,C	A	A	A
5	AA	ac_ac_Ab_Ab	A,C	A,C	A	A
6	AA	Ab_Ab_ac_ac	A,(B)	A,(B)	A	A
7	ABB	Ab_Ba_ac_Ba	A,(B)	A,B	A	A
8	ABB	Ab_Ba_Ba_ac	A,(B)	A,B	A,B	A
9	ABB	Ba_Ba_Ab_ac	B,(A)	B,(A)	A,B	A
10	AABB	Ab_Ab_Ba_Ba	A,(B)	A,(B)	A,B	A,B

## Results

In all non-ambiguous item types the single correct diagnosis is denoted "A" (see Table 2). In the ambiguous item type AABB\_10, both "A" and "B" were correct diagnoses consistent with the pattern of symptoms. In every trial, the following spatial relations held between chemicals in the A-, B-, C-, and D-roles: the B-chemical was located horizontally next to the A-chemical, the C-chemical was diagonally opposite to the A-chemical, and the D-chemical was below or above the A-chemical (see Figure 1). When the layout on the screen was flipped for the second half of the first session, eight participants immediately noticed the flipped layout, eleven participants noticed the change at some point during the 40 trials, and the remaining seventeen apparently did not notice the change at all. Because of this variability, we focus on diagnostic reasoning sections with original layouts.

**Accuracy.** The mean proportion of A-diagnoses for each item type is shown in Figure 2. The item types are ordered by the combination of specific symptoms that they contain and numbered as in Table 2. Overall, accuracy was high. For the ambiguous item type AABB\_10, the mean proportion of A- or B-diagnoses was .99 and .98 in the first and second session, respectively (both  $SEs$  .01).

The five ABB item types did not differ significantly in accuracy. The two AA item types were similar in accuracy as well. Thus, we computed mean accuracy for ABB and AA for a comparison with AB and BB item types in a repeated-measures ANOVA including session and item type (AA, AB, ABB, and BB). Accuracy was higher in the second session,  $F(1, 31) = 5.49$ ,  $MSE = 0.011$ ,  $p = .03$ , the main effect of item type was significant,  $F(3, 93) = 6.43$ ,  $MSE = 0.015$ ,  $p = .002$ , and there was no significant interaction,  $F < 0.9$ . In both sessions, accuracy for AA was similar to AB, higher than ABB (Cohen's  $d = 0.64$  and  $0.77$

in sessions 1 and 2, respectively), but only slightly higher than BB ( $d = 0.34$  and  $0.27$ ).

Figure 2. Mean proportions of A-diagnoses; for AABBB items B-diagnoses were correct as well

**Response times.** Response times were measured from the onset of the fourth symptom. Median response times for A-responses were computed after trimming outliers 3 *SD* above the individual session means (2.2 % of all A-responses). As shown in Figure 3, median response time was prolonged for the ambiguous item type AABBB\_10 in both sessions. In the first session, median response time was also prolonged for ABB items, in which the final diagnosis was determined late with the third symptom (ABB\_8 and ABB\_9), and for the BB item. These three item types differed significantly from all other non-ambiguous item types with  $d$ s varying between 0.31 and 1.06. In the second session, these differences between the nine non-ambiguous item types were attenuated,  $F(8,232) = 2.02$ ,  $MSE = 851180$ ,  $p = .045$ .

**Fixation proportions on quadrants.** Gaze data were analyzed for trials with correct responses, in which the original layout had been presented. Trials with more than 40% missing gaze data were discarded (2.4 % in the first session, 4.0 % in the second session). We focus on aggregated gaze data to examine the distribution of gaze allocation between screen quadrants representing diagnostic hypotheses in response to each symptom.

The quadrants of the screen were defined as areas of interest and each trial was divided in four intervals defined by the onsets of the four symptoms and the response after the fourth symptom. For each interval in a trial, the proportions of total fixation time that fell upon the four quadrants were computed and coded as A, B, C, or D according to a quadrant's chemical's role in the respective trial. Means of these fixation proportions were computed separately by session and item type for each participant. For the ambiguous AABBB item type, mean fixation proportions were computed separately for trials with A- and B-responses.

Figure 3. Median response times for A-diagnoses

Plots of mean fixation proportions across the four intervals of a symptom sequence are shown for three exemplary non-ambiguous item types in Figure 4. The three non-ambiguous item types are BB\_1 starting with a Ba-symptom, ABB\_3 starting with an ac-symptom, and ABB\_8 starting with an Ab-symptom. In addition, plots for item type AABBB\_10 separated for trials with A-responses and trials with B-responses are shown.

Apparent from a brief inspection, the item types induced very different fixation patterns, which were replicated for each item type with only small deviations in the second session one week later. In the interval from the onset of the first symptom to the onset of the second symptom, mean fixation proportions reflected how much the first symptom supported the individual hypotheses. With Ba as the first symptom, the largest proportion (nearly 40%) of fixations in the first interval was directed to the B-quadrant, a smaller proportion (about 20%) to the A-quadrant, and only about 10 % to the C- and D-quadrants, respectively. With Ab as the first symptom, the analogous pattern was observed except for the ambiguous AABBB items that were answered with B finally. With ac as the first symptom, both A- and C-quadrants were fixated for a similar proportion (nearly 30%) and longer than the B- and D-quadrants.

As soon as an ac-symptom had occurred with either an Ab- or a Ba-symptom, the diagnosis A was determined. In the following intervals, fixation proportions for all other hypotheses dropped sharply and remained low (third and fourth intervals for BB\_1 and ABB\_3). Thus, later symptoms triggered only fixations to the A-quadrant, but not to quadrants with which they were associated as well and which were fixated in the first interval for the respective symptom. For example, the B-quadrant received a large proportion after Ba as the first symptom but only a small proportion after Ba as the third symptom in BB\_1. Similarly, the C-quadrant received hardly any fixations after ac as a later symptom in BB\_1 and ABB\_8 compared to after ac as the first symptom in ABB\_3.

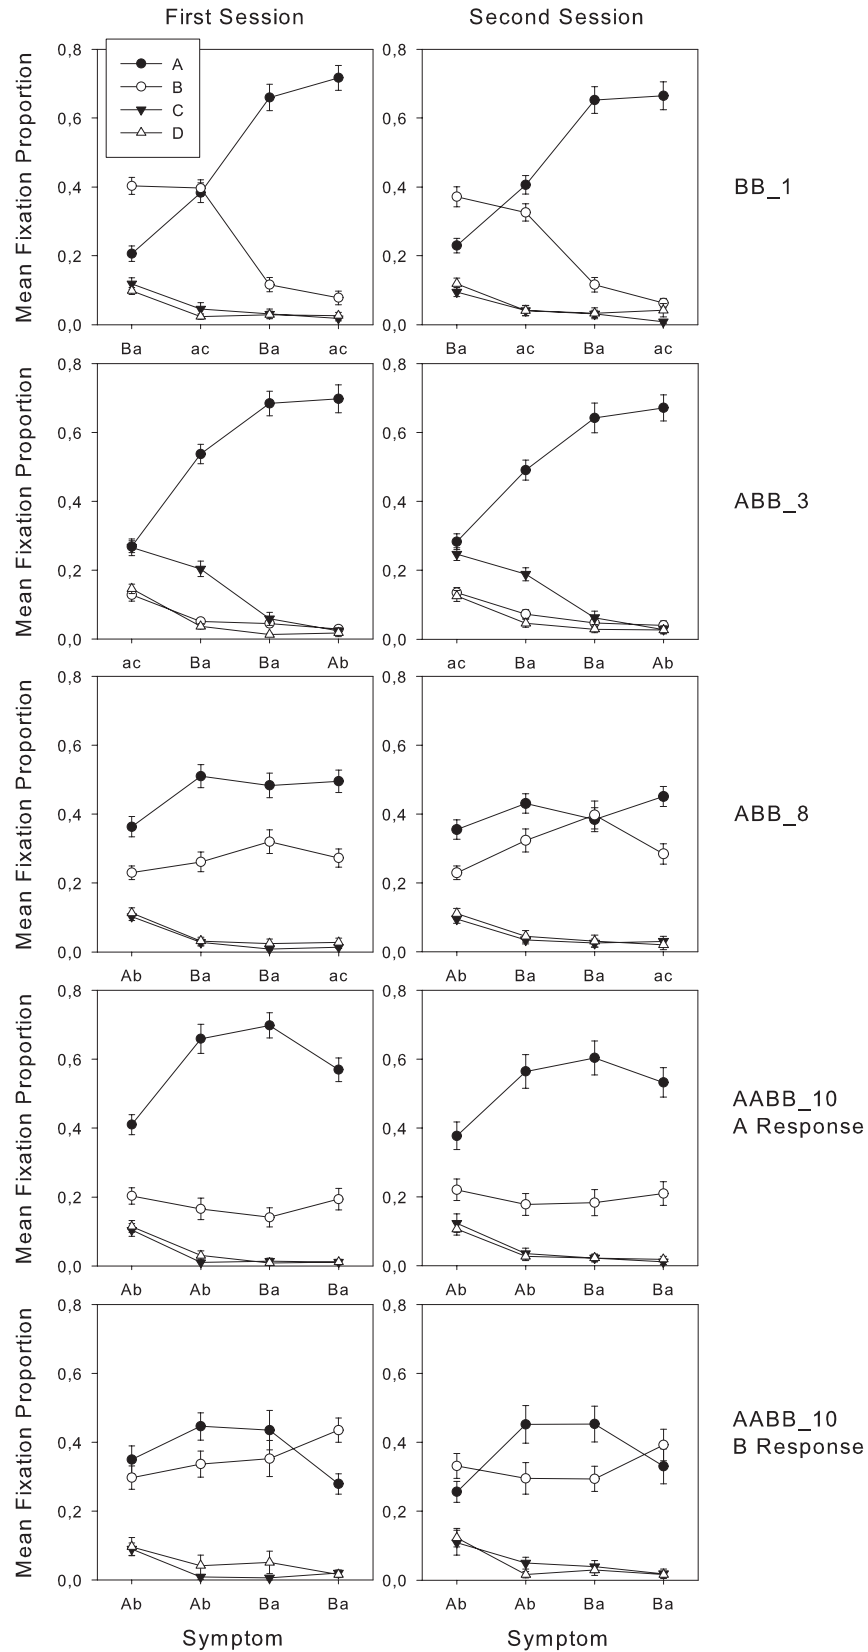

Figure 4: Mean fixation proportions on A-, B-, C, and D-quadrants in each interval of a symptom sequence. Fixation proportions for the ambiguous item type AABB\_10 are shown separately for trials answered with A and those answered with B. Error bars show the standard error of the mean.

When the diagnosis was determined late with an ac-symptom as the fourth symptom (ABB\_8) or not at all (AABB\_10), the alternative hypothesis B received considerable fixation proportions even in the fourth interval. In AABB\_10, fixation proportions were higher for B in the trials that were finally answered with B than in those finally answered with A.

Furthermore, ABB\_8, in which the diagnosis was determined late, showed a strong influence of the first symptom. The A-hypothesis that was supported more strongly by the first symptom and remained consistent with the following symptoms drew a larger fixation proportion than the alternative B-hypothesis in the second interval although the alternative was equally supported. For ABB\_8 in the first session, the A quadrant received a larger proportion even in the third interval although B was more strongly supported at this time. For the ambiguous item type AABB\_10, in which support was equal for A and B, fixation proportions were also influenced by the first symptom but finally rose for B above A when responded with B.

Overall, fixation proportions were similar in both sessions with a tendency towards fixation proportions better reflecting support for alternative hypotheses in the second session.

## Discussion

Process models of diagnostic reasoning postulate selective and changing activation of hypotheses in working memory during sequential symptom processing (Mehlhorn et al., 2011). To observe correlates of these memory dynamics, we have assigned the hypotheses to spatial locations and applied eye tracking for process tracing. Fixation proportions were influenced by memory activation because the possible causes (candidate hypotheses) had been spatially indexed during learning. Thus, process tracing was possible despite purely memory-based diagnostic reasoning. Extending previous successful applications of memory indexing (Renkewitz & Jahn, in press) and previous studies of looking-at-nothing (Richardson & Spivey, 2000), we found surprisingly stable patterns of fixation proportions one week after learning. Associations with locations and geometric figures in long-term memory strongly influenced gaze behavior similar to knowledge triggering fixations in the visual world paradigm.

The first symptom triggered fixations to its possible causes that are set up as focal hypotheses in working memory according to process models. The participants had to remember the symptom class that the first symptom belonged to and which chemicals could cause this symptom class. The result that fixation proportions were higher for more strongly supported hypotheses suggests that relative status as a focal hypothesis and the according activation level in working memory directed fixations. Hence, not just retrieval from long-term memory, but also rehearsal in working memory seems to trigger looking-at-nothing.

Excluded hypotheses did receive hardly any fixations in the subsequent intervals. Thus, fixations were not involuntarily directed towards any location associated with presented symptoms. Instead, symptoms supported the remaining focal hypothesis, and its location was fixated.

The unique information to be gained by memory indexing is clearly shown, for example, in the symptom sequence that starts with a symptom supporting strongly a hypothesis that is not the correct final diagnosis (BB\_1). The time course of fixation proportions reveals the change of the initial focal hypothesis that, of course, left no trace in the final response. And for the ambiguous item, for which the final response varied, memory indexing reveals that the finally chosen hypothesis is reflected in the relative weighting of focal hypotheses right from the beginning of the ambiguous symptom sequence.

Possibly, gaze was not only a correlate of memory activation, but also actively used as a deictic pointer to support or relieve working memory. In this study, gaze as deictic pointer was particularly useful because the spatial array of hypotheses matched the arrangement of response keys. Consequently, fixation proportions may reflect both memory activation and intended memory retention. Nonetheless, memory indexing revealed the current status of hypotheses in diagnostic reasoning, which proves this method as a valuable tool for informing and testing process models of information integration in reasoning and decision making.

## Abstract

Can gestures alter thought? Thinking about time is deeply interlinked with actions in space, and gestures are abstracted actions. Four experiments showed that gestures alter thinking about time. Participants heard the same speech accompanied by different gestures. The viewed gestures biased listeners toward circular or linear thinking, toward parallel or sequential thinking, toward moving-ego or moving-time perspectives. Gestures can abstract and show mental models more directly and succinctly than speech.

**Keywords:** Gesture, space, time, metaphor, diagram

## Introduction

As they say, life is just one thing after another. But there is more complexity to thinking about events in time. Historical and autobiographical events are often regarded as on a timeline, but events can also happen simultaneously, not a simple single sequence. Repeating events like seasons, days, and the cell cycle can be regarded as circular. Moreover, reasoning about events in time entails taking a perspective on the timeline. Two common perspectives are *moving-ego*, thinking of yourself as moving along a timeline (we're approaching summer), or *moving-time*, thinking of yourself as stationary on a timeline with events moving past you (summer is approaching) (e. g., Clark, 1973). These perspectives are analogous to a route or intrinsic or egocentric perspective in space; the viewpoint is embedded in space or in time, with ego as the reference (e.g., Levinson, 1996; Tversky, 1996). But just as it is possible to take an external or survey or absolute perspective on space, it is possible to take an external or absolute or calendar view on time, an outside perspective regarding events as ordered by dates. In the case of survey/absolute spatial perspective, the reference points are landmarks and the terms of reference are typically north-south-east-west. For external/absolute/calendar temporal perspective, the reference points are dates or events, and the terms of reference are earlier/later.

Whatever the perspective, how people think about events in time is highly interlinked to actions in space (Talmy, 2000; Tversky, 2011). The strong association between action, space, and time is reflected in the language people use when talking about time, the diagrams they draw when conveying events in time, and the gestures that accompany narratives of events in time. People say time "marches on", we "move through" time, one event occurs "before"

another, "time has passed", and "the future is ahead of us" (e. g., Clark, 1973; Evans, 2003; Lakoff and Johnson, 1999, Moore, 2006; Nunez, 1999). People's diagrams of events in time, such as the meals of a day, are typically ordered in reading order on a horizontal line (Tversky, Kugelmass, & Winter, 1991). When relating events in time, English speakers often move their hands from left to right, event by event (e.g. Cienki, 1998); they point frontwards for the future and backwards for the past (e.g. Cooperrider & Nunez, 2009). Language, diagrams, and gestures are ways of externalizing thought, and are congruent with thinking (Tversky, 2011).

If people use actions in space to express their conceptions of events in time, will seeing different forms of actions in space change their understanding of time? We address this question here, by explaining temporal events with identical language but different gestures.

Speakers everywhere gesture while they speak. Most gestures are redundant with the speech they accompany (McNeill, 1992), but gestures sometimes express information that is not expressed in speech (e. g., McNeil, 1992; Church & Goldin-Meadow, 1986; Goldin-Meadow, Alibali, & Church, 1993; Perry, Church, & Goldin-Meadow, 1988). Although some have questioned the communicative significance of gestures (Krauss, 1998; Rauscher, Krauss, Chen, 1996; Rimè & Shiaratura, 1991), there is good evidence that speakers often intend their gestures to be communicative (e. g., Cohen, 1977; Cohen & Harrison, 1973; Alibali, Heat, & Myers, 2001; Emmorey & Casey, 2001), and that gestures, whether redundant or mismatching, influence addressees' comprehension (Goldin-Meadow & Sandhofer, 1999; Thompson & Massaro, 1994).

Can the unique information in gesture alter listeners' mental models of a highly abstract yet familiar concept? In a series of studies on reasoning about time, we demonstrate that gestures affect addressee's conceptions of time by keeping speech constant but altering gestures.

## 1: Circular vs. Linear Thinking: Diagram

Prior work (Kessell & Tversky, submitted) has shown that people are biased towards linear thinking. Participants were asked to diagram four-step *cyclical* or *sequential* processes. Most participants drew linear diagrams even for cycles. Expecting congruency between conception and visualization, Kessell and Tversky concluded that circular

thinking is harder or less natural than linear thinking. Regarding time as a cycle is difficult because it requires abstraction from a particular instance of an event (i.e. a seed to a flower) to general classes of events. Thinking of time cyclically also requires ignoring the forward progression of time to thinking of time as traveling in a circle with no beginning, middle, or ending.

Even though participants did not produce a preponderance of circular representations for cycles, they did comprehend circular diagrams (Kessell & Tversky, submitted). Could circular hand gestures prime cyclical thinking?

## Method

**Participants.** 63 (40 female, 23 male) volunteers, mostly graduate students from Columbia University, participated.

**Procedure and Design.** All participants consented verbally to participate in the study. An experimenter said to each participant: "I will tell you about some events. I'd like you to think about these events and then construct a simple schematic diagram to convey them." One-third of participants were then told twice about one of the three cycles below:

Cycles
<b>Seed to flower:</b> <ul style="list-style-type: none"> <li>• A seed germinates</li> <li>• A flower grows</li> <li>• The flower is pollinated</li> <li>• A new seed is formed</li> </ul>
<b>Events of a day:</b> <ul style="list-style-type: none"> <li>• Wake up</li> <li>• Go to work</li> <li>• Come home</li> <li>• Go to sleep</li> </ul>
<b>Clothing Cycle:</b> <ul style="list-style-type: none"> <li>• Take clothes out</li> <li>• Wear clothes</li> <li>• Wash clothes</li> <li>• Put clothes away</li> </ul>

Figure 1: Cyclical Stimuli

Each example was identically worded but accompanied by linear, circular, or no gestures. For the *linear* condition, the experimenter made 4 discrete slicing gestures right to left for the 4 stages in the spoken text. For the *circular* condition, the experimenter made 4 pointing gestures at 12, 9, 6, and 3 o'clock for the 4 stages in the spoken text. The right-to-left and counter-clockwise directions were from the experimenter's point of view so compatible with the subject's perspective. For the *no-gesture* group, the experimenter kept her hands in pockets.

## Results

**Coding the diagrams.** Participants' diagrams were coded blindly as either linear, or circular. In circular (or repeating) diagrams the last event was connected back to the first, but not in linear (or ending) diagrams. Two of the diagrams

from the circular-gesture condition, and 2 from the no-gesture condition were coded as "other" (see Figure 2).

Figure 2: Examples of Diagrams

**Findings.** Of those who saw circular gestures, 66.7% drew circular diagrams. Of those who saw linear gestures, only 14.3% drew circular diagrams whereas 85.7% drew linear ones. As expected, of those who saw no gestures, 66.7% drew linear diagrams. Figure 3 shows the percent of linear, circular, and "other" types of diagrams for the three gesture conditions.

The form of gesture participants saw influenced the diagrams (excluding "other" diagrams) they drew; in a log-linear analysis, the two-way association between gesture condition and diagram type was significant,  $\chi^2(2)=17.668$ ,  $p=.000$ .

Post-hoc analyses showed significant effects of circular vs. linear gesture,  $\chi^2(1)=16.851$ ,  $p=.000$ , and circular vs. no-gesture,  $\chi^2(1)=10.556$ ,  $p=.001$ , on diagrams. No significant differences were found for linear vs. no-gesture conditions,  $\chi^2(1)=0.902$ ,  $p=.342$ . The number of circular diagrams was significantly higher than the number of linear diagrams in the circular-gesture condition,  $\chi^2(1)=4.439$ ,  $p=.035$ . As expected, the number of linear diagrams was significantly greater than the number of circular diagrams in the linear-gesture,  $\chi^2(1)=11.872$ ,  $p=.001$ , and no-gesture conditions,  $\chi^2(1)=4.439$ ,  $p=.035$ .

Figure 3: Proportion of linear, circular, and "other" diagrams by gesture conditions

## Discussion

Gestures had powerful effects on people's diagrams of events in time. People were asked to diagram a cyclical sequence of four events. Without gestures, a majority of participants drew linear diagrams. However, with circular gestures, a majority drew circular diagrams. If the way people diagram reflects the way they think, and there is considerable evidence for this (e. g., Tversky, 2011; Tversky, et al., 2002), then we can conclude that gestures affect the way people think about temporal events. However, it could be argued that participants copied the diagram the experimenter drew in the air. The next study obviates that objection by asking participants to make inferences.

## 2: Circular vs. Linear Thinking: Next Step

If seeing circular gestures induces cyclical thinking about time, then when participants are asked what comes after the "last" step they should tend to respond with the "first" step. This tendency should be reduced if linear gestures promote linear thought.

## Method

**Participants.** 60 volunteers, mostly graduate students from Columbia University participated in this study.

**Procedure and Design.** The procedure and design were the same as the previous experiment except that the no-gesture condition was eliminated, only the seed cycle was used, and instead of being asked to produce a diagram, participants were asked: "What comes after the new seed forms?"

## Results

**Coding.** Participants' answers to the question "what comes after?" were coded as linear or circular. Circular answers included repeating the first or any other stage and saying words such as *repeating* and *cycle*. Any other answers, such as "that was the last stage," "nothing," or "a fruit" were coded as linear.

**Findings.** In the circular gesture condition, 90% responded with circular answers, but in the linear gesture condition, only 60% responded circularly (Figure 4). In a log-linear analysis, the two-way association between gesture condition and answer type was significant,  $\chi^2(1) = 7.595$ ,  $p = .006$ . Interestingly, 30% of those who answered circularly in the linear gesture condition seemed unsure about their answers as they answered with a question tone.

## Discussion

The previous experiment had shown effects of gesture form on diagram form. Here, we found effects of gesture on inferences. When asked "what comes after?" once hearing the last of four stages of a cycle, participants who saw circular gestures were far more likely to respond with the first or subsequent step of the cycle than those who saw linear gestures. Will gesture affect other kinds of thinking about time?

Figure 4: Proportion of linear and circular answers for each gesture condition

## 3: Perspective: Moving Ego/Time

The first two experiments showed that circular gestures promoted cyclical conceptions of time. The next experiment asks whether gestures can bias perspectives on time.

When people are asked "Next Wednesday's meeting has been moved forward two days; when is the meeting now that it has been rescheduled?" half say Friday, and half say Monday (Boroditsky, 2000; McGlone & Harding, 1998). Those answering Friday see themselves as moving through time, taking an ego-moving perspective. Those who answer Monday see themselves as stationary and time as moving past them, taking a time-moving perspective (Boroditsky, 2000; McGlone & Harding, 1998; McTaggart, 1908). In a series of clever experiments, Boroditsky & Ramscar (2002) showed that although people have strong intuitions about which answer is correct, their answers change dramatically depending on how recently they have moved or seen movement in space. For example, people who have just landed at an airport are more likely to take an ego-moving perspective than those waiting to meet passengers. People sitting still but watching things move are more likely to take a time-moving perspective. Will seeing actions in space, notably gesture, have similar effects on temporal perspective taking?

## Method

**Participants.** 40 volunteers (25 female, 15 male), mostly graduate students from Columbia University participated in this study.

**Procedure and Design.** All participants consented verbally to participate in the study. While standing side by side, an experimenter told each participant: "Next Wednesday's meeting has been moved forward two days. What day is the meeting, now that it has been rescheduled?"

Participants were divided into two conditions: (1) forward sagittal gesture, and (2) backward sagittal gesture. In both conditions, the experimenter made a slice in the space in front of her body, with her palm facing her, while saying "next Wednesday's meeting", and then moved her hands away from her body for the *forward-gesture*, and towards

her for *backward-gesture* condition while saying “has been moved forward”. Note that participants and experimenter had identical points of view.

## Results

The majority of participants who saw the forward gesture answered that the meeting was moved to Friday whereas the majority who saw the backward gesture answered that the meeting was moved to Monday (Figure 5). One participant answered “not sure” and another, “Based on your gesture I’d say Friday, but based on your words, Monday”; these were coded as “other” and not included in the statistical analysis. In a log-linear analysis, the two-way association between condition (forward versus backward sagittal gesture), and answer type (Friday versus Monday) was significant,  $\chi^2(1)=21.510$ ,  $p=.000$ .

Figure 5: Proportion of participants answering “Friday” and “Monday” in each gesture conditions

## Discussion

When people are told that Wednesday’s meeting was moved forward two days and asked when the meeting is now, half spontaneously take an *ego-moving perspective*, answering Friday, and half take a *time-moving perspective*, answering Monday (e. g., Boroditsky, 2000; McGlone & Harding, 1998; McTaggart, 1908). Actually moving in space biases respondents toward the ego-moving perspective and watching movement from a stationary position biases the time-moving perspective (Boroditsky & Ramscar, 2002). Here, we found that observing representational actions, namely, gestures, also dramatically affected temporal perspective-taking. The experimenter first established a reference point for Wednesday in front of her body. When she gestured in a frontwards direction away from her body, a majority of participants responded that the meeting was moved to Friday, taking an ego-moving perspective, and when she moved her hand in a backwards direction towards her body, a majority of participants responded that the meeting was moved to Monday, taking a time-moving perspective.

Notably, the gestures were along the sagittal front-to-back axis of the body. For English speakers, the ego is the reference point, with future in the front of ego and the past behind (Cooperrider & Nunez, 2009). Here, the

experimenter made a new reference point by placing her hand in front of her body saying “Next Wednesday’s meeting,” so the reference is Wednesday rather than the ego. Then, the experimenter moved her hand along the axis either to the front of the reference point or to the back of the reference point with respect to the body. There is another possible account for the effects of the gestures, and some participants could have adopted one, some the other. Participants could have taken an external or calendar perspective, with the sagittal axis as a timeline and Wednesday as the reference point, with later events away from the body and the earlier events closer to the body. Either way, the gestures disambiguated the language and determined participants’ responses.

## 4: Parallel vs. Sequential Thinking

So far our experiments have shown that gestures alter the way people think of a sequence of events in time. Yet in life, people often have to keep track of events that happen simultaneously, a task that can be difficult (e. g., Bauer & Johnson-Laird, 1993). In one study, students had difficulties comprehending that the two middle steps of a four-step procedure for writing a paper were simultaneous. A diagram showing the simultaneous events side-by-side helped (Glenberg & Langston, 1992). Like diagrams, and in contrast to serial language, gestures can organize things in space and show simultaneity (e. g., Tversky, Heiser, Lee, & Daniel, 2009). Might gestures help people think about parallel events in time?

## Method

**Participants.** 60 volunteers, mostly graduate students from Columbia University participated in this study.

**Procedure and Design.** After receiving verbal consent for participation, an experimenter said to each participant: “I will tell you about a procedure, and then ask you a quick question about it”. Participants were then told the following procedure for writing a paper (based on Glenberg & Langston, 1992): “There are four steps to be taken when writing a paper. The first step is to write a first draft. The next two steps should be taken at the same time: One of the steps is to consider the structure; the other step is to address the audience. The final step is to proofread the paper.”

Participants were divided into two conditions: (1) parallel-gesture, and (2) sequential gesture. For the *parallel-gesture condition*, the experimenter made a slice in the air in front of her face, with her right hand palm facing down, while saying “the first step is to write a first draft”. Next, she made two slices with two hands simultaneously below her first hand gesture, while saying “the next two steps should be taken at the same time”. Next, she moved her right hand back and forth from her wrist, in place, with her left hand still in the air, while saying, “one of the steps is to consider the structure”. Then, she reversed those hand actions while saying, “the other step is to address the audience”. Next, she took away her left hand and made a slice with her right hand facing down, below its previous spot, while saying, “the

final step is proof read the paper.” For the *sequential-gesture* condition, the experimenter made 4 slices with her right hand facing down, from top to bottom on a vertical line in front of her, for the 4 steps in the procedure.

After hearing the description twice, participants were asked: “Here is the question now: According to the procedure I just gave you, what should one do immediately after writing the first draft/ before proof reading the paper?” Half of the participants in each condition were asked about steps *after* writing the first draft, and the other half were asked about steps *before* proof reading the paper.

## Results

**Coding.** Participants’ answers to before/after questions were coded as sequential, parallel, or other. Answers that mentioned only one of the two steps (*considering the structure* or *addressing the audience*) were coded as sequential. Answers that mentioned both steps were coded as parallel. Any other answer was coded as “other”.

**Data analysis.** In the *parallel-gesture* condition, 76.7% mentioned both steps while only 56.7% in the *sequential-gesture* condition gave *parallel* answer. Forty percent of participants in the sequential-gesture condition but only 10% of subjects in the *parallel-gesture* condition mentioned a single step (Figure 6). Four participants in the parallel-gesture condition, and one in the sequential-gesture condition mentioned other steps and were excluded from the data analysis.

In a log-linear analysis, the two-way association between gesture type and answer was significant,  $\chi^2(1) = 6.276$ ,  $p = .012$ . However, the two-way association between question type (before vs. after) with answer (parallel vs. sequential) was not significant,  $\chi^2(1) = 1.988$ ,  $p = .159$ , nor was its three-way association with condition (parallel- vs. sequential-gesture) and answer type,  $\chi^2(1) = 0.114$ ,  $p = .736$ .

In addition, significantly more participants in the parallel-gesture condition gave parallel answers than sequential answers,  $\chi^2(1) = 17.447$ ,  $p = .000$ . There was no significant difference between number of parallel and sequential answers in the sequential-gesture condition,  $\chi^2(1) = 0.866$ ,  $p = .35$ .

Figure 6: Proportion of parallel, sequential, and “other” answers in parallel- and sequential-gesture conditions

## Discussion

We have shown yet again that gesture influences how people think about time. Previous research (e. g., Bauer & Johnson-Laird, 1993) had shown that people find it difficult to conceptualize parallel events. Here we showed that gestures that indicate the parallel structure of events help people to reason about simultaneity of events.

## General Discussion

One way that people think of events in time is through space, as dots, representing events, on a line, representing time. The line can be regarded as straight, a linear sequence of events, perhaps, as in most narratives, having a beginning, middle, and end. For events that repeat, like the parts of the day or the seasons of the year, the line can be regarded as circular. Simultaneous events can be thought of as parallel lines. The mental time lines typically have a spatial orientation and a perspective. When straight, that line can be regarded as horizontal in reading order, vertical in top-down order (Boroditsky 2001; Tversky, et al., 1996) or sagittal from front to back (Cooperider & Nunez, 2009). Thinking and talking about time use target and reference events and a perspective on time, just like thinking and talking about space (e. g., Talmy, 2000). People can take an external perspective on the line, as in looking at a calendar or a timeline, much like taking an overview of an environment or looking at a map. Alternatively, they can see themselves embedded in time just as they can see themselves embedded in space. The ego can serve as a reference point, located on the timeline. In the ego-moving perspective, ego moves along events on the timeline; in the time-moving perspective, ego is stationary and events move past ego. Either way, changes in time are conceived of as actions in space. If changes in time are conceived of as actions in space, then actions in space might affect conceptions of time. Indeed, Boroditsky and Ramscar (2002) showed exactly that, that moving in space or watching movement in space alters temporal perspective. Here we found that information in gestures but not in speech could also alter people’s conceptions of time. Circular gestures biased thinking about a series of events as a cyclical rather than linear. Frontwards gestures away from the body biased taking an ego-moving perspective on time and gestures toward the body biased taking a time-moving perspective. Finally, gestures that traced parallel paths helped people think about simultaneous events.

Why do gestures have such powerful effects on thought? Many gestures are miniature actions in space that represent actual actions. For representing time, the gestures traced temporal paths in space, and indicated specific events along the paths. In representing paths as lines and events as dots, gestures are like diagrams (Tversky, 2011; Tversky, et al., 2009). The set of gestures both abstracts a model of time and shows it, a more direct way to communicate than purely symbolic speech.

## Abstract

In two experiments, we aimed to show the importance of task characteristics in scalar implicature production. In Experiment 1, we found that five-year-olds were significantly more pragmatic when given an Action-Based Task (ABT), in which they had to respond by performing an action than in a Truth-Value Judgement Task (TVJT), in which they had to evaluate the truth-value of statements. Experiment 2 showed that seven-year-olds were almost exclusively pragmatic on the same ABT and TVJT used in Experiment 1. However, we found a 22% drop in pragmatic responses when the TVJT contained world-knowledge statements (rather than statements about simple objects such as marbles). Together, these two experiments provide evidence that not only the nature of the task, but also its specific content is crucial in determining the extent to which young children produce scalar implicatures.

**Keywords:** scalar implicatures; task characteristics; ABT; TVJT.

## Introduction

People communicate with each other to express what they feel, think, want, etc. Although this seems to happen effortlessly and automatically, the communication process is more than just the simple encoding and decoding of a message by a messenger and a receiver. Not only the literal meaning of a sentence is important, but also the implicit meaning that the speaker wants to communicate. The first systematic attempt to explain how these inferences are derived, belongs to Paul Grice. He offered a comprehensive framework of the mechanics of inferential communication (Grice, 1975). According to Grice, communication is a co-operative enterprise between people, governed by certain relational expectations about how a conversational exchange should be conducted. These relational expectations are called 'maxims' and Grice proposed four of these maxims: the Maxim of Quantity, the Maxim of Quality, the Maxim of Relation and the Maxim of Manner. These maxims respectively imply that interlocutors are always expected to offer contributions which are informative, truthful, relevant to the goals of the conversation and appropriately phrased. Grice introduced the term 'implicature', which refers to the

meaning that is implied by the speaker but not explicitly stated.

Considerable experimental research has been devoted to *scalar implicatures*, i.e. implicatures based on the existence of ordered terms on a scale of informativity (e.g., <all, most, many, some>). The general consensus is that the weaker term (e.g., the quantifier *some*), while logically compatible with a stronger term from the same scale (e.g., *all*), prompts the inference that '*all*' is not the case because the speaker did not use the stronger term. Therefore, the scalar expression '*some*' can be interpreted in two ways: either in an inference-driven, pragmatic reading, which excludes '*all*', or in its literal, semantic meaning, which is compatible with '*all*'.

Recent experimental investigations into children's interpretation of scalar terms have concluded that preschool children are often insensitive to scalar implicatures in tasks involving language comprehension (Chierchia et al., 2001; Noveck, 2001). In these studies, children, although otherwise linguistically competent, were shown to attend only to the logical/semantic meaning of the scalar terms. For example, Noveck (2001) found that 89% of the seven-to-eight-year olds in his study agreed with statements such as 'Some giraffes have long necks.' Such behavior has led Noveck (2001) to conclude that "younger, albeit competent reasoners, initially treat a relatively weak term logically before becoming aware of its pragmatic potential", and that, in this respect, "children are more logical than adults" (Noveck, 2001, p. 165).

The availability of cognitive resources is often used to explain this typically found pragmatic delay in children. As suggested by Noveck (2001), a plausible explanation for this delay is that inferring scalar implicatures requires effort and that children have less cognitive resources available than adults. Two different theories make different predictions regarding this issue. According to the neo-Gricean theorists (e.g., Levinson, 2000), implicature production happens automatically and only its inhibition demands processing costs. Relevance Theory (Sperber & Wilson, 1995) in contrast, suggests that an implicature will only be produced if it is relevant in the context and they state that this production requires additional processing costs. Evidence in favour of Relevance Theory, regarding scalar implicatures, has been presented among others by Noveck and Posada

(2003). Their experiments indicated that pragmatic answers require more time than logical answers. Assuming that longer time is associated with more processing costs, this provides indirect evidence for Relevance Theory.

In contrast to research showing that children initially reason logically, there is also substantial experimental evidence that children are not incapable of drawing scalar inferences and that they are aware of the pragmatic potential of scalar expressions. In these kinds of studies, the prime interest is to discover what conditions facilitate implicature production for children. A key factor seems to be the nature of the task. For instance, Foppolo, Guasti, and Chierchia (2004) conducted experiments concerning the quantitative scale <all, some> using two different tasks: a Truth-Value Judgement Task (TVJT) (Crain & Thornton, 1998), in which participants had to decide whether (under-informative) statements were true or false, and a Felicity Judgement Task (FJT) (Chierchia et al., 2001). In the FJT, participants were presented with a pair of utterances with the same truth-value but different levels of appropriateness and were asked to choose the most felicitous description.

When five-year-olds completed the FJT, the number of pragmatic responses was 95% while the number of pragmatic responses in the TVJT was only 50%.

Pouscoulous et al. (2007) also examined the role of the nature of the task. In their first experiment, they replicated earlier findings showing that nine-year-olds were more likely than adults to consider as true statements such as 'Some turtles are in the boxes' (uttered when all turtles are in the boxes) in a TVJT. In their second experiment, they presented an Action-Based Task (ABT), in which participants did not have to give a metalinguistic evaluation of statements but had to respond by performing an action. Children were presented with five boxes and five tokens. They were asked to adapt the situation to make it compatible with a statement. For example, if they were told "I would like all the boxes to contain a token" and two of the five boxes already contained a token, they were expected to put a token in every empty box. The results showed that, when children were asked to perform an action rather than give a metalinguistic truth evaluation, the number of implicatures made by the children increases.

In our own study we built on these experiments by Pouscoulous et al. (2007).

## Experiment 1

Our primary goal was to directly test the role played by the nature of the task in implicature production by five-year-olds. We therefore made three important changes to the Pouscoulous et al. (2007) study.

First, we presented the same group of children with both a TVJT and an ABT: manipulating the nature of the task within subjects allowed direct comparison between the two tasks.

Second, there was an important difference in content between the ABT and TVJT used by Pouscoulous et al. (2007). Whereas the ABT in Pouscoulous et al. (2007) only used tokens and boxes, in the TVJT, the children were presented with three types of animals that remained in front of them throughout the task. For each statement, they had to focus on one type of animal and ignore the other animals. Since the statements were randomly ordered, they constantly had to switch their attention between the three types, which placed greater demands on information processing than in the ABT. To remedy this problem, we made the two tasks more similar in design.

Third, we measured children's working memory (WM) capacity and compared a group of low WM-span children with a group of high WM-span children. As Pouscoulous et al. (2007) suggested, cognitive resources are important in implicature production and may explain why easier tasks, that require less cognitive resources, lead to more pragmatic answers than more difficult tasks. In adults, it has been shown that burdening WM decreases implicature production by 10% (De Neys & Schaeken, 2007). Consequently, it can be assumed that people with less cognitive resources will be less pragmatic than people with more cognitive resources. But so far, no research has been conducted on children that directly investigated the role of cognitive resources. That is why we will measure WM-capacity in the children in our experiments and investigate whether children with a high WM-capacity produce more scalar implicatures than children with a low WM-capacity.

## Method

**Participants** The sample comprised 48 five-year-olds (28 boys and 20 girls) between the ages of 5.2 and 6.1 with a mean age of 5.6 (SD=1.15), recruited from two different schools in Belgium. All were native Dutch speakers.

**Action-Based Task (ABT)** The ABT consisted of three scenarios, each involving five plastic boxes and five marbles. In the 'All-scenario', all five boxes contained a marble. In the 'None-scenario', all the boxes were empty. In the 'Subset scenario', two boxes contained a marble. In each scenario, a puppet, handled by the experimenter, was used to utter the same four requests: 'I would like all the boxes to contain a marble' ('Ik zou willen dat er in alle dozen een knikker zit'), 'I would like some boxes to contain a marble' ('Ik zou willen dat er in sommige dozen een knikker zit'), 'I would like none of the boxes to contain a marble' ('Ik zou willen dat er in geen van de dozen een knikker zit') and 'I would like some boxes not to contain a marble' ('Ik zou willen dat er in sommige dozen geen knikker zit'). This amounted to a total of 12 requests. The participants were instructed to make changes to the scenario to comply with the puppet's requests. For example, if the puppet said 'I would like all the boxes to contain a marble' in the 'Subset-scenario', the child was expected to put a marble in the three empty boxes.

There were two critical situations and 10 control statements. The first critical statement occurred in the 'All-scenario' when the puppet stated 'I would like some boxes to contain a marble'. If the child interprets 'some' logically, he or she will make no changes to the scenario. However, if the child grasps the implicature, he or she will take at least one of the marbles away. The second critical statement occurred in the 'None-scenario' when the puppet uttered the statement 'I would like some boxes not to contain a marble'. In this case, if the child interprets the statement logically, no action should be taken. A pragmatic interpretation, on the other hand, would require an action (adding at least one marble to the boxes).

For the 10 control statements, there was no distinction possible between pragmatic and logic interpretations. An example is 'I would like all the boxes to contain a marble' in the 'None-scenario'. In this case the child is expected to put a marble in all 5 empty boxes.

**Truth-Value Judgement Task (TVJT)** The children were presented with five boxes and five marbles in the three same scenarios as in the ABT. In each scenario, a puppet made the same four statements (amounting to a total of 12 sentences): 'All the marbles are in the boxes' ('Alle knikkers zitten in de dozen'), 'Some marbles are in the boxes' ('Sommige knikkers zitten in de dozen'), 'None of the marbles are in the boxes' ('Geen van de knikkers zit in een doos') and 'Some marbles are not in the boxes' ('Sommige knikkers zitten niet in de dozen'). After each statement, participants had to decide whether it was true or false. The two critical statements were '*Some marbles are in the boxes*' in the 'All-scenario' and '*Some marbles are not in the boxes*' in the 'None-scenario'. In both cases, 'true' would be the logical answer, whereas 'false' would be the pragmatic answer.

The other 10 statements were control statements (e.g. '*Some marbles are in the boxes*' in the 'Subset-scenario').

**Working Memory Tasks** The children performed three WM-tasks. First, the auditory (phonological loop) component was measured using the Digit Span Forward task in which subjects have to repeat an orally presented list of numbers. The list starts with a sequence of two numbers and keeps increasing until the child makes two errors within one block of the same digit-length. Second, the visual component (visuo-spatial sketchpad) was measured using the Corsi Block Span test. In this test, the children were presented with nine wooden blocks on which the experimenter tapped a pattern and the children were instructed to repeat the sequence. The sequence becomes longer until the child makes two errors within one block of the same difficulty level. The third WM task, which was intended to provide a 'central executive' measure, was the Digit Span Backward task. This task is identical to the Digit Span Forward, except that the subject needs to repeat the numbers in reverse order. The raw scores for each of these tasks (i.e. the total number of correct answers) were

converted into z-scores, which were then added up to compute the WM span.

**Procedure** Each participant was interviewed individually for about 20 minutes. Participants first completed the three WM tasks. The order of the other two tasks was randomized, so that half of the participants started with the TVJT and the other half with the ABT. In both tasks, the experimenter used a puppet called Minnie. In the TVJT, the children were informed that the puppet sometimes says things that are correct and sometimes says things that are wrong. In the ABT, the children were told that the puppet would give instructions regarding the boxes and the marbles and that they would either have to remove marbles, add marbles, or make no changes. Before the start of the experiment, the children were given three practice questions in the ABT. These questions were very similar to the experimental sentences but employed numbers instead of quantifiers. The three training questions were: '*I would like two boxes to contain a marble*', when only one box contained a marble, '*I would like three boxes to contain a marble*', when three boxes contained a marble and '*I would like two boxes to contain a marble*', when three boxes contained a marble. These training questions were constructed so that the participants had to remove marbles, add marbles and change nothing. This way, they got acquainted with all types of actions they would have to perform during the experiment. If the children made errors on these training questions, the experimenter corrected them and explained their mistakes.

## Results

We hypothesized that there would be differences in implicature production and performance between the TVJT and the ABT. Our hypothesis about the difference in performance was confirmed by the finding that the TVJT leads to significantly more errors than the ABT on the control statements (9% versus 5%, respectively. Wilcoxon Matched Pairs test,  $n=23$ ;  $T=57.5$ ;  $p=.011$ ).

With regard to the critical sentences, we hypothesized that the ABT would lead to more pragmatic answers than the TVJT. Again, our hypothesis was confirmed. The children responded pragmatically to the critical sentences in 91% of the instances on the ABT, compared to 70% on the TVJT (Wilcoxon Matched Pairs test,  $n=20$ ;  $T=22.5$ ;  $p=.002$ ). These results are shown in Table 1.

For both tasks, we compared a high WM-span group ( $N=16$ ;  $M=2.13$ ;  $SD=0.82$ ) with a low WM-span group ( $N=16$ ;  $M=-2.37$ ;  $SD=1.42$ ) with regard to the number of correct answers to the control sentences and the number of pragmatic responses. While there were no significant differences in pragmatic processing, the number of correct responses to the unambiguous control sentences differed significantly between the two groups. The high-span group was more accurate than the low-span group on both the ABT (98% vs 91% correct answers; Mann-Whitney U test,

Table 1: Percentage of logical responses in each scenario of the TVJT and ABT (Experiment 1).

Utterance	Task	All-scenario	None-scenario	Subset-scenario
(1) All the marbles are in the boxes.	TVJT	100%	100%	98%
(1) I would like all the boxes to contain a marble.	ABT	98%	100%	100%
(2) Some marbles are in the boxes.	TVJT	<b>23%</b>	100%	96%
(2) I would like some boxes to contain a marble.	ABT	<b>4%</b>	96%	98%
(3) None of the marbles are in the boxes.	TVJT	96%	85%	88%
(3) I would like none of the boxes to contain a marble.	ABT	98%	92%	98%
(4) Some marbles are not in the boxes.	TVJT	94%	<b>37%</b>	58%
(4) I would like some boxes not to contain a marble.	ABT	92%	<b>15%</b>	83%

Note: critical statements are in bold

$n_1=16$ ,  $n_2=16$ ;  $U=96.5$ ;  $z=-1.72$   $p=.04$ ) and the TVJT (94% vs 87% correct answers; Mann-Whitney U test,  $n_1=16$ ,  $n_2=16$ ;  $U=76$ ;  $z=-2.06$ ;  $p=.02$ ).

## Discussion

The ABT led to significantly more pragmatic answers than the TVJT. In addition, the five-year-olds made fewer mistakes on the ABT control statements than on the TVJT control statements.

These results indicate that meta-linguistic tasks are harder than tasks that require no verbal response.

Our results show that even five-year-old children are competent pragmatic reasoners. Their competence is still ‘vulnerable’, but taking into account certain factors such as task complexity, task content, context, training, etc., they are capable of producing scalar implicatures on a high level. This confirms the findings of Pouscoulous et al. (2007). Moreover, the validity of our results was enhanced by manipulating the nature of the tasks within participants and by changing the design of the TVJT to make it more comparable to the ABT. This allows us to attribute the results to the task’s cognitive demands and to conclude that the nature of the task is crucial in implicature processing in five-year-olds.

Our WM-measures revealed no significant differences in implicature processing between a group of low-span children and a group of high-span children. Although the high-span children made significantly fewer errors on the control statements, these WM-results do not allow us to draw firm conclusions about the role of WM in implicature processing.

Remarkably, the five-year-olds in our experiment produced a much higher percentage of pragmatic answers than the children tested in Pouscoulous et al. (2007). They were equally pragmatic on the ABT and more pragmatic on the TVJT than the seven-year-olds and the adults in Pouscoulous et al. (2007), who conclude that “Only 7-year-olds reveal behavior that approaches that of adults among the standard cases and even among them adultlike implicature performance is less likely when it concerns negative sentences” (Pouscoulous et al., 2007, p.371). Since we had only investigated one age-group (five-year-olds) and

since the age of seven is mostly found to be the age at which children really begin to demonstrate pragmatic skills (Guasti et al., 2005), we ran the same experiment with a group of seven-year-olds. We expected them to be even more pragmatic than the five-year-olds. In addition to the ABT and TVJT used in Experiment 1, we included a TVJT that is often used in experimental research on implicatures, i.e. the world-knowledge TVJT from Noveck (2001).

## Experiment 2

### Method

**Participants** Thirty-four seven-year-olds (18 girls, 16 boys) between the ages of 6.9 and 8.5 with a mean age of 7.5 ( $SD=.32$ ) participated in this experiment. All participants were recruited from the same school and were native Dutch speakers.

**TVJT, ABT and WM Tasks** The same TVJT, ABT and three WM tasks were used as in Experiment 1.

**World-knowledge TVJT** In order to investigate whether the specific content of the task plays a role in implicature production, the seven-year-olds conducted a task based on Noveck (2001; Experiment 3). In this task, the children were presented with 30 statements (translated into Dutch) and were instructed to indicate whether or not they agreed with each statement. The sentences were based on three types of information: factually universal (that elephants have trunks is arguably best represented with the quantifier All), factually existential (that birds live in cages is arguably best represented with Some), and absurd (that stores are made of bubbles is arguably false with both kinds of quantifiers). The statements can be categorized in six subgroups:

- (a) Five absurd *All* sentences (e.g. All birds have telephones.)
- (b) Five absurd *Some* sentences (e.g. Some fish are made of leaves.)
- (c) Five true *All* sentences (e.g. All elephants have trunks.)

- (d) Five true (and felicitous) *Some* sentences (e.g. Some flowers are yellow.)
- (e) Five false *All* sentences (e.g. All dogs have spots.)
- (f) Five true (but pragmatically infelicitous) *Some* sentences (e.g. Some giraffes have long necks.)

We were particularly interested in the sentences from category (f). If children agree with such statements they are responding logically, while disagreeing implies a pragmatic response. If we look at the different types of statements, it is clear that switching quantifiers can make (c) interchangeable with (f) as well as (d) with (e). In this way, we created two versions of this task. In each version, both the *All* and the *Some* sentences were randomized, as were the different types of statements.

**Procedure** The procedure was exactly the same as in Experiment 1. However, an additional test was administered after all other tests were performed. All children received a paper with the 30 statements included in the world-knowledge TVJT. These statements were read out to them and they were asked to indicate, for each statement, whether they agreed or disagreed by circling the appropriate answer.

## Results

The TVJT control statements led to 96% correct answers, compared to 99% for the ABT (Wilcoxon Matched Pairs test,  $n=11$ ,  $T=66$ ,  $p=.001$ ). For the control statements of the world-knowledge TVJT, the number of correct answers was 94%, which differed significantly from the ABT (Wilcoxon Matched Pairs test,  $n=3$ ,  $T=42$ ,  $p<.001$ ), though not from the other TVJT (Wilcoxon Matched Pairs test,  $n=9$ ,  $T=133$ ,  $p=.11$ ). Regarding the critical sentences, there were no significant differences between the TVJT and the ABT in the number of pragmatic answers (91% versus 94%, respectively; Wilcoxon Matched Pairs test,  $n=5$ ,  $T=22.5$ ,  $p=.48$ ). In contrast, the world-knowledge TVJT only yielded 69% pragmatic answers, which differed significantly from the other TVJT (Wilcoxon Matched Pairs test,  $n=3$ ,  $T=46.5$ ,  $p=.005$ ) and from the ABT (Wilcoxon Matched Pairs test,  $n=3$ ,  $T=34.5$ ,  $p=.003$ ). The results of the ABT and the TVJT

are shown in Table 2 whereas the results of the world-knowledge TVJT are shown in Table 3.

As in Experiment 1, we compared a group of high WM-span children ( $N=11$ ;  $M=2.32$ ;  $SD=1.07$ ) with a low-span group ( $N=11$ ;  $M=-2.38$ ;  $SD=1.06$ ). No significant differences were found between the two groups on any of the three tasks, neither in pragmatic responses, nor in performance on the unambiguous sentences.

## General Discussion

The two studies reported in this article investigated the role of the task in scalar implicature production in young children. Our goal was to show that the kind of task and even the specific task content has an important impact on scalar implicature production. In Experiment 1, we investigated five-year-old children. We found, as expected, that a more difficult TVJT caused the children to be less accurate and less pragmatic than an ABT in which children did not have to answer verbally. Given our methodological improvements, this difference was not caused by a difference in task design but by a difference in task complexity. Manipulating the nature of the task is sufficient to show that, under the right circumstances, children as young as five years are capable of spontaneously producing implicatures.

In Experiment 2, we investigated a group of seven-year-olds whom we expected to be even more pragmatic than the five-year-olds in Experiment 1. This expectation was confirmed by the results: the pragmatic response rate was so high that it did not lead to a significant difference between the ABT and the TVJT. However, when the children performed a TVJT involving world-knowledge statements, pragmatic responses dropped by 22%. For the world-knowledge TVJT, the children need to rely on the knowledge they have stored in their memory, whereas in the simple TVJT, they just have to rely on the boxes and marbles in front of them, which is less demanding on memory resources.

Table 2: Percentage of logical responses in each scenario of the TVJT and ABT (Experiment 2).

Utterance	Task	All-scenario	None-scenario	Subset-scenario
(1) All the marbles are in the boxes.	TVJT	100%	100%	100%
(1) I would like all the boxes to contain a marble.	ABT	100%	100%	100%
(2) Some marbles are in the boxes.	TVJT	<b>0%</b>	100%	94%
(2) I would like some boxes to contain a marble.	ABT	<b>3%</b>	100%	100%
(3) None of the marbles are in the boxes.	TVJT	97%	94%	97%
(3) I would like none of the boxes to contain a marble.	ABT	100%	100%	100%
(4) Some marbles are not in the boxes.	TVJT	97%	<b>18%</b>	79%
(4) I would like some boxes not to contain a marble.	ABT	100%	<b>9%</b>	91%

Note: critical statements are in bold

Table 3: Percentage of logical responses on the world-knowledge TVJT (Experiment 2).

Sentence type	Correct Response	
Utterances expressed with All		
Absurd (false) (e.g. All birds have telephones)	No	97%
Appropriate (true) (e.g. All elephants have trunks)	Yes	94%
Inappropriate (false) (e.g. All dogs have spots)	No	92%
Utterances expressed with Some		
Absurd (false) (e.g. Some fish are made of leaves)	No	100%
Appropriate (true) (e.g. Some flowers are yellow.)	Yes	82%
<b>Inappropriate (true though pragmatically infelicitous)</b> <b>(e.g. Some giraffes have long necks)</b>	<b>Yes</b>	<b>31%</b>

Note: critical statements are in bold

Another difference between the two TVJT's is that the TVJT with the marbles and the boxes is based on visual input (the marbles and the boxes) whereas the world-knowledge TVJT is not based on visual input. The hypothesis that easier tasks lead to significantly more pragmatic answers than more difficult tasks is based on the assumption that cognitive resources are critical in implicature production (De Neys & Schaeken, 2007). As easier tasks require fewer cognitive resources than complex tasks, more cognitive resources remain available for producing implicatures.

Based on these assumptions, we hypothesized that children with a high WM-capacity would be more pragmatic than children with a low WM-capacity since they have more cognitive resources available. This hypothesis was not confirmed.

Even when we performed the WM-analyses on the combined sample from both experiments (with the highest scoring children in each experiment as the 'high-group' and the lowest scoring children as the 'low-group'), we did not find a significant WM-effect. Although a certain trend can be observed in our WM-data, we are unable to find a single significant WM-effect. However, this is hardly surprising given that the significant WM-effect found in adults is small (De Neys and Schaeken, 2007), which ensures a smooth flow of communication.

In sum, the key finding of the present study is that the nature of the task and the specific task content are very important in scalar implicature production in young children: more cognitive tasks or more cognitive task content cause a decrease in implicature production. This factor has to be taken into account when investigating implicature production in children. Another factor that might need to be taken into account in future research is a

measure of general language ability. Since it was found that metalinguistic tasks are harder than action-tasks, it is plausible that general language ability may account at least partly for these results.

## Acknowledgments

We would like to thank all schools – Sint-Pietersschool Korbeek-Lo', 'Ark Leuven' and 'Gemeentelijke basisschool Pellenberg'- for allowing us to run our experiments. Leen Janssens is a research assistant from the Fund for Scientific Research Flanders.

## Abstract

Observing the actions of other people allows us to learn not only about their mental states, but also about hidden aspects of a shared environmental situation – things we cannot see, but they can, and that influence their behavior in predictable ways. This paper presents a computational model of how people can learn about the world through these social inferences, supported by the same *Theory of Mind* (ToM) that enables representing and reasoning about an agent’s mental states such as beliefs, desires, and intentions. The model is an extension of the Bayesian Theory of Mind (BToM) model of Baker et al. (2011), which treats observed intentional actions as the output of an approximately rational planning process and then reasons backwards to infer the most likely inputs to the agent’s planner – in this case, the locations and states of utility sources (potential goal objects) in the environment. We conducted a large-scale experiment comparing the world-state inferences of the BToM model and those of human subjects, given observations of agents moving along various trajectories in simple spatial environments. The model quantitatively predicts subjects’ graded beliefs about possible world states with high accuracy – and substantially better than a non-mentalistic feature-based model with many more free parameters. These results show the power of social learning for acquiring surprisingly fine-grained knowledge about the world.

**Keywords:** Social Cognition; Theory of Mind; Social Learning; Reinforcement Learning

## Introduction

The most obvious way to learn about the world is by direct observation. You may believe there is a Starbucks across the street from your office because you have passed it many times, and believe it is open at this moment because you just passed by a few minutes ago and saw a number of people going in and out. But many aspects of the world are unobservable and must be inferred indirectly, often based on observing the actions of other people who know or perceive what you do not. Consider the situation of driving or biking and needing to turn left at an intersection onto a busy street, across oncoming traffic. Of course before turning you will check to see whether there are any cars coming down the busy street from the left, but suppose there is a large truck parked on the street, blocking your view so that you cannot see whether there is any oncoming traffic. You may inch out slowly until you can see, but you may also observe what other drivers or pedestrians are doing. If they are in a position to see the oncoming cars that you cannot, and if they are crossing the busy street at the same point you wish to turn, then it is a good bet that your turn would also be safe.

Making such a judgment is literally betting your life on a mental model of another person’s cognitive processes – a Theory of Mind (ToM) (e.g. Dennett, 1987; Wellman, 1990;

Gopnik & Meltzoff, 1997). Implicitly you assume basic aspects of rationality in the person you see crossing the street: that they want to cross safely, that they update their beliefs about the presence of oncoming cars based on what they can see, and that they plan their actions appropriately to achieve their goals given their beliefs. If they are clearly paying attention to the side of the street you cannot see, and they are walking across unhurriedly and unworriedly, it is then a good bet that no traffic is headed imminently toward them; if they are jumping or dashing out of the way, that is another story.

Accounts of distinctively human cognition often emphasize the sophisticated representational power of people’s ToM, as in the capacity to represent arbitrary belief states, false beliefs as well as true ones, and predict how people will act accordingly. But just as or more important is the sophisticated inferential power of ToM: how we can learn about the contents of other agents’ mental states, or even the structure of the world, by reasoning backwards to the best explanations of agents’ observed behaviors. This kind of inverse reasoning underlies not only the traffic example above, but many other situations of practical importance for everyday cognition. For example, if you see people filing out of a new restaurant with contented looks, it is a good bet the food inside is satisfying. If you see someone enter the restaurant with an expression of eager anticipation, then exit a moment later and start looking for a different place to eat, you might guess that the restaurant is unexpectedly closed – or perhaps he mistook it for a different place. If your friend the foodie goes far out of his way while visiting a new city to visit a particular restaurant, you can bet that place is one of the city’s best.

In this paper, we present a computational model of this social-learning capacity – inferring the world’s state from observing other agents’ behavior, guided by ToM. Similar inferential abilities have been studied in infants (Csibra, Biró, Koós, & Gergely, 2003) and adults (Goodman, Baker, & Tenenbaum, 2009), and the latter paper presented a computational model similar to ours in key respects (but focused on causal learning). Our work is the first to test people’s social learning against rational model predictions in a large-scale quantitative experiment, showing that people can form surprisingly accurate fine-grained beliefs about the relative probabilities of different possible worlds from sparse social observations – just a single agent moving along a single goal-directed path of intentional action. We contrast our model with a non-intentional, non-ToM account based on low-level features of the agent’s motion. Even when we introduce many free parameters in the form of variable feature weights,

and optimize their values to best fit people’s world-state inferences, the feature-based alternative performs substantially worse than a ToM-based model with many fewer parameters.

## Computational framework

A rapidly growing body of research suggests that human judgments about intentional agents’ mental states (goals, preferences, beliefs) can be modeled as probabilistic inverse planning, inverse optimal control, or inverse decision-making: Bayesian inferences over predictive models of agents’ rational behavior (Baker, Saxe, & Tenenbaum, 2009; Lucas, Griffiths, Xu, & Fawcett, 2009; Bergen, Evans, & Tenenbaum, 2010; Jern, Lucas, & Kemp, 2012; Baker, Goodman, & Tenenbaum, 2008; Ullman et al., 2010; Tauber & Steyvers, 2011). Here we adopt the Bayesian ToM (BToM) formulation of Baker, Saxe, and Tenenbaum (2011), expressing relations between the world’s state, an agent’s state, and the agent’s observations, beliefs, desires, and actions in terms of a rational-agent model known as a partially observable Markov decision process (POMDP) (Kaelbling, Littman, & Cassandra, 1998). This captures a probabilistic version of the classical rational agent who updates their beliefs to conform with their observations and chooses sequences of actions expected to achieve their desires given their beliefs. The causal schema for BToM is shown in Fig. 1(a).

Baker et al. (2011) used the BToM model to explain human observers’ joint inferences about agents’ beliefs and desires, based on how these mental states guided agents’ actions exploring a small, spatially structured world with different sources of utility (candidate goals) in different locations. Observers had full knowledge of the agent’s situation and world state, but the agent only learned about the world piecemeal (based on line-of-sight perceptual access) as it explored. In contrast, in this paper we consider scenarios where *neither* the agent nor the observer have full access to the state of the world. The agent again has line-of-sight perceptual access, but the observer sees none of the utility sources (candidate goals) in the environment; these must be inferred from observing the agent’s movements. At first blush, this inference problem might seem hopelessly underconstrained; however, we will show that when the observer knows the agent’s preferences, and if those preferences are strong enough, then joint inferences about the agent’s beliefs and the unobservable world state are possible.

To illustrate how this works, consider the scenario shown in Fig. 2. At a certain university food hall, every day at lunchtime three different food carts arrive: an Afghani (A) cart, a Burmese (B) cart, and a Colombian (C) cart. The food hall contains three rooms, West (W), North (N) and East (E), and on any given day, any cart can be in any room. Harold, the student shown in the figure, always prefers to eat at cart A over carts B and C, and prefers to eat at cart B over cart C. Furthermore, carts A and B can be *open* or *closed* when Harold arrives; he only goes to a cart if he sees that it is open. Cart C is always open and is the last resort when all others are

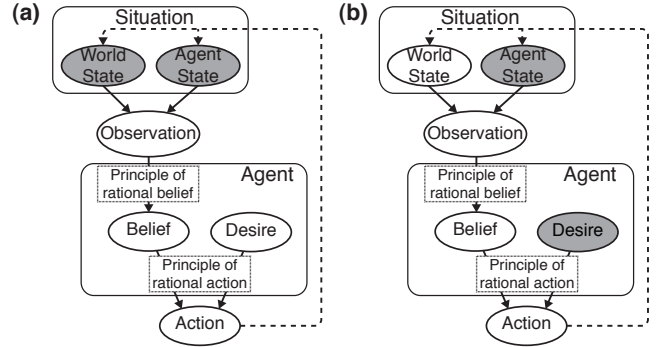

Figure 1: Causal structure of Theory of Mind. Traditional accounts of ToM (e.g., Dennett, 1987; Wellman, 1990; Gopnik & Meltzoff, 1997) have proposed informal versions of these schemata, characterizing the content and causal relations of ToM in commonsense terms, e.g., “seeing is believing” for the principle of rational belief. (a) Schematic of the Bayesian theory of mind (BToM) model proposed by Baker et al. (2011). Grey shaded nodes – World State and Agent State – are assumed to be observed (for the observer; not necessarily for the agent, as described in the main text). (b) Our extension of BToM to allow inference of hidden aspects of the World State by observing an agent’s behavior. Here, the Agent State and Desire are observed, but the World State is only partially observable for both agent and observer.

closed.

Fig. 2(a) shows a hypothetical path that Harold could take, ending in the North room. What, if anything, does this tell us about the cart locations? From where Harold enters the food hall, he can observe the cart in the North room. Next, he checks the East room, indicating that either cart A is not in the North room, or that cart A is in the North room, but is closed. When Harold returns to the North room, only one possibility remains: that he saw cart A in the East room, but it was closed, so he returned to the North room to eat at cart B, which was open (this cart configuration is shown in Fig. 2(d), row 1, column 3). Crucially, this inference also depends on Harold’s *not* checking the West room, which is consistent with several other configurations in Fig. 2(d). In our experiment, 66% of participants rated the correct configuration to be the most likely in this condition (chance = 17%).

## Informal Model Sketch

Fig. 1 sketches the causal schema for BToM. For concreteness, we will describe the content of the model in terms of our food carts scenario, but in principle the BToM framework can be defined over arbitrary state and action spaces. In our food cart examples, there are 24 possible World States: 6 possible cart configurations (shown in Fig. 2(d)) times 4 possible joint combinations of open/closed for carts A and B. There are 12 possible Agent States, one for each grid square in the food hall scenario. Agents’ Observations provide information about the World State, conditioned on the Agent State, and are based on line-of-sight visibility – Fig. 2(b,c) give examples of what can be seen from different vantage points. The observer represents an agent’s Belief as a probability distribution over possible World States. The observer maintains a

Figure 2: Example experimental stimulus. (a) Example of an observed path. The task is to figure out where each of three food carts is, given the trajectory the agent took. (b) In the agent’s initial position he can observe the North spot with food truck B in it. However, he doesn’t know where his favorite cart A is. (c) Agent’s state when he travels to the entrance of the East hallway. He can now observe cart A being closed and remembers having seen cart B in the North spot. With this information he can deduce that cart C is in the West room and so his best option is to choose the North spot, producing the path shown in (a). (d) Possible configurations the carts can take independent of them being closed or open. In the experiment, subjects ranked these six configurations for each path.

finite set of possible Beliefs the agent could hold, drawn from a prior over initial Beliefs, and simulates the agent’s Belief update for each possible Observation, given the Agent State and World State. An agent’s Desire is captured by utilities for each cart which capture the preference relation  $A \succ B \succ C$ .

Given the representational content of the nodes, BToM expresses the functional form of the causal relations in Fig. 1 in terms of POMDPs, which capture the dual principles of rational Belief and Action in Fig. 1. To generate a POMDP policy for each initial Belief point, we employ an implementation of the SARSOP algorithm (Kurniawati, Hsu, & Lee, 2008), provided by the APPL POMDP solver. These policies represent a predictive, Belief- and Desire-dependent distribution over the agent’s actions.

The schema in Fig. 1 illustrates the conditional dependencies involved in the model of the agent. For clarity, in this informal sketch we suppress the temporal nature of the model; technical details of dynamic inference are provided in Baker et al. (2011). The predictive distribution over the agent’s Action, given its Desire, Beliefs, the World State and the Agent State (abbreviating variable names as A, D, B, W, S respectively) is:

$$p(A|D, W, S) = \sum_B p(A|B, D) \sum_O p(B|O) p(O|W, S). \quad (1)$$

In Fig. 1(b), the World State is unknown, and the problem of “learning what is where” involves inferring the World State, given an agent’s Desire and Action using Bayes’ rule:

$$p(W|A, D, S) \propto p(A|D, W, S) p(W). \quad (2)$$

Intuitively, this involves evaluating the likelihood of every possible World State, given the agent’s Action, Desire and Agent State, and integrating these likelihoods with the prior over possible World States. Evaluation of each likelihood also requires simultaneously inferring and updating the agent’s Beliefs over time.

### An alternative cue-based model

To assess the intrinsic difficulty or logical complexity of our task, we formulated a cue-based alternative to our BToM account of social inference of food cart locations. We name the alternative model F-40; the model considered 7 key features and fit 40 free parameters (one for each feature, plus an additive constant, multiplied by 5 independent response variables) using multinomial logistic regression to minimize the error in prediction of human judgments. The features were chosen to capture key moments in the paths that were strongly indicative of a preferred cart being in a particular location. Specifically, for each room, we assigned a unique vantage point at which the agent could see what was in that room, and could choose to either commit to eating at that room by moving North/South, or commit to moving to another vantage point by moving East/West. The set of vantage points is indicated by the marked cells in Fig. 5. Features Toward and Away were computed for each room by counting the number of times the agent moved to or away from that room, starting from that room’s vantage point. In addition to the 6 Toward and Away features, the 7th feature recorded whether or not the condition was part of the introduction (in which carts could not be closed) or the main experiment. Because of its large number of free parameters, we hypothesized that F-40 would capture those regularities in people’s judgments that could be explained by low-level movement properties.

## Experiment

### Design

Fig. 2 illustrates our experimental design. On each trial, subjects were shown either a complete or an incomplete path that the agent took. They were then asked to rate on a scale from 0 to 10 (with 0 meaning “Definitely Not”; 10 “Definitely”; and 5 “Maybe”) how much they believed each possible configuration of carts was the real one. Fig. 2(d) shows the six possible configurations of carts that subjects rated on each trial. Food cart names as well as stimulus order were randomized across subjects. For simplicity we will refer to the carts as Afghani (A), Burmese (B), and Colombian (C), always with the preference order:  $A \succ B \succ C$ .

In this scenario there are 24 possible worlds (6 possible permutations of the cart's locations multiplied by 4 permutations of carts A and B being open or closed). Stimuli were generated as follows. We assume that the agent always starts at the entrance of the North hallway, being able to choose between entering that hall, going to the West hall, or going to the East hall. An exhaustive list of possible paths was constructed by listing all possible combinations of the short-term goals of the agent (go to entrance of W hall, go to entrance of N hall, and go to entrance of W hall), assuming that the first time a hall is selected it is for the purpose of exploration, and any selection of a hall that had been selected before is for exploitation, meaning the agent has chosen where to eat. From the eleven exhaustively enumerated paths, two paths that only produced permutations of beliefs were removed, leaving a total of 9 complete paths. In addition, 7 incomplete paths (subsequences of the 9 complete paths) which produce different judgments were selected. Lastly, three of these paths were duplicated in initial displays in which all carts are assumed to be open, shown to subjects to familiarize them with the task. This produced a total of 19 different paths (see Fig. 3) for which each subject rated the six possible configurations of carts, for a total of 114 judgments per subject.

## Participants

200 U.S. residents were recruited using the Amazon Mechanical Turk. 176 subjects were included in the analysis, with 24 excluded due to server error.

## Procedure

Subjects first completed a familiarization stage, which began with an explanation of the basic food cart setting, and allowed subjects to provide judgments for three paths where the food carts were assumed to always be open. Next, the possibility that carts could be closed was introduced with a step by step example. The experimental stage immediately followed.

## Results

We begin by analyzing the fit between people's judgments and our two models. Fig. 3 shows the average human rating of the likelihood of each cart configuration, the BToM model, and the F-40 model. In Fig. 3 it is clear that both models perform well in capturing the general contours of the mean subject belief, but with a quantitative difference in their explanatory power.

The BToM model has four parameters that were not fit to the data: three parameters indicating how strong the preference for each food cart is, and a discount parameter indicating the tradeoff between immediate and delayed rewards. Intuitively, these four parameters together determine whether an agent is willing to spend time and energy finding food carts he likes better or whether he should settle for a closer cart. These parameters were set only qualitatively, to ensure that the agent would have a strong preference order that would motivate him to explore the environment until he finds the best option.

In contrast, the F-40 model has forty free parameters fit to the average subject ratings, and so, by construction, the fit is very close to human judgment. Looking deeper into the model, there were no outstanding predictive features of the path that would determine the food cart ordering. That is, F-40 shows a great capacity to mimic human reasoning, but it fails to capture the essence of the task. This is clear in Fig. 4, where we can see that mean human judgments have a  $r = 0.91$  correlation with the BToM model, but a correlation of  $r = 0.64$  with the F-40 model. As we can see in the scatterplot, BToM comes much closer to explaining the variance in the human data, while F-40 is much less accurate overall. Fig. 4(c) shows that for a strong majority of individual subjects, the BToM model provides a superior fit. To further assess the statistical significance of the models we performed a Bootstrap Cross-Validated Correlational Analysis (Cohen, 1995). For 10,000 iterations, we trained F-40 on randomly selected subsets of paths and compared its performance on the remaining untrained paths. This produced average correlations of  $r = -0.0733$ ,  $-0.0832$  and  $0.0830$ , for training sets of size 16, 17 and 18 (and testing sets of size 3, 2, and 1), respectively. A similar analysis with BToM (for which no parameters were fit to data) yielded correlations of  $r = 0.9015$ ,  $0.8922$  and  $0.8714$  for testing sets of size 3, 2 and 1, respectively. These analyses suggest that the feature-based model is not tapping into the cognitive mechanisms underlying human performance, but rather just fitting the data without strong predictive power.

This is clear in Fig. 5, where two paths that contrast the models' performance are shown. For path 1, BToM is capable of realizing that if the carts were set as C, B, A/closed in positions West, North, and East respectively, then the agent would have no reason to visit the West position, since by the time it has observed B and A/closed it already has all the information it needs to make its final choice. It is this type of fine grained reasoning that allows BToM to make subtle inferences when F-40 fails as a result of mimicking the data rather than predicting it.

## Discussion

In this work we have proposed a Bayesian Theory of Mind model to explain how we make sense of the world by observing how others interact with it. Our experiment shows that subjects produce very similar predictions to that of the ideal Bayesian observer. We have compared the BToM model to a feature-based regression model (F-40) that was fit to subjects' mean judgments. Although the F-40 model appears to be a good competitor, we show that at both the individual and average level, the correlation with the BToM model is substantially higher compared to the correlation with F-40. Further analysis showed how BToM is capable of more subtle, fine-grained reasoning, making sensible inferences in several situations where F-40 gives counter-intuitive predictions.

One interesting point is that the BToM model is more sensitive to the precise geometry of the environment than humans

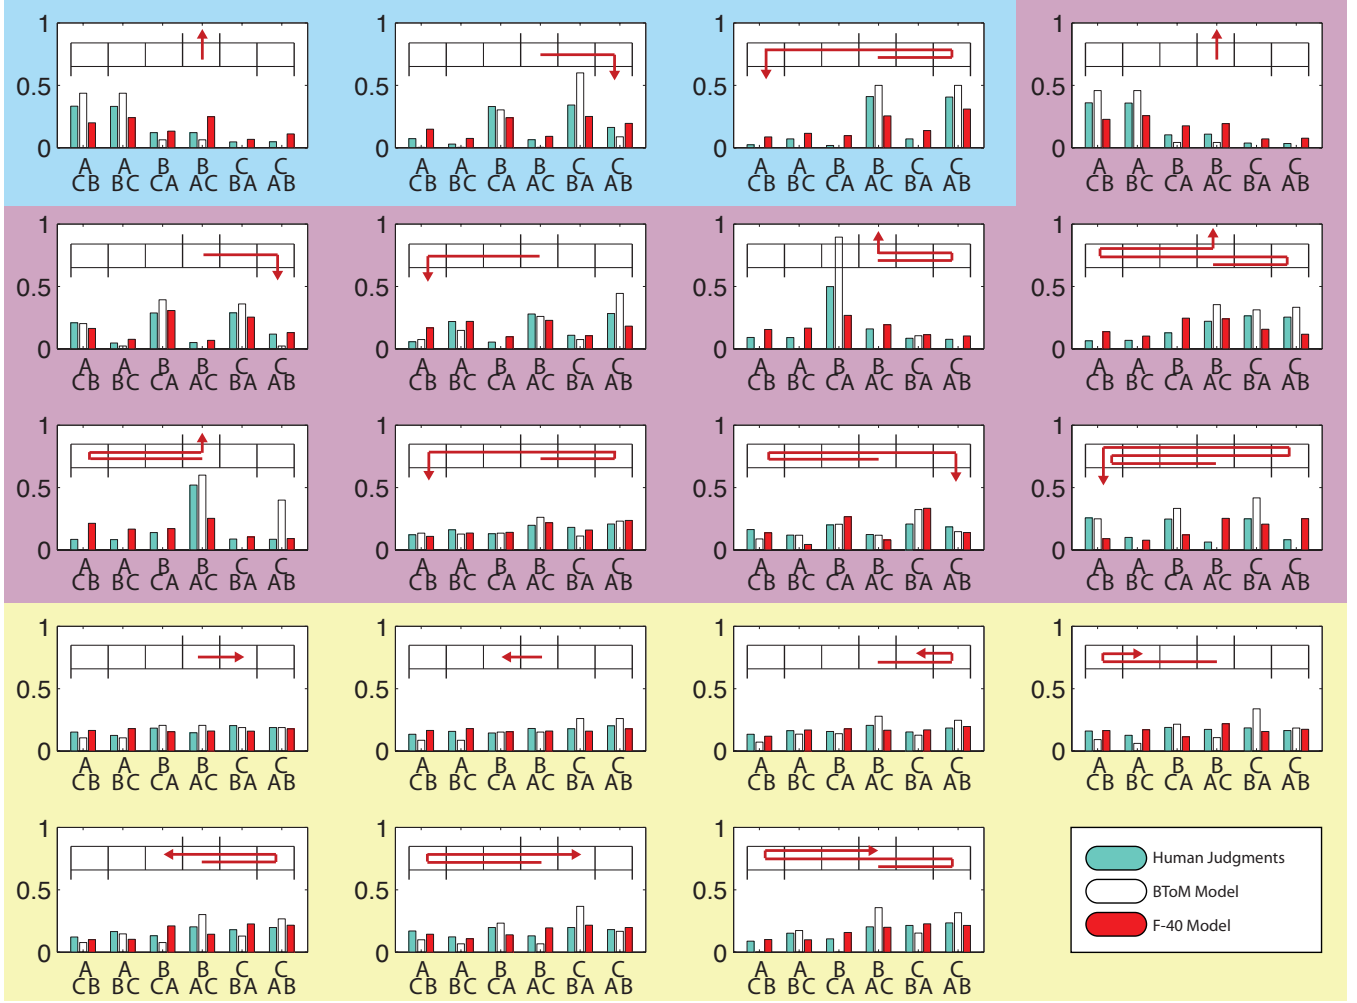

Figure 3: Mean subjects' judgments (normalized degrees of belief in each of six possible configurations of the food carts), along with BToM and F-40 predictions for the 19 displayed paths. The agent's preference order for these carts is always known to be  $A > B > C$ , and carts A and B may be open or closed. The first three conditions were those used in the familiarization phase. The second block used "completed" paths, in which the agent committed to a particular cart in the last frame. The last block of conditions used "incomplete" paths, in which the agent's final destination had not yet resolved.

seem to be. Specifically, because of the asymmetry of the hallway in our experiment, the model assigned a significantly higher cost to checking the West hallway versus checking the East hallway. Thus, when the model observed the agent going West, it reasoned that the agent must have had some prior belief in the presence of a high value cart in the West hallway or a low value cart in the East hallway that made him go through the more lengthy path versus the shorter path to check the East hallway. In contrast, subjects did not appear to be sensitive to the distance mismatch and produced relatively symmetric judgments on paths that had the same structure but traveled in opposite directions. This is particularly evident in the plot (3,1) of Fig. 3. In this path, subjects believed that the agent had already found carts (A) and (B) and therefore had no need to visit the East room. The model however, when observing the agent choose the longer path, reasoned that there was some prior belief the agent had that could have been wrong. This leads the model to consider it possible that

the (B) food truck was in the East room but that the agent had a prior belief that it was closed and therefore did not bother checking it. Analogous disparities were found by Baker et al. (2011), and in ongoing work we are investigating more qualitative representations of the spatial structure of the environment that might support a closer match between BToM model reasoning and human judgments.

In sum, these results show the power of social inference for acquiring surprisingly fine-grained knowledge about the world. ToM is typically thought of as a system of knowledge for reasoning about the mental states and actions of intentional agents, but it is not only that. In the context of a Bayesian framework, actions of other agents become clues to any aspects of the environment that causally influence their behavior – sometimes the only clues available. ToM thus also provides an essential tool for learning about the world.

Figure 4: Comparison of models and normalized human judgments. (a) BToM vs. mean normalized human judgments. Each point represents a mean human rating plotted against the corresponding model prediction; there are 114 points in all (19 conditions times ratings for 6 possible cart configurations), with an overall correlation of  $r = 0.91$ . (b) F-40 vs. mean normalized human judgments; analogous to analysis (a), with an overall correlation of  $r = 0.64$ . (c) Scatter plot of individual subjects' correlations with BToM vs. individual subjects' correlations with F-40; 176 points in all (one point for each subject). For 80% of subjects, the correlation between BToM and that subject's ratings is higher than the correlation of F-40 with that subject's ratings. The bold "X" plots the correlation of BToM with the mean human judgments vs. that of F-40.

## Abstract

We present a laboratory study investigating the generalization of learning across two games of strategic interaction. The participants' performance was higher when a game was played after, as compared to before, a different game. We found that the generalization of learning from one game to another was driven by both surface and deep similarities between the two games. We developed a computational cognitive model to investigate mechanisms of generalization. Model development highlighted some of the challenges of cognitive modeling in general and modeling strategic interaction in particular. We found that development of reciprocal trust was a key factor that explained the observed generalization effect.

**Keywords:** Cognitive modeling; Game theory; Strategic interaction; Generalization of learning.

## Introduction and Background

Games of strategic interaction have successfully been used to model various real-world phenomena. For example, the game Prisoner's Dilemma has extensively been used as a model for real-world conflict and cooperation (Rapoport, Guyer, & Gordon, 1976). There has been a recent tendency toward studying ensembles of games, as most real-world "games" rarely occur in isolation; more often they take place either concurrently or in sequence (Bednar, Chen, Xiao Liu, & Page, in press). For instance, when games are played in sequence, an effect known as "spillover of precedent" may occur: a precedent of efficient play in a game can be transferred to the next game (e.g., Knez & Camerer, 2000). We refer to this effect as *generalization of learning in games of strategic interaction*. This effect has important practical implications. For example, most organizations employ training exercises to develop cooperation and trust among their employees. The assumption is that what is learned in a very specific, ad-hoc exercise generalizes to organizational life once the training is over.

Research on what factors cause generalization of learning in games of strategic interaction can be summarized as follows: (1) Bednar and colleagues (in press) use the concept of *entropy* or strategic uncertainty to explain when learned behavior is likely to spillover from one game to another. They suggest that prevalent strategies in games with low entropy are more likely to be used in games with high entropy, but not vice versa (Bednar et al., in press). In

other words, individuals develop strategies for easier games and apply them to more complex games. (2) Another explanation says that expecting others to do what they did in the past (and expecting that they will think you will do what you did in the past, etc.) can coordinate expectations about which of many equilibria will happen (Devetag, 2005). (3) Finally, Knez and Camerer (2000) found that generalization of learning across games strongly depended on the presence of superficial, surface similarity (what they call 'descriptive' similarity) between the two games. When the games differed in (what we call) surface characteristics (e.g., actions were numbered differently in the two games) transfer of learning from one game to another did not occur. This result is at odds with what is known from the literature on individual problem solving: generalization of learning is facilitated by our ability to perceive abstract, deep-level similarities, and it can be impeded by the presence of superficial, surface similarities (Holyoak & Thagard, 1995).

In this paper we present an experiment aimed at studying generalization of learning in games of strategic interaction. We want to understand when, why, in which direction, and under what conditions generalization occurs. We also present a computational cognitive model as an aid in our attempt to explain the empirical results and settle any potential inconsistencies in the literature.

The next section introduces the experiment and discusses its results. Then the cognitive model is described and its correspondence with the human data is discussed. The paper ends with a general conclusion.

## Experiment

Due to space limitation, only a brief description of the experiment is given here. A more detailed description was presented elsewhere (Juvina, Saleem, Gonzalez, & Lebiere, submitted). We selected two of the most representative games of strategic interaction: Prisoner's Dilemma (PD) and the Chicken Game (CG). They are both mixed-motive non-zero-sum games that are played repeatedly. Players can choose to maximize short- or long-term payoffs by engaging in cooperation or defection and coordinating their choices with each other. These features give these games the strategic dimension that makes them so relevant to real-world situations (Camerer, 2003). What makes PD and CG particularly suitable for this experiment is the presence of theoretically interesting similarities and differences,

providing an ideal material for studying generalization of learning. Table 1 presents the payoff matrices of PD and CG.

Table 1: Payoff matrices of PD and CG.

PD	A	B	CG	A	B
A	-1,-1	10,-10	A	-10,-10	10,-1
B	-10,10	1,1	B	-1,10	1,1

Both PD and CG have two symmetric (win-win and lose-lose) and two asymmetric (win-lose and lose-win) outcomes. Besides these similarities there are significant differences between the two games. In CG, either of the asymmetric outcomes is more effective in terms of joint payoffs than the [1,1] outcome. This is not the case in PD where an asymmetric outcome [10,-10] is inferior in terms of joint payoffs to the win-win outcome [1,1]. Mutual cooperation in CG can be reached by a strongly optimal strategy (i.e., alternation of [-1,10] and [10,-1]) or a weakly optimal strategy [1,1]. The optimal strategy in PD corresponds to the weakly optimal strategy in CG numerically, while the strongly optimal strategy of alternation in CG shares no surface-level similarities with the optimal strategy in PD. Thus, although mutual cooperation corresponds to different choices in the two games (i.e., surface-level dissimilarity), they share a deep-level similarity in the sense that mutual cooperation is, in the long run, superior to competition in both games. This provides a perfect test for our first hypothesis stating that individuals who have learned how to find an optimal strategy in one game will be more likely to find an optimal strategy in the next game even if those optimal strategies are different across the two games.

In both PD and CG, learning must occur not only at an individual level but also at a dyad level. If learning occurs only in one of the players in a dyad, the outcomes are disastrous for that player, because the best solution also bears the highest risk. For example, if only one player understands that alternating between the two moves is the optimal solution in CG, the outcome for that player can be a sequence of -1 and -10 payoffs. Only if both players understand the value of alternation and are willing to alternate, the result will be a sequence of 10 and -1 payoffs for each player, which in average gives each player a payoff of 4.5 points per round. Thus, the context of interdependence makes unilateral individual learning not only useless but also detrimental. The two players must jointly learn that only a solution that maximizes joint payoff is viable long term. However, this solution carries the most risk and thus it is potentially unstable in the long term. To ensure that the optimal solution is maintained from one round to another, there must exist a mechanism that mitigates the risk associated with this solution. It has been suggested that trust relations are self-sustaining once they have been developed (Hardin, 2002). In situations where there are benefits to individuals that can only be generated through mutual trust, each individual has an incentive to

maintain the relation. A trust relation develops through gradual risk-taking and reciprocation (Cook, Yamagishi, Cheshire, Cooper, Matsuda, & Mashima, 2005). In turn, as trust develops, risk is reduced and the trust relation becomes more stable. Our second hypothesis states that participants develop reciprocal trust throughout the first game, which facilitates learning of the optimal solution in the second game.

## Participants and Design

One hundred and twenty participants were paired with anonymous partners (leading to 60 pairs) and were asked to play the two games in sequence. The 60 pairs were randomly assigned to two conditions defined by the order in which the games were played: PD-CG and CG-PD. Participants played 200 unnumbered rounds of each game. At the end of each game, participants completed a five-item questionnaire assessing: how trustful they were of the opponent; how trustful of them the opponent was; how fair they thought the opponent's actions were; how fair the participants' actions were towards their opponents; and how satisfied they were with the overall outcome of the game.

## Results<sup>1</sup> and Discussion

To study generalization of learning across the two games, we analyzed the outcomes of a game according to when it was played. We also analyzed the round-by-round dynamics of these outcomes. The statistical significance of the observed effects was tested with the aid of Linear Mixed Effects analysis (*lmer* analysis from the LME4 package in R). This analysis was preferred instead of the classical analysis of variance (ANOVA) because the data violated the assumption of normality.

**Similarities and differences** The frequencies of the most relevant outcomes (i.e., the two symmetric ones and an alternation of the two asymmetric ones) are displayed in Figure 1 on a round-by-round basis. The first thing to notice is how different the two games are from each other from a behavioral perspective: the [1,1] outcome increases in PD but decreases in CG; alternation is prominent in CG but almost nonexistent in PD; and the mutually destructive outcome ([-1,-1] in PD and [-10,-10] in CG) is more frequent in PD than in CG. However, in spite of these apparent differences, the two games are similar in the sense that mutual cooperation emerges as the preferred solution and it becomes more and more stable over time. These patterns are in line with previous findings (e.g., Rapoport et al., 1976). Given this deep-level similarity, we expect players to be able to generalize their learning of the optimal strategy across the two games, although surface similarities might impede this process (Holyoak & Thagard, 1995). Since we ran the games in both orders (i.e., PD-CG and CG-

<sup>1</sup> Only a summary of the results is provided here as a context for understanding the cognitive model. A more detailed presentation of the results was given in Juvina et al., submitted.

PD), we can also test whether generalization occurs only in one direction, from low to high entropy, as suggested by Bednar and colleagues (in press).

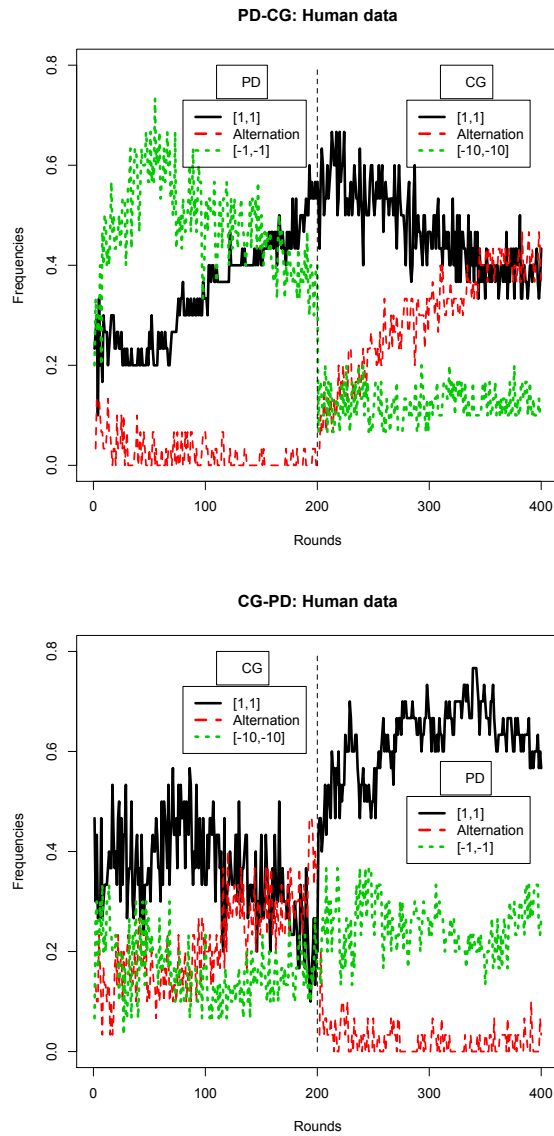

Figure 1: Frequencies of the most relevant outcomes in PD and CG by order (PD-CG on top and CG-PD on bottom) and round averaged across all the human participants.

**Generalization Driven by Surface Similarities** If learning across games is driven by surface similarities, one would expect the strategy that is learned in the first game to be applied in the second game as well, even though it may not be appropriate for the second game. This is indeed the case with regard to the  $[1,1]$  outcome in the PD-CG order: players learn that  $[1,1]$  is long-term optimal in PD and they are more likely to achieve it in the subsequent CG, even though it is only weakly optimal in CG. A LME model with occurrence of  $[1,1]$  as a dependent variable (binomial distribution), order, round, and their interaction as fixed factors, and participant as a random factor was used to test

the observed effects. There was a main effect of order ( $z = 2.21, p = 0.027$ ) and a main effect of round ( $z = -8.171, p < 0.001$ ); the interaction between order and round was also significant ( $z = -7.196, p < 0.001$ ) indicating that the main effect of order is larger at the beginning of the game and it progressively becomes smaller.

In the CG-PD order, if generalization of learning across games were driven by surface similarities, one would expect the strategy of alternating between the two asymmetrical outcomes to be attempted in the second game as well, at least in the beginning of the game. The main effect of order was non-significant ( $z = 1.476, p > 0.10$ ), suggesting that the strongly optimal strategy in CG (alternation) was not transferred as such (based on surface similarities) to PD. There remains the possibility that the  $[1,1]$  outcome was transferred as such from CG to PD. Even though the  $[1,1]$  outcome is only weakly optimal in CG, it was selected with relatively high frequency (see Figure 1) and it might have been considered optimal by some participants. We will revisit this point in the section on combined effects of surface and deep-level similarities.

#### Generalization Driven by Deep-Level Similarities

If learning across games was driven by deep-level similarities, one would expect learning the optimal strategy in the first game to increase the probability of learning the optimal strategy in the second game, even though there is no surface similarity between these strategies. These strategies ( $[1,1]$  in PD and alternation in CG) are similar only on an abstract, deep level: they both aim at maximizing joint payoff in a sustainable way, which in these two games is realistically possible only if the two players make (approximately) equal payoffs on a long run. On a surface level, these two strategies are very different. The  $[1,1]$  strategy in PD requires that players make the same move at each trial and they do not switch to the opposite move. In contrast, the alternation strategy in CG requires that players make opposite moves at each round and they continuously switch between the two moves. A LME model with occurrence of the alternation outcome in CG as a dependent variable, order, round and their interaction as fixed factors, and participant as a random factor revealed a main effect of order ( $z = -2.014, p = 0.044$ ) indicating a higher level of alternation when CG was played after PD, a main effect of round ( $z = 16.205, p < 0.001$ ) indicating that more and more pairs of participants discovered the alternation strategy as the game unfolded, and a significant interaction between order and round ( $z = 8.5, p < 0.001$ ) indicating that the optimal strategy was learned faster when CG was played second. The same analysis was conducted for the occurrence of the  $[1,1]$  outcome in PD and it revealed a main effect of order ( $z = -4.340, p < 0.001$ ) indicating that more pairs of participants discovered the optimal strategy in PD when it was played after CG, a main effect of round ( $z = 10.149, p < 0.001$ ) indicating that more and more pairs of participants found the optimal strategy as the game unfolded, and a significant interaction between order and round ( $z = 12.689,$

$p < 0.001$ ) indicating that the optimal strategy reached a ceiling when PD was played after CG, whereas it increased continuously when PD was played before CG. These results supported our first hypothesis. Specifically, learning the optimal strategy in the first game increased the probability of learning the optimal strategy in the second game, even though the optimal strategies were different in the two games. This generalization effect was significant in both directions (PD-CG and CG-PD) suggesting that entropy (Bednar et al., in press) has little explanatory relevance. If entropy were the causing factor, generalization would have only occurred in one direction.

**Combined Effects of Surface and Deep Similarities** In the case of deep-level generalization, the main effect of order was smaller in magnitude for CG ( $z = -2.014$ ,  $p = 0.044$ ) than for PD ( $z = -4.340$ ,  $p < 0.001$ ). It seems as if CG has a stronger impact on PD than vice versa. A possible explanation for this difference is based on how surface and deep-level similarities combine with each other to drive generalization of learning across games. They may have congruent or incongruent effects. Thus, in the PD-CG order, surface and deep-level similarities act in a divergent, incongruent way: surface similarity makes it more likely that the [1,1] outcome is selected whereas deep-level similarities make it more likely that the alternation outcome is selected. In other words, generalization based on surface similarity interferes with generalization based on deep-level similarity. In contrast, in the CG-PD order, both types of similarities act in a convergent, congruent way: they both increase the probability that the [1,1] outcome is selected. There is no impeding effect of surface similarity on PD because there is no optimal strategy in CG that is similar enough to a non-optimal or sub-optimal strategy in PD. The impeding and/or enabling effects of surface similarities on deep-level generalization are revisited in the modeling section.

**Reciprocal Trust** In addition to game choices, we analyzed the debriefing questionnaires that were administered at the end of each game. Since the answers to these questions were highly correlated with each other for any one individual participant, we averaged them in one composite variable that we call Reciprocal Trust. Since the debriefing questions were administered twice (at the end of each game) we refer to them as T1 and T2. We calculated correlations between these two trust variables and the variables indicating mutual cooperation in the two games. Spearman's  $\rho$  coefficient was used for correlations because the data failed to meet the normality assumption. We found that the more frequent mutual cooperation was in the first game the more likely the players were to rate each other as trustworthy at T1 ( $r = 0.75$ ,  $p < 0.001$  for PD and  $r = 0.42$ ,  $p < 0.001$  for CG). In addition, the more trustworthy players rated each other at T1, the more likely they were to enact mutual cooperation in the second game ( $r = 0.28$ ,  $p = 0.03$  for CG and  $r = 0.47$ ,  $p < 0.001$  for PD). Finally, mutual cooperation in the second

game predicted high levels of trust at T2 ( $r = 0.67$ ,  $p < 0.001$  for CG and  $r = 0.88$ ,  $p < 0.001$  for PD). As expected, the level of reciprocal trust increased from T1 to T2 (mean<sub>T1</sub> = 11.8, mean<sub>T2</sub> = 14.1,  $t = -3.247$ ,  $p = 0.001$ ). These correlations between trust and the frequency of mutual cooperation corroborate our second hypothesis. They suggest that generalization of learning driven by deep-level similarity is facilitated by development and maintenance of reciprocal trust. This finding will be essential for model development.

## A cognitive model of generalization of learning

Modeling generalization of learning across games of strategic interaction provides an opportunity to address some of the ongoing challenges of computational cognitive modeling. Three of these challenges are particularly relevant here and are described below as the model is introduced. The model is developed in ACT-R and it will be made freely available to the public on the ACT-R website<sup>2</sup>.

## Interdependence

In games of strategic interaction, players are aware of each other and their interdependence. In a previous study we showed that game outcomes were influenced by players' awareness of interdependence. In PD, the more information the two players in a dyad had about each other's options and payoffs the more likely they were to establish and maintain mutual cooperation (Martin, Gonzalez, Juvina, & Lebiere, submitted). Consequently, a cognitive model playing against another cognitive model in a simultaneous choice paradigm needs to develop an adequate representation of the opponent. We use instance-based learning (IBL) and sequence learning (SL) (Gonzalez, Lerch, & Lebiere, 2003) to ensure that the opponent is dynamically represented as the game unfolds. Specifically, at each round in the game an instance (snapshot of the current situation) is saved in memory. The instance contains the previous moves of the two players and the opponent's current move. Saved instances are used to develop contextualized expectations about the opponent's moves based on ACT-R's memory storage and retrieval mechanisms (Anderson, 2007). Expectations can explain some of the spillovers across games (Devetag, 2005).

## Generality

Before one attempts to build a model of generalization of learning across two games, one needs to have a model that is able to account for the human data in both games. Although by and large cognitive models are task-specific, there is a growing need to develop more general, task-independent models and there are a few precedents: Lebiere, Wallach, and West (2000) developed a model of PD that was able to account for human behavior in a number of other 2X2 games; and Salvucci (under revision) developed a "supermodel" that accounts for human data in seven

<sup>2</sup> <http://act-r.psy.cmu.edu/>

different tasks. We build upon these precedents of generality by developing a single model to account for round-by-round human data in both PD and CG. We achieve this generality by using instance-based learning for opponent modeling (as described in the previous section) and reinforcement learning for action selection. Both instance-based learning and reinforcement learning are very general learning mechanisms that can produce different results depending on their input. Specifically, at each round in the game, the model predicts the opponent's move based on the opponent's past behavior and selects its own move based on the utilities of its own past moves in the current context. The input that the model receives as it plays determines the model's behavior. The input is represented by opponent's move, own move, and the payoffs associated with these moves.

An important question is what constitutes the reward from which the model learns the utilities of its actions (moves). Players may try to maximize their own payoff, the opponent's payoff, the sum of the two player's payoffs, the difference, etc. Thus, a large number of reward structures can be imagined. A complicating assumption is that the reward structure might change as the game unfolds depending on the dynamics of the interaction between the two players. This indeed seems to be the case here, as we have realized after a large number of model explorations: no single preset reward structure is sufficient to account for the human data. One could try to computationally explore the space of all possible reward structures and their combinations to find the one that best fit the human data, but the value of this approach is questionable, because it may lead to a theoretically opaque solution. Instead, we chose to employ a theoretically guided exploration that drastically reduces the number of possible reward structures and, more importantly, gives us a principled way to describe the dynamics of players' motives as the game unfolds (see its description in the next section).

### Generalization of learning

When the model relies only on the two learning mechanisms described above (i.e., instance-based learning and reinforcement learning) it is able to only account for the generalization driven by surface similarities. Thus, the opponent is expected to make the same move in a given context as in the previous game. Similarly, an action that has been rewarded in the first game tends to be selected more often in the second game. It is impossible in this framework to account for generalization driven by deep-level similarities. For example, if the opponent used to repeat move B when it was reciprocated in PD, there is no reason to switch to alternation between A and B when none of these moves are reciprocated in CG. Moreover, learning within a game may in fact hinder generalization of learning across games if surface similarities are incongruent with the optimal solution in the target game. To find a solution to the deep generalization problem, we need to return to a theoretical and empirical analysis of the two games.

As mentioned in the introduction, in both PD and CG the long-term optimal solution bears the highest risk and, thus, it is unstable in the absence of reciprocal trust. We indeed found that self-reported trust increases after game playing and it positively correlates with the optimal outcome. It may well be that trust explains the deep-level generalization of learning across games. Players learn to trust each other and this affects their reward structure.

Recent literature on trust (e.g., Castelfranchi & Falcone, 2010) suggests that trust is essentially a mechanism that mitigates risk and develops through risk-taking and reciprocity. Inspired by this literature, we added a "trust accumulator" to our model – a variable that increases when the opponent makes a cooperative (risky) move and decreases when the opponent makes a competitive move. In addition, a variable called "willingness to invest in trust" was necessary to overcome situations in which both players strongly distrust each other and persist in a mutually destructive outcome, which further erodes their reciprocal trust, and so on. In such situations, the empirical data shows that players make attempts to develop trust by gradual risk-taking. When these attempts are reciprocated, trust starts to re-develop. In the absence of reciprocation these attempts are discontinued. The willingness to invest in trust increases with each mutually destructive outcome and decreases with each attempt to cooperate that is not reciprocated.

The variables "trust accumulator" and "willingness to invest in trust" are used to determine the dynamics of the reward structure. They both start at zero. When they both are zero or negative, the two players act selfishly by trying to maximize the difference between their own payoff and the opponent's payoff. This quickly leads to the mutually destructive outcome, which decreases trust but increases the willingness to invest in trust. When the latter is positive, a player acts selflessly, trying to maximize the opponent's payoff. This can lead to mutual cooperation and development of trust or players may relapse into mutual destruction. When the trust accumulator is positive, a player tries to maximize joint payoff and avoid exploitation. Thus, the model switches between three reward functions depending on the dynamics of trust between the two players. This mechanism provides a principled solution to the problem of selecting the right reward structure and in the same time solves the generalization problem: due to accumulation of trust in the first game, the model employs a reward structure that is conducive to the optimal solution and thus better performance in the second game.

### Modeling results

A cognitive model incorporating the principles described above was developed and fit to the human data presented in the previous section. Fitting the model to the human data was done manually by varying a number of parameters (of which some are standard in the ACT-R architecture and others were introduced as part of the trust mechanism) and trying to increase correlation ( $r$ ) and decrease root mean square deviation (RMSD) between model and human data.

The results of the current best model ( $r = 0.89$ ,  $\text{RMSD} = 0.09$ ) are presented in Figure 2.

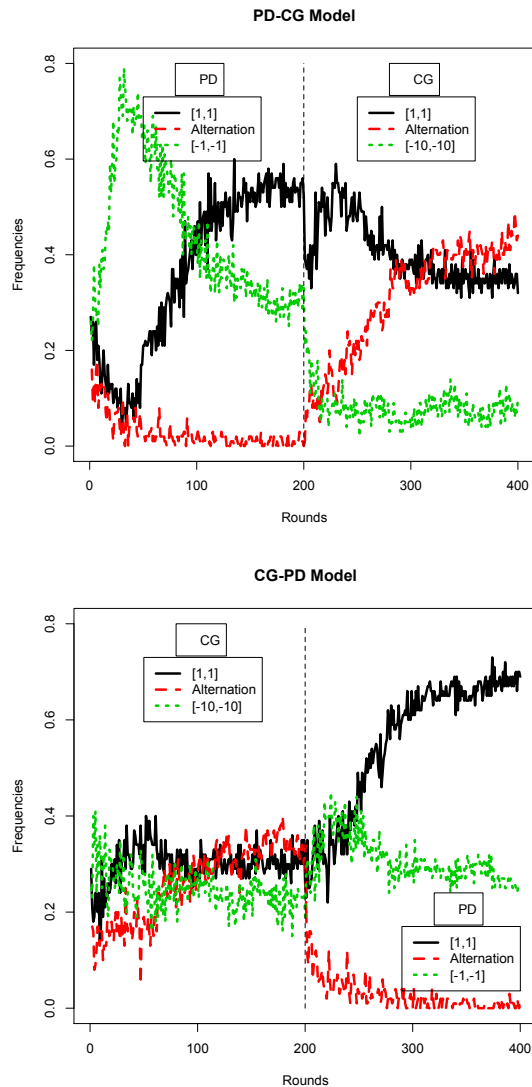

Figure 2: Results of model simulation.

Overall, the model matches the trends in the human data reasonably well (compare to Figure 1). More importantly, the generalization effects are also accounted for.

## Discussion and Conclusion

We found that generalization of learning across two games of strategic interaction is driven by deep-level similarities between the two games. Surface similarities may facilitate or hinder generalization depending on whether they are congruent or incongruent with the optimal solution. We used one cognitive model to account for human data in both games. This model helped to explain the observed generalization effect: reciprocal trust was necessary to mitigate the risk associated with the long-term optimal solution. We can conclude that some of the factors suggested in the literature are not necessary (entropy,

cognitive load) or insufficient (expectations, surface similarities), while others are essential (deep-level similarity and reciprocal trust) for generalization of learning in games of strategic interaction.

## Abstract

Previous research shows that people can use the co-occurrence of words and objects in ambiguous situations (i.e., containing multiple words and objects) to learn word meanings during a brief passive training period (Yu & Smith, 2007). However, learners in the world are not completely passive, but can affect how their environment is structured by moving their heads, eyes, and even objects. These actions can indicate attention to a language teacher, who may then be more likely to name the attended objects. Using a novel active learning paradigm in which learners choose which four objects they would like to see named on each successive trial, this study asks whether active learning is superior to passive learning in a cross-situational word learning context. Finding that learners perform better in active learning, we investigate the strategies that were most successful, discuss the implications, and model the results.

**Keywords:** active learning; statistical learning; cross-situational learning; temporal contiguity; language acquisition

## Introduction

Human infants learn words quite quickly despite many challenges facing them, including uncertainty and ambiguity in the language environment. Recent research has studied how learners may acquire word meanings from regularities in the co-occurrence of words and referents (e.g., objects). Such cross-situational statistical word learning relies on two assumptions: 1) that spoken words are often relevant to the visible environment, and 2) that learners can to some extent remember the co-occurrence of multiple words and objects in a scene. Thus, as words and their intended referents are observed in different situations over time, learners can apprehend the correct word-object mappings. Relying only on the regularity of the linguistic environment and basic memory and attention processes, this may be an important method of learning nouns for infants, and even adult travelers.

In adult cross-situational learning studies (e.g., Yu & Smith 2007), participants are asked to learn the meaning of alien words by watching a series of training trials. On each trial learners see an array of unfamiliar objects (e.g., four sculptures) and hear pseudowords (e.g., *stigson*, *bosa*). The meaning of each pseudoword is ambiguous on a given trial, because although each word refers to a single onscreen object, the intended referent is not indicated. In a typical learning scenario, participants attempt to learn 18 word-object pairings from 27 trials, with four words and four objects given per trial. In this design, each word-referent pair is presented six times over the five-minute training period. Learning a correct word-object pairing requires some form of accumulation of word-object co-occurrences.

When tested on each word and given four trained objects to choose from, participants chose the correct object for half of the 18 words, on average (Yu & Smith, 2007).

However, in the real world even infant learners are not passive observers, merely watching the world go by. As learners shift their attention, their eyes, head and hands move, changing the objects in their view. If caregivers notice these attention shifts, they may be more likely to name objects that are currently being attended to. Thus, learners may in essence be able to increase the likelihood an object is named by shifting their attention to include this object. This is a form of active learning, a concept studied extensively in machine learning (cf. Settles, 2009), in which a learner can query an information source for the labels of particular data points.

In this study, we introduce active cross-situational word learning, in which learners choose which four objects they would like to see named on each successive trial. Thus, learners control when to repeat pairs, when to stop experiencing pairs they feel they know, and when to attempt to learn more pairs. This gives us a glimpse of their preferred strategies. For example, participants may choose to repeat a single pair from the previous trial, and leverage working memory to quickly learn that the repeated word refers to the repeated object, while ignoring the other three word-object pairs on the trial. Equivalently, a learner may prefer to repeat three pairs from the previous trial, and quickly learn the novel pairing that was not present. Kachergis, Yu, & Shiffrin (2009a) manipulated this sort of temporal contiguity in a passive cross-situational study and found not only that repeated pairs are learned more easily, but so are unrepeated pairs in conditions with some repeats. This suggests that simple inference supported by working memory is not the only learning mechanism at work.

In fact, investigating active learning can reveal what information and mechanisms a learner has at their disposal, and characterizing the observed strategies—and their performance—will motivate learning models. For example, our recent associative model of cross-situational learning assumes that learners have access to both their familiarity and their uncertainty about the word-object pairings present on a given trial, and that attention competes for uncertain stimuli and for already-strong pairings (Kachergis, Yu, & Shiffrin, 2012). This model matches adult behavior in passive cross-situational experiments investigating mutual exclusivity, a bias to find 1-to-1 word-object mappings that is present even in 2.5-year-olds (Markman & Wachtel, 1988). If active learners have access to their knowledge of pairing strength and stimulus uncertainty, these cues can be combined to produce a few active learning strategies. One

strategy is to choose one object you have never seen before (i.e., one with maximal uncertainty), and fill the remaining three slots on the trial with familiar objects. Alternatively, learners may choose novel combinations of familiar objects in order to disambiguate mappings; we have previously found such contextual diversity to aid learning (Kachergis, Yu, & Shiffrin, 2009b). Detailed analysis of active learning strategies can reveal what knowledge is available to learners and how they attempt to employ it to learn the correct mappings. It may even be that people are worse at actively structuring the learning environment than the randomly-constructed passive trial sequences they normally experience in word-learning experiments.

In the Experiment, participants do two blocks of passive cross-situational learning, as well as of two blocks of active cross-situational learning in which they choose the objects that they see named on each successive trial. Although there are many other possible formulations of active cross-situational learning, we choose this instantiation because it most closely matches the passive task, and it somewhat matches the real world, where learners can attend to objects and likely increase the chance of a teacher labeling those objects.

## Experiment

Participants were asked to learn 18 word-referent pairs from a series of individually ambiguous training trials using the cross-situational word learning paradigm (Yu & Smith, 2007). Each training trial was comprised of a display of four novel objects and four spoken pseudowords. With no indication of which word refers to which object, learners have little chance of guessing the four correct word-referent mappings from the 16 possible pairings. However, since words always appear on trials with their proper referents, the correct pairings may be learned over the series of trials.

The key manipulation of this study is to allow learners in active conditions to choose which four objects they want to see named on the next trial. In both conditions, 18 word-referent pairs were experienced over a series of 27 training trials. Importantly, the same pair was never allowed to appear in neighboring trials in passive conditions. In both conditions, each pair could only appear six times during the training session. Thus, both the number of exposures per pair and the ambiguity on each trial (i.e., number of pairs) were matched in active and passive learning conditions. In order to compare passive and active learning performance, each participant underwent two training and test blocks of each.

## Subjects

Participants were 41 undergraduates at Indiana University who received course credit for participating. None had participated in other cross-situational experiments.

## Stimuli

Each training trial consisted of an array of four uncommon objects (e.g., sculptures) and four spoken pseudowords. The 72 pseudowords generated by computer are phonotactically-

probable in English (e.g., “bosa”), and were spoken by a monotone, synthetic female voice. These 72 objects and 72 words were randomly assigned to four sets of 18 word-object pairings, one set for each training condition.

Training for each condition consisted of 27 trials. Each training trial began with the appearance of four objects, which remained visible for the entire trial. After 2s of initial silence, the four words were heard in a random order (1s per word, with 2s of silence after each) for a total duration of 14s per trial.

## Procedure

Participants were told they would see a series of trials with four objects and four alien words, but that the order of presentation of the words was random. They were also told that their knowledge of which words belong with which objects would be tested at the end. In the active learning conditions, participants were instructed that they would be able to choose four objects they wanted to see named next. In active learning training blocks, after each trial a display of all 18 objects in the to-be-learned set was shown, and participants chose four to be named on the next trial. Objects that had already been chosen six times were not

After each training block, participants’ knowledge of word-object mappings was assessed using 18-alternative forced choice (18AFC) testing: on each test trial a single word was played, and the participant was instructed to choose the appropriate object from a display of all 18 trained objects. Each of the 18 words was tested once in a random order.

Every participant did four blocks of training and testing: half did two active learning blocks followed by two passive learning blocks, and the other half did the reverse.

## Results & Discussion

A repeated measures ANOVA on accuracy<sup>1</sup> by training type (active or passive) and training type repetition (1<sup>st</sup> or 2<sup>nd</sup>), nested by condition order (active-first or passive-first) revealed a significant main effect of training type ( $F(1,39) = 15.17$ ;  $p < .001$ ). Test performance after active learning is far better than after passive learning (active  $M = .59$ ; passive  $M = .35$ ), confirming that adults can use knowledge of their internal state to structure their environment for better learning. Moreover, participants did not improve much on their second block of either training type: there was no significant effect of repetition ( $F(1,39) = 2.08$ ;  $p = .15$ ). There was no significant interaction of condition order and repetition ( $F(2,38) = 1.62$ ;  $p = .20$ ), nor of training type and repetition ( $F < 1$ ), but there was a significant interaction of training type and condition order ( $F(2,38) = 4.53$ ;  $p < .05$ ). As shown in Figure 3, doing active learning first improves performance in the passive conditions (passive  $M = .30$  if passive-first,  $M = .39$  if active-first). This is somewhat surprising, as it is easy to imagine that doing passive first

<sup>1</sup> Data from one subject were excluded after it was found that their average performance in all four blocks was below chance (chance in an 18AFC test is .056).

might give learners an idea for better active learning strategies, whereas it is difficult to see how practice at active learning can improve one's performance in conditions with no command. However, it may be that active learning also allows learners to practice different rehearsal strategies, and helps them choose better ones even when they cannot control the structure of the trials. In any case, individual performance after the different types of training was significantly correlated (Pearson's  $r=.62$ ,  $t(38)=4.81$ ,  $p<.001$ ). Figure 2 shows that almost every participant performed at least as well after active training as passive training.

Figure 1: Accuracy by type of first condition and training type in the Experiment. Active learning resulted in far higher test performance than passive learning. Moreover, learners who did active learning first performed better in the passive learning conditions. Error bars show  $\pm$ SE.

Figure 2: Comparison of performance after passive vs. active learning for each participant. Performance after the

two types of training is correlated ( $r=.62$ ), but learners are almost universally better after active training.

Given that adults can actively structure their environment in order to effectively learn the word meanings, we next investigate the strategies effective learners use to disambiguate mappings. However, we must first consider that there are many strategies, and that not all of them result in swift learning. Performance in cross-situational word-learning is typically highly variable, both within- and between-subjects. This is likely because what is learned on a given trial depends on what has been learned on all previous trials, and both the ambiguity on each trial and the fallibility of human memory means that people often learn different things. Giving learners an opportunity to structure training may yield a more diverse set of learning states, and thus may increase variability in performance. Figure 3 shows a histogram of learning performance after each block of active and passive learning. While accuracy after passive training is unimodal and positively skewed, accuracy after passive learning looks roughly bimodal, with peaks at .25 and at .95, which may reflect strategies of differing utility. In the following analysis, we will examine strategy differences both by doing a median split on the performance of active learners and analyzing the strategies used by each group, and by clustering the active training trials and looking at the mean performance of each cluster.

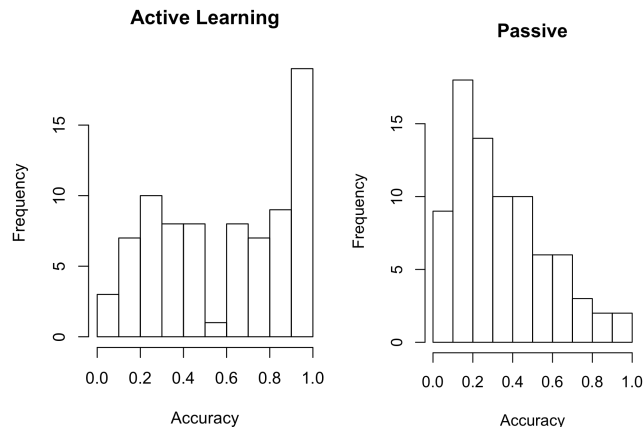

Figure 3: Histograms of performance after active learning (left) and passive learning (right) training blocks (2/subject/condition). Accuracy after active learning is bimodal, indicating that some strategies are quite successful while others are mediocre.

As mentioned earlier, one obvious active learning strategy is to choose to repeat some pairs from this trial on the next trial. If constructed randomly, a given trial would contain only .22 pairs repeated from the previous trial. In our passive training conditions, no pairs were allowed to repeat. The overall mean number of repeated pairs selected by active learners was 1.5—learners are using repetition to disambiguate pairs. To distinguish individual strategies (e.g., repeating one vs. repeating three), we clustered the

trial-by-trial number of repetitions chosen in each active learning training block. Using partitioning around medoids we found two clusters, estimated by the optimum average silhouette width (Kaufman & Rousseeuw, 1990). Cluster 1 contained 33 of the active training structures, and Cluster 2 contained the other 47. Figure 4 shows the trial-by-trial average number of repeated pairs for each cluster. Although people in both clusters initially repeat around one pair per trial, learners in Cluster 1 soon began to repeat two or more pairs on average, while those in Cluster 2 stayed closer to one repeat, until the last few trials<sup>2</sup>. Overall, Cluster 1 repeated 1.9 pairs per trial, significantly more than Cluster 2's mean of 1.1 repetitions (Welch  $t(60.7) = 9.09, p < .001$ ). From Figure 5, which shows how many pairs were repeated trial-by-trial in each cluster, it is clear that learners in Cluster 2 often chose to repeat single pairs until the very end. Cluster 1 shows a much more varied approach, repeating anywhere from one to three pairs. It turns out that these strategy clusters—constructed solely from the active training data—result in different overall levels of performance: Cluster 1's mean of .71 is significantly higher than Cluster 2's mean of .50 (Welch  $t(69.8) = 3.00, p < .01$ ). Repeating more than one pair seems to be a good strategy—indeed, the mean number of pairs repeated per trial in active training is correlated with learning (Pearson's  $r = .30, t(78) = 2.82, p < .01$ ). Corroborating this clustering result, a median ( $Mdn = .61$ ) split on active learning performance identifies a similar grouping: Cluster 1 contained 22 of the 33 better blocks, whereas Cluster 2 contained 30 of the 47 worse blocks ( $\chi^2 = 6.05, p = .01$ ). A graph of the active learning blocks identified by median split looks much like Figure 5, showing that better learners repeat more pairs.

Figure 4: The mean number of word-object pairs repeated on consecutive trials by the two clusters of active learners. Learners in Cluster 1 repeated more pairs per trial than Cluster 2, except at the beginning, when both repeated  $\sim 1$ . Error bars show  $\pm$ SE.

<sup>2</sup> Due to the constraint of each pair appearing only six times—as in passive training—there are only a few objects remain to choose from, with the final trial being completely determined.

Figure 5: The number of pairs active learners chose to repeat on each consecutive trial, accumulated for each of the two clusters (red=0, white=27). Learners in Cluster 2 most often repeated one—or even zero—pairs, while Cluster 2 chose anywhere from one to three repeats per trial.

How is it that repeating more than one pair on each trial can further improve learning? Working memory can likely be used to segregate repeated and unrepeated pairs on a given trial. Thus, choosing one or three objects for repetition allows the learner to infer that the single repeated or new word goes with the repeated or new object. Repeating two pairs also yields information—only 8 associations are reasonable using repetition information, instead of 16 on a normal trial—but is most useful if a learner already knows one of the repeated pairs: then they may learn the unknown pair, and practice the known pair. To elucidate what learners are doing in active training when repeating multiple pairs, we extend a recent associative model of cross-situational word learning with a working memory mechanism.

## Model

The Experiment showed that adults learn many more words from active cross-situational training than passive training. Our analysis of active learning strategies found that most people repeated one or more pairs in consecutive trials, and that repeating more pairs helped: many excellent learners repeated close to two pairs per trial. To understand how this is helpful, we will introduce and then extend an associative model of cross-situational word learning proposed by Kachergis, Yu, and Shiffrin (2012).

The model assumes that learners do not equally attend to all word-object pairings on a trial (i.e., store all co-occurrences). Rather, selective attention on a trial is drawn to strengthen associations between words and objects that have co-occurred previously. This bias for familiar pairings competes with a bias to attend to stimuli that have no strong associates (e.g., as a novel stimulus). The competing familiarity and uncertainty biases allow the model to exhibit fast mapping, since a novel word-novel object combination will demand more attention, and mutual exclusivity: a novel

word will only become weakly associated with an already-known referent (Kachergis, Yu, & Shiffrin, 2012). For example, suppose word  $w_1$  and object  $o_1$  have appeared together and are thus somewhat associated, while  $w_7$  and  $o_7$  are novel. Given a trial with both pairs:  $\{w_1, o_1, w_7, o_7\}$ ,  $w_1-o_1$  demands more attention than  $w_7-o_1$ ,  $w_1-o_7$ , or  $w_7-o_7$ , since  $w_1-o_1$  is stronger than baseline. However, attention is also pulled individually to  $w_7$  and to  $o_7$ , since both of these novel stimuli have no strong associates. Uncertainty is measured by the entropy of each stimulus' association strengths. Because of the high joint uncertainty of  $w_7$  and  $o_7$ , more attention is given to the association  $w_7-o_7$ . Thus, attention is mostly divided between  $w_1-o_1$  and  $w_7-o_7$ , although the other pairings will be strengthened a bit.

Formally, let  $M$  be an  $n$  word  $\times$   $n$  object association matrix that is incrementally built during training. Cell  $M_{w,o}$  will be the strength of association between word  $w$  and object  $o$ . Strengths are subject to forgetting (i.e., general decay) but are augmented by viewing the particular stimuli. Before the first trial,  $M$  is empty. On each training trial  $t$ , a subset  $S$  of  $m$  word-object pairings appears. If new words and objects are seen, new rows and columns are first added. The initial values for these new rows and columns are  $k$ , a small constant (here, 0.01).

Association strengths are allowed to decay, and on each new trial a fixed amount of associative weight,  $\chi$ , is distributed among the associations between words and objects, and added to the strengths. The rule used to distribute  $\chi$  (i.e., attention) balances a bias for attending to unknown stimuli with a bias for strengthening already-strong associations. When a word and referent are repeated, extra attention (i.e.,  $\chi$ ) is given to this pair—a bias for prior knowledge. Pairs of stimuli with no strong associates also attract attention, whereas pairings between uncertain objects and known words, or vice-versa, draw little attention. To capture stimulus uncertainty, we allocate strength using entropy ( $H$ ), a measure of uncertainty that is 0 when the outcome of a variable is certain (e.g., a word appears with one object, and has never appeared with any other object), and maximal ( $\log_2 n$ ) when all of the  $n$  possible object (or word) associations are equally likely (e.g., when a stimulus has not been observed before, or if a stimulus were to appear with every other stimulus equally). In the model, on each trial the entropy of each word (and object) is calculated from the normalized row (column) vector of associations for that word (object),  $p(M_{w,\cdot})$ , as follows:

$$H(M_{w,\cdot}) = - \sum_{i=1}^n p(M_{w,i}) \cdot \log(p(M_{w,i}))$$

The update rule for allocating attention and adjusting strengths for the stimuli presented on a trial is:

$$M_{w,o} = \alpha M_{w,o} + \frac{\chi \cdot e^{\lambda \cdot (H(w) + H(o))} \cdot M_{w,o}}{\sum_{w \in S} \sum_{o \in S} e^{\lambda \cdot (H(w) + H(o))} \cdot M_{w,o}}$$

In this equation,  $\alpha$  is a parameter governing forgetting,  $\chi$  is the weight being distributed, and  $\lambda$  is a scaling parameter

governing differential weighting of uncertainty and prior knowledge (familiarity). As  $\lambda$  increases, the weight of uncertainty (i.e., the exponentiated entropy term, which includes both the word's and object's association entropies) increases relative to familiarity. The denominator normalizes the numerator so that exactly  $\chi$  associative weight is distributed among the potential associations on the trial. For stimuli not on a trial, only forgetting operates. After training, a learner is tested with each word and chooses an object from  $n$  alternatives in proportion to the association strengths of each alternative to that word.

Using competing biases for familiar pairings and uncertain stimuli, this associative model learns on a trial-by-trial basis by distributing attention in a way that corresponds with both our intuitions about word-learning and a number of empirical findings. However, although this model does exhibit training order effects, it has no working memory component that would confer additional benefit for successively repeated pairs. Thus, we augment the **baseline** model with a mechanism that segregates words and objects repeated from the last trial from unrepeated stimuli, and only strengthens associations within these subsets. This working memory (**WM**) model will learn better than the baseline model whenever there are repetitions, because of the 16 possible associations on the trial, it will not attend to the spurious ones between repeated stimuli and unrepeated stimuli: 6 in the case of one or three repeated pairs, and 8 in the case of two repeated pairs. To estimate whether people are attending more to the repeated or unrepeated stimuli, we added an attention parameter  $\beta$  to the WM model that apportions more weight to associations between repeated stimuli as  $\beta$  approaches 1, and more weight to unrepeated pairs as  $\beta$  approaches 0. When  $\beta = .5$ , the attention given to repeated vs. unrepeated associations is proportional to the size of each subset.

Three parameters ( $\chi$ ,  $\alpha$ , and  $\lambda$ ) were fit to each active training order for the baseline model, and four ( $\chi$ ,  $\alpha$ ,  $\lambda$ , and  $\beta$ ) were fit to the WM model. Fitting only to the overall mean accuracy of each active training order—two conditions per learner—does not capture detail of repetition's effect on accuracy, which may vary in different active training sessions. Instead, we fit to the accuracy for each subgroup of pairs that were repeated different numbers of times (0-5, as each pair was seen 6 times). An ANCOVA shows number of repetitions significantly affected accuracy ( $F(1,209) = 8.50, p < .01$ ), discussed in more detail later.

## Results & Discussion

Overall, both models achieved quite good fits to the data, with  $R^2 = .901$  for the baseline model, and  $R^2 = .925$  for the WM model. The WM model's BIC was 577.7 and the baseline model's BIC was 565.9, so the WM model is preferred, despite the additional parameter. Figure 5 shows mean accuracy for humans and both models on the subsets of pairs that were repeated on pairs of consecutive trials. Accuracy increases from 0 to 3 repetitions, while the few people who repeated pairs 4 or 5 times improved less, though with great variability.

Figure 5. Human and model accuracy on actively-learned subsets of items that were repeated 0-5 pairs of trials (not necessarily consecutive for all repetitions—except in the rare case of 5 repetitions). Error bars are  $\pm$ SE.

Given the large number of repetitions used by active learners, it is surprising that the baseline model can approach the fit of the WM model without explicit awareness of repetitions. This may indicate that individual differences (e.g., in learning rate) contribute much of the variability. However, the WM better accounts for the data, and contains a parameter,  $\beta$ , that should be valuable in our pursuit to understand the range of strategies. Do learners focus more on repeated ( $\beta \approx 1$ ) pairs, unrepeatd pairs ( $\beta \approx 0$ ), or do they split attention ( $\beta \approx .5$ )? Figure 6 shows the trimodal distribution of the estimated  $\beta$  values: many people focused almost exclusively on learning the repeated pairs, but several attended only to unrepeatd pairs, and the majority split attention roughly equally. Once again, we see individual differences spanning the range of possibilities, although the peaks are of interest. However,  $\beta$  values were uncorrelated with accuracy ( $r = .06$ ), and people with modal  $\beta$  values showed no different accuracy, on average. Thus, the WM model found three attention strategies for repeated pairs, but the strategies alone do not predict performance.

Figure 6: Histogram of best-fitting  $\beta$  values, showing a trimodal distribution peaked (highest to lowest) at 1—attend repeated pair, .5—split attention, and 0—attend unrepeatd.

## General Discussion

Active learning can speed language acquisition if the learner can implement an appropriate strategy based on the

information available to them. In the context of cross-situational word learning, we have shown that many adults can generate strategies that improve their overall learning. Indeed, people who did active learning first were better at passive learning, suggesting that some strategies carried over, which is somewhat puzzling because many of the active learning strategies involved trial-to-trial repetitions of at least one word-object pair—many more, in the most successful active learning blocks. Given that active learners were using many repetitions, but with apparently diverse strategies and outcomes, we extended a word-learning model with a working memory mechanism to attempt to see how people were leveraging repetitions. Overall, the model accounted for active learning accuracy very well, but parameters told of a plurality of strategies: many people ignore unrepeatd pairs while several only attend to these pairs, but the majority fall roughly in the middle, attending to both repeated and unrepeatd pairs. It may be that this focus often shifts during a block, as knowledge develops. Future work should also focus on predicting which pairs people will choose next, perhaps based on their current knowledge state.

In summary, active noun learners use many repetitions, and successfully learn far more than in passive training. Infants may also benefit from such repeated labeling, and fortunately there is much autocorrelation in scenes (as you turn your head or shift your eyes, many objects remain in view) and in language (conversations drift over minutes). Moreover, we suggest that infants likely influence their learning environment in a way that is analogous to the active learning paradigm we present here. By choosing to look longer at some objects, they may increase the likelihood that a caregiver will label one of those objects. Active learning is clearly a powerful learning aid, and with better understanding it can likely be harnessed in education to speed learning in many domains.

# Learning Nouns with Domain-General Associative Learning Mechanisms

George Kachergis

Bloomington, IN 47405 USA

## Abstract

Associative learning has been meticulously studied in many species, and diverse effects have been explained using a handful of basic assumptions and mechanisms. Human language acquisition proceeds remarkably quickly and is of great interest, but is arguably more difficult to capture under the microscope. Nonetheless, empirical investigations have led researchers to theorize a variety of language learning principles and constraints. While there may indeed be language-specific learning mechanisms that are distinct from more universal associative learning mechanisms, we seek to explain some basic principles of language acquisition using domain-general mechanisms. Using an experiment and a model, we show how the principles of mutual exclusivity—an assumption of 1-to-1 word-object mappings, contrast, and other constraints related to fast mapping may stem from attention mechanisms attributed to associative learning effects such as blocking and highlighting, but directed by competing biases for familiar and unfamiliar pairs instead of surprise.

**Keywords:** statistical learning; language acquisition; cross-situational learning; associative learning; attention

## Introduction

All organisms learn, but only humans master human languages. Since many neural structures and basic learning mechanisms are conserved across species, it bears asking how much of human language learning can be explained with domain-general mechanisms, without appealing to innate (i.e., evolved) linguistic knowledge, exemplified by the work of Noam Chomsky, or domain-specific principles and constraints, whether innate or developed early in life (e.g., Markman, 1992).

One essential part of language learning is learning word-object mappings—nouns. Two border collies have been shown to learn hundreds of nouns over years of training (Pilley & Reid, 2011; Kaminski, Call, & Fischer, 2004). Of course, this feat pales in comparison to human language learning: infants begin producing words at 1 year, and by the end of high school have command of 60,000 words, conservatively (Bloom, 2000). However, both dogs and infants have been shown to fast map: given a new word, they will choose a new object over an object with a known label, and retain the mapping weeks later (see Bloom, 2000). Fast mapping is a powerful ability for word learning, but is it based on domain-general or domain-specific learning mechanisms?

One approach to studying language acquisition views word learning as a problem of induction with an enormous hypothesis space, and proposes a number of constraints to restrict the space (Markman, 1992). In this view, infants generate hypotheses that are consistent with this set of constraints and principles. The present paper is concerned

with a subset of these principles that relate to how people map new words to objects.

Mutual exclusivity (ME) is the assumption that every object has only one name (Markman & Wachtel, 1988). A fill-the-lexical gap bias, which causes children to want to find a name for an object with no known name, has also been proposed (Clark, 1983) and argued (Merriman and Bowman, 1989). When given a set of familiar and unfamiliar objects, it has been shown that 28-month-olds assume that a new label maps to an unfamiliar object (e.g., Mervis & Bertrand, 1994). Similarly, the principle of contrast states that an infant given a new word will seek to attach it to an unlabeled object (Clark, 1983). Fill-the-gap, ME, and contrast make many of the same predictions made by the more general novel name-nameless category principle (N3C), which states that novel labels map to novel objects (Golinkoff, Mervis, & Hirsh-Pasek, 1994).

It is not our goal to explore the overlapping and nuanced ways that these various principles interact. Indeed, we hope to avoid this confusing plurality of explanations by showing that many of the behaviors ascribed to these theories can be explained by domain-general learning mechanisms uncovered by studies of associative learning. Nor are we the first to suggest that human language acquisition—as fast and yet difficult as it is—can be explained with domain-general learning mechanisms: Smith (2000) argued as much, and much recent work in statistical learning (described below) is motivated by this premise. Recent work has even found that children show a 1-to-1 bias in domains other than language: voices to faces (Moher, Feigenson, & Halberda, 2010) and actions to objects (Childers & Tomasello, 2003). However, few direct analogies have been drawn between the models and paradigms of word learning and associative learning, but see Ramscar et al. (2010). After introducing some associative learning paradigms and linking them to word learning, we discuss how universal attentional biases may account for many behaviors observed across domains. Finally, we report a new empirical word learning study using an associative learning highlighting design, and explain the results with a word-learning model that has competing attentional biases for familiarity and uncertainty.

## Associative Learning

Associative learning paradigms typically present one or more perceptual cues (e.g., objects, sounds), learners make a response (e.g., a button press), and feedback is given (e.g., food, a shock). When one cue  $q_1$  is paired with outcome  $o$  on each trial, the resulting  $q_1$ - $o$  association is stronger than  $q_1$ - $o$  when two simultaneous cues  $\{q_1, q_2\}$  predict  $o$  during training; thus,  $q_2$  is said to *overshadow*  $q_1$  (Pavlov, 1927). A

reasonable way to explain overshadowing is that attention is split between the two cues, and thus the associations  $q_1-o$  and  $q_2-o$  grow more slowly than when  $q_1$  appears alone. Attention is also used to explain the *blocking* effect (Kamin, 1968), which can be induced using a design with two training stages. In the early stage, cue  $q_1$  is repeatedly paired with outcome  $o$ , and in the late stage  $q_1$  and  $q_2$  appear jointly preceding  $o$ . The association between  $q_2$  and  $o$  is found to be much weaker than when only the late stage occurs. Thus  $q_2$  has been blocked by  $q_1$ 's earlier association with  $o$ —much like mutual exclusivity (ME) states that learners will not map a second label ( $q_2$ ) to a known object ( $o$ ). Learning models, updating knowledge trial-to-trial, account for blocking using selective attention to  $q_1$ : since  $q_1$  already predicts  $o$ , there is no need to strengthen  $q_2-o$  (e.g., Rescorla & Wagner, 1972; Pearce & Hall, 1980). Is blocking found in word-learning experiments? Can ME be thought of as blocking? As it happens, two cross-situational word-learning studies can be seen to address these questions.

### Cross-situational Word Learning

A key challenge in early word learning is to deal with the referential uncertainty intrinsic to complex scenes and utterances. Recent research has focused on how regularities in the co-occurrence of words and objects in the world can significantly reduce referential ambiguity across situations. Statistical word learning relies on two assumptions: 1) that spoken words are often relevant to the current situation, and 2) that learners can remember to some degree the co-occurrence of multiple words and objects in a scene. Thus, as the same words and objects are observed in different situations across time, people can learn the correct word-object mappings.

In adult cross-situational learning studies (e.g., Yu & Smith, 2007), participants are asked to learn the meaning of alien words from a series of training trials, each of which contains a few spoken words and a few objects. Although each word refers to a particular onscreen object, the intended referent is not indicated in any way, leaving meanings ambiguous on individual trials. Ichinco, Frank, and Saxe (2009) used a cross-situational word-learning task in which learners are first exposed to 1-to-1 pairings on a series of trials with four word-object pairs per trial. In the late stage, after people had presumably learned some of the mappings, a fifth object (or word, in another condition) began to consistently co-occur with one of the early words (or objects). The result was little learning of the association between old word (or object) and new object (or word) association, consistent with ME. However, this design can be seen to closely match a blocking design (see Table 1), with a few notable differences.

First, it is unclear whether words should be construed as cues and objects as outcomes, or the reverse—an issue we will return to. Second, a cross-situational trial has multiple outcomes, unlike associative learning paradigms. Finally, no trial-to-trial feedback is given, but the learner may generate it on the basis of the preceding training trials. We contend that none of these differences are a fundamental problem

with seeing cross-situational learning as associative learning. Indeed, if anything the learning problem in the real world is more like cross-situational learning: with a multitude of stimuli that may simultaneously serve as either cues or outcomes for as many other stimuli, learners attempt to associate correlated stimuli.

Training Stage	Ichinco et al., 2009	Kamin, 1968
Early	$\{w_1, w_x, w_y, w_z\} - \{o_1, o_x, o_y, o_z\}$	$q_1-o$
Late	$\{w_1, w_x, w_x, w_z\} - \{o_1, o_2, o_x, o_y, o_z\}$	$\{q_1, q_2\}-o$

Table 1: Comparison of the blocking paradigm (right) with a cross-situational word learning paradigm (left). In both paradigms, the late-stage stimulus ( $q_2 / o_2$ ) is blocked from becoming associated with the outcome ( $o / w_1$ ), despite consistent co-occurrence in the late stage.

Thus, learners in the Ichinco et al. study may not learn the extra association ( $w_1-o_2$ ) because attention remains focused on strengthening the still-present early-trained association ( $w_1-o_1$ ). This attentional account is equivalent to the popular account for blocking, and is corroborated by an earlier result that defies ME: Yurovsky and Yu (2008) used a two-stage cross-situational design much like Ichinco et al., but in the late stage when adding a new stimulus to an existing association, removed the old object (or word). Faced with a word ( $w_1$ ) they have associated with  $o_1$ , but now seeing  $o_2$  without  $o_1$  repeatedly, people learned the association, but also retained  $w_1-o_1$  at test. Yurovsky & Yu's learners cast about for a new associate, unblocked by the presence of an old associate to attend to—unlike in Ichinco et al.'s study. In summary, by establishing an analogy of cross-situational learning as a complex associative learning paradigm, we found that two cross-situational studies can be explained with a domain-general selective attention mechanism, without recourse to a language-specific constraint such as ME. To further examine the role of attention in cross-situational learning, we do a word learning experiment using a design that in associative learning yields the interesting order effect of highlighting.

### Experiment: Highlighting

Like blocking, highlighting is a learning order effect that has been attributed to selective attention (Medin & Edelson, 1988; Kruschke, 1996). In an early stage of training, a cues *PE* (Perfect Early) and *I* (Imperfect) jointly appear on each trial, followed by outcome *E* (Early). In a late stage, cue *I* appears with *PL* (Perfect Late), followed by outcome *L*. Thus, *I* imperfectly predicts both outcomes, having first predicted *E*, and later *L*. On the other hand, *PE* perfectly predicts *E*, and symmetrically, *PL* perfectly predicts *L*. As depicted in Figure 1, learners show an order effect: *PE* and *I* both become associated with *E* in the early stage, and then *PL* becomes more strongly linked with *L* while *I-PL* languishes. This is presumably because attention is shifted away from *I*, since it already predicts *E* in the early stage.

Formerly known as the inverse-base rate effect (note that *I* is twice as frequent as *PE* or *PL*), Kruschke (2009) presented a study with balanced frequency of the early and late training stages and still found highlighting, lending further credence to the attention account.

Figure 1: The co-occurrences of cues and outcomes in the highlighting design (right), and the estimated strength of associations between each cue and outcome (left), shown by the thickness of the lines.

Following a similar design, we use the Experiment to ask 1) whether highlighting occurs in a cross-situational framework with no explicit feedback on each trial, and 2) if words are cues and objects are outcomes, vice versa, or if they are interchangeable. As shown in Figure 2, this is done by making the cues in a highlighting design correspond to either words or objects, resulting in 2 words (cues) and 1 object (outcome) per trial, or 2 objects (cues) and 1 word (outcome) displayed per trial. Seeing a highlighting effect in one condition and not the other may suggest one correspondence over the other, whereas highlighting in both conditions suggests that words and objects can act as either cues or outcomes. Finally, finding no highlighting would suggest that domain-specific mechanisms may be at work in word learning.

Figure 2: Highlighting designs in the Experiment (left), with word x object co-occurrence matrices (right). In the words as cues condition, 2 words and 1 object were given on each trial (top), while 2 objects and 1 word were given in the objects as cues condition (bottom).

## Subjects

Participants were 67 undergraduates at Indiana University who received course credit for participating. None had previously participated in cross-situational experiments.

## Stimuli & Procedure

Twelve pseudowords and 12 objects were randomly drawn from larger sets of stimuli, randomly paired, and split between the two conditions. The pseudowords (words) are phonotactically-probable in English (e.g., “bosa”), and were spoken by a monotone, synthetic female voice. The objects were photographs and drawings of uncommon objects (e.g., sculptures, specialty tools). Each training trial in the **words as cues** condition consisted of one object and two spoken words, while training trials in the **objects as cues** condition had two objects visible while one word was spoken. In both conditions, the object(s) remained visible for the duration of the trial. Each trial began with 2s of silence before the first 1s word was heard. In the words as cues condition, the second word was played after 1s of silence. In both conditions, the last word was followed by 3s of silence. In total, each trial in the objects as cues condition lasted 6s and trials in the words as cues condition lasted 7s.

Training for each condition consisted of 28 trials. The highlighting structures shown in Figure 2 were replicated within each condition: in words-as-cues, people heard six words and saw four objects, while in objects-as-cues, people heard four words and saw six objects. Knowledge was assessed after the completion of each condition using 6AFC testing: learners were asked to choose the best object for each of the six words. That is, we are probing the conditional probability objects, given a word. Note that in words-as-cues, two of the six objects available at test had not been seen during training, while in objects-as-cues, two words were never heard. These were not removed to keep the conditions symmetric, and in case systematic response deviations were found. Words were tested in random order. Note that the test in the words as cues condition corresponds most directly to associative learning testing: participants are given a cue (word) and asked to predict the outcome (object). In the objects as cues condition, we are actually asking learners to choose the best cue (object) when given an outcome (word). Participants completed both conditions in counterbalanced order.

## Results & Discussion

Figure 3 displays the conditional probabilities of choosing each object<sup>1</sup>, given each word, and the corresponding estimated relative strengths of each word-object association. The results in both conditions exhibit all the characteristics of highlighting: cue *I* is more strongly linked to *E* than *L*, and although *PE-E* and *PL-L* are both quite strong, *PL-L* is stronger. In the words as cues condition, object *o*<sub>1</sub> (*E*) was

<sup>1</sup> As noted before, there were two highlighting replications in each condition, so there were six objects available at test. Here we have collapsed the two replications for ease of presentation, and left out incorrect responses (e.g., choosing *o*<sub>4</sub>, *o*<sub>5</sub>, or *o*<sub>6</sub> for *w*<sub>1</sub>, *w*<sub>2</sub>, or *w*<sub>3</sub>). The mean response probability for these cells is .08.

chosen significantly more than  $o_3$  ( $L$ ; .51 vs. .25) for word  $w_3$  ( $I$ ;  $\chi^2(1, N=79) = 9.23, p < .01$ ). In the objects as cues condition,  $o_3$  ( $I$ ) was chosen significantly more often for  $w_1$  ( $E$ ) than  $w_3$  ( $L$ ; .28 vs. .16;  $\chi^2(1, N=73) = 6.04, p = .01$ ). Thus, the early association of  $I$  with  $E$  kept  $I$  from becoming strongly associated with  $L$ —much like a mutual exclusivity constraint would keep people from associating a second word with an already-labeled object. Given words as cues,  $L$  ( $o_3$ ) was chosen more often for  $PL$  ( $w_2$ ) than  $E$  ( $o_1$ ) was chosen for  $PE$  ( $o_1$ ; .82 vs. .69), though the difference was not significant ( $\chi^2(1, N=157) = 1.08, p = .30$ ). Similarly, given objects as cues,  $PL$  ( $o_2$ ) was chosen more often for  $L$  ( $w_3$ ) than  $PE$  ( $o_1$ ) was chosen for  $E$  ( $w_1$ ; .71 vs. .60), but again the difference was not significant ( $\chi^2(1, N=215) = 1.68, p = .20$ ). Despite not being statistically significant<sup>2</sup>, these conditional response rates match a highlighting result in both cases:  $PL$ - $L$  is learned faster (stronger) because little attention is given to  $I$ - $L$ , as cue  $I$  is already associated with  $E$ . In terms of word learning, this is much like the novel name-nameless category principle (N3C; Golinkoff et al., 1994): given a new object (or word— $PL$ ), it is reasonable to associate this with a new word (or object— $L$ ), rather than a word (or object— $PE$ ) with an already-known associate ( $E$ ).

Figure 3: Collated response probabilities ( $p(o|w)$ ) for the two conditions in the Experiment (right). Both conditions show evidence of highlighting, with estimated association strengths shown by thickness of cue-outcome links (left).

In summary, the Experiment shows that highlighting can take place in a cross-situational word learning context, both with objects as cues and words as outcomes, and vice versa. The selective attention account of highlighting holds that the early association of  $PE$  and  $I$  with  $E$  reduces attention to the

later co-occurrence of  $I$  with  $L$ , thereby leaving  $PL$ - $L$  to gain more attention (i.e., strength). We contend that this domain-general account explains word-learning behavior not only in this Experiment, but in many situations that have motivated verbal theories of language-specific constraints. In the next section, we introduce a version of a recent associative model of word learning that shows what sort of attentional biases can account for highlighting—and word learning.

## Model

Familiarity and novelty are among the simplest ways to be aware of one's knowledge state about stimuli, and both biases have been observed in infants—inferred from their influence on attention (for an overview, see Hunter & Ames, 1988). Kachergis, Yu, and Shiffrin (2012) introduced an associative model with these biases, and showed that it accounts for fast mapping in adults, as well as gradual relaxation of ME with further training. The model assumes that word-object pairings on each trial compete for attention (i.e., associative strength). Attention is preferentially given to word-object pairings that are already associated by previous co-occurrence. Such a mechanism naturally exhibits blocking, since after the early association of  $q_1$  with  $o$ , it will continue to strengthen  $q_1$ - $o$  in the late stage, barely attending  $q_2$ - $o$ . However, the model's bias for familiar pairings competes with a bias to attend to stimuli with no strong associate (e.g., a novel stimulus). This bias can help explain behaviors covered by language-learning principles such as contrast and N3C. We describe the model below, and show how it accounts for highlighting using competing attention for familiar pairings and uncertain stimuli.

Formally, let  $M$  be an  $m$  word  $\times$   $m$  object association matrix that is arbitrarily large (here,  $m=100$ ). Cell  $M_{w,o}$  is the strength of association between word  $w$  and object  $o$ . Strengths are subject to forgetting (i.e., general decay) but are augmented by viewing the particular stimuli. Before the first trial,  $M$  has no information: each cell is set to  $1/m$ . On each training trial  $t$ , a subset  $S$  of words and objects appear.

Association strengths are allowed to decay, and on each new trial a fixed amount of associative weight,  $\chi$ , is distributed among the associations between words and objects, and added to the strengths. The rule used to distribute  $\chi$  (i.e., attention) balances a preference for attending to unknown stimuli with a preference for strengthening already-strong associations. When a word and referent are repeated, extra attention (i.e.,  $\chi$ ) is given to this pair—a bias for prior knowledge. Pairs of stimuli with no or weak associates also attract attention, whereas pairings between uncertain objects and known words, or vice versa, do not attract much attention. To capture stimulus uncertainty, we allocate strength using entropy ( $H$ ), a measure of uncertainty that is 0 when the outcome of a variable is certain (e.g., a word appears with one object, and has never appeared with any other object), and maximal ( $\log_2 n$ ) when all of the  $n$  possible object (or word) associations are equally likely (e.g., when a stimulus has not been observed before, or if a stimulus were to appear with

<sup>2</sup> Testing the relative strength of  $PE$ - $E$  and  $PL$ - $L$  would ideally be done with a trial that presents both cue  $PE$  and  $PL$ , and asks learners which outcome is preferred. However, a test of this sort is difficult to do in a paradigm with spoken words, and we instead chose to match previous word learning paradigms for consistency.

every other stimulus equally). In the model, on each trial the entropy of each word (and object) is calculated from the normalized row (column) vector of associations for that word (object),  $p(M_{w,\cdot})$ , as follows:

$$H(M_{w,\cdot}) = - \sum_{i=1}^n p(M_{w,i}) \cdot \log(p(M_{w,i}))$$

The update rule for adjusting and allocating strengths for the stimuli presented on a trial is:

$$M_{w,o} = \alpha M_{w,o} + \frac{\chi \cdot e^{\lambda \cdot (H(w) + H(o))} \cdot M_{w,o}}{\sum_{w \in S} \sum_{o \in S} e^{\lambda \cdot (H(w) + H(o))} \cdot M_{w,o}}$$

In this equation,  $\alpha$  is a parameter governing forgetting,  $\chi$  is the weight being distributed, and  $\lambda$  is a scaling parameter governing differential weighting of uncertainty and prior knowledge (familiarity). As  $\lambda$  increases, the weight of uncertainty (i.e., the exponentiated entropy term, which includes both the word and object's association entropies) increases relative to familiarity. The denominator normalizes the numerator so that exactly  $\chi$  associative weight is distributed among the potential associations on the trial. For stimuli not on a trial, only forgetting operates. After training, for each word the model's choice probabilities on  $k$  alternative objects is determined by the softmax choice rule (Bridle, 1990):

$$p(o|w) = \frac{\exp(\phi M_{w,o})}{\sum_k \exp(\phi M_{w,o_k})}$$

where  $\phi$  is a scaling parameter that determines the level of discrimination the model shows:  $\phi$  values above 1 amplify small differences in association weights.

The model was trained on the same 28 trials of word-object co-occurrences experienced by participants in the two conditions, and the four parameters were fit to minimize the discrepancy between the model's predicted response rates and the 36 human choice proportions for each condition. In the words as cues condition, the best-fitting parameters ( $\chi=.11$ ,  $\lambda=.46$ ,  $\alpha=1$ ,  $\phi=6.16$ ) achieved an  $R^2$  of .984 (MSE=9.5e-4). In the objects as cues condition, the best-fitting parameters ( $\chi=.12$ ,  $\lambda=.37$ ,  $\alpha=1$ ,  $\phi=6.16$ ) achieved an  $R^2$  of .884 (MSE=.0044). Both fits are quite good, and the best-fitting parameters are close in value. With  $\alpha=1$ , forgetting was not operating; perhaps memory is not taxed by such a small number of words and objects—cross-situational studies typically have more than a dozen pairs. With  $\phi=6.16$ , the model showed good discrimination at test.

Shown in Figure 4, the model's response proportions are close to the data and fit qualitatively well, showing the highlighting effect in both conditions. How does the model do this? In the first stage of words-as-cues, when  $w_1$  (*PE*) and  $w_3$  (*I*) co-occur with  $o_1$  (*E*), attention is split between the associations  $w_1-o_1$  and  $w_3-o_1$ , and the uncertainty about all three stimuli drops as knowledge grows. Moving to the second stage, when  $w_2$  (*PL*) and  $w_3$  (*I*) appear with  $o_3$  (*L*),  $w_2-o_3$  demands more attention than  $w_3-o_3$  because  $w_3$  has lower uncertainty from early training, while  $w_2$  is novel and has no associates. During the second stage,  $w_2-o_3$  thus gets

more attention than  $w_3-o_3$ , and becomes relatively stronger than the early  $w_1-o_1$  association. Thus, using competing biases for uncertain stimuli and familiar associations, the model mimics the highlighting effect shown by people.

#### Words as Cues (2 words, 1 object)

	Model				Human

		Object							

Figure 4: Human response probabilities (right) and model response probabilities (left) closely match in the words as cues condition (top), and match well with objects as cues, showing highlighting in both cases.

Intriguingly, the model shows an asymmetry between conditions that is less striking in humans. With objects as cues, when given  $w_1$  (*E*), the model shows less bias towards  $o_1$  (*PE*) than humans do: people choose  $o_1$  twice as often as  $o_3$  (*I*), whereas the model chooses  $o_1$  only a bit more than  $o_3$ . Humans may show a stronger bias for  $o_1$  (*PE*) because they have retrospectively decreased the association between  $o_3$  and  $w_1$  once  $o_3$  began appearing with  $w_3$ . Another possibility is that people use uncertainty at test:  $o_1$  (*PE*) has lower entropy than  $o_3$  (*I*) since it only occurred with  $w_1$ . With words as cues, both objects have equal entropy. This asymmetry deserves future study, and may yet leave room for language-specific constraints.

### General Discussion

We have presented an analogy between cross-situational word learning and associative learning, shown how a study of the former (Ichinco et al., 2009) is a blocking design, and suggested the result is straightforwardly explained with the same domain-general attention mechanism. As evidence that attention creates order effects in word learning, we found highlighting—an associative learning effect ascribed to attention (Medin & Edelson, 1988; Kruschke, 1996)—in a cross-situational word learning experiment. Moreover, we showed that an associative word-learning model with competing attentional biases for familiarity and uncertainty (Kachergis, Yu, & Shiffrin, 2012) accounts for these results.

By linking word learning to associative learning, as suggested by Smith (2000), we may find that the plurality of overlapping language-specific constraints (e.g., ME, N3C, contrast, and fill-the-gap) are unnecessary to explain many

language learning behaviors. Instead, we predict that a more parsimonious explanation will emerge, built upon a foundation of domain-general mechanisms. Language-specific principles and constraints may yet exist, but we should first see how far more universal mechanisms take us.

Moreover, note that this bridge between domains is two-way: the present study used what was originally a word-learning model to explain highlighting. Although our model's attentional account is similar to the account given by other learning models (for an overview see Kruschke, 2011), other models do not use competing uncertainty and familiarity biases to shift attention. Instead, many models use a measure of prediction error to determine the rate of association change (e.g., Rescorla & Wagner, 1972; Pearce & Hall, 1980). In language, objects produce words in speakers ("Watch out—snake!"), but words predict objects for listeners. For language learners, we have shown that both directions of training produce a highlighting effect, captured by our model's symmetric associations and simple biases without generating predictions. These mechanisms, based on some of the simplest cues of knowledge state, may also fare well in other associative learning paradigms—in and out of a word-learning context.

Thus, future work in both domains can benefit from an exchange of ideas to uncover commonalities and differences, and to flesh out and refine verbal theories. We hope that others will find it enlightening to explore the link between associative learning, language acquisition, and other domains.

### Acknowledgments

Thanks to John K. Kruschke and Stephen Denton for helpful discussions, to Daniel Yurovsky for comments, and to Patrick LaFree, Jennifer Lee, and Kim Mullen for data collection.

## Abstract

The primacy effect in free recall is commonly attributed to more frequent rehearsals for stimuli in the first few serial positions. Using event-related potentials (ERPs), we investigated whether the first list position also provides a distinctive feature to the stimulus, which enhances its encoding and aids retrieval on a recall test. The amplitude of the P300 elicited by stimuli that deviate physically or semantically from their context has previously been shown to correlate with the probability of later recall when participants use rote rehearsal. We reasoned that if the temporal distinctiveness of the first item in a list contributes to its enhanced recall, such a P300 subsequent memory effect should be present for this item as well. Participants studied and immediately recalled lists of 15 words including one physically deviant “isolate” while their EEG was recorded. We quantified P300 amplitude by a principal component analysis, and applied a correction for inter-trial latency jitter. The first words in a list and isolates were better recalled than regular words in the middle list positions, and the P300 elicited by these words was correlated with subsequent recall. Regular words in the middle list positions, as well as words in the second list position, did not show such a P300 subsequent memory effect. These results support a distinctiveness-based explanation of the primacy effect in free recall.

**Keywords:** Primacy effect; event-related potentials; free recall; P300; subsequent memory effect.

## Introduction

We tested the hypothesis that items in the first serial position of a study list are distinctive, which accounts for the primacy effect in free recall. We used the P300 event-related potential (ERP) as an index of distinctiveness. Prior studies have shown that under rote rehearsal the amplitude of the P300 elicited by physically or semantically deviant study items is correlated with later recall success (Fabiani & Donchin, 1995; Fabiani, Karis & Donchin, 1990; Karis, Fabiani & Donchin, 1984). We investigated whether this same effect is also observed for the first list item, which would support a distinctiveness-based explanation of the primacy effect in free recall.

The term “primacy effect” refers to the increased probability of free recall of the first few, compared to the middle items within a study list. The most influential explanation for this effect attributes it to more frequent

rehearsals of primacy items (e.g., Rundus, 1971). However, some data indicate that part of the recall enhancement for the first item (at least when it is also the first item retrieved) cannot be explained by rehearsal frequency (e.g., Howard & Kahana, 2002). The first item is also at a unique list position that may make this item stand out. Therefore, the distinctiveness of the first item may contribute to its greater probability of recall success (e.g., Brown, Neath & Chater, 2007).

One difficulty in testing distinctiveness-based explanations of behavioral phenomena lies in the fact that “distinctiveness” refers to a subjective experience rather than a physical property of an object (Hunt, 2006). Therefore, it is essential to find a measure of distinctiveness that is independent of the enhanced recall. To this end, a neural index of perceived distinctiveness is the P300 component of the ERP (Sutton, Braren, Zubrin & John, 1965), which peaks between 300 and 700 ms after the presentation of stimuli that are rare, unexpected, as well as task-relevant (for a review see Donchin, 1981). The *context updating model* (Donchin, 1981; Donchin & Coles, 1988) associates P300 amplitude with the degree to which novel information conflicts with expectations derived from a mental schema; information thus registered as unexpected, or distinctive, is then incorporated to update the schema. Since this process occurs interactively with information in long-term memory, this theory closely relates the P300 to memory processes.

To the extent that P300 indexes distinctiveness, the results of Ritter, Vaughan and Costa (1968) support the idea that stimuli at the beginning of a sequence are distinctive when their onset is unpredictable. They showed that, in addition to physically deviant stimuli, only the first stimulus in a monotonous sequence elicited a P300. By contrast, the second stimulus and all subsequent stimuli that did not stand out from the sequence, did not elicit a P300.

Items that stand out from their study list are more likely to be recalled than non-distinctive items (Von Restorff, 1933). Several studies have shown that when participants use rote rehearsal, physically distinctive words that elicit larger P300 amplitudes are more likely to be recalled on a later free recall test (Fabiani & Donchin, 1995; Fabiani et al. 1990; Karis et al. 1984; Otten & Donchin, 2000). Since the variance in P300 amplitude and the variance in recall

probability are correlated, the enhancing effects of distinctiveness on recall can be indexed by this correlation.

The design used in these studies, as well as in the present study, is known as the *subsequent memory paradigm*. Participants view several study items while their brain activity is recorded and later complete a memory test. Then, their brain activity is sorted according to the degree to which items were subsequently remembered (the *subsequent memory effect*, for a review see Paller & Wagner, 2002).

Previous studies examining primacy subsequent memory effects using the P300 have yielded inconsistent results. Azizian and Polich (2007) reported that P300 amplitude elicited by words in the initial list positions was correlated with recall; however the authors collapsed ERPs across the first three list positions – a disadvantage from the standpoint of our hypothesis that P300 amplitude will be correlated with recall only for position 1. By contrast, Wiswede, Ruesseler and Muentz (2007) reported that although the first word elicited a P300, there was a P300 subsequent memory effect only for the *final* study words. A problem with this study is that only 11 out of 18 participants showed a primacy effect; a subsequent memory effect may have been obtained if the behavioral effect was more reliable. A third study found only a small primacy effect and no P300 subsequent memory effects for either primacy or recency positions (Rushby, Barry & Johnstone, 2002). This study, however, averaged over 5 consecutive list positions, again preventing conclusions about the first item only.

All three studies ignored the possibility that P300 latency may have varied between trials and participants - as their broad ERP waveforms suggest. Since such *latency jitter* can reduce average ERP amplitudes, a correction allows for more meaningful comparisons between conditions (e.g., Spencer, Abad, & Donchin, 2000). A further shortcoming is that all studies used mean- or peak amplitude measures to quantify the P300, which are not able to disentangle overlapping ERP components. Finally, no study included a manipulation known to elicit a P300, such as the isolation of a word by its font size; such a manipulation would allow for a direct comparison of subsequent memory effects for the first list position and isolates.

Some support for the idea that primacy items may show a P300 subsequent memory effect comes from an fMRI study in which the first list items elicited stronger activity in brain areas known to generate the P300 (the temporoparietal junction) when these words were later successfully retrieved in an associative recall test (Sommer, et al., 2006). However, fMRI has a lower temporal resolution than ERPs and the design differed from typical free recall studies, so our distinctiveness hypothesis remains to be tested.

We addressed the shortcomings of the prior ERP studies by including a physical “isolate” in each list, by applying a principal component analysis (PCA), and by correcting for latency jitter. We hypothesized that, similar to the isolates, words in list position 1 are distinctive and therefore elicit a P300, which will be larger for those words that are later successfully recalled, compared to forgotten items.

## Methods

For this study we combined data from two experiments, each employing 20 critical lists (i.e., lists of interest for the present analysis) randomly interspersed with other list types. Each list was presented as part of a study-recall sequence. Critical lists consisted of 15 words, including one physically deviant word (see below). In one study, lists that varied in word frequency ( $n=23$ ) were randomly interspersed with the critical lists; in the other study, word lists of varied emotional content were employed ( $n=22$ ). Here, we only report data from the critical list type. A comparison of the recall- and ERP data ensured that there were no differences between the samples.

**Participants.** Forty five college students participated in exchange for course credit ( $n=33$ ) or \$7 per hour ( $n=12$ ). The data from 14 participants were excluded from the analysis due to excessive artifacts in their EEG<sup>1</sup>, and one participant was excluded due to non-compliance with the instructions. The remaining 22 female and 8 male participants were between 18 and 45 years old ( $M=22.57$ ). All participants gave written informed consent, and all procedures were approved by the institutional review board.

**Stimuli.** Each study list contained 15 words, presented one at a time in white 16 pt font of Arial Unicode style, on a black screen. Stimuli included emotionally neutral nouns, verbs and adjectives with a word frequency of 11-50 per million according to Francis & Kucera (1982), and were between 3 and 8 letters long. The composition of each list and the order of words within a list were randomized, and no word was presented to the same participant twice. Words were presented for 250ms, followed by a fixation cross for 2s. Each critical list contained an “isolate” in a larger font size (24 pt), which was randomly placed between serial positions 6 and 10. After the last word of each list, a grey triangle appeared indicating the start of the recall phase.

**Procedure.** The experiment consisted of two sessions, each up to 2 1/2 hours long. Over the course of the two sessions, participants studied a total of 70 (exp 1) or 80 (exp 2) word lists, including 20 critical lists. The first session also contained 2 practice lists. After the preparations for the EEG recording, participants were seated at a distance of 60cm from the computer screen and instructed to memorize the words using rote rehearsal. After each list, participants wrote down every word they remembered in any order. Recall lasted at least 45s, but participants were allowed to write down words for as long as they wished. Participants initiated the start of the next list with a button press and breaks were allowed after sets of 4 lists. After the second session participants were debriefed about their encoding strategies.

---

<sup>1</sup> The high number of participants excluded due to artifacts was due to frequent movement artifacts at the beginning of the lists, possibly because participants were still getting comfortable.

**EEG Recording and Analysis.** The EEG was recorded with a 128 channel Electrical Geodesics, Inc. (EGI) system, digitized with a sampling rate of 250 Hz and referenced to electrode Cz. For all off-line analysis we used NetStation (EGI) software, the EEGLab toolbox (Delorme & Makeig, 2004), J. Dien's EP toolkit (Dien, 2010), as well as self-written MATLAB scripts. The data were low-pass filtered at 20 Hz and segmented into epochs of 400 ms before to 2000 ms after word onset. Segments were corrected for eye blink artifacts using independent component analysis. Segments still containing artifacts were excluded and the data were mathematically re-referenced to linked mastoids and baseline corrected for a time window of 400 ms before the stimulus. We computed ERPs separately for regular words in serial positions 6-10 (henceforth referred to as "standards"), words in a larger font size ("isolates"), and for words in serial positions 1, 2, and 3.

**Principal Component Analysis (PCA).** To quantify ERP amplitudes, we conducted a spatio-temporal PCA (Spencer, Dien & Donchin, 1999). This approach has been widely used as temporal PCA (Donchin, 1966; Donchin & Heffley, 1978) in the analysis of ERP data. With the advent of dense electrode array EEG recordings, spatial PCA was developed to identify ERP component's spatial distributions (Spencer, Dien & Donchin, 1999); this is then followed by a temporal PCA to identify time courses. The PCA approach allows parsing of the ERP into components and yields measures of component amplitudes (factor scores) that can be used for testing hypotheses.

Submitted to the PCA were the ERP averages of isolates, standards (list positions 6-10), and words in positions 1, 2, and 3. We rotated 15 factors, as identified by a scree test (Cattell, 1966), using the Promax rotation method (e.g., Dien, Beal & Berg, 2005). The factor score coefficients of the PCA factor corresponding to the P300 were then applied to each EEG trial to calculate "virtual ERPs" (factor scores plotted across the time points; Spencer et al., 1999).

Since the broad peaks of the virtual ERPs indicated that P300 latency varied between trials, they were corrected for latency-jitter using a cross-correlation technique (see Gratton, Kramer, Coles & Donchin, 1989, for a review of this and other jitter correction techniques). The grand average P300 virtual ERP was used as a template, which was cross-correlated with every trial. The point of maximal cross correlation was then used to determine a lag to shift this trial, with the restriction that the P300 peak had to lie within 450 and 750ms after word onset. Each trial was baseline corrected again for 200ms, and the average over the latency corrected trials was computed for each word type and recalled and not recalled words. Since isolates and words in positions 1-2 had low trial numbers and since the number of trials included in an ERP average can affect ERP amplitudes, we matched the recalled and not recalled categories for trial number by randomly selecting the same number of trials. This resulted in an average of 5 trials contributing to the recalled- and the not recalled isolates,

and an average of 4.8 and 4.6 trials for the recalled- and not recalled words in positions 1 and 2, respectively.

Finally, we quantified P300 amplitude by applying a temporal PCA on the jitter-corrected virtual ERPs to obtain a single factor score for each participant, word type, and for recalled and not recalled words. In the temporal PCA we rotated 15 factors with the Promax technique.

**Statistical Analysis.** Since the data violated the assumption of sphericity necessary for repeated measures ANOVA, we conducted a MANOVA on the recall rates for words in position 1, standards and isolates; as well as a 2x4 MANOVA on the P300 amplitudes (as quantified by the factor scores) testing for differences between word types (isolates, standards, position 1 and position 2), and recalled and not recalled words. Words from position 3 were not included in the statistical analysis since the ERPs showed the same pattern as position 2, and since one participant had no artifact-free trials for the "position 3/recalled" category.

## Results

**Behavioral Data.** The debriefing confirmed that most participants had used a rote memorization strategy. This was supported by the serial position curve (figure 1), which showed the typical shape, with a primacy effect for the first three to four serial positions and a recency effect over the last five serial positions.

Recall rates differed between words at serial position 1, isolates, and standards [Wilk's Lambda=.14,  $F(2,28)=87.07$ ,  $p<.01$ ]. Paired samples t-tests showed that recall for words in list position 1 was superior to recall for both standards,  $t(29)=8.46$ ,  $p<.01$ , and isolates,  $t(29)=2.41$ ,  $p<.05$ , while isolates were recalled with a higher probability than standards,  $t(29)=8.18$ ,  $p<.01$ . All but 4 participants showed superior recall for words in position 1 and all but 3 participants (a different set than the aforementioned 4) showed superior recall for isolates, compared to standards.

Figure 1. Serial position curve for regular-sized words ("standards"), and isolates. Note: percent recalled for isolates is averaged across positions 6-10.

**Event-Related Potentials.** The spatial PCA solution accounted for a total of 85% of the variance in the data. Based on its parietal distribution, the fourth spatial factor was identified as the P300. Figure 2a displays the loadings of this factor, which accounted for 7% of the total variance.

a. Spatial factor loadings

e. Spatio-temporal factor scores

Figure 2. P300 PCA factor. a. Spatial factor 4; loadings over all 128 electrodes. b. Virtual ERPs for standards, isolates, and words in serial position 1 and 2 by subsequent recall. c. Latency-jitter corrected virtual ERPs. d. Temporal factor 2; loadings over all time points. e. Factor scores, indexing P300 amplitude, by word type and subsequent recall.

Figure 2b shows the raw virtual ERPs of the P300 factor by word type and subsequent recall. The P300 peaked between 500 and 700 ms after word onset. The broad peaks for isolates and words in position 1 strongly suggest the presence of latency jitter. The latency jitter corrected virtual ERPs are displayed in figure 2c. A comparison of figures 2b and 2c indicates that the jitter correction was successful, producing narrower peaks and higher amplitudes. Note that it is not unusual that even standards and words in position 2 now exhibit a small positivity, since the algorithm picks the point of maximal cross-correlation, and thus tends to bias the jitter-corrected average towards the template. It is also important to note that the direction of the difference between recalled and not recalled words was not changed by the jitter correction for any word type.

The second temporal factor, which accounted for 14% of the variance of the P300 virtual ERPs, lined up with the P300 peak and was therefore identified as the temporal P300 factor. Temporal factor loadings are displayed in figure 2c. Figure 2d shows the mean spatio-temporal factor scores, as a measure of P300 amplitude, for the four word types and for recalled and not recalled words.

The 2x4 MANOVA revealed that P300 amplitude differed between later recalled and not recalled items, Wilk's Lambda=.66,  $F(1,29)=14.77$ ,  $p<.01$ , which was qualified by an interaction between word type and recall success, Wilk's Lambda=.64,  $F(3,27)=4.98$ ,  $p<.01$ . There was no main effect for word type, Wilk's Lambda=.93,  $F(3,27)=63$ , *ns*. Critically, subsequent paired samples *t*-tests revealed a significant difference in P300 amplitude between recalled and not recalled words for isolates,  $t(29)=2.28$ ,  $p<.05$ , and words in position 1,  $t(29)=3.09$ ,  $p<.01$ , but not for standards,  $t(29)=1.21$ , *ns*, or words in position 2,  $t(29)=-.8$ , *ns*.<sup>1</sup>

To test whether overall, isolates and words in position 1 elicited a larger P300 than the other word types, we conducted planned comparisons between the combined P300 amplitude values of isolates and position 1; and the combination of standards and position 2, separately for recalled and not recalled words. Although for both recalled and not recalled words, isolates and words in position 1 elicited larger P300 amplitudes than the other word types, the difference only reached significance for the recalled words,  $t(29)=2.7$ ,  $p<.05$ .

## Discussion

We found a correlation of P300 amplitude with subsequent recall for isolates, replicating prior studies (e.g., Karis et al., 1984). Critically, the analogous subsequent memory effect

was evident for items in the first list position. Words in the middle- and the second list positions, by contrast, did not show this pattern. Since the P300 subsequent memory effect indexes the enhancing effects of item distinctiveness on recall, our results support the hypothesis that the first serial position provides a distinctive feature to the stimulus, thus enhancing encoding and aiding later retrieval.

Although Azizian and Polich (2007) reported a P300 subsequent memory effect for the first list positions, our study provides stronger support for the distinctiveness hypothesis of the primacy effect. First, our data indicate that the P300 subsequent memory effect is only present for the first word, suggesting that temporal distinctiveness does not extend to later serial positions. Second, by using PCA we were able to disentangle the P300 from other overlapping components. Furthermore, our latency-jitter correction insured that (1) differences between item types were not due to differences in P300 latency variability and (2) any true differences were not obscured by latency jitter, as may have been true in Wiswede et al. (2007) and Rushby et al. (2002). Finally, we were able to directly compare the subsequent memory effects for physical isolates and words in position 1, and these showed remarkable similarities (figure 2c).

Our distinctiveness explanation does not contradict the well-supported idea that rehearsal frequency accounts for the primacy effect (e.g., Rundus, 1971). Indeed, items at the first list position showed higher recall than the isolates, suggesting that item distinctiveness may not be the only factor enhancing recall of the first item. Recall was also enhanced for positions 2 and 3 (figure 1), which did not show a P300 subsequent memory effect. Therefore, we suggest that the temporal distinctiveness of the first item adds to the recall advantage by enhancing encoding and/or providing a distinctive retrieval cue. Further studies are necessary to investigate whether the effects of rehearsal frequency and distinctiveness are additive or synergistic.

Note that the P300 only indexes distinctiveness to the extent that the participant registers the distinctive feature at the time of stimulus encounter. It cannot index other conceptualizations of distinctiveness, such as distinctiveness of the first item due to the relatively early output position during recall (cf., Brown et al., 2007).

We did not have enough trials in the "position 15/not recalled" category to conduct a subsequent memory analysis for the recency positions. However, the last list item may also be perceived as distinctive, and therefore future studies should focus on such an analysis. Finally, an analysis of the relationship between individual differences in P300 amplitude and the behavioral effects was beyond the scope of this paper, but will be investigated in the future.

In conclusion, our study provides psychophysiological evidence for the hypothesis that the primacy effect in free recall is in part due to the enhancing effect of the first item's distinctiveness on recall. Our analysis focused only on the P300, but future studies will also be focused on the interaction of serial position effects with frontal slow wave subsequent memory effects, which are thought to index

<sup>1</sup> A supplementary analysis on the mean amplitudes of the raw ERPs between 500 to 700 ms at two parietal electrodes revealed the same patterns of results, with the exception that the subsequent memory effect for position 1 only approached significance ( $p=.11$ ). This may be due a decreased power for this comparison due to latency jitter.

working memory processes that support between-item elaborative encoding (e.g., Fabiani & Donchin, 1995).

# Modeling Learning of Relational Abstractions via Structural Alignment

Subu Kandaswamy (subu@u.northwestern.edu)

Kenneth D. Forbus (forbus@northwestern.edu)

Qualitative Reasoning Group, Northwestern University, 2133 Sheridan Road  
Evanston, IL 60201 USA

## Abstract

Learning abstract relationships is an essential capability in human intelligence. Christie & Gentner (2010) argued that comparison plays a crucial role in such learning. Structural alignment highlights the shared relational structure between compared examples, thereby making it more salient and accessible for subsequent use. They showed that 3-4 year old children who compared examples in a word-extension task showed higher sensitivity to relational structure. This paper shows how a slight extension to an existing analogical model of word learning (Lockwood et al 2008) can be used to simulate their experiments. This provides another source of evidence for comparison as a mechanism for learning relational abstractions.

## Introduction

Our ability to abstract and reason with relations between objects is an essential part of our intelligence. As children, we acquire a variety of relations, including spatial relations such as *above*, and *on*, and functional relations like *edible* and *dangerous*. How children acquire and use such relational abstractions is an important question in cognitive development. Gentner (2003) has argued that comparison promotes learning new relational abstractions. The idea is that structural alignment highlights common structure, which becomes more salient and available for subsequent use.

One line of evidence for this theory comes from an experiment by Christie & Gentner (2010). To show that children (ages 3-4) were learning new relations, they used novel spatial relational categories in a word extension task, as illustrated in Figure 1. Here the relationship might be characterized as “An animal above another identical animal”. In the Solo condition, children were shown a single standard (here, Standard 1) and told it was a novel noun (e.g. “Look, this is a jiggy! Can you say jiggy?”). In the Comparison condition, children were invited to compare two examples (e.g. “Can you see why these are both jiggies?” when presenting Standard 1 and Standard 2 simultaneously). In both conditions, children were then presented with a forced-choice task, where they had to choose which one of the alternatives is a jiggy (e.g. “Which one of these is a jiggy?” when presented with the relational match and object match cards). Children in the Solo condition preferred the object match, while those in the Comparison condition chose relational matches twice as often as object matches. This provides evidence that comparison can lead to learning new relational abstractions. In a second experiment, a third condition, Sequential, was added, where children saw two standards serially, to test

whether or not simple exposure to more examples was sufficient to promote learning. They found significant differences between Sequential and Comparison, and between Solo and Comparison, but the difference between Sequential and Solo were not significant. This provides additional evidence that it is comparison specifically that is promoting learning.

This paper shows that this phenomena falls out of computational models of analogical generalization already proposed for word learning. We start by summarizing the necessary background, including the models of analogical matching and generalization used and how we use sketch understanding to reduce tailorability by producing portions of the input representations automatically. Next we describe an extension to a similarity-based word learning model (Lockwood et al 2008) that enables it to model this task. Then we describe two simulation experiments that demonstrate that this model is capable of exhibiting behavior consistent with that described in Christie & Gentner (2010), including sensitivity analyses to shed light on why it does so. After discussing related work, we close with a discussion of future work.

## Background

Our model is based on Gentner’s (1983) structure-mapping theory of analogy and similarity. In structure-mapping, comparison involves a *base* and *target*, both structured, relational representations. Comparison results in one or more *mappings*, which contain a set of *correspondences* that describe how the elements in the structured representations align, a *score* that indicates the overall structural quality of the match, and possibly *candidate inferences* representing knowledge that could be projected from base to target (as well as from target to base). Our computational model of comparison is the *Structure-Mapping Engine*, SME (Falkenhainer et al 1989; Forbus et al 1994). Here SME is used both as a component in our model of analogical generalization (described below) and in making the decision in the forced-choice task. The score is normalized to be between zero and one, by dividing it by the score obtained for the maximum self-mapping of base and target.

Analogical generalization is modeled via SAGE (*Sequential Analogical Generalization Engine*), an extension of SEQL (Kuehne et al 2000) which incorporates probabilities and analogical retrieval. Information about concepts is stored in *generalization contexts* (Friedman & Forbus, 2008). Each generalization context maintains a set of examples of that concept, plus generalizations concerning it. Examples are provided incrementally. For each new example, the most similar prior examples and generalizations are retrieved via a model of analogical reminding (MAC/FAC, Forbus et al 1995). The retrieved items are compared, via SME, with the new example. For each comparison, if the score of the best mapping is over a threshold (the *assimilation threshold*), the compared items are assimilated into a generalization – a new one in the case of two examples, or an updated version of the existing generalization in the case of an example and a generalization. The assimilation process keeps the common structure of the mapping, replacing non-identical entities with abstract place-holders. Associated with each fact in generalizations is a probability, based on the number of times a statement aligning with it appears in an example (Halstead & Forbus, 2005). For example, in a generalization about swans, the fact that swans are birds might have a probability of 1.0, while the probability that their color is white might be 0.999 while the probability that their color is black might be 0.001. Non-overlapping facts are kept, albeit given a low probability (i.e.,  $1/N$ , where  $N$  is the number of examples assimilated into that generalization). Facts whose probability drops below the *probability cutoff* are removed from the generalization. SAGE is the central component in our word-learning model, as explained below.

Tailorability is an important problem in cognitive simulation. To reduce tailorability, we use automatically constructed visual and spatial representations. These representations are computed by CogSketch (Forbus et al 2011), an open-domain sketch understanding system. CogSketch uses models of visual and spatial processing to

compute qualitative relationships from digital ink. For example, it automatically computes topological relationships (e.g. inside, touching) and relative positions (e.g. above, right of) for the entities in a sketch. It also includes a model of mental rotation, which uses SME to first do a qualitative shape match which then guides a quantitative match (Lovett et al 2009). This enables it to compute relationships such as *sameShape*, *reflectedOnXAxis*, and so on. Conceptual information can be introduced by adding attribute information to entities in the sketch. For example, the top entities in Standard 1 of Figure 1 might be described as identical elephants, one positioned above the other. The attributes are derived from a large, independently-developed knowledge base<sup>1</sup>. The relationships automatically computed by CogSketch, along with the conceptual attributes provided for an entity, provide the inputs for our simulation. Moreover, CogSketch provides a mechanism for dividing a sketch into *subsketches*, which is what we use to combine all of the elements of a stimulus set onto the same sketch, for convenience. Figure 2 provides an example of a sketched stimulus set.

## Word Learning via Analogical Generalization

We model the learning of words as follows. For each word, there is a generalization context. Every time the word is used, an appropriate subset of the world is encoded to capture information about what that word denotes, and is provided to the generalization context for that word as an example. The generalizations constructed by SAGE can be considered as the meanings for the words. Note that such meanings can be probabilistic, since SAGE computes frequency information for every statement in the generalization. The ability to track multiple generalizations provides a mechanism for handling multiple senses of a word. The ability to store unassimilated examples provides a means of handling edge cases, and helps provide noise immunity in the face of changes in the underlying distribution of examples of a concept.

This account has been used to successfully model spatial propositions of contact in English and in Dutch (Lockwood et al 2008). It makes no commitment to the particulars of encoding, because this is a complex issue, especially since evidence from studies of novice/expert differences suggest that encoding strategies evolve with learning (Chi et al 1981). When using CogSketch as a source of stimuli, we use an entire subsketch as the relevant material to encode.

## Simulation Experiments

Now let us see how this model can be used to simulate the experiments of (Christie & Gentner, 2010). We begin with their Experiment 1.

### Simulation Experiment 1

Recall that Experiment 1 used two conditions to show children the new concept, followed by a forced-choice task. We model these as follows:

- **Forced-choice task:** Each of the choices is used with the generalization context for the word to retrieve the most similar generalization or example for that choice. The choice whose similarity score is highest constitutes the decision. For simplicity, We start with an empty generalization context for every novel word used.
- **Solo Condition:** The single example is added to the generalization context for the word.
- **Comparison Condition:** The two examples are added to the generalization context, but since the experimenter has asserted that they are both examples of the concept, we assume that the child is more likely to assimilate them into a generalization, which is modeled by lowering the assimilation threshold from its default of 0.8 to 0.1. We also assume that the probability cutoff is 0.6, so that facts which do not appear in the shared structure will be eliminated from the generalization.

The original experiment used 8 stimulus sets. We encoded 8 sketches of animals, using CogSketch. Each element of the stimulus set (e.g. Standard 1, Standard 2, etc.) was drawn as a separate subsketch. CogSketch’s default encoding methods were used, plus an additional query to ascertain if any of the entities in a subsketch had the same shape as any other, and if so, what transformation held between them (where no transformation implies the relationship `sameShape`). Moreover, filters were used to automatically remove three types of information: Redundant information (e.g. `given (rightOf B A), (leftOf A B)` is redundant), irrelevant information (e.g., global estimates of glyph size like `MediumSizeGlyph`), and bookkeeping information (e.g. relationships describing timestamps). The table below shows the final encoding for the sketches stimulus set (Figure 2) and the resultant generalization.

Table 1: Encoding for the sample sketch.

Standard-1	Standard-2
<pre>(sameShapes Object-99                   Object-420) (above Object-99         Object-420) (isa Object-420 Elephant) (isa Object-99 Elephant)</pre>	<pre>(sameShapes Object-104                   Object-425) (above Object-104         Object-425) (isa Object-425 Dog) (isa Object-104 Dog)</pre>
Generalization for “jiggy”	
<pre>(above (GenEntFn 1 0 jiggy) (GenEntFn 0 0 jiggy)) (sameShapes (GenEntFn 1 0 jiggy) (GenEntFn 0 0 jiggy))</pre>	

An interesting open parameter concerns the number of conceptual attributes that children might be encoding. While we suspect that a large number of attributes would be encoded<sup>2</sup>, we do not know of data that provides specific estimates. Consequently, we perform a sensitivity analysis by running the simulation while varying the number of conceptual attributes to ascertain their impact on the results. Specifically, we varied the number of attributes from zero to nine. We assumed that encoding is reasonably uniform, i.e. that the same attributes would always be computed for identical objects. For simplicity, we further assumed that the set of attributes computed for one entity had no overlap with the set of attributes computed for another entity whose shape is different. Given these assumptions, we used synthetic attributes (e.g. `Uniquetandard-1MtAttribute8`) for convenience.

Figure 3 shows the results. From the data, we can see that the model chose the relational match 100% of the time for the Comparison condition. This is qualitatively consistent with the behavior of participants in the Comparison condition, where participants chose the relational match around 60% of the time. We believe that the lack of object matches in this simulation condition are due to the use of completely independent attributes for each entity type in the

<sup>2</sup> See the Specificity Conjecture (Forbus & Gentner 1989).

stimuli sets. Since they are independent, no attributes are left in the generalization after assimilation. The more overlapping attributes there are, the more likely an object match is to become possible.

Returning to Figure 3, in the Solo condition, as the number of attributes rises, the proportion of object matches rises (i.e., the proportion of relational matches falls). Again, this provides a good qualitative fit for the results of (Christie & Gentner 2010) Experiment 1. Since attributes are more salient to children, due to lack of relevant domain knowledge (Ratterman & Gentner, 1998), it is reasonable to assume that they would encode more attributes than relations, which is compatible with the simulation results.

Recall that we assume that the probability cutoff is set high enough that non-overlapping information is immediately filtered out. (Since these are novel concepts, there can be at most two examples in any generalization, and hence the probability of any fact not in the overlap would be 0.5, which is less than the 0.6 threshold.) Would adding in probabilistic information improve the fit of the model to human data? To determine this, we tried changing the probability cutoff to its usual default of 0.2. This leads to all attributes remaining in the generalization, which results in the score for the object match being boosted so high that it always wins over the relational match, regardless of the experimental condition used. This suggests that when children are invited to compare, they do indeed restrict themselves to keeping exactly the overlapping structure.

Figure 3: Results for Simulation Experiment 1

## Simulation Experiment 2

Experiment 2 in (Christie & Gentner 2010) actually consists of two experiments. Both involved a new condition, the Sequential condition, designed to rule out non-comparison explanations. In Experiment 2a, fillers, in the form of pictures of familiar objects, were interposed between the serial presentation of the standards. No invitation to compare was issued. In Experiment 2b, no fillers were used, and the Solo and Comparison conditions from Experiment 1 were added, by way of replication. In our

model, fillers would be added to some other generalization context, thus 2a and 2b look identical from the perspective of our model. We model the new condition as follows:

- **Sequential Condition:** The two examples are added to the generalization context, but with the default assimilation threshold 0.8.

Again we varied the number of conceptual attributes, in the same way as in Simulation Experiment 1.

Figure 4: Results of Simulation Experiment 2

Figure 4 illustrates the results. As anticipated, the results for the Sequential condition are identical to the results the model generates for the Solo condition. This is because of the model does not generalize the two standards, and hence the choices will be compared to the exemplars in the generalization context. This makes the results of the

Figure 5: Sensitivity analysis

Comparison condition be the same as the Solo condition.

We know of no psychological evidence that would provide constraints on the value of the assimilation threshold. Consequently, we performed a sensitivity analysis by varying the assimilation threshold between 0.1 and 0.9, while varying the number of attributes from zero to nine. Figure 5 illustrates the results. The region marked as

black indicates a high proportion of relational match choices and then the contour fades down gradually.

The slope of the contour indicates that the model readily generalizes the standards when both the assimilation threshold and the number of object attributes are low. This can be interpreted as follows. A low assimilation threshold corresponds to a higher willingness to accept the standards as belonging to the same category, which fits the assumptions of our model. A low number of object attributes indicates a leaner encoding i.e. not enough attention was paid to the object, or it may be unfamiliar. This is a second possible explanation for why some children chose the relational match for the Sequential condition.

## Related Work

There have been several prior computational models of word learning. For example, Siskind (1996) developed an algorithm for cross-situational learning of word/meaning mappings. He used synthetic conceptual representations and lexicons to examine its scaling properties and noise immunity. Our use of arbitrary predicates is similar to his use of synthetic conceptual representations, but our visual representations are grounded in prior cognitive science research. It is an open question whether Siskind's algorithm would work on realistic conceptual representations, and similarly, it is an open question as to whether our word learning algorithm can scale to the size of vocabularies that his does. Another model, described in (Roy and Pentland 2002) uses speech and vision signals as input, to tackle the problem of how children learn to segment these perceptual streams while at the same time learning word meanings. A particularly novel aspect of their approach was modeling a corpus of infant-directed speech they gathered, to ensure their inputs were naturalistic. Our use of sketch understanding is motivated by the hypothesis that it forces us to incorporate high-level vision, while factoring out most of the complexities of signal processing. The relatively crude visual processing techniques used in Roy & Pentland's system, compared to mammalian vision systems, suggests that theirs, too, is an approximation, albeit a more signal-rich version than ours. Neither of these models, nor any other word learning model that we are aware of, has tackled the role of comparison in learning relational abstractions.

## Discussion

We have shown that a model of word learning based on analogical generalization, using automatically encoded sketches augmented by conceptual information, can simulate the behavior found in (Christie & Gentner 2010). The invitation to compare, we argue, leads the child to aggressively attempt to form a generalization between the two new exemplars, as modeled by lowering the assimilation threshold and only keeping overlapping structure. This finding is robust across a wide range of choices for the number of object attributes. Moreover, serial presentation to the model, as with humans, does not lead to

relational learning, as measured by responses in the forced-choice task.

There are several lines of future work that suggest themselves. First, we intend to explore if the model can handle closely related phenomena (e.g. Gentner & Namy 1999, who used a similar experimental paradigm but with pre-existing concepts instead of novel concepts). Second, we plan on exploiting more of CogSketch's automatic encoding capabilities, by using it to automatically decompose object-level spatial descriptions into edge-level representations. The sketches in the stimuli will be represented by a set of constituent edges, their attributes and relations that hold between them (e.g. (`isa edge2 StraightEdge`) (`edgesParallel edge2 edge4`)). For example, a square can be segmented into four constituent edges. These more detailed spatial representations will contain more shared attributes and relations and hence would naturally introduce more overlap between entities. This would provide a test of our hypothesis that such overlap is responsible for participants in the Comparison condition sometimes choosing the object match. Finally, we plan to extend this model to explore how object labels promote uniform relational encoding and re-representation (Gentner, 2010).

## Abstract

Understanding dynamic concepts is more difficult than understanding static ones. The present study showed that understanding dynamic concepts can be enhanced by gestures that convey action. Participants learned how an engine worked from one of two videos, with identical verbal scripts and identical diagrams. One video was accompanied by gestures showing the structure of the system; the other was accompanied by gestures showing the actions of the system. Both groups learned the basics of the system. Participants who saw the action gestures depicted more dynamic information in their visual explanations of the system and included more dynamic information in their verbal explanations of the system. Because they are inherently dynamic, gestures appear to be especially suited for conveying dynamic information.

**Keywords:** gesture; diagram; complex systems; knowledge construction

## Knowledge in the hands

When people explain something, they typically use gestures as well as speech. Gestures can carry information that is redundant with speech, reinforcing the message by presenting information in two modalities. Importantly, gestures sometimes carry information that is not carried in speech (e. g., Bavelas, 1994; Church & Goldin-Meadow, 1986; Perry, Church, & Goldin-Meadow, 1988). In some cases, speech refers listeners to gesture, as in “turn this way,” but in other cases, there is no cuing of the gestures. Nevertheless, the information carried solely in gesture can reveal the thought of speakers and affect the thought of both those who make gestures and those who watch them (e.g., Beattie & Shovelton, 1999; Chu & Kita, 2011; Goldin-Meadow, Cook, & Mitchell, 2009; Goldin-Meadow, Kim, & Singer, 1999; Hegarty, Mayer, Kriz, & Keehner, 2005; Kessel & Tversky, 2006; Singer & Goldin-Meadow, 2005; McGregor, Rohlfing, Bean, & Marschner, 2009; Ping & Goldin-Meadow, 2008; Schwartz & Black, 1996; Thompson, Driscoll, & Markson, 1998; Valenzano, Alibali, & Klatzky, 2003).

It is primarily iconic and deictic gestures that reveal the thought of those who make them and affect the thought of those who make them or observe them. Deictic gestures

point to places or things in the world or in a virtual world. Iconic gestures show what something looks like or acts like (e.g., McNeill, 1992; Goldin-Meadow, 2003). Together, these kinds of gestures can carry rich semantic content. A train of integrated deictic and iconic gestures can be used on virtual stages to create detailed models of situations, such as environments (e. g., Emmorey, Tversky, & Taylor, 2000) and actions, such as how a lock works (e. g., Engle, 1998). Are such gestures successful in communicating knowledge as well as in representing it?

## Knowledge on the page

As such, sequences of organized gestures can serve much like diagrams. In fact, many kinds of gestures can be mapped to kinds of diagrammatic features; that is, they carry the same meanings (Tversky, Heiser, Lee, & Daniel, 2009). Diagrams have some advantages over gestures as a means of representing knowledge. Diagrams have permanence, so they can be inspected and reinspected. Because they are external and persist, they do not need to be kept in mind, so the mind is free to use the diagram as a basis for reorganization, for inference, and for discovery. Diagrams use elements and spatial relations on a page to represent elements and relations that are actually spatial, as in maps or architectural plans, or that are metaphorically spatial, as in the periodic table or organization charts (e. g., Tversky, 2011; Tversky, et al., 2009). Gestures, like language, are external, but lack permanence. A series of gestures used to create a model of a situation requires working memory to create, understand, and remember, and can tax working memory. On the other hand, diagrams are static, so it can be challenging to convey action, change, and process in diagrams. Typically, arrows are used, but they can be ambiguous (e. g., Heiser & Tversky 2006; Tversky, 2011; Tversky, Heiser, MacKenzie, Lozano, & Morrison, 2007). Gestures are by nature dynamic, so they can portray action, if schematically (e. g., Kita & Özyürek, 2003; Rizzolatti & Arbib, 1998). In fact, when gestures are used with diagrams in explanations, diagrams are often used to convey structure, and gestures to portray action (e. g., Engle, 1998).

## Complex systems

Many explanations, in conversational as well as learning situations, are of complex systems, scientific, mechanical, social, athletic, or political. Complex systems typically have elements--actors or agents or object--that have properties and structure, social or geographic or other relations. They also have action or behavior: the actors or agents or objects act or are acted on in some sort of systematic ways usually associated with their properties and their relationships or structure. Many complex systems, from traffic patterns to election procedures, from spread of disease to workings of the nervous system, from the operation of an engine to a court of law, can be explained, especially when accompanied by deictic and iconic gestures. They can also be diagrammed, and, as noted, diagrams readily portray the structural relations of agents, actors, and objects, but do not easily portray the action or behavior of systems. Yet, it is the action of a system and its outcomes that is hardest for novices to comprehend (e. g., Hmelo-Silver and Pfeffer, 2004). Making inferences about action or function separates novices and experts across domains (e.g., Suwa & Tversky, 1997). Here we ask whether gestures showing action can promote understanding of the behavior of complex systems.

To ask whether iconic gestures that convey action can promote understanding of explanations of complex systems, we compared explanations that were identical except for gesture. One explanation was accompanied by gestures that portrayed action, and a control explanation used gestures to convey the form and structure of the parts of the system. Students viewed one of two videos of explanations of the operation of a four-stroke engine, the typical engine in an automobile. The language of the explanations was identical, and each explanation was based on a diagram of the structure of the engine superimposed to the front and side of the explainer. Because enactive gestures can convey action directly and information about action is more difficult, we were especially interested to know if gestures conveying action help students comprehend action information.

Performance was assessed in several ways: by questions about structure and action, by diagrams, by visual explanations, and by live explanations of the systems by the students. The questions could be answered solely on the basis of the language of the explanations and served partly as a manipulations check. Hence, if students who view action gestures have a better understanding of the action of the system than those who viewed structure gestures, they should be more likely to include action information, in their diagrams, and they should be more likely to deliver action information and use action gestures themselves in their later explanations to new learners.

## Method

**Participants** 59 (15 male) university students ranging in age from 20 to 36 with an average age of 26 ( $SD = 3.50$ ), participated in the study. They were all native English speakers and did not have prior knowledge of the system to be learned.

**Materials** We created two videos explaining how a four-stroke engine works. The videos were identical in language and number of gestures but differed in kinds of gesture. A diagram typical of those in science and engineering showing the labeled parts and configuration of the system was superimposed in front and to the side of the explainer. The explanations began with an introduction overviewing the structure using deictic gestures. The core portion of the explanation was a step-by-step explanation of the processes comprising the workings of the system. The final portion of the explanation explained how the process caused the car's wheels to rotate. Because the diagram showing the structure was always in view and because the introduction to both explanations overviewed the system structure, the gestures emphasizing structure served as a control and were not expected to affect performance on the questions.

For the core portion of the explanation, in the action video, the explainer used only gestures that portrayed the action of each part, always in the same location, so no structural information was provided. In the control structure video, the explainer used only gestures that pointed to the location of the parts of the system and showed the shape of each part as the process was explained. The accompanying verbal script explained both the locations of the parts and the actions of the parts identically. Figure 1 shows snapshots of two instructional videos.

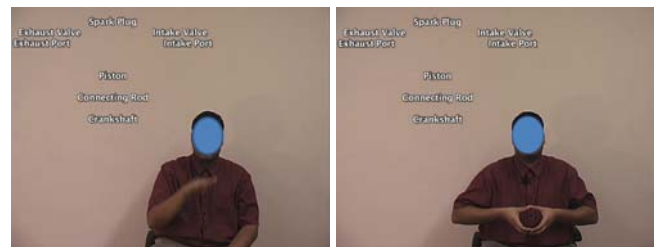

Figure 1. Still shots from the *action* (left) and *structure* (right) videos showing the superimposed diagrams.

The information in the script was categorized as structure or action, and gestures appropriate for each were devised. For the action gesture video, the explainer showed the rotational motion of the crankshaft, the direction of the piston's movement, the flow of fuel and air, the movement of the intake and exhaust valves, and so on with his hands. The action gestures were performed in the same place off the diagram, avoiding any positional information.

For the structure gesture video, the explainer used his hand(s) successively to show the shapes of the crankshaft, piston and cylinder, and showed the positions of the piston, crankshaft, spark plug, intake port, intake valve, exhaust port, exhaust valve, and mixture of fuel and air.

To eliminate any biasing effects of lexical stress (Heuven, 1988; Field, 2005), the speaker practiced the script several times, making sure to stress the actions and the parts for both videos.

**Posttests** The verbal posttest was based on the information in the script with 20 recognition questions, 16 True/False, and 4 multiple-choice questions. Of the 16 True/False

questions, 8 queried action and 8 queried structure. Action questions referred to movement, or causal relations of the parts and their consequences. Structure questions referred to shapes and positions of the parts of the system. Four multiple-choice questions queried general knowledge. The questions were presented in random order. Because the verbal posttest was based entirely on the verbal script, differences dependent on viewed gesture were not expected. The test served as a manipulation check.

The second posttest was a diagramming task. Participants were asked to diagram a visual explanation of how a four stroke engine works based on what they learned from the video. Finally, participants made a video to explain the workings of the four-stroke engine to a peer. It was expected that participants who viewed the videos with action gestures would include more action information in the latter two less-constrained measures.

**Procedure** Participants were seated at a table with a laptop computer with a 15.4 in screen. They were randomly assigned to either the action gesture or the structure gesture video group. The participants were then told: “Today, your job is to watch a video of how a four stroke engine works four times<sup>1</sup> in a row and explain the concept in the video to a peer coming later. However, since you are not directly explaining a concept, your explanation will be videotaped and showed later either to him or her. He or she will learn about the concept from your explanation.” Participants were not allowed to take notes or to pause or stop the video. The experimenter left the room while participants watched the video. After watching the video, participants were given the verbal and diagrammatic posttests, and then made a video explaining the system to a peer. The video camera was set opposite the participant 3 meters away. Participants were allowed to spend as much time as they wanted.

## Results

**Verbal Posttest** As expected, the type of gesture viewed yielded no differences in performance on action ( $p = .08$ ), structure ( $p = .85$ ) or general ( $p = .92$ ) questions, nor were there interactions between gesture viewed and question type,  $F(1, 114) = 1.70$ ,  $p = .20$ . However, in within group comparisons, those who viewed action gestures performed better on action questions than on structure questions,  $t(28) = 3.56$ ,  $p < .01$ ,  $d = 0.82$ . There were no differences between action and structure questions for those who viewed gestures conveying structure ( $p = .11$ ).

**Diagram Posttest** Two coders coded the diagrams for action components. The reliability for action words was  $Kappa = .56$  ( $p < .001$ ), for action arrows,  $Kappa = .63$  ( $p < .001$ ), for action effects,  $Kappa = .65$  ( $p < .001$ ), for labeling arrows,  $Kappa = .60$  ( $p < .001$ ), and for labeling lines,  $Kappa = .73$  ( $p < .001$ ). Action effects were depictions of actions, such as explosions. The means of the visual components by type of viewed gesture appear in Figure 2.

<sup>1</sup> A pilot study had revealed that two viewings were insufficient to achieve above chance performance.

The means were compared using Poisson regression analysis with the assumption that the conditional means equal the conditional variances.

\*  $p < .05$ , \*\*  $p < .01$

Figure 2. Mean number of visual components in diagrams. Error bars represent standard errors of the means.

Overall, those who viewed action gestures used more visual components than those who saw structure gestures ( $p < .05$ ). In addition, those who viewed action gestures produced more action arrows ( $p < .05$ ) and action effects ( $p < .05$ ) and labeled fewer lines ( $p < .01$ ) than those who saw structure gestures. Labeled lines typically linked names and parts; that is, structural information. Thus, for the diagrams, those who saw action gestures included more information about action and those who saw structure gestures included more information about structure, showing that the viewed gestures affected viewers' comprehension and later production.

**Explanations to a peer** Recall that after learning the system, participants made videos explaining the four-stroke engine to novices. Will those who saw action gestures use more of them in their own explanations? A gesture unit was defined as “the period of time between successive rests of the limbs (McNeill, 1992).” If the hands did not return to a resting position between two gestures, the boundary was defined by a pause in motion and an obvious change in shape or trajectory. If participants used both hands simultaneously to describe one object, concept, or part, it was regarded as one gesture. If participants used one hand to describe an object, a concept, or a part and the other hand a different concept, the gestures were coded as two different gestures.

For this study, only gestures conveying action or structure were coded. Action gestures were defined as showing the action of a part or process of a system. Structure gestures were defined as showing the location or static properties, notably shape, of objects or parts of the system. Inter-rater reliability was assessed on randomly selected 240 subsets (18%) of the data by a second coder who was trained and blind to the experimental design. Agreement for identifying gestures was 87.8% and for categorizing gestures was 99.6%.

For the speech analysis, the participants' verbal descriptions were segmented into propositions (following

Heiser & Tversky, 2006). The information units were coded as *action*, *structure*, or *other*. Propositions that contained action such as movement of each part within a cylinder were coded as *action* information, for example, “...that byproduct is pushed back up through the exhaust valve...”. Propositions that contained ‘is-a’ or ‘has-a’ were coded as *structure* information unless they referred to action, for example, “...then it has an exhaust valve”. *Other* information included greetings, such as “Good evening,” introductory information such as “I’m going to explain how a four stroke engine works,” and meta-comments such as “...let me tell you a little bit more about each stage...”

**Gesture analysis**<sup>2</sup> The average explanation time was 177.14 sec ( $SD = 56.84$ ) for the action group and 152.34 sec ( $SD = 55.94$ ) for the structure group (ns.  $p = .10$ ). There were a total of 1306 gestures: 754 by those who had viewed action gestures, 552 by those who had viewed structure gestures (ns.  $p = .13$ ). The means of action and structure gestures produced by participants who viewed action and structure videos are shown in Figure 3.

There was an interaction between type of gesture viewed and type of gesture produced,  $F(1,112) = 8.58, p = .004 < .01, \delta = .84$ . In within group comparison by paired sample t-test, even though participants in both groups delivered more action gestures than structure gestures, the action group ( $t(28) = 7.15, p < .0001, d = 1.49, r = .60$ ) reliably used more action gestures, when compared to the structure group ( $t(28) = 2.88, p = .008 < .01, d = 0.58, r = .28$ ).

Figure 3. Mean number of type of produced gesture by type of viewed gesture. Error bars represent standard errors of the means.

It is possible that the number and the pattern of gestures differed by length of explanation. Although there were no significant differences in the overall gesture use, explanations in the action group were longer. Consequently, the next section presents more detailed analyses of the results by gesture rate, that is, gestures per minute.

<sup>2</sup> One participant’s explanation was not recorded because of malfunctioning of a video camera. Therefore, 58 participants’ videos were analyzed.

The same pattern of gesture use was observed. The action group used 6.89 ( $SD = 4.13$ ) action gestures per minute and 1.45 ( $SD = 1.35$ ) structure gesture per minute. The structure group used 4.62 ( $SD = 3.49$ ) action gestures per minute and 2.51 ( $SD = 2.38$ ) structure gesture per minute.

In group comparison, there was an interaction such that the action group used more action gestures and the structure group used relatively more structure gestures,  $F(1,112) = 8.83, p = .004, < .01, \delta = .84$ . In within group comparison, when compared to the structure group ( $t(28) = 3.08, p = .005 < .01, d = 0.71, r = .33$ ), the action group ( $t(28) = 7.95, p < .0001, d = 1.77, r = .66$ ) reliably used more action gestures than structure gestures.

**Speech analysis** The participants delivered a total of 2550 information units in their speech. Among them, 1607 conveyed *action* information, 737 *structure* information, and 206 *other* information. Those who saw action gestures delivered a total of 1425 information units. Among them, 929 conveyed action, 387 conveyed structure, and 109 conveyed other information. Those who saw structure gestures delivered a total of 1125 information units, 678 conveying action, 350 conveying structure and, 97 conveying other information. Figure 4 shows mean number of information units delivered by two groups.

Overall, those who viewed action gestures ( $M = 49.14, SD = 20.81$ ) delivered more information units than those who viewed structure gestures ( $M = 38.79, SD = 17.22$ ),  $F(1,56) = 4.25, MSE = 364.75, p = .044 < .05$ . In addition, those who viewed action gestures delivered more action information than the structure group,  $F(1,56) = 6.87, MSE = 158.03, p = .01 < .05$ . There were no differences in the quantity of structural information ( $p = .52$ ) or other information ( $p = .66$ ), but there was an interaction between kind of information and kind of viewed gesture ( $p = .02 < .05$ ). Post hac tests (Tukey HSD) showed that more action information was given than structural information ( $p < .001$ ) and more structure information than other information ( $p < .001$ ).

Figure 4. Mean kinds of information units by viewed gestures. Error bars represent standard errors of the means.

**Proportion of information types in speech** Although there were no group differences in explanation time, the group

who had viewed action gestures took more time and delivered more information units than the group who viewed structure gestures. To take that into account, percentages of information types were analyzed and appear in Figure 5.

Figure 5. Mean percentage of kinds of information units by viewed gesture. Error bars represent standard errors of the means.

For those who viewed action gestures, action information accounted for an average of 66.62% ( $SD = 10.30$ ), structure information accounted for an average of 25.76% ( $SD = 10.13$ ), and other information accounted for an average of 7.61% ( $SD = 7.30$ ). For those who viewed structure gestures, 59.28% ( $SD = 15.89$ ) was action information, 31.59% ( $SD = 13.28$ ) was structure information, and 9.14% ( $SD = 8.34$ ) was other information. There was an interaction between group and information type,  $F(2,168) = 5.16$ ,  $MSE = 126.74$ ,  $p = .007 < .01$ . Those who viewed action gestures delivered relatively more action information than those who viewed structure gestures and those who viewed structure delivered relatively more structure information than those who viewed action group. Thus, in their own explanations, those who had viewed action gestures produced both more verbal information about action and showed more action in their gestures. Similarly, those who had viewed structure gestures used more structure gestures and included proportionately more verbal structure information than those who had viewed action gestures.

### Discussion

Understanding the behavior of complex systems is challenging (e. g., Hmelo-Silver & Pfeffer, 2004). Actions are not apparent in static diagrams, and the nature of actions often has to be imagined from purely symbolic language. Animations are typically too complex and too fleeting to be comprehended (e. g., Tversky, Morrison, & Betrancourt, 2002) and are not part of most natural settings for explanations. There is abundant evidence that gestures provide a rich source of information, including information about structure and process (e. g., Beattie et al., 1999; Becvar, Hollan, & Hutchins, 2008). Here we asked if gestures can successfully transmit dynamic information, over and above verbal and diagrammatic explanations,

simply and abstractly at a pace that allows comprehension. We taught a complex system, the operation of a four-stroke engine, to novices under two conditions. One group saw action gestures that conveyed the behaviors of the parts of the system; the other group saw structure gestures that conveyed static qualities of the parts of the system and their structure. Both groups heard exactly the same explanation and saw the same structure diagram of the parts of the system. The verbal explanation was sufficient to convey the basics of the structure and the dynamics of the engine. A number of posttests were administered: a verbal test based on the verbal explanation, a visual explanation task, and a videotaped explanation of the system to new novices.

The verbal memory test showed that both groups adequately learned the essentials of the structure and the operation of the system. However, the diagramming and the explanation tasks revealed substantial differences in the understanding of the behavior of the systems; the group who had viewed the action gestures appeared to have a deeper understanding of the behavior of the system than the group who had viewed the structure gestures. In the visual explanation task, those who had seen action gestures depicted more specific actions of the system than the group who had viewed the structure gestures. Furthermore, the group who had viewed the action gestures used more action gestures in their videoed explanations than the group who had viewed the structure gestures. Although the increase in the number of action gestures in explanations might be attributable at least in part to imitation of what they had viewed, the increase in number of depictions of specific actions cannot. The depictions of action must come from a deeper understanding of the specific chain of behaviors of the system. Moreover, many of the gestures used differed from those viewed.

The effects of the viewing the gestures that conveyed the structure of the system were weaker but evident both in diagrams and in explanations. The structure of the system was apparent from the diagram that was displayed during the viewed explanation, and the structure of the system was described in the verbal portion of the explanation. Furthermore, the structural information is easier than the behavioral because it was apparent in the diagram.

In both groups, gestures conveying action far outnumbered gestures conveying structure, suggesting that participants regarded the behavior of the system as paramount and regarded gesture as a good means for conveying action, over and above language.

Discourse in the wild, including explanations, is an integrated combination of word, gesture, and props, elements in the world (such as a diagram) or in a virtual world that can be continuously referred to during the course of the discourse. Each, word, gesture, prop, plays roles, sometimes overlapping, sometimes complementary. Understandably, actions, even miniature schematic ones as those in gestures, appear to be especially effective for conveying action, another example of cognitive congruence (e. g., Tversky, et al., 2002).

## Abstract

Many previous studies of graph comprehension have confirmed that information gleaned from a graph is greatly influenced by its representation. When explaining data with a graph, writers/researchers must generate graphs whose representation is consistent with the explanation contents. In the current study, we defined those who engage in academic activities using graphs on a daily basis as expert graph users and investigated whether they and undergraduates (non-experts) can adaptively generate a consistent graph with explanations from the viewpoint of the consistency of the contents and graph representation. Experiment 1 indicated that expert graph users adaptively generate a graph whose structure is consistent with the explanation contents. On the other hand, Experiment 2 suggests that undergraduates cannot do so. But in Experiment 3 undergraduates were supported by selecting graphs from provided candidates, but there was a limited concordance between the type of explanation and graph representation.

**Keywords:** Diagrammatic representation; Graph; Explanation.

## Introduction

Many previous studies confirmed that using diagrams is effective for understanding information. In a pioneering psychological paper, Larkin & Simon (1987) theoretically demonstrated the efficacy of using diagrams while solving a problem and suggested that diagrammatic representation simplifies access to relative information more than sentential representation does, and transforms the cognitive processes into more efficient ones.

Norman (1991) pointed out that task difficulties depend on such visual representation as figures and tables and promote problem solving performance. He also suggested that a cognitively consistent correspondence between internal representation and external world is crucial.

In this study, we experimentally investigated the consistency of the contents of the explanations and the representations of graphs for the explanation. Kosslyn (2006), who marshaled psychological findings about graph design, argued that graph representation must be examined, especially based on the human cognitive system for effectively conveying information. And also, Hegarty (2011) mentioned the importance of cognitive science to design visual-spatial displays.

Graphs, which are pictures that convey logical relationships among numbers for a specific purpose, include line graphs, bar graphs, step graphs, and pie charts. Specific

examples of graph usage are demonstrated in the *Publication Manual of the American Psychological Association* (2001).

Experimental studies of graph comprehension confirmed that the information from a graph is greatly influenced by its representation. Graphs can be represented in various forms. Different representations generated from an identical data set elicit different interpretations of the graphs. For example, in studies of inferences from bar and line graphs, viewers are more likely to describe x-y trends when viewing line graphs than bar graphs (Zacks & Tversky, 1999; Shah, Mayer, & Hegarty, 1999). Peebles and Cheng (2003) suggested that the comprehension time of certain information differs depending on the graph structure.

Although many studies on graph comprehension have been conducted, graph generation is also an important issue. In the current study, we deal with the issue of arrangements of variables on graphs when generating them. Shah and Carpenter (1995) confirmed that x-y trends were comprehended easily, although z-y trends were comprehended with difficulty using three-variable line graphs (e.g., Carpenter & Shah, 1998; Kanzaki & Miwa, 2011). The reason may be that visual chunks are constructed for every line in a line graph, and the graph is interpreted based on each chunk.

Consider the case indicated in Table 1 where a line graph is depicted from the data that consist of two independent Variables, A and B, and one dependent variable, Variable C. Two types of graphs are considered. One is a graph in which Variable A is put on the x-axis and Variable B on the z-label (Figure 1(a)), and on the other Variable B is put on the x-axis and Variable A on the z-label (Figure 1(b)). According to Larkin & Simon (1998), these two graphs are informationally equivalent but computationally different; they are equivalent because they are constructed from identical data sets, but they are different since different chunks are constructed in each of the graphs and the information may be read in different ways. When explaining

Table 1: Variable C vs. Variables A and B.

		Variable B		
		10	30	50
Variable A	10	20	50	80
	30	50	50	50
	50	80	50	20

Figure 1: Graphs made from Table 1.

the data of Table 1, one of two alternative graphs must be generated whose structure is consistent with the explanation.

Consider a more specific situation in which we must adjust independent Variable B with an uncontrollable change of Variable A to intentionally control the quantity of dependent Variable C. When explaining how to manage Variable B in this situation, the explanation is classified into two types from the viewpoint of the representation of Variable A. In one explanation, Variable A is described discretely. In this classification, the explanation is generated for each level of Variable A, such as “when Variable A is at ..., you should set Variable B to ...” In the other explanation, Variable A is described continuously. In this classification, the explanation reflects whether its value is larger than a specific value, such as “when Variable A is larger than ..., set Variable B to ...”, or from the viewpoint of a continuously changing variable A, such as “according to the increase of Variable A.”

When two independent variables are placed on a line graph, one variable is commonly put on the x-axis and the other on the z-label. In such a situation, it is contemplated that the variable on the x-axis is regarded as a continuous variable, and the one on the z-label is regarded as a discrete variable because the x-axis is represented as a continuous factor and the z-label as a discrete factor.

Kosslyn (2006) noted that “the continuous rise and fall of a line is psychologically compatible with the continuous nature of an interval scale. . . Time, temperature, and amount of money are measured using an interval scale.” Additionally, Kanzaki & Miwa (2011) suggested that an explanation based on each line increases the comprehension of a line graph because a chunk of each line is generated (e.g., Carpenter & Shah, 1998; Shah & Carpenter, 1995). These studies indicate that a variable on the z-label in a line graph is regarded as a discrete variable.

The above investigations propose a hypothesis, where in a normative graph, an independent variable is put on the x-axis when the variable is regarded as a continuous variable in the explanation; in contrast, an independent variable is put on the z-label when it is regarded as a discrete variable.

If this hypothesis is correct, we predict the following when we must explain how to adjust independent Variable B, with the uncontrollable change of independent Variable A to control the quantity of dependent Variable C:

1. Participants who treated Variable A as a continuous variable in their explanation put it on the x-axis (Figure 1(a)).

2. Participants who treated Variable A as a discrete variable in their explanation put it on the z-label (Figure 1(b)).

In the current study, expert graph users participated in Experiment 1, whom we defined as those who daily engage in academic activities using graphs. Our first objective is to confirm whether such experts adaptively generate graphs that are consistent. We expected them to do so because they have much experience giving presentations with graphs and reading them in research papers.

Our second aim is to perform a similar experiment with undergraduates as novices. Undergraduates who have not received systematic training in statistics participated in our second and third experiments. We propose a hypothesis that they may have trouble generating consistent graphs when they are required to adaptively generate graphs based on understanding such highly abstract mathematical concepts as continuousness and discreteness.

Recently, various types of software have been developed for making graphs. User can automatically generate them by simply choosing some properties. In this situation, users select a graph rather than generate one. The third objective is to examine whether undergraduates can select a consistent graph when they are presented alternative candidates of consistent graphs.

## Experiment 1

Experiment 1 investigated whether people who use graphs daily can adaptively generate consistent graphs when constructing an explanation with them.

We set a situation in which either “air temperature” or “humidity” was adjusted to promote the growth of “newly discovered mushrooms.” Two dependent variables, air

temperature and humidity, can be treated either as continuous or discrete. An independent variable is the “amount of mushroom growth.” The table used in our experiments is the same as Table 1, but Variables A, B, and C were replaced with specific factors: humidity, air temperature, and amount of growth. The shape of the line graph generated from the table is also the same as in Figure 1. These two graphs’ shapes were controlled to be the same in order that the ease of constructing explanation should not be affected by the shapes of the graphs.

In our experiments, we set two situations for a particular explanation context. In one situation, participants explained how to promote mushroom growth by adjusting the humidity, where air temperature was not controllable. In the other situation, they did so by adjusting the air temperature, where the humidity was not controllable. These two situations were counter-balanced in the experimental procedure.

## Method

**Participants** The participants in Experiment 1 were either university associate professors or doctoral students in experimental psychology. 22 researchers participated as experts. 17 had Ph. Ds. All participants had published one or more peer-reviewed academic journal papers.

**Procedure** The experiment was performed individually or in small groups. The participants were presented the table shown in Table 1 and given the following instructions:

“A new kind of mushroom was recently discovered whose growth greatly depends on air temperature and humidity. Its growth at specific temperatures and humidities is shown in this table.”

Half of the participants were given a situation where the amount of growth was controlled by adjusting the humidity, but the temperature was not controllable. For these participants, the following instructions were given:

“You are a salesperson of mushroom seedlings. Your customers can adjust the humidity in their mushroom greenhouses, but they cannot adjust the temperature. Explain how to grow the mushrooms by adjusting the humidity with uncontrollable changes of temperature. Use a line graph in your explanation.”

For counter-balance manipulation, the other half was given a situation where the humidity could not be adjusted, and temperature was replaced by humidity in the instructions.

They wrote their explanation in ten minutes and then drew a graph on an experimental sheet shown in Figure 2 in five minutes, labeling the x-axis and the z-legend by themselves.

Figure 2: Graph format used in Experiments 1 and 2.

**Classifying generated graphs** The generated graphs were classified by the placement of an unadjustable variable in the graphs. The following were the classification criteria:

- (1) *X-axis unadjustable* graph: an unadjustable variable is put on the x-axis
- (2) *Z-legend unadjustable* graph: an unadjustable variable is put on the z-legend

**Classifying explanations** The participant explanations were classified depending on whether the unadjustable variable was described as a continuous or a discrete variable. The following were the classification criteria:

- (1) *Continuous explanation*: an unadjustable variable is described continuously. The following are example explanations in this category for a situation where the temperature is not adjustable: “When the temperature is above 30°C,” “according to the increase of temperature,” and so on.
- (2) *Discrete explanation*: an unadjustable variable is described discretely. Example explanations in the same situation include, “When the temperature is at 10°C,” “when the temperature is low,” and so on.

When both types of descriptions appeared in an explanation, the classification was made based on the description that was part of the conclusion. Such descriptions were usually seen in the last part of the explanation.

## Results and discussions

The participants were grouped depending on whether they generated *continuous* or *discrete explanations*. Those who generated *continuous explanations* were classified as the *continuous explanation* group, and those who generated *discrete explanations* as the *discrete explanation* group. Ten of the 22 participants were categorized in the *continuous explanation* group and the other twelve in the *discrete explanation* group.

Figure 3 shows the proportions of the graphs classified into each category in the two groups.

To examine whether the structure of the generated graphs was influenced by the described explanation, a two difference in the distribution ( $\chi^2(1, N=22) = 6.42, p < .05$ ).

Figure 3: Proportions of participants who generated *x-axis* or *z-legend unadjustable* graphs in Experiment 1.

(*continuous* and *discrete* explanation groups) x two (*x-axis* and *z-legend* generated graphs) chi-square test was performed on their distribution. There was a significant A residual analysis shows that both the numbers of the participants who generated *x-axis unadjustable* graphs in the *continuous explanation* and *z-legend unadjustable* graphs in the *discrete explanation* group were greater than the expected values (the residual value was 2.53). On the other hand, both the numbers of participants who generated *z-legend unadjustable* graphs in the *continuous explanation* group and *x-axis unadjustable* graphs in the *discrete explanation* group were less than the expected values (the residual value was -2.53).

This result suggests a tendency to generate specific line graphs in which an unadjustable variable was put on the x-axis when it was regarded as a continuous variable in an explanation. On the other hand, there was a tendency to generate graphs in which an unadjustable variable was put on the z-legend when it was regarded as a discrete variable. This result implies that the participants, who use graphs on a daily basis, adaptively generate graphs whose structures are consistent with their explanations.

## Experiment 2

In Experiment 1, we confirmed that expert graph users adaptively generate graphs whose structures are consistent with their explanations. In Experiment 2, we performed the same investigation with undergraduates who have little experience of making graphs when explaining something.

### Method

In the following, descriptions are omitted about the same procedures as in Experiment 1.

**Participants** 44 undergraduate Liberal Arts majors who had not completed a course in statistics participated. Half were given a situation where the growth was controlled by adjusting the humidity, but the temperature was not controllable, and for counter-balance manipulation, the

Figure 4: Proportions of participants who generated *x-axis* or *z-legend unadjustable* graphs in Experiment 2.

other half was given a situation where the growth was controlled by adjusting the temperature, but the humidity was not controllable.

**Procedure** The procedure of Experiment 2 was the same as that of Experiment 1.

### Results and discussions

Seventeen of the 44 participants were categorized in the *continuous explanation* group and the other 27 in the *discrete explanation* group.

Figure 4 shows the proportions of graphs classified into each category in the two groups.

To examine whether the structure of the generated graphs was influenced by the described explanation, a two (*continuous* and *discrete* explanation groups) x two (*x-axis* and *z-legend* generated graphs) chi-square test was performed on the distribution of the generated graphs. There was no significant difference in the distribution ( $\chi^2(1, N=44) = 0.02, ns$ ). This result suggests that undergraduates cannot generate consistent graphs.

## Experiment 3

In Experiment 2, we confirmed that undergraduates did not necessarily make graphs whose structure is consistent with their explanations. In Experiment 2, the participants generated graphs by themselves. But in Experiment 3, we gave them two candidates of consistent graphs and let them select one to investigate whether they could adaptively select a consistent graph from two alternatives.

### Method

In the following, descriptions are omitted about the same procedures as in Experiment 2.

**Participants** 57 undergraduate Liberal Arts majors who had not completed a statistics course participated. 29 were given a situation where the growth was controlled by adjusting the humidity, but the temperature was not controllable, and for the counter-balance manipulation, the other 28 were given a

Figure 5: Proportions of participants who selected x-axis or z-legend unadjustable graphs in Experiment 3.

situation where the growth was controlled by adjusting the air temperature, but the humidity was not controllable.

**Procedure** The experiment was performed as part of their class assignments. The participants wrote a script for the given situation and presented the table used in Experiments 1 and 2. They were also presented two types of line graphs made from the table, such as those in Figure 1, and required to select a suitable one.

## Results and discussions

Five participants were excluded from analysis because they failed to follow the instructions. 20 were categorized in the *continuous explanation* group and the other 32 in the *discrete explanation* group.

Figure 5 shows the proportions of graphs classified into each category in the two groups.

To examine whether the structure of the selected graphs was influenced by the described explanation, a two (*continuous* and *discrete* explanation groups) x two (*x-axis* and *z-legend* selected graphs) chi-square test was performed on their distribution. There was a significant difference ( $\chi^2(1, N=52) = 5.62, p < .05$ ). A residual analysis shows that both the numbers of the participants who selected *x-axis unadjustable* graphs in the *continuous explanation* group and *z-legend unadjustable* graphs in the *discrete explanation* group were greater than the expected values (the residual value was 1.96). On the other hand, both the numbers of the participants who selected *z-legend unadjustable* graphs in the *continuous explanation* group and *x-axis unadjustable* graphs in the *discrete explanation* group were less than the expected values (the residual value was -1.96).

This result implies that undergraduates tended to adaptively select consistent graphs if alternatives were presented to them. However, in Experiment 3, the proportions of participants who selected *x-axis unadjustable* graphs were greater than those in the result of the expert graph users in Experiment 1. We discuss this point below.

## Discussion and conclusions

In this study, we investigated whether expert graph users and undergraduates make consistent graphs from given data to construct explanations. The result of Experiment 1 confirmed that expert graph users successfully generated graphs in relation to their explanations. On the other hand, Experiment 2 showed that undergraduates failed to indicate this tendency.

We discuss the results in the light of our hypothesis proposed in the introduction by analyzing the proportions of each type of graphs in each explanation group.

In the result of Experiment 1 (Figure 3) in the *discrete explanation* group, the proportion of *z-legend unadjustable* graphs was significantly larger than that of the *x-axis unadjustable* graphs ( $p = .019$ , one-tailed Fisher's exact tests). This means that the clearly greater use of a discrete factor in the graph was due to the influence of the greater use of discrete expressions in the explanation. In other words, there was a consistency between the explanation and the graph. On the other hand, in the *continuous explanation* group, although the proportion of *x-axis unadjustable* graphs was larger than that of the *z-legend unadjustable* graphs, there was no significant difference in their proportions ( $p = .172$ , one-tailed Fisher's exact tests). Three of the ten experts in the *continuous explanation* group put the variable described as a continuous one on the z-legend, contrary to our expectation. When analyzing their explanations, two of the three generated explanations based on the slopes of the lines. For example, in the humidity unadjustable situation, "when the humidity is lower than 30%, the mushroom growth proportionally increases with the air temperature because the line slope is positive." Since a line slope is described based on each label of the z-legend, and a line slope is represented continuously in a line graph, they put the continuous variable on the z-legend. The above investigation supports that, as a whole, expert graph users adaptively generated consistent graphs both in the *continuous* and *discrete explanation* groups.

Next, we discuss the graph generation by undergraduates in Experiment 2 (Figure 4). To generate consistent graphs, we must examine what should be represented based on deep consideration of explanations (Kosslyn, 2006). Our result implies that undergraduates tend to use graphs without such consideration.

On the other hand, when selecting a graph in Experiment 3, undergraduates were given choices. Such given choices might enable them to consider the consistency of their explanation and graph representation.

As Norman (1992) noted: "to think of the problem of designing something that people will find understandable and easy to use as the same problem as writing something that other people will understand and find easy to read." The process of generating a graph for conveying information resembles the process of writing. A cognitive writing model proposed by Hayes & Flower (1980) consists of *planning*, *translating* (text production), and *reviewing*. Similarly, the process of generating a graph also involves *planning*, in

which people discuss how to present information, *translating* (depicting), in which people depict a graph, and *reviewing*, in which people review whether the graph is appropriate for their purpose. Studies on writing point out the troubles of the *planning* phase in novices: e.g., not considering situations and objectives for explanation (Flower & Hayes, 1980) and tending to ignore planning (Carey, Flower, Hayes, Schriver, & Haas, 1989).

When selecting a graph from the candidates in Experiment 3, the undergraduates were only required to *review* a graph in the light of explanation without *planning* and *translating*. This may explain why more consistent graphs were selected in Experiment 3 than in Experiment 2.

In Experiment 3 (Figure 5), although we confirmed that the proportions of each type of graphs adaptively changed depending on the explanation contents, as a general tendency, the proportion of *x-axis unadjustable* graphs exceeded that of the *z-legend unadjustable* graphs. This tendency was also shown in Experiment 2 (Figure 4). These results suggest that undergraduates tended to put an unadjustable variable on the x-axis without considering their explanations.

In this study, we defined the normative consistency of explanation and graph representation from the viewpoint of the variable's continuousness and discreteness. Scrutiny is needed to confirm whether such graph consistency actually promotes understanding. Such investigation remains important future work.

Finally, even if the automatic generation of graphs with spreadsheet software simplifies their utilization, this study's results indicate that undergraduates still have trouble selecting consistent graphs. On the other hand, presenting candidate graphs improved the selection of consistent graphs, implying that presenting undergraduates with variations of possible graphs and having them consider the relation of what they wish to explain and the candidate graphs may be an effective method in tutoring graph construction.

## Abstract

The purpose of the present research is to investigate whether virtual agents can help enhance participants' performance, effort and motivation in mathematics. We hypothesize that a minimal amount behavioral realism induced by display of rapport is necessary for any social effects to occur in human-computer interaction. Further, we examine whether social facilitation effects occur depending on the gender of the participants and the interacting virtual agents. In a 2x2 between subjects design, participants interacted with a male or female virtual agent that either displayed rapport or no rapport. Our results confirm that gender plays a role when interacting with virtual agents that are capable of establishing rapport. Participants' performance and effort were significantly enhanced when interacting with an agent of opposite gender that displayed rapport. Our results have implications on designing agents for education and training purposes.

**Keywords:** social facilitation, STEM, rapport, virtual agents

## Introduction

There is considerable interest in factors that enhance science and math performance. Recently, there has been an upsurge of interest in educational technology that exploits social and motivational factors that enhance math performance in general, and reduce gender inequality in particular (Kim, 2004; Baylor & Ryu, 2003). This work builds on the phenomena that people often treat computers as social actors. Therefore, psychological factors that improve people's performance in traditional face-to-face settings can be simulated by technologies in form of virtual learning companions or virtual instructors. In this paper, we seek to address two related goals. First, we aim to show that certain social psychological phenomena can enhance math performance in a human-computer setting. Specifically, we show that a form of social facilitation can improve performance on standardized math tests. Second, we seek to provide further evidence that people do treat computers as social actors and help elucidate the design principles that foster this effect. We specifically demonstrate that virtual agents must possess a minimum level of behavioral realism to achieve any social effects.

Rapport has been shown as an effective way to create behavioral realism in virtual agents. In social psychology, rapport is described as the establishment of a positive relationship among interaction partners by rapidly detecting and responding to each other's nonverbal behavior (Gratch et al., 2007a). This includes displaying behaviors that indicate positive emotions (such as head nods and smiles), showing mutual attentiveness (such as mutual gaze) and certain coordination behaviors (such as postural mimicry and synchronized movement) (Tickle-Degnan & Rosenthal, 1990). Niewiadomski et al. (2010) reports that when an agent displays appropriate and socially adapted emotional expressions, he is perceived as more human-like than an agent that shows human expressions which are inappropriate or not socially adapted. Garau et al. (2005) conducted a study showing that only participants who interacted with an agent that was responsive to their movements, experienced a sense of personal contact with the agent which influenced them to behave more socially considerate as opposed to interacting with a static or moving but unresponsive agent. This indicates that rapport is an important feature in order for the agent to be perceived as human-like and for any social effects, such as social facilitation, to occur.

Previous research on social facilitation/inhibition illustrates how the presence of others affects an individuals' task performance either positively or negatively (Guerin & Innes, 1982; Zanjong, 1965; Sanders, Baron & Moore, 1978). Whether or not similar facilitation/inhibition effects occur in presence of virtual agents has been subject to several studies. Rickenberg and Reeves (2000) found that tasks are facilitated or inhibited by the "social" presence of a virtual agent. A study by Zambaka et al. (2004) indicates that when asked to perform a task, participants reacted similarly to the presence of a virtual agent as they would have in the presence of another human. A follow-up study by Zambaka et al. (2007) demonstrates that the presence of a virtual agent inhibits the performance of participants on a mathematical task. The limitation of this study was that the sample consisted of only female participants being confronted with an agent of matching gender. Hayes et al. (2010) found a similar decrease in performance with regard

to male participants interacting with an agent of the same gender. However, the study demonstrated that when male participants interacted with an agent of the opposite gender their performance improved. The authors argued that participants experienced a stronger feeling of “being in the room with the agent” when interacting with an agent of opposite gender. A post-hoc explanation for Hayes et al.’s findings is that the improvement may have been caused of social facilitation effects.

## Experiment

Our goal in this paper is to investigate whether a virtual agent can motivate participants and help to improve their performance in a mathematical task. For this purpose, we examine whether social facilitation effects occur when participants interact with virtual agents and how gender and rapport influence these effects. We extend the previous findings of Hayes et al. (2010) by including both, male and female participants, in an experiment in which they interact with a virtual agent of either matching or opposing gender.

We hypothesize that interacting with a human-like rapport agent of the opposite gender facilitates participants’ performance on mathematical tasks. First, we assume that social facilitation effects will cause participants’ to show more motivation, invest more effort and achieve a higher improvement of performance when interacting with an agent of the opposite gender. Second, we further expect such social facilitation effects only to occur when rapport is displayed by the agent. The reason is that rapport has been shown to be necessary for an agent to be perceived as a (human-like) social entity, which is required for social effects to occur.

In order to test these assumptions, we designed an experiment in which we manipulated virtual agents’ gender and rapport behavior. We recruited male and female participants and had them perform two mathematical tasks, one before interacting with an agent and one during the interaction. Each participant was either confronted with an agent of matching gender or of opposing gender. The agents used in the rapport condition were capable of showing appropriate positive responses such as head nods and smiles in reaction to the participants’ verbal and nonverbal behavior. The agents in the no-rapport condition only show minimal unresponsive movements such as breathing or blinking. We explored the effects of our experimental conditions by comparing the participants’ performance before and during the interaction with the agent. We also investigated participants’ motivation and increase of effort to solve the math problems.

## Participants

We recruited seventy-four participants (58.1 % females), from the greater Los Angeles area. Their age ranged from 18 to 34 years with an average age of 23.64 (SD=3.97). 16.2% of participants had high school education, 78.4% collage education and 5,6% went to graduate school. Participants were recruited by responding to recruitment

posters posted on craigslist.com and were paid \$30. The experiment took about 60 minutes.

## Design

We used a 2x2 full factorial between subjects design, with the first variable being the gender of the agent matching the gender of the participant (gender match/gender no match) and the second variable being whether or not the agent displayed rapport (rapport/no rapport). Participants were randomly assigned to one of the four conditions.

Improvement in performance, motivation and increase in effort were measured as dependent variables. We calculated participants’ performance improvement by the difference in their performance before and during the interaction with the agent. For this purpose, we subtracted the number of math problems they solved correctly in the second task from the number they solved correctly in the first task. To measure participants’ motivational state with regards to the mathematical tasks we used the Situational Motivation Scale (SIMS) by Guay et al. (2000). By subtracting the number of solved math problems in the second task from the number solved in the first task, we calculated the increase in effort. This variable was interpreted as an additional indicator for their situational motivation.

### Sample of three questions in the first task:

- A) The child care center charges \$11 an hour plus a daily \$3 drop-off fee. How many hours of childcare did Robert pay for if he dropped his son off 3 days last week and paid \$130 at the end of the week?
- B) A rental store charges a fine of 25 percent of the usual full-day rental rate for each hour that an item is late. Ryan rented a rototiller for one day for \$40. He returned it 3 hours late. How much was his total bill for the rental and the fine?
- C) What is the value of the expression  $3 + 4 \times 6 - 2(5 \times 8)$ ?

### Sample of equivalent questions in the second task:

- A) To do a 12-page report, a word processor charges \$26.50. His fee includes a \$2.50 delivery charge. How much does he charge per page?
- B) Mr. Smith rented a car for 7 days. The car rental charges 500 \$ per week and a fine of 15% for each day the car is returned late plus a handling fee of 15 \$. He returned the car 2 days late. How much did he have to pay in the end?
- C) Evaluate the following expression:  $4(12 - 9)2$ .

Figure 1: Sample of math problems

## Mathematical Tasks

Two mathematical tasks were presented to the participants. Each task consisted of a set of 24 math problems comparable to original GRE and SAT math items (for samples of these questions please refer to Figure 1). The math problems were selected out of a larger set of questions pretested with regard to their difficulty. By pretesting the problems we made sure that both tasks have approximate levels of difficulty and require the same sets of skills. Also, tasks had enough number of questions to prevent ceiling effects due to participants finishing all the math problems in less than ten minutes. To avoid an improvement in performance in the second task due to simple learning/practice, the math problems were modified with regard to their wording and surface features. This way the first and the second task appeared distinct from each other while they still each required the same set of skills.

## Rapport Agent

Participants interacted with a female or male virtual agent with a human-like appearance. Four different characters were used: two male and two female (Figure 2) to control for possible effects of particular agents. We used the Rapport Agent developed by Gratch et al. (2006). To create rapport with the participant, the agent displayed positive listening behaviors (such as nodding and smiling) that correspond to the verbal and nonverbal behavior of a human speaker. Previous studies of the rapport agent have shown that it is highly capable of creating the experience of rapport comparable with a face-to-face condition (Gratch et al.,

2006, 2007a, 2007b). To produce listening behaviors, the Rapport Agent first collects and analyzes audiovisual features from the speaker's voice (silence, speech) and upper-body movements (head nod, smile, eye gaze) in real time. This happens via a microphone and a Videre Design Small Vision System stereo camera, which was placed in front of the participants to capture their movements. Watson, an image-based tracking library developed by Morency (2005), uses images captured by the stereo camera to track the participant's head position and orientation. Acoustic features are derived from properties of the pitch and intensity of the speech signal using a signal processing package, LAUN (Gratch et al., 2006). The Rapport Agent displays behaviors that show that the animated character is "alive" (eye blinking, breathing), and listening behaviors such as posture shifts and head nods automatically triggered by the system corresponding to participants' verbal and nonverbal behavior. This allows the agent to provide contingent feedback while the speaker is speaking by following a response model (Huang et al., 2011) to decide which behavioral response would be most appropriate (such as head nod or smile). The different animations are converted into Behavior Markup Language (BML) (Kopp et al., 2006), send to an action scheduler (to determine the duration of each animation) and passed on to Smartbody, an animation system that blends the different animations naturally into each other (Thiebaux & Marsella, 2007). The commercial game engine Gamebryo then renders the animations and displays them to the user.

Figure 2: Agents used in the experiment

## Procedure

After an explanation of the study and obtaining consent, participants were led to a private room where they completed the experiment individually. Participants were seated at a desk with two monitors that were positioned next to each other. They were then instructed to work on a mathematical task for ten minutes, which was presented as a computer-based survey on one of the monitors. The second monitor was turned off at this point. To minimize self-presentation concerns, the anonymity of task performance results and the non-competitiveness of the task were emphasized. The experimenter left the room for the duration of the working period. Participants' answers were not reviewed by the experimenter and they were not given any performance feedback. Next, the experimenter provided detailed (verbal and written) instructions on the following interaction with the virtual agent. It was emphasized that the agent is a computer program and that participants will be alone during their interaction period. The agent was then launched and displayed on the second monitor. The experimenter would leave the room before the interaction started and then would control the virtual agent's speech over a separate computer in a different location, without the participants' knowledge. The agent's nonverbal behaviors were automated by the system according to the condition (rapport/no rapport) as described above. First, the agent asked how the participants estimated their performance on a 5-point Likert-scale (*very poor* to *very good*). Next, they were asked to rate how difficult they thought the math problems were on another 5-point Likert-scale (*easy* to *hard*). This was followed by the second task period that was part of the interaction. The agent would instruct the participants to load the task on the other monitor and work on it for a time period of ten minutes. During that time the agent reminded the participants twice of the time remaining (5 minutes and 1 minute left) and also let them know when time was up. Afterwards, the agent asked the participants to estimate their performance with regard to the second task on the same scale. At the last part of the interaction, the agent interviewed the participants concerning their experiences while working on the tasks and their attitudes towards

mathematics in general. Then, the agent would announce the end of the interaction and would disappear from the monitor. Finally, situational motivation and demographic variables were measured in a post survey without the virtual agent visible or the experimenter present. Subsequently, participants were debriefed. During debriefing it was made sure that participants had not been aware during the experiment that the experimenter or any other human was involved and/or had any part in the interaction (for an overview of the study flow, see Figure 3).

## Results

We first verified that agent appearance did not affect the results. As anticipated, there were no significant differences between agents with the same gender but different appearances. Therefore, the data was collapsed for further analysis.

There was an overall improvement of performance between the first task when the agent was absent ( $M = 3.86$ ,  $SD = 2.72$ ) and the second task when the agent was present ( $M = 5.49$ ,  $SD = 3.33$ ,  $t(73) = -7.29$ ,  $p = 0.001$ ). Also, self-evaluation of participants increased from the first task ( $M = 2.93$ ,  $SD = 1.00$ ) to the second task ( $M = 3.15$ ,  $SD = 1.08$ ,  $t(73) = -2.44$ ,  $p = 0.017$ ). Moreover, Participants showed significantly more effort by attempting to solve more math problems in the second task, when the agent was present, ( $M = 10.01$ ,  $SD = 3.67$ ) compared to the first task ( $M = 8.41$ ,  $SD = 3.49$ ;  $t(73) = -4.70$ ,  $p = 0.001$ ).

A 2 X 2 ANOVA, with the first factor being the display of rapport by the agent (rapport/no rapport) and the second factor being the gender condition (matching gender/opposing gender) showed a main effect of rapport on the improvement in performance ( $F(71) = 4.96$ ,  $p = 0.029$ ) (Figure 4). When the agent displayed rapport ( $M = 2.09$ ,  $SD = 1.96$ ), participants showed a significantly higher improvement in performance than without rapport ( $M = 1.21$ ,  $SD = 1.79$ ;  $t(72) = 2.02$ ,  $p = 0.047$ ). Specifically, in the opposing gender condition, there was a significant difference between the rapport ( $M = 2.56$ ,  $SD = 1.59$ ) and no-rapport conditions ( $M = 0.87$ ,  $SD = 1.92$ ), with

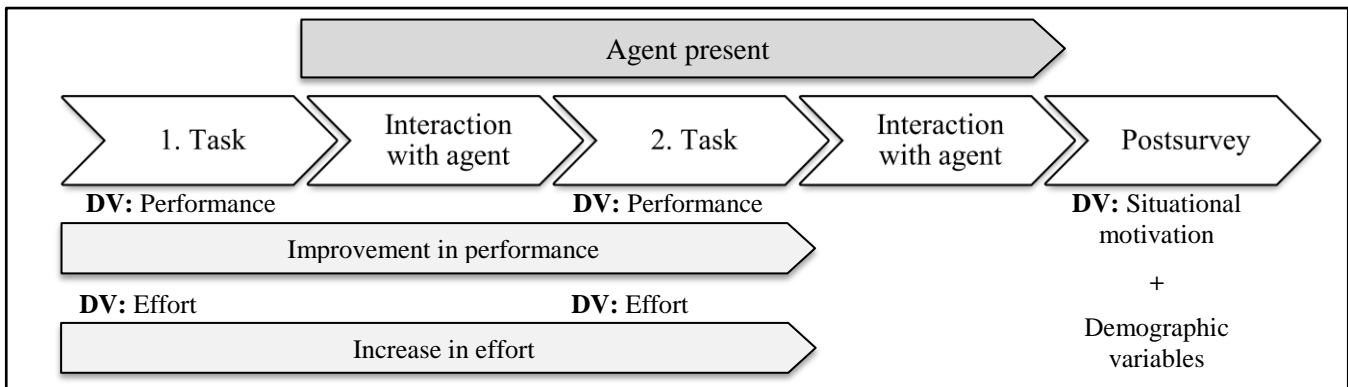

Figure 3: Study Flow

Figure 4: Performance Improvement

significantly higher performance in the rapport condition ( $t(29) = 2.68, p = 0.012$ ). The difference in improvement in the no-match condition did not reach significance.

We expected performance improvement to occur due to an increase of effort and motivation, thus we used one-tailed t-tests for these two variables. In the opposing gender condition participants invested more effort when rapport was displayed ( $M = 2.25, SD = 3.17$ ) compared to no displayed rapport ( $M = 0.27, SD = 3.37, t(29) = 1.69, p = 0.051$ ). In the opposing gender condition, there was a significant trend in increase of motivation between the rapport ( $M = 63.50, SD = 8.16$ ) and no rapport ( $M = 56.13, SD = 12.78$ ) condition ( $t(29) = 1.93, p = .032$ ). Within the matching gender condition the display of rapport did not show any influence on the dependent variables.

## Discussion

We expected that facilitation effects to occur when participants interact with a virtual agent of opposite gender and that this will only be the case if the agent displays rapport. The results of this study support these hypotheses. When rapport was displayed, participants' improvement was higher when they interacted with an agent of opposite gender than with an agent of matching gender. The same patterns were found for effort. This indicates that a social facilitation effect only occurs under a certain gender condition, i.e. opposing gender, and when rapport is displayed by the agent. Participants' performance improved most when they interacted with a virtual agent of opposite gender that displayed rapport and it improved least with an agent of the opposite gender who did not display rapport. This indicates that rapport has an effect on participants' improvement in performance only when the agents' gender

does not match their own. Research in social psychology has shown that establishing rapport between people and their instructors in face-to face interactions increases desirable outcomes such as motivation and improvement in task success (Granitz et al., 2009; Thomas et al., 1982). Our results show that rapport has a similar positive effect on performance in human-computer-interaction.

Overall, interacting with a virtual agent significantly enhanced participants' performance and effort. Our findings indicate that interacting with virtual agents of opposite gender that are capable of displaying rapport behavior improves participants' performance on mathematical tasks most. It supported participants' motivation and increased their effort to perform well by attempting to solve a higher number of math problems. We hope to further examine whether and how gender differences play a role in this interaction.

## Conclusion

In summary, contributions of this work are three-fold. First, the study adds to literature on human-computer-interaction with regard to virtual agents by showing that the agent's gender and rapport are both key factors for achieving desirable outcomes such as motivation, effort and performance with regard to mathematical tasks. Virtual Agents which are capable of establishing rapport can contribute to improve people's performance in mathematics, specifically with regard to standardized math tests. This observation may support the development of useful and effective applications in mathematical education and training, such as virtual instructors, tutors or learning companions. Second, it shows that social facilitation effects occur when interacting with virtual agents of opposing gender. Finally, this work makes a methodological contribution to the fields of experimental psychology and human-computer-interaction.

## Abstract

The current project is a case study—and an extension—of the traditional investigation into sound symbolism (Hinton et al., 1994). Several studies have shown that certain sounds evoke images of particular shapes; for example, oral stop consonants are often associated with angular shapes, whereas sonorants (nasals, liquids, and glides) are associated with round shapes (Berlin, 2006; Köhler, 1947). Berlin (2006) attributes these associations to the similarities between abrupt acoustic amplitude modulation of stop consonants and abrupt change of the directions of lines, i.e., abrupt visual changes. In this study, we extend the stop-angular sound symbolic relation to the domain of emotions. Stops not only evoke the images of angular shapes, but are also associated with emotions that involve abrupt onsets. We further show that angular shapes themselves are associated with such emotions. Our three experiments thus establish a tripartite trans-modal symbolic relationship among three domains of cognition (sounds, shapes, and emotions). As an additional general implication, we argue that our experimental results support acoustic, rather than articulatory, bases of sound symbolism.

**Keywords:** sound symbolism; stop consonants; sonorants; angularity; emotions; abrupt modulations; modularity; synesthesia

## Introduction

A prevalent assumption in modern linguistics is the autonomy of semantics (meanings) from sounds. One of the Saussurian principles of languages suggests that there is no inherent connection between meanings and sounds. For example, there is no inherent reason why what we call [k<sup>h</sup>æt] is called in such a way. In fact, different languages call that animal by different names. Therefore, the argument goes, the sound-meaning relationship must be arbitrary. Saussure in fact raises this principle of arbitrariness as a first principle of natural languages (de Saussure, 1960).

However, evidence for an opposing view—that there is some inherent connection between sounds and meanings—is also available, and proponents of this view date back to at least Cratylus in Plato (Harris & Taylor, 1989). Especially since the seminal experimental work by Sapir (1929), a substantial body of experimental work shows that sounds are often associated with particular meanings. This relationship, often referred to as sound symbolism, is usually not absolute, and comes with some lexical

exceptions. For example, Sapir found that English speakers tend to associate [a] (back and low vowels) with big objects and [i] (high front vowels) with small objects; however, there are lexical items such as *big* that go against this trend. Since Sapir's work, the tendency to associate lower and backer vowels with bigger objects have been found in many other languages (e.g. Shinohara & Kawahara (2012) among many others).

In short, the previous work on sound symbolism in natural languages has established that we can at least identify stochastic tendencies toward some connection between sounds and meanings (despite the fact that some lexical items may not strictly follow such connections) (Hinton et al., 1994).

There is thus little doubt, albeit perhaps in non-categorical ways, that there are some associations between sounds and meanings. Moreover, these associations between sounds and meanings tend to make phonetic sense. For example, [a] is often considered to be larger than [i] in many different languages, and this association arises because [a] has wider opening of the mouth than [i] (Sapir, 1929; Shinohara & Kawahara, 2012). Alternatively, viewed from a (psycho)acoustic perspective, [a] involves lower second resonant frequency (F2) than [i], which would imply a larger resonator (Ohala, 1994). See also Shinohara & Kawahara (2012) for the comparison of these two theories of sound symbolism.

Figure 1: The roadmap of this paper.

In the current project, we focus on the meanings of oral stop consonants (like [p, t, k]), which acoustically involve abrupt amplitude changes, as opposed to sonorants, which involve gradual amplitude changes (nasals, liquids, glides, like [n, l, r, j]) (see section 2 for the illustration of these phonetic concepts.). We show that these acoustic characteristics of stops are associated with angular shapes

by native speakers of English (Experiment I). Furthermore, Experiment II shows that the acoustic characteristics of stops are also associated with emotion types with abrupt onsets, as opposed to those that involve gradual onsets. The final experiment goes beyond the traditional sound symbolism studies and shows that there is a direct connection between the emotion types with abrupt onsets and angular shapes. The last two experiments were motivated by a recent finding with Japanese speakers that particular types of emotions can be associated with particular sounds and shapes (Shinohara et al., 2011). Overall, our experiments show a tripartite relationship between three domains of cognition (auditory sounds, visual shapes, and emotion types). The overall conclusion and the roadmap of this paper are illustrated in Figure 1.

### Background: Phonetics of stops and sonorants

Oral stops are those sounds that are made with complete oral occlusion (and without the leakage of air through the nasal cavity), which results in rise of the intraoral air pressure (Ohala, 1983). The acoustic consequence of the rise in intraoral air pressure, upon the release of the stop occlusion, is abrupt bursts. Stop consonants thus involve a burst with abrupt amplitude changes after the release of the oral closure. Figure 2 shows a waveform of the 0.05 sec (=50 ms) interval centering around a stop burst of [t]. It represents amplitude changes on the y-axis across time on the x-axis. The transition from a closure phase (oral occlusion) into a burst is rather abrupt, and the burst itself involves abrupt amplitude changes.

Figure 2: A waveform illustrating a closure phase and a burst of [t]. It shows amplitude changes within a 0.05 sec interval centering around a stop burst. A silent closure is followed by a burst with an abrupt onset.

Sonorants, on the other hand, include a class of sounds consisting of nasals ([m, n]), liquids ([l, r]), and glides ([w, j]) ([j] is the sound that is often represented with “y” in English orthography, as in *young*). In contrast to obstruents, sonorants do not involve rise in the intraoral air pressure because their aperture is wide enough to allow spontaneous vibration of vocal folds (Chomsky & Halle, 1968). Sonorants are thus characterized by energies with gradual changes, and their boundaries with respect to surrounding vowels are gradual. Figure 3 illustrates 0.05 sec intervals of

transitions from a vowel to a nasal [n] and to a glide [j]. As observed in the figure, the transitions from the vowel to sonorants are blurry, and the sonorants themselves are characterized by gradual amplitude changes.

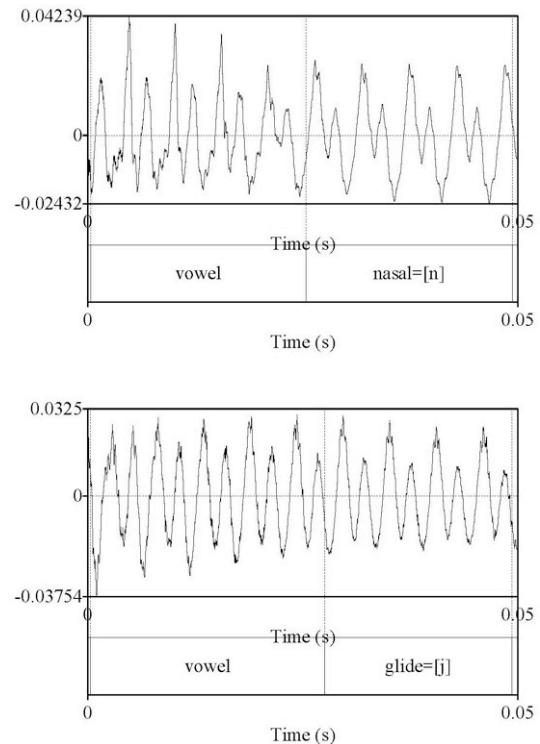

Figure 3: Wave forms of [n] and [j], illustrating 0.05 sec intervals including transitions from the preceding vowels to the sonorants. The boundaries between the vowels and the sonorants are blurry. The consonants themselves involve energies with gradual change.

### Experiment I: Sounds-Shapes

As observed in Figures 2 and 3, stops acoustically involve abrupt amplitude changes whereas sonorants involve gradual amplitude changes. Previous experiments have shown that speakers map these acoustic characteristics to the visual domain, considering stops to be more angular than sonorants. Köhler presented two types of figures, one with an angular shape and one with a round shape (see Figure 4), with two sound stimuli, *takete* and *maluma*. The result was that people often associate *takete* with the angular shape and *maluma* with the round shape. Berlin combined this observation and Ohala’s theory of sound symbolism (Ohala, 1994) to investigate animal nomenclature patterns (Berlin, 2006). He suggests [p. 34] that “[a]n angular, sharp, long-legged, streamlined bodied rail ought to show a preference for voiceless consonants, especially voiceless stops, while the rounded, short-legged tinamou should not favour these sounds.” (see also Ramachandran & Hubbard (2001) and footnote 2 for other sound distinctions that may yield the images of angularity and roundness.) Experiment I replicates these findings by testing whether English speakers

map the acoustic characteristics of stops and those of sonorants to a visual domain. For this purpose, we auditorily presented stimuli with stops and those with sonorants together with pairs of angular shapes and round shapes, and asked them to match each stimulus sound with either an angular shape or a round shape.

Figure 4: Our reproduction of a pair of shapes used by Köhler (1929/1947). The pair was also used in Experiments I and III.

## Method

Experiment I expanded on the previous results (Köhler, 1947; *et seq.*), and tested the connection between stops and angular shapes. The experiment used many stimulus pairs to test the generality of this connection. Furthermore, to avoid the effects of orthography, we used auditory stimuli.

**Stimuli** The stimuli were all disyllabic CVCV nonce words (i.e. nonexisting words in English). In one condition, both syllables contained stop onsets; in the other condition, both syllables contained sonorant onsets.<sup>1</sup> The vowel quality was controlled between the two conditions: the first vowels were [a, e, ɪ, o, u], and the second vowels were [ə, i] (10 vowel combinations). Two items were included for each vowel combination. The stimulus list is provided in Table 1.

Two native English speakers (one female, one male) pronounced all the stimuli three times in a sound-attenuated booth, at the sampling frequency of 44.1k Hz. To control for potential effects of F0 contour on the listeners' judgments about the images of the stimuli's shapes, the recorded tokens were acoustically resynthesized with a uniform falling contour from the first vowel to the second vowel. For the female speaker, F0 of the first syllable was adjusted to 300 Hz, and F0 of the second vowel to 200 Hz, with linear interpolation in between. For the male speaker, the two F0 parameters used were 150 Hz and 100 Hz, again with linear interpolation. Also, to control for the potential effects of amplitude, peak amplitude of all the stimulus files was modified to 0.7 by using Praat (Boersma & Weenink, 1999-2012). Together with 40 nonce words consisting of stops and 40 nonce words consisting of sonorants, seven different pairs of shapes, each pair consisting of an angular shape and a round shape, were prepared, as exemplified in Figure 5 (the experiment also included the pair of shapes similar to

Köhler's, shown in Figure 4). The experiment thus had a total of 560 stimuli (80 auditory stimuli \* 7 figure pairs).

Table 1: The stimulus list for Experiments I and II.

	Stop condition	Sonorant condition
a-ə	[tagə] [bakə]	[jamə] [ralə]
e-ə	[depə] [tekə]	[wejə] [rewə]
ɪ-ə	[kɪbə] [tɪbə]	[jimə] [wijə]
o-ə	[døkə] [dopə]	[jorə] [nojə]
u-ə	[dukə] [pukə]	[munə] [mujə]
a-i	[kabi] [tadi]	[maji] [jawi]
e-i	[tegi] [tepi]	[reni] [jewi]
ɪ-i	[tɪpi] [tɪgi]	[jini] [nɪwi]
o-i	[boki] [pobi]	[joli] [woji]
u-i	[buki] [gugi]	[wuni] [luri]

Figure 5: A sample pair of visual cues used in Experiments I and III.

**Procedure** For each trial, the participants were presented with a pair of objects, one angular and one round, immediately followed by a stimulus sound. They were then asked to choose a shape that better matched each auditory stimulus. The maximum time for the participant to respond to each trial was 3000 ms; if they did not respond within this time limit, that trial was skipped. The inter-trial interval was 250 ms. The visual and audio stimuli were presented using Superlab ver. 4.0 (Cedrus). All the participants wore high quality headphones (Sennheiser HD 280 Pro), and registered their responses using an RB-730 response box (Cedrus).

The experiment started with a practice block in order for the participants to familiarize themselves with the procedure. To avoid loss of attention due to exhaustion, the main session was organized into two blocks. The first block contained the combination of all the auditory stimuli with four pairs of shapes; the second block presented the rest of the three visual pairs. The two blocks were separated by a self-timed break. The order of trials within each block was randomized per each participant by Superlab.

<sup>1</sup> The current stimuli do not include fricatives, which also involve frication with abrupt amplitude changes. Testing the visual images associated with fricatives awaits further experimentation.

**Participants** Seventeen native speakers of English participated in the experiment in a sound attenuated room. They were all undergraduate students at Rutgers University, and received extra credit for linguistics classes.

**Statistics** Since the responses were categorical (angular or not), a logistic linear mixed model regression was run in which the dependent variable was the angular response and the independent variables were the difference between stops and sonorants as a fixed factor and subject as a random factor. All statistical analyses in this paper were performed using R.

## Results and discussion

Figure 6 presents the percentages of angular responses for the stop condition and the sonorant condition.<sup>2</sup> As observed in Figure 6, English listeners associated angular shapes much more frequently with the stop stimuli than with the sonorant stimuli. This difference between the two conditions is statistically significant ( $z = 35.00$ ,  $p < .001$ ). We thus conclude that stops, which involve bursts with abrupt amplitude changes, are associated with angular shapes, and that sonorants, which involve energies with gradual changes, are associated with round shapes.<sup>3</sup>

## Experiment II: Sounds-Emotions

Experiment II extended the results of Experiment I to the domain of emotions. We tested whether acoustic abrupt changes of stop consonants are projected on the domain of emotion types. We tested a pair of two emotions like “shocked” and “sad”, the former of which involves an abrupt onset; i.e. those types of emotions that start abruptly. The prediction is that, if there is a trans-modal relationship between sounds and emotion types, stops are more likely to be associated with emotions with abrupt onsets (Shinohara et al., 2011).

<sup>2</sup> A signal detection analysis would have been an alternative, which would tease apart sensitivity from bias (Macmillan and Creelman, 2005). We report percent correct analyses throughout this paper for the ease of interpretation.

<sup>3</sup> One remaining question to be addressed in future research is the effect of place of articulation and voicing. Ramachandran & Hubbard (2001) show that [kiki] is considered to be more angular than [bouba]—both of these nonce words contain stops. It seems that, in addition to the differences in vowels, [k] is more angular than [b]. Furthermore, this difference seems to arise because [b] is both labial and voiced. Labial sounds may be associated with round images because they involve movement of lips; voiced stops may be more round than voiceless stops, because their bursts are usually weaker, and voiced stops involve voicing during closure (intervocally), which consists of gradual amplitude changes (Berlin, 2006; Ohala, 1983). Testing the effect of place of articulation and voicing (and vowels, for that matter) requires future experimentation. See also Jakobson (1978) for discussion on the effect of the acute/grave distinction on the images of sharpness.

Figure 6: The percentages of angular responses in Experiment I. The error bars are 95% confidence intervals.

## Method

The auditory stimuli were identical to those used in Experiment I. For emotion types, we used a pair of negative emotions (“shocked” vs. “sad”) and a pair of non-negative emotions (“surprised” vs. “happy”).

In this experiment, the participants were told that they would be hearing words of a language that they do not know. After each auditory stimulus was presented, they were presented with one of the two pairs of words in English orthography (“shocked” vs. “sad” or “surprised” vs. “happy”). They were instructed to choose the meaning that better matches the auditory stimuli. Other details of the experiment were identical to Experiment I, except that there was no short break because the experiment was much shorter (80 auditory stimuli \* 4 emotions = 320 stimuli). Experiment II was conducted right after Experiment I after a short break with the same participants (seventeen native speakers of English). A logistic regression was run on abrupt responses, with the difference between stops and sonorants and the two types of pairs (negative vs. non-negative) and their interaction as fixed factors and subject as a random factor.

## Results and discussion

Figure 7 shows “abrupt responses” (“shocked” for the negative pair and “surprised” for the non-negative pair) for each condition. We again observe that English listeners associated stops with those emotions with abrupt onsets. The difference between stops and sonorants was significant ( $z = -7.80$ ,  $p < .001$ ). The difference between the two types of pairs was also significant ( $z = 2.13$ ,  $p < .05$ ), because abrupt responses were generally higher for the negative pair of emotions. The interaction term, however, was not significant ( $z = -1.53$ , *n.s.*), showing the difference between the stop condition and the sonorant condition was consistent between the two pairs. Experiment II thus shows that stops are not only associated with angular shapes, but also with emotion types that involve abrupt onsets. This finding, together with Shinohara et al. (2011), as far as we know,

adds a new type of sound symbolism to the sound symbolism literature.

Figure 7: The percentages of abrupt responses in Experiment II.

### Experiment III: Shapes-Emotions

The final experiment tested the relationship between emotion types and shapes, the question being whether those emotion types with abrupt onsets are associated with angular shapes. The previous two experiments established that these two are both associated with stops, and the final experiment addressed whether emotions and shapes are directly related. The prediction from the previous two experiments is that English speakers would associate angular shapes with those emotions that involve abrupt onsets.

### Method

The stimuli were 16 pairs of angular and round shapes, as exemplified in Figure 5.<sup>4</sup> In this experiment, the participants were instructed to be an assistant of Steven Spielberg, a film-director. They were told that in his new movie, the setting is an extraterrestrial planet where people communicate using visual symbols rather than sounds. The participants were presented with a pair of visual cues, one with a round shape and the other with an angular shape (see Figure 5), and were asked to choose which one better matches a particular meaning (“shocked” or “sad”, “surprised” or “happy”). Experiment III was conducted as an online questionnaire survey, as it did not involve auditory stimuli. The experiment was created and distributed using surveymonkey, and the participants were recruited on Psychology on the Net, an online forum for psychology experiments. 37 native speakers of English voluntarily participated in the experiment. No compensation was offered for this experiment.

<sup>4</sup> Since Experiment III tested the combination of only two pairs of emotions (see below), it allowed us to use more pairs of visual stimuli than Experiment II.

## Results and discussion

Figure 8 represents the percentages of how often the angular shapes were associated with each emotion in Experiment III.

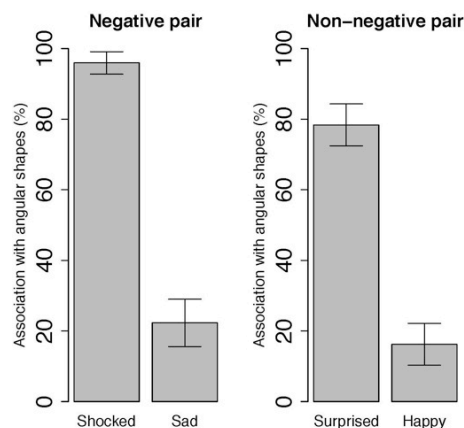

Figure 8: The percentages of how often the angular shapes were associated with each emotion in Experiment III.

We observe that the predictions are borne out: angular shapes were associated more frequently with “shocked” and “surprised” than with “sad” and “happy”, i.e. those emotions that involve abrupt onsets. Statistically, the difference between the two types of emotions (those with abrupt onsets vs. those without) was significant ( $z = 9.57, p < .001$ ). There was no overall difference between the negative pair (“shocked” vs. “sad”) and the non-negative pair (“surprised” vs. “happy”) in terms of angular responses ( $z = -1.21, n.s.$ ). The interaction was significant ( $z = -2.66, p < .01$ ), because the difference between the two emotions was more pronounced in the negative pair than in the non-negative pair. Since the interaction was significant, simple analyses were run separately for the negative pair and non-negative pair. They revealed that the difference within each pair was significant ( $z = 9.50, p < .001$  for the negative pair, and  $z = 9.35, p < .001$  for the non-negative pair).

### General discussion

To summarize, Experiment I has shown that English speakers associate oral stop consonants with angular shapes, supporting the previous work on this sound symbolic relationship. Experiment II shows that stops are also associated with emotion types that involve abrupt onsets. This sound-emotion connection, to the best of our knowledge, is new and adds a new instance of a sound symbolic relation to the literature. More generally, the results from these two experiments lend further support to the existence of sound symbolism, a general idea that there are particular sound-meaning relationships. Experiment III, going beyond traditional sound symbolic studies, has shown that angular shapes are associated with those types of emotions that involve abrupt onsets. Taken together, our three experiments establish a tripartite trans-modal symbolic relationship between three domains of cognition (auditory

sounds, visual shapes, and emotions), among those that involve abrupt modulation, as summarized in Figure 1.

In addition to establishing this tripartite trans-modal relationship among stops, angular shapes, and emotions with abrupt onsets, we suspect that the results of Experiment I have one implication for a general debate about sound symbolism: the debate concerning whether sound symbolism is based on articulation or acoustics. It seems plausible to assume that the image of angular shapes comes from the bursts of stops; i.e. it makes acoustic sense. Acoustically, the stop bursts with abrupt amplitude changes look “spiky” if we track the amplitude changes of stop bursts across time, as we illustrated in Figure 2. By contrast, if we track amplitude changes of sonorants across time, they look “roundish”, as in Figure 3. The association between stops and angular shapes and the one between sonorants and round shapes can be considered as projection of the acoustic characteristics of sounds to the visual domain.

On the other hand, an articulation-based explanation of the current results seem difficult, because there is nothing in the articulation of stops that is angular. In fact, the only superlaryngeal articulatory difference between [t] and [n] is opening of velum in [n], and it is not immediately clear why the opening of the velum can be associated with round shapes.<sup>5</sup>

Independent of our speculation about the basis of sound symbolic relationships, our results show that characteristics of sounds can be projected onto the domain of emotions. We have further shown in Experiment III that such a trans-modal relationship directly holds between the domain of visions and emotions. We hope that further research will address how different modalities of cognitions are linked to one another. We suspect that this line of research may go in tandem with general research on synesthesia (Ramachandran & Hubbard, 2001), as our results show that there may be tighter relationships between different modalities of cognitions than previously assumed. Finally, to strength our claim about the trans-modal relationship, it would be desirable to test the claim with more instances of

emotions, and with a wider range of experimental paradigms. We leave this task for future research.

## Acknowledgments

We thank the research assistants at the Rutgers Phonetics Laboratory for their assistance with this project. For comments on earlier draft of this paper, we thank Kimi Akita, Young Ah Do, Shinsuke Nakajima, Seunghun Lee and two anonymous reviewers.

<sup>5</sup> It is of course possible that an articulatory basis exists for the stop-angular sound symbolic relationship, which we are simply unaware of. However, a follow-up study of the current study provided further evidence for the acoustic basis of the angularity image. The follow-up study presented English listeners with non-speech sounds like sine waves and square waves. They were told that these sounds were used by an extraterrestrial language, and asked to judge whether sine waves and square waves mean “abrupt” or “gradual”. The results show that square waves, which acoustically involve more abrupt change, are indeed judged to mean “abrupt” more often. The result shows that English speakers can map abrupt acoustic change of non-speech to semantic meaning of abruptness, which is presumably the basis of the results of Experiment I. Since the non-speech sounds used in this follow-up experiment are unlike human sounds, whose articulatory origin cannot even be speculated by listeners, the results support the acoustic basis of the images of abruptness.

# Negating compound sentences

## Abstract

How do reasoners negate compound sentences, such as conjunctions of the form *A and B* and disjunctions of the form *A or B or both*? A theory based on mental models posits that reasoners negate each clause independently, and enumerate the various possibilities consistent with the negation. It makes a novel prediction: negations of conjunctions should be more difficult to comprehend than negations of disjunctions. Two experiments corroborate the prediction. Experiment 1 tested participants' ability to comprehend sentential negations by giving them assertions of the form: *Bob denied that he wore a yellow shirt and he wore blue pants on Tuesday*. Participants selected the clothing options that Bob possibly wore on Tuesday. Experiment 2 gave participants descriptions such as *Bob loves Mary or Mary loves John or both*, and they were required to formulate a denial by completing a sentence that started with "No, ...". In both studies, participants' responses were more accurate for denials of disjunctions than denials of conjunctions.

**Keywords:** enumerative negation, sentential negation, conjunctions, disjunctions, and mental models

## Introduction

Consider the following two sentences:

- 1a. It's not the case that *both* Pat loves Viv *and* Viv loves Pat.
- 1b. It's not the case that Pat loves Viv *or* Viv loves Pat, *or both*.

How do people understand and reason about negated compound sentences like the negated conjunction (1a) and the negated disjunction (1b) above? Which one of the sentences is easier to process? Naïve individuals, i.e., those with no background in logic, syntax, or semantics, should have difficulty understanding the logical negation of multiple clause assertions, particularly when those assertions are complex (Clark, 1974; Clark & Chase, 1972; Hoosain, 1973). Nevertheless, people use negations frequently in everyday reasoning. Indeed, many of the world's languages contain a linguistic construction geared towards negating a disjunction, *neither A nor B*, where *A* and *B* stand for any clauses. Similar constructions exist in many other languages (Gazdar & Pullum, 1976) including

German, Malay, and Portuguese. And in logic, the negations of conjunctions and disjunctions, i.e., the NAND and the NOR connectives, can be used to derive every other logical connective. Negations therefore have powerful semantic implications, and they're used often in daily life, but individuals probably do not comprehend the full logical implications of a complex negated assertion. So, how do reasoners cope with sentential negations? In the present paper, we show that the theory of mental models can account for how individuals interpret such negations.

## Mental models and enumerative negation

The theory of mental models – the “model” theory for short – posits that individuals use the meaning of an assertion and any relevant knowledge to envisage what is possible (Johnson-Laird, 1983), and that they interpret negations by considering the various possibilities to which the negations refer (Khemlani, Orenes, & Johnson-Laird, 2012). Consider the examples above. When individuals represent the sentential negation of a conjunction, such as (1a), they need to consider the three separate possibilities that render it true. That is, the negation is true when a) neither loves the other; b) Pat doesn't love Viv but Viv loves Pat; or c) Pat loves Viv but Viv doesn't love Pat. In contrast, the sentential negation of the disjunction is consistent with only one possibility: neither loves the other. Assertion 1a above has the grammatical form:

2. It's not the case that both P and V.

where *P* stands for *Pat loves Viv*, and *V* stands for *Viv loves Pat*. According to the model theory, the core interpretation of negation and conjunction, (1a) refers to the following mental models:

¬ P	¬ V
¬ P	V
P	¬ V

where ‘¬’ denotes the symbol for negation. And (1b) refers to only the first of these models.

How do individuals construct the models for the assertions above? If individuals had prior knowledge of De

Morgan's laws for interrelating conjunctions and disjunctions, then they would not need to build models, and could simply apply the laws to infer the correct negation. Naïve individuals are unlikely to have mastered De Morgan's laws, however, and so the model theory postulates a more plausible hypothesis. The theory assumes that individuals think about discrete possibilities, where a possibility consists of a conjunction of individuals, their properties, and the relations among them. In the diagram above, the three rows refer to models of three separate possibilities consistent with the negation of the conjunction. To interpret the negation of a multiple-clause assertion, such as (1a), individuals envisage these models separately: they make a series of independent negations of individual clauses *P* and *V*. Hence, with *It is not the case that both P and V*, individuals begin with the possibility in which the negation is applied to each clause: *not-P* and *not-V*. This possibility is not consistent with the original affirmative assertion, *P* and *V*, and so they realize that it is one possibility in which the negation holds. At this point, some reasoners may stop and consider only this initial possibility in which both clauses are negated. However, if individuals go further, they apply the negation to only one of the clauses, e.g., *not-P* and *V*. Once they do, they can detect that it too is inconsistent with the original affirmative and accordingly a possibility consistent with the negation. Likewise, they may grasp that *P* and *not-V* is also a possibility that renders the negation true. Finally, reasoners need to consider the case, *P* and *V*. The possibility is consistent with the unnegated conjunction, and it is therefore inconsistent with the negation of the conjunction.

The general procedure, which we refer to as *enumerative negation*, is to construct a series of models of conjunctive possibilities for any sort of complex compound assertion. It starts with negations of both clauses, and checks whether the resulting possibility is consistent with the unnegated assertion. It then negates each clause, and accepts only those possibilities that are not consistent with the unnegated assertion. Finally, it affirms both main clauses. In each case, if a model is consistent with the unnegated assertion, it is rejected; otherwise, it is accepted as consistent with the negation. This hypothesis applies to all connectives between main clauses, but it is recursive so that it can cope with clauses within clauses. To be right for the right reasons depends on completing the full sequence of all possible conjunctions based on the two clauses.

There is an important rider to enumerative negation: individuals are likely to fail to construct the full sequence of models, which is difficult and time-consuming to envisage. Hence, they should be more likely to respond correctly if they are asked to evaluate given possibilities. In sum, naïve individuals should formulate the denial of compound assertions with multiple main clauses by envisaging, one at a time, the various sorts of possibility in which the denial holds. The order of constructing the models is unlikely to be constant, but it should usually begin with the negations of both clauses.

The model theory of negation makes a novel, and perhaps counterintuitive prediction. In the case, of affirmative assertions, conjunctions are easier to understand than disjunctions, but this difference should switch in the case of their negations. A conjunction has a single model; an inclusive disjunction has multiple models. But, the negation of a conjunction has multiple models; and the negation of an inclusive disjunction has one model. The relation is complementary. The prediction presupposes that the greater the number of mental models of various sorts of compound assertions, the harder it should be to understand them. The effect is easy to understand in the case of compound assertions such as conjunctions and disjunctions. Two atomic propositions and their respective negations yield four possible models:

A	B
A	¬ B
¬ A	B
¬ A	¬ B

A conjunction of the form, *A and B*, refers to only one of these models, but an inclusive disjunction of the form, *A or B or both*, refers to the first three of them. Hence, the conjunction should be easier to understand than the disjunction. In contrast, the negation of the conjunction, *not both A and B*, refers to the three models that are the complement of the model of the original conjunction, *A and B*, whereas the negation of the disjunction, *not (A or B)*, refers to the one model that is the complement of the three models of the original disjunction, *A or B or both*. This predicted interaction hinges, of course, on the theory that individuals construct mental models of assertions, and on the core meaning of negation. Theories in which models of possibilities play no part are unlikely to make the prediction (cf., e.g., Braine & O'Brien, 1998; Rips, 1994).

To test this prediction, we carried out two experiments examining the negation of conjunctions and disjunctions. In both studies, the participants had to deal with denials instead of negations, because pilot studies showed that naïve reasoners don't understand what it means to "negate" a sentence. The studies also examined the denials of conditional *if-then* assertions. The theory predicts that conditionals should be complicated to deny. On the one hand, denials of conditionals should be easier to comprehend than denials of conjunctions because individuals are likely to reduce the scope of the negation to the subordinate *then*-clause (the consequent). On the other hand, the correct negation of the conditional, *A and not-B*, is unlikely to be the first model that reasoners enumerate, so it should be difficult. Thus, the theory predicts that denials of conditionals should be an intermediate case, i.e., not as difficult to understand as denials of conjunctions but more difficult to understand than denials of disjunctions. The results of both studies corroborated the predictions of the model theory.

## Experiment 1:

### Understanding sentential negations

Experiment 1 tested the enumerative negation hypothesis for the task of listing what is possible given affirmations and denials of three sorts of statement: *A and B*, *A or B or both*, and *if A then B*. Conditionals are complicated. Their affirmations should yield two or three possibilities depending on whether participants make a biconditional, (e.g., If and only if A then B) or a regular conditional interpretation. Their negations, however, should either reduce the scope of the negation to the main clause, *If A then not-B*, or else be the correct response, *A and not-B*.

We carried out various preliminary studies, both online and face-to-face, which showed that the task was difficult. For example, when we asked participants to list what was impossible given a sentential negation, their performance was almost at chance. As a result of these initial studies, we settled on a task in which participants judged whichever of four cases: *A and B*, *A and not-B*, *not-A and B*, *not-A and not-B*, was “possible” given a statement. The statements, in turn, were either affirmations or denials of the three sorts of assertion.

### Method

*Participants.* 22 adult native-English speaking participants were recruited through an online system, Mechanical Turk, hosted by Amazon.com that allows people to volunteer for experiments for monetary compensation.

*Design and materials.* Participants acted as their own controls and selected the possible instances of three affirmations (based on *and*, *or*, and *if*) and the possible instances of their three denials. The sentences were presented as a block of affirmations and a block of denials in a counterbalanced order. The actual sentences concerned the color of the clothes of various individuals, who affirmed or denied what they wore on a particular day, e.g.,

*Bob [asserted/denied] that he wore a yellow shirt [and/or] he wore blue pants on [Monday/Tuesday/...].*

*Bob [asserted/denied] that if he wore a red shirt then he wore pink pants on [Monday/Tuesday/...].*

We used adverbial phrases, such as “on Tuesday”, to convey that the statement was about what a person wore on a particular occasion. For the preceding example, the participants indicated whichever of the following cases they judged to be possible given the statement:

*Bob wore a yellow shirt and he wore blue pants.*

*Bob wore a yellow shirt and he wore non-blue pants.*

*Bob wore a non-yellow shirt and he wore blue pants.*

*Bob wore a non-yellow shirt and he wore non-blue pants.*

The participants were told to select all the cases that they judged to be possible for each sentence. The order of

presentation of the four cases was counterbalanced over the trials.

### Results and discussion

No reliable difference occurred in the accuracy of the responses in the two blocks, and so we pooled the data for subsequent analyses. The predicted interaction between polarity and the connectives (conjunctions and disjunctions) was reliable. For affirmations, conjunctions yielded 86% correct responses and disjunctions yielded 68% correct responses; whereas for denials, conjunctions yielded 18% correct responses and disjunctions yielded 89% correct responses (Wilcoxon test,  $z = 3.47$ ,  $p < .0005$ ). Denials of conjunctions were very difficult: the participants’ mainly judged *not-A and not-B* alone as possible (45%), and 14 out of the 22 participants thought of only one possibility, whether right or wrong (Binomial  $p < .005$ , given a prior probability of .33).

The data for the conditionals also corroborated the model theory. Their affirmations yielded 45% conditional interpretations, 18% biconditional interpretations, and 27% interpretations equivalent to conjunctions – a phenomenon that occurs in judgments of probability (Giroto & Johnson-Laird, 2004; Johnson-Laird, Byrne, & Giroto, 2009), and which suggests a regression to a more child-like interpretation in a difficult task (see Barrouillet, Grosset, & Lecas, 2000). The denials of conditionals fell mainly into the two predicted categories: an interpretation that reduced the scope of the negation, *if A then not-B* (59%, see Khemlani et al., 2012, for an elaboration of this effect) or the correct response, *A and not-B* (14%). No one selected the correct possibilities for the denial of a biconditional despite the fact that this interpretation occurred in the affirmation.

The task called for the participants to understand affirmative and negative statements and to evaluate explicit possibilities in relation to them. When connectives interrelate main clauses, the model theory predicts the interaction with polarity: conjunctions are easier than disjunctions when they are affirmed, but their relative difficulty is reversed when they are denied. Conditionals also yield the predicted but unusual pattern of judgments: many individuals take the denial of a conditional, *if A then not-B*, to hold in some of the same possibilities as its affirmation, *if A then B*. Since this interpretation yields only a contrary to the affirmed conditional, such “small scope” interpretations are predictable, but erroneous.

When individuals have to formulate a denial of an assertion, their task is to map their models of the possibilities into a conclusion. Hence, the task should be easier in case their starting point is only one model as in the case of a denial of a disjunction than in case it is several models as in the case of a denial of a conjunction. In this way, the enumerative negation hypothesis yields predictions about the formulation of negative statements. Experiment 2 tested these predictions.

## Experiment 2:

### Formulating sentential negations

The previous study examined participants' understanding of denials; Experiment 2 examined their formulation of denials. A preliminary study showed that when individuals are asked to "negate" a conditional, they tended to negate both of its clauses: they did so on 69% of trials. This result suggests that the task of "negating" a compound sentence is unfamiliar to naïve individuals. The present experiment, like the one before it, was accordingly framed in terms of the semantic task of "denial". The participants had to formulate denials of three sorts of sentence:

- conjunctions, *A and B*;
- inclusive disjunctions, *A or B or both*;
- conditionals, *If A then B*;

The enumerative negation hypothesis predicts that individuals should construct a set of conjunctive models and retain those that are inconsistent with the statement. It follows that the participants should tend to be most accurate in denying inclusive disjunctions, because the first conjunction that they are likely to consider, *not-A and not-B*, is the one and only correct denial. They should be less accurate with conditionals, because they are likely to have to construct more than one conjunction before they encounter the correct denial: *A and not-B*. And another factor of greater importance may intervene. Individuals may reduce the scope of the negation, and this process is likely to apply to conditionals too. Hence, some individuals should assert *if A then not-B* as the denial of the affirmative conditional. Finally, the participants should tend to be least accurate with conjunctions, because their correct denial depends on enumerating three models of possibilities: *not-A and not-B*, *not-A and B*, and *A and not-B*. These possibilities are equivalent to the inclusive disjunction: *not-A or not-B*, but this realization is likely to be beyond anyone who does not know De Morgan's laws.

### Method

*Participants, design, and procedure.* 21 native English-speaking participants were recruited through the same participant pool as in Experiment 1. They acted as their own controls and had to formulate denials of six conjunctions, six disjunctions, and six conditionals, all of which were expressed in English, and which were presented to each participant in a different random order. They were instructed to deny the statements by formulating a complete sentence that began with the word, *No*, as a preface to their denial, and the sentence could be of any length. Each clause in the statements to be denied contained two noun phrases based on proper nouns, a transitive verb, and one co-reference, e.g., "If Bob loves Mary then Mary hates Julie." The materials were constructed so that no proper name or transitive verb occurred more than once in the experiment.

## Results and discussion

Table 1 presents the percentages of the various sorts of denial. The participants corroborated the predicted trend: they made correct denials for 67% of inclusive disjunctions (*not-A and not-B*), 28% of conditionals (*A and not-B*), and 0% of conjunctions (*not-A or not-B*, or the list of three conjunctive possibilities). The predicted trend was highly reliable (Page's  $L = 281.5$ ,  $z = 4.55$ ,  $p < .00001$ ). The conditionals also elicited 34% of denials of the form: *If A then not-B*, which is consistent with the hypothesis that reasoners reduce the scope of the negation to make it easier to comprehend. The participants making this response tended to be different from those who made the correct denials: 7 out of the 21 participants responded *if A then not B* on half or more of the trials, and 10 out of the 21 participants responded *A and not B* on half or more of the trials. The difference between these two post-hoc groups in the frequency with which they responded *if A then not B* was highly reliable (Mann-Whitney test,  $z = 3.50$ ,  $p < .0001$ ). In accord with the enumerative negation hypothesis, when participants had to deny statements, they were most accurate in denying inclusive disjunctions and least accurate in denying conjunctions. The model theory predicts this result, but it is contrary to Rips's PSYCOP theory (1994, p. 113), which makes the opposite prediction based on its formal rules for De Morgan's laws:  $\neg(A \& B)$ , therefore,  $\neg A \vee \neg B$ ; and  $\neg(A \vee B)$ , therefore,  $\neg A \& \neg B$ . For rules that work forwards from premise to conclusion, a single step yields the inference from the negation of a conjunction, whereas three steps based on different rules are needed for the inference from the negation of a disjunction.

Table 1: The percentages of the different denials of disjunctions, conditionals, and conjunctions in Experiment 2, where the balances of responses in each column were different miscellaneous errors that occurred on less than 10% of trials.

The structure of the participants' denials	Type of assertion to be denied		
	Disjunctions: <i>A or B or both.</i>	Conditionals: <i>If A then B.</i>	Conjunctions: <i>A and B.</i>
<i>No, not A and not B.</i>	67	9	66
<i>No, A and not B.</i>	2	28	9
<i>No, if A then not B.</i>	0	34	0
<i>No, not A.</i>	11	3	8
<i>No, not B.</i>	2	21	6

In sum, the model theory may be unique in its prediction that negated conjunctions should be more difficult than negated disjunctions, and the data from Experiment 2 corroborate the hypothesis.

## General Discussion

Two experiments showed that participants find negated conjunctions more difficult to understand and to formulate than negated disjunctions, whereas previous research has established that affirmative conjunctions are easier to understand than affirmative disjunctions (García-Madruga, Moreno, Carriedo, Gutiérrez, & Johnson-Laird, 2001). The data therefore revealed a novel interaction between the grammatical form of a sentence and its polarity, and they corroborated a theory of negation based on mental models (Khemlani et al., 2012). The theory posits that individuals do not know the negations corresponding to the different sentential connectives. They have to construct them on an ad hoc basis, so they consider a sequence of conjunctive models of possibilities, checking that they render the corresponding affirmative assertion false. This *enumerative negation* hypothesis predicts that individuals should find it easy to comprehend and formulate denials of inclusive disjunctions of the form *A or B or both*, because the first model that individuals should consider is the only true negation of the disjunction: *not-A and not-B*. In contrast, the hypothesis predicts that a conjunction, *A and B*, should be difficult to deny, because its denial is equivalent to *not-A or not-B or neither*, and so individuals need to envisage fully explicit models of three separate possibilities.

Denials of conditionals with the structure *if A then B* are an intermediate case. They should be easier to comprehend than denials of conjunctions but harder to comprehend than denials of disjunctions. The correct negation of the conditional, *A and not-B*, should be more difficult to envisage because, according to the enumerative negation hypothesis, this model is unlikely to be the first one that comes to mind. And their denials should also be susceptible to a reduction of scope, because *if* introduces a subordinate clause, whereas neither of the other sorts of compound contains a subordinate clause. Hence, some individuals should deny a conditional by using another conditional: *if A then not-B*.

When individuals had to understand affirmations and denials in Experiment 1, their evaluations of what was possible corroborated the model theory's predicted interaction. For affirmations, they found it easier to understand conjunctions than disjunctions, but for denials, they found it easier to understand disjunctions than conjunctions. The affirmation of a conjunction yields one possibility, and the affirmation of a disjunction yields three possibilities. In contrast, the denial of a conjunction requires an inference of three possibilities, and the denial of a disjunction requires an inference of only one possibility. The inferential aspect of this task for negatives may explain why it is so much harder than merely listing the three possibilities corresponding to an inclusive disjunction. Experiment 2 corroborated the interaction. Both experiments also revealed the occurrence of two sorts of negation of conditionals, as did a study by Handley and colleagues (Handley, Evans, & Thompson, 2006). These authors argue that the negation of a conditional, *if A then B*,

should be *if A then not-B*. This view, however, has a major drawback: it no longer treats negations as contradicting corresponding affirmatives. Likewise, it offers no principled explanation of why some individuals do take *A and not-B* to be the denial of a conditional, or why most people take it to falsify a conditional too (Espino & Byrne, 2011; Evans, Newstead, & Byrne, 1993; Johnson-Laird & Tridgell, 1972).

## Abstract

The mReactr system is a computational implementation of the mental model theory of reasoning (Johnson-Laird, 1983) that is embedded within the ACT-R cognitive architecture (Anderson, 1990). We show how the memory-handling mechanisms of the architecture can be leveraged to store and handle discrete representations of possibilities, i.e., mental models, efficiently. Namely, the iconic representation of a mental model can be distributed, in which each component of a model is represented by a “chunk” in ACT-R’s declarative memory. Those chunks can be merged to create *minimal* mental models, i.e., reduced representations that do not contain redundant information. Minimal models can then be modified and inspected rapidly.

We describe three separate versions of the mReactr software that minimize models at different stages of the system’s inferential processes. Only one of the versions provides an acceptable model of data from an immediate inference task. The resulting system suggests that reasoners minimize mental models only when they initiate deliberative mental processes such as a search for alternative models.

**Keywords:** reasoning, mental models, immediate inferences, mReactr, ACT-R

## Introduction

People regularly make complex deductive inferences. For instance, if you know that *none of the lawyers in the room are men*, you might refrain from asking any of the men in the room for legal advice. If so, you have made an “immediate” inference from a single premise:

1. None of the lawyers are men.  
Therefore, none of the men are lawyers.

The inference is *valid* because its conclusion must be true given that its premise is true (Jeffrey, 1981, p. 1). You likely followed up the deductive inference above with an inductive inference:

2. None of the men are lawyers.  
Therefore, they do not possess legal knowledge.

The second inference is inductive – the conclusion is not necessary given the truth of the premise.

How do reasoners make deductive and inductive inferences like the ones above? One prominent answer is that they construct mental simulations of the things they already know or believe. They then manipulate those simulations to obtain information they did not have at the outset. The idea that reasoning depends on building

simulations, or mental models, is the fundamental intuition behind the mental model theory of reasoning (Johnson-Laird, 1983). In the present paper, we outline the theory and address one of its major limitations, namely its inability to explain how models are stored and manipulated in memory. We describe a computational implementation of the theory that is embedded within the ACT-R cognitive architecture (Anderson, Bothell, Byrne, Douglass, Lebiere, & Qin, 2004), and we show how the memory-handling mechanisms of the architecture can be leveraged to store and handle mental models efficiently.

## Reasoning and mental models

The “model” theory of reasoning proposes that when individuals comprehend discourse, they construct mental models of the possibilities consistent with the meaning of the discourse (Johnson-Laird, 2006). The theory depends on three main principles: 1) Individuals use a representation of the meaning of a premise and their knowledge to construct mental models of the various possibilities to which the premises refer. 2) The structure of a model corresponds to the structure of what it represents (see Peirce, 1931-1958, Vol. 4), and so mental models are iconic insofar as possible. 3) The more models a reasoner has to keep in mind, the harder an inference is. On a model-based account, a conclusion is *necessary* if it holds in all the models of the premises and *possible* if it holds in at least one model of the premises.

mReasoner (Khemlani, Lotstein, & Johnson-Laird, under review) is a unified computational implementation of the mental model theory of reasoning. It implements two interoperating systems for reasoning:

- a) An intuitive system (system 1) for building an initial mental model and drawing rapid inferences from that model
- b) A deliberative system (system 2) for more powerful recursive processes that search for alternative models. This system can manipulate and update the initial model created in system 1, and it can modify conclusions

The system is akin to dual-process models of reasoning (see, e.g., Evans, 2003, 2007, 2008; Johnson-Laird, 1983, Ch. 6; Kahneman, 2011; Sloman, 1996; Stanovich, 1999; Verschueren, Schaeken, & d’Ydewalle, 2005). Below, we describe the various processes that each system implements.

# The intuitive system

*Model building.* The system builds an initial model from the meaning of a premise, and it updates that initial model if additional premises occur. The system begins by building a model with a small, arbitrary set of individuals. For example, the model of *some of the artists are bohemians* is built by first constructing a set of artists:

artist  
artist  
artist  
artist

In the diagram above, each row represents an individual with the property of being an artist, and so the model as a whole represents a finite number of individuals. Mental models are representations of real individuals, not letters or words, which we use here for convenience. The meaning of the assertion *some of the artists are bohemians* provides instructions for the system to add additional properties, namely the property of being bohemian. The model is updated accordingly:

artist	bohemian
artist	bohemian
artist	
artist	
	bohemian

The model therefore represents a set of individuals, some of whom are both artists and bohemians, some of whom are just artists, and one who is just a bohemian. Once a premise has been represented, the system can assess whether the given conclusion is true in the initial model.

*Assessing initial conclusions.* When reasoners have to assess a given conclusion, the system inspects the initial model to verify that the given conclusion holds or does not hold. For instance, suppose that reasoners are asked to decide whether it is possible that *all bohemians are artists* given the previous premise. From the model above, the system initially responds in the negative, i.e., the putative conclusion is impossible. The process is simple, and the response is rapid. However, it is incorrect: the system's ability to assess and generate initial conclusions is fallible. For instance, one can indeed show that *all of the bohemians are artists* is possible. To revise its initial conclusion, the system needs to find an alternative model in which both the premise and conclusion hold. We turn to the second system to explain how such a model is found.

# The deliberative system

*Searching for alternative models.* In the preceding section, we focused on how the system assesses conclusions based on an initial model. However, the conclusions it draws can be invalid. System 2 attempts to revise initial conclusions by searching for alternative models. To do so, it uses three

separate operations: *adding* properties to individuals, *breaking* one individual into two separate individuals, and *moving* properties from individual to another (see Khemlani, Lotstein, & Johnson-Laird, under review). The operations correspond to those that naïve participants spontaneously adopt when they reason about syllogisms (as evidenced by their manipulations of external models, see Bucciarelli & Johnson-Laird, 1999). Consider our example above. After an individual represents the initial model and provides an initial conclusion that is false, it can modify that conclusion by adding properties to the initial model. If the system can successfully create a model in which *some of the artists are bohemians* and *all of the artists are bohemians* are both true, then it can conclude that it is possible, but not necessary that all of the artists are bohemians. By adding properties, the system finds such a model:

artist	bohemian
artist	bohemian
artist	bohemian
artist	bohemian
artist	bohemian

The new model, which contains individuals who are all artists and bohemians at the same time, refutes the conclusion that it is impossible that *all the bohemians are artists*. However, the search for alternative models places a considerable tax on working memory. Until now, the limitations of the model theory have prevented it from characterizing the cost of holding models in memory.

# Limitations of the model theory

The model theory and its unified implementation explain many aspects of how people make inferences. The theory provides an explanation of how discourse is mapped to high-level representations. It accounts for why some reasoning problems are hard and others are easy (Khemlani & Johnson-Laird, 2012). It provides working algorithms for how individuals assess whether a given conclusion is possible, necessary, or consistent with a given set of premises. And the model theory as a whole can explain deductive, inductive, and abductive inferences (Johnson-Laird, 2006). As such, it represents a unified theory of reasoning.

The theory is limited by design, however, in that most of its predictions are qualitative. For instance, it can explain that an inference that requires a reasoner to hold one model in working memory should be easier than an inference that requires three models in memory, but it cannot explain or predict the degree of the difficulty. Is the former inference twice as easy or thrice as easy as the latter? And how long should each inference take? The computational model is silent on these matters, because it specifies only those algorithms that are pertinent to how individuals make inferences. It ignores other aspects of cognition, such as how models are stored in working memory and how they are retrieved. To overcome these limitations, we

implemented the theory in the ACT-R cognitive architecture, and we describe the resulting hybrid system below. The framework, which we call *mReactr* (mReasoner + ACT-R), imbues the model theory with a more robust account of how models are represented and manipulated. It also stands as a novel application of the ACT-R system, which has had only limited success in accounting for behavior on high-level deductive tasks (e.g., Emond, 2003, and Ragni, Fangmeier, & Brüssow, 2010).

### mReactr: Mental models in memory

The ACT-R cognitive architecture is a modular computational theory of human cognition (Anderson et al., 2004). It is a collection of interoperating modules that store and retrieve information relevant to a particular task. The central control system, called the *procedural* module, directs the way the system accesses capacity-limited buffers. The system also contains a *declarative* module for storing knowledge of facts and procedures. Facts are stored in structures called *chunks*, and procedures are represented by *productions*, i.e., condition-action pairings. The productions direct the procedural model to monitor the buffers for the existence of certain sorts of chunks, and if a chunk appears in a buffer in the manner that a production expects, the relevant action will be initiated. Each chunk has an associated level of activation. If the chunk’s activation is low, ACT-R will take longer to retrieve it, but if it is high, it will be retrieved quickly. Accordingly, the system automatically calculates the time it takes to trigger productions, modify goals, retrieve chunks, and clear buffers.

The architecture efficiently manages chunks in declarative memory. In particular, if it detects that two chunks are identical in every respect, it merges those chunks into one chunk. The merged chunk will then have a higher activation than either individual chunk. This “chunk-merging” feature of the system is particularly important for how mental models are handled.

The mReactr system is an implementation of mental model theory in ACT-R. The system can build initial models and assess putative conclusions (system 1) and likewise it can modify those models to search for alternative models (system 2). It stores models in declarative memory by assigning each individual to a separate chunk. Thus, the system will store the model of *all the artists are bohemians* as five separate chunks:

artist	bohemian	(chunk 1)
artist	bohemian	(chunk 2)
artist		(chunk 3)
artist		(chunk 4)
	bohemian	(chunk 5)

The system therefore represents the model in a distributed fashion, as a collection of chunks with similar properties. However, several of the separate chunks are identical to one another, and so ACT-R will try to merge those chunks

automatically, to produce just a condensed version of the model:

artist	bohemian	(chunk 1')
artist		(chunk 3')
	bohemian	(chunk 5')

By merging the chunks, the underlying architecture automatically produces a *minimal* mental model, i.e., a model that only retains information about the different *types* of individuals. The process of minimizing mental models is not something that is built into mental model theory as yet; the basic mechanisms of memory management within ACT-R provide a way to efficiently store and retrieve models. But, is there any evidence that reasoners minimize models? And if so, do they minimize models at the outset, or at a later stage of processing? To answer both of these questions, we compared mReactr’s accuracy and latency predictions against data from a recent reasoning experiment.

### An assessment of the model

We assessed whether the mReactr system could model that data from a recent study on so-called “immediate” deductive inferences akin to our introductory example above (1). Psychologists have investigated immediate inferences for many years (e.g., Begg & Harris, 1982; Newstead & Griggs, 1983; Wilkins, 1928), but have yet to resolve how logically untrained individuals make them. The inferences are based on singly-quantified assertions in four different *moods* of the premise:

- All the Xs are Ys
- Some of the Xs are Ys
- None of the Xs are Ys
- Some of the Xs are not Ys

and 8 different sorts of conclusion (4 moods by 2 *figures*, i.e., arrangements of terms ‘X’ and ‘Y’). Therefore, there are 32 possible immediate inference problems based on these premises. A typical problem looks like this:

Suppose that some of the students are Virginians.  
Is it possible that all of the Virginians are students?

Immediate inferences were chosen because the model theory and mReactr distinguish between the relative difficulties of three sorts of immediate inference: a) zero-model inferences, b) one-model inferences, and c) multiple model inferences.

Zero-model inferences are those in which the conclusion is identical to the premise, and so individuals needn’t even build a model to be able to solve the problem. For instance, consider the following problem:

All the aldermen are barters.  
Is it possible that all the aldermen are barters?

Reasoners should realize that the answer is true immediately; however, they should nevertheless need to extract the meanings from the assertions, and they need to establish a set of subgoals in order to infer a conclusion.

One-model inferences are those in which the conclusion holds in the initial model of the premise, and so individuals can rapidly determine that an assertion is possible. For example:

All the aldermen are barters.

Is it possible that some of the barters are aldermen?

Reasoners have to construct the meanings of the assertions, use them to build a model, and evaluate the truth of the conclusion in the model.

When the conclusion fails to hold in the initial model, but does hold in an alternative to it, then participants have to search for that alternative model. We refer to such problems as multiple-model inferences. For instance:

All of the aldermen are barters.

Is it possible that some of the barters are not aldermen?

For multiple-model inferences, mReactr predicts that reasoners extract the meaning of the assertion and build an initial model, but their initial model suggests an erroneous evaluation of whether or not the conclusion is possible. To obtain a correct evaluation, reasoners have to modify their initial model to produce an alternative model. The theory therefore predicts that zero-model inferences should be easier than one-model inferences, and one-model inferences should be easier than multiple-model inferences. Likewise, mReactr provides precise latency predictions for how long zero-, one-, and multiple-model inferences should take.

We used mReactr to simulate an experiment conducted by Khemlani, Lotstein, & Johnson-Laird (in revision). In the study, the participants carried out all 32 problems (4 sorts of premise x 8 sorts of conclusion), and they responded “yes” or “no” to a conclusion about a possible conclusion to each problem. The contents of the problems were based on nouns referring to common occupations. The instructions stated that the task was to respond to questions about a series of assertions concerning what was possible given the truth of the assertion.

## Simulation

Our goals in simulating immediate inference data were two-fold. First, we sought to test the fidelity of the mReactr system as an instantiation of the model theory. We restricted our simulation to valid immediate inferences, i.e., 22 of the 32 problems. The theory distinguishes between three sorts of problem, and so mReactr should reflect the same distinction. A failure of the computational model to capture those data indicates a poor implementation of the model theory. We retained all of the default values of the ACT-R architecture, except we increased the architecture’s default

tracking ability so that it could track 10 individual chunks (i.e., the :declarative-num-finsts parameter).

Second, we attempted to examine whether mReactr could fit the data better when it actively engaged in minimizing models by merging chunks. We created three separate versions of mReactr:

- 1) no chunk-merging version
- 2) system 1 chunk-merging version
- 3) system 2 chunk-merging version

In the *no chunk-merging* version, chunks were kept separate and ACT-R’s automated chunk-merging capability was disabled. In the *system 1 chunk-merging* version, chunks were merged before the system engaged in any inferential processes. And in the *system 2 chunk-merging* version, chunks were kept separate in the initial model. They were merged only when mReactr initiated a search for alternative models. The best performing version of the theory can help establish whether and when models should be minimized.

## Results and discussion

The results of the experiment corroborated the theory’s predictions of difficulty (Khemlani et al., in revision), and they yielded the following trend: reasoners were 98% correct for zero-model problems, 85% correct for one-model problems, and 71% correct for multiple-model problems (Page’s trend test,  $L = 340.0$ ,  $z = 3.88$ ,  $p < .0001$ ). Immediate inferences are relatively easy to deduce, nevertheless participants exhibit predictable patterns of difficulty. The mean latencies also corroborated the predicted trend: 4.30 s for zero-model problems, 5.17 s for one-model problems, and 5.41 s for multiple-model problems (Page’s trend test,  $L = 336.0$ ,  $z = 3.33$ ,  $p < .0005$ ).

Figure 1 illustrates the empirical latencies and the predicted latencies from the different versions of mReactr. As the figure shows, the system yielded the closest match to

Figure 1: Participants’ mean latencies (in s) to solve zero-, one-, and multiple-model problems, and the latencies predicted by the three separate versions of mReactr.

mReactr version	Model fits			
	R <sup>2</sup>	RMSE	Goodness of fit	
			D	p
<i>a) By problem type</i>				
No chunk-merging	.99	.40	.67	.60
System 1 chunk-merging	.94	.54	.67	.60
System 2 chunk-merging	.99	.18	.67	.60
<i>b) By immediate inference</i>				
No chunk-merging	.45	.70	.41	.05
System 1 chunk-merging	.23	.86	.50	.008
System 2 chunk-merging	.45	.57	.18	.86

Table 1: Model fits for the three versions of mReactr by problem type (zero-, one-, and multiple-model problems) and by the 22 valid immediate inferences. Note: a lack of significance for the Kolmogorov-Smirnov D statistic indicates a good fit.

the data when chunk-merging was initiated at a later stage of processing, i.e., the *system 2 chunk-merging* version ( $R^2 = .99$ ,  $RMSE = .18$ ). When chunk-merging was disabled in the *no chunk-merging* version, the system did well, but it took too long to search for alternative models, ( $R^2 = .99$ ,  $RMSE = .40$ ). In the *system 1 chunk-merging* version, mReactr performed faster than participants tend to perform, yielding a poorer fit of the data ( $R^2 = .94$ ,  $RMSE = .54$ ).

Across all three simulations, the system negatively correlated with participants' accuracy ( $r$ 's  $< -.90$ ,  $p$ 's  $< .0001$ ). Likewise, the simulations fit the latencies well. Table 1a gives the model fits for the three separate versions of the system across the three types of problems as a whole, as well as across the 22 different problems separately.

We ran a separate set of analyses to examine how the three versions of the system modeled the 22 valid immediate inferences separately (see Table 1b). This set of analyses would by definition yield poorer model fits as a result of the inherent variation between different problems, and so any significant correlation can be construed as support for the theory. The analysis replicated and elaborated upon the aggregated results. The system fit the data moderately well with chunk-merging turned off, but its RMSE was relatively high ( $R^2 = .45$ ,  $RMSE = .70$ ), and a Kolmogorov-Smirnov goodness of fit analysis indicated that the system exhibited reliably different distributional properties than that of the experiment ( $D = .41$ ,  $p = .05$ ). Likewise, the system provided a relatively poor fit of the data when models were minimized at the outset ( $R^2 = .23$ ,  $RMSE = .86$ ) and so mReactr produced results that came from a separate distribution (Kolmogorov-Smirnov test,  $D = .50$ ,  $p = .008$ ). Only when models were minimized before the system searched for alternative models did the system fit the data well ( $R^2 = .45$ ,  $RMSE = .57$ ), and the goodness-of-fit analysis indicated a close match between mReactr and the data (Kolmogorov-Smirnov test,  $D = .18$ ,  $p = .86$ ).

The results of the simulations showed that across all three version of mReactr, the system successfully implemented

the model theory's predictions of difficulty, and it distinguished between zero-, one-, and multiple-model problems. However, the system performed best only when it initiated chunk-merging before it began a search for alternative models. The results have important implications for an overlooked process in the psychology of reasoning: representational minimization.

## General Discussion

The computational theory, mReactr, is system implemented in the ACT-R cognitive architecture that simulates the construction of mental models in order to draw immediate inferences from singly-quantified premises. The cognitive architecture comes equipped with the ability to manage its declarative memory efficiently, namely by merging identical chunks. mReactr repurposes this chunk-merging functionality to produce minimal mental models at a particular stage of inference. At the outset, mReactr uses the same collection of iconic representations as is specified in the model theory. However, the full representation is ephemeral, and it lasts only until the system starts to modify the model. If and until the system initiates a search for alternative models, it minimizes the model. This process maps onto the psychological strategy of abstracting over the different sorts of individuals.

The theory predicts that individuals should be faster and more accurate when an inference can be drawn from an identity in the meanings of the assertions, i.e., when they do not need to consult a mental model. They should be next fastest and accurate when an inference can be drawn from the initial model constructed in system 1. And they should be slowest and least accurate when an inference can be drawn only from the discovery of an alternative model constructed in system 2. These rank-order predictions were borne out in the data from an experiment that tested all 22 valid inferences about possible conclusions in the set of 32 inferences.

The system we describe is limited, however, and it can be improved to yield a more fine-grained processing account of the data. We suggest two separate ways of proceeding. One way to improve the fit of the system is to make the system sensitive to the direction in which it scans models. For instance, if reasoners read a particular premise, e.g., *all artists are bohemians*, they may be biased to scan the model in the opposite directions by considering bohemians before artists. This *figural* bias is widely documented in syllogistic reasoning (Khemlani & Johnson-Laird, 2012) and it is likely to make a difference when reasoning about immediate inferences as well.

Another way to improve the system's overall performance is to consider the process of model minimization as something that may or may not occur depending on strategy and individual differences (Bucciarelli & Johnson-Laird, 1999). Some reasoners may be more likely to minimize their models, and others might prefer to keep the full model representation in mind.

In sum, model minimization is an important way in which individuals can optimize the storage and retrieval of mental models. It is embodied in the computational system of deductive reasoning that we developed.

## Abstract

Phonetic variation is sensitive to lexical properties of words, such as frequency and neighborhood density, as well as contextual properties, such as predictability. Previous studies of lexically-induced variation have observed that both vowels and consonants are phonetically enhanced in words from dense neighborhoods, and have suggested that this effect is modulated only by the number and frequency of the neighbors. To determine whether contextual variation is driven by cognitive processes similar to those underlying lexical enhancement, three experiments examined the effect of contextually salient neighbors on the phonetic realization of vowels and initial consonant aspiration. Enhancement was found only for consonants, and only when the neighbor differed from the target word in a single feature. Unlike lexical effects, contextually-driven phonetic enhancement reflects a highly specific competition among words, a finding that can be rationalized in terms of the utility of speaker effort within a Bayesian model of word communication.

**Keywords:** Speech production; lexical competition; communication; Bayesian modeling

## Introduction

Competition among alternatives, and the need to resolve competition efficiently and correctly, are pervasive in speech perception and speech production (e.g., Luce & Pisoni 1998, Marslen-Wilson & Zwitserlood 1989, Dell & Gordon 2003). Listeners must determine the speaker's intended message as rapidly as possible given an inherently ambiguous signal. In speech production, words and sublexical units that are partially consistent with the intended message compete for realization at multiple levels of processing. A number of studies have examined how such competitive processes are reflected in the fine-grained phonetic realization of speech sounds.

The number and relative frequency of phonologically-similar words in the lexicon (lexical neighbors) are known to affect phonetic realization. We refer to such affects as *offline* because they appear to depend on relatively static lexical relationships among words rather than dynamic contextual factors. Researchers have found that “hard” words, those with low lexical frequency and many high frequency neighbors, tend to be phonetically enhanced relative to “easy” words with high frequency and few neighbors. Hard words beginning with aspirated consonants have longer aspiration (as measured by voice onset time, VOT) than easy words (Goldinger & Summers, 1989). They are pronounced with an expanded vowel space (Munson & Solomon, 2004; Wright, 2003), and also show increased vowel nasalization and vowel-to-vowel coarticulation (Scarborough, 2004).

Interestingly, offline phonetic enhancement effects seem to be rather general: they appear to depend only on the (frequency-weighted) density of a word's neighborhood, not on the precise phonological relationships between the word and its neighbors. For example, Scarborough (2004) found that words that were particularly confusable by their nasal consonant (i.e., had one or more lexical neighbors that differed in the position of the nasal) did not show greater vowel nasalization than words that were not similarly confusable. Words like *stem*, with minimal pair neighbor *step*, showed similar levels of nasalization as words like *plank*, with no nasal-differing neighbors in the lexicon. Similarly, Goldinger & Summers (1989) found more VOT enhancement for voiceless-initial words from dense neighborhoods than those from sparse neighborhoods, even though both sets of words had exactly one minimal pair lexical neighbor that began with a voiced sound. The generality of offline phonetic enhancement suggests that it is driven by competition among entire lexical items, not among sublexical units.

Unlike offline effects, *online* effects on phonetic realization by definition depend on the context in which a word is uttered, such as the discourse topic, transitional probabilities conditioned on preceding material, and other contextually-salient words. A classic online effect is the Lombard Reflex, a set of vocal changes that include increases in amplitude and pitch that occur when speakers attempt to talk over noise (Lau, 2008; Zhao & Jurafsky, 2009). More recently, a number of corpus-based studies have found that the contextual predictability of speech elements, including phonemes and syllables, is inversely related to their length. Less predictable elements tend to be longer (e.g., Cohen-Priva & Jurafsky 2008, Aylett & Turk 2004, van Son & Pols 2003).

This paper aims to expand our understanding of online phonetic enhancement effects, looking not just at predictability effects but at how a word's phonological neighborhood in context — the sound structure of contextually salient competitors — affects phonetic realization along several dimensions of possible hyperarticulation. This will provide further insight into how competition between similar words plays out during speech production. In previous work, Baese-Berke & Goldrick (2009) found that VOT is lengthened when a voiceless-stop initial word is pronounced in the context of a voiced-initial neighbor (in comparison to the context of a phonologically unrelated filler word). For example, *cot* shows increased initial VOT in the context of *got*, but not in

the context of *fan*.

Baese-Berke & Goldrick additionally put forward the claim that this online enhancement of VOT, and perhaps online enhancement effects in general, have the same underlying cognitive mechanism as the offline enhancement effects reviewed earlier. If this hypothesis were true, we would expect offline and online effects to be empirically parallel. In particular, we would expect to find an online analogue of every offline effect. Baese-Berke & Goldrick’s VOT enhancement effect mirrors that found offline by Goldinger & Summers (1989), providing partial support of the hypothesis. However, to our knowledge researchers have yet to investigate online analogues of other offline effects, including vowel space expansion and vowel nasalization.

Furthermore, if offline and online phonetic variation are driven by the same processes of cognitive competition, we would expect the generality of offline effects to be found in online enhancement as well. Just as offline VOT enhancement does not seem to be modulated by the specific phonological structure of a word’s lexical neighbors, online VOT enhancement should not be affected by the sound structure of the words that have become salient in the speech discourse. That is, any type of neighbor that is active in the speech context should induce online enhancement. Baese-Berke & Goldrick (2009) investigated only contextually salient neighbors of one kind, namely those differing in the voicing of the initial consonant, and consequently the results of that study cannot determine whether online competition is general or specific.

We examined this issue in three experiments, and found that online phonetic enhancements differ from offline effects in two significant respects. Most importantly, online effects appear to be sensitive to the phonological properties of words in the local discourse. Only competitors that have particular phonological relations with the target word — relations defined by word position and segmental makeup — induce online hyperarticulation. We show that these results are predicted if speakers expend the effort involved in phonetic enhancement only when that could contribute to listeners’ recognition accuracy, assuming a Bayesian model of word recognition.

## Experiments

All experiments used an experimental paradigm adapted from Baese-Berke & Goldrick (2009). The goal behind the paradigm is to simulate a situation where a speaker must accurately communicate a word to a listener even though contextually salient competitor words provide opportunities for miscommunication. The paradigm involves two participants, one playing the role of speaker and the other the role of listener. Each participant sits at a separate computer terminal, which is not visible to the other participant. In each trial of the experiment, two or more words appear on both screens: a target word along with competitor words that are sometimes neighbors of the target. After approximately 1000ms,

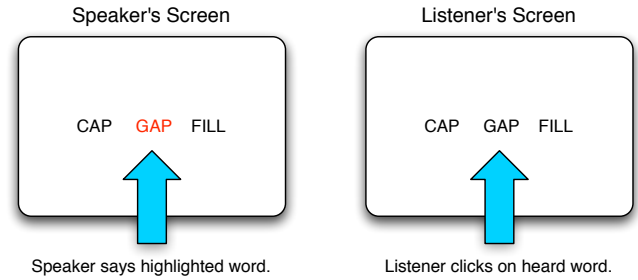

Figure 1: Experimental paradigm.

the target word becomes highlighted on the speaker’s screen, who then produces it aloud. At this point, the listener clicks the word that was heard — the same word produced by the speaker, if communication is successful. The speaker’s pronunciation of the target is recorded and analyzed acoustically after the experiment. The experimental setup is illustrated in Figure 1. This paradigm has the advantage of being able to precisely control a target word’s “context” (the neighbors that appear on-screen with it) and including motivation for the speakers to communicate clearly, as they are made aware if the listener fails to select the target word.

### Experiment 1: Online Vowel Space Expansion

If online effects have the same underlying cause as offline effects, we expect to find an online vowel expansion effect mirroring the offline effect found (e.g., Munson & Solomon 2004). To test this hypothesis, we presented target words in the context of neighbors that differed from the target only in the vowel position. A condition where the same targets were presented with unrelated filler words was used as a baseline for comparison.

Table 1: Table of conditions for Experiment 1.

Target	Vowel	Filler
CAT	KIT	DOLL

Following previous work on vowel space dispersion, the dependent acoustic variable measured was the Euclidean distance of each target vowel from the center of each subject’s vowel space (defined as the subject’s mean F1 and F2 formant values). Participants (N=18) produced each of 16 target words in each condition. Target position on screen was counterbalanced across speakers. Order of conditions for a given target was also counterbalanced to avoid confounds with repetition effects. Results were analyzed using linear mixed results regression (*lme4*) in R, with condition as a fixed effect and subject and target item as random effects. Results are summarized in Table 2; p-values were obtained using Markov Chain Monte Carlo (*pMCMC*). There was no significant effect of onscreen neighbor on vowel space dispersion in comparison to onscreen filler words, suggesting that there is

no online analogue to offline vowel space dispersion effects. This provides evidence that online and offline effects do not share the same underlying cause.

Table 2: Experiment 1: Statistical results.

Condition	Coeff	SE	<i>t</i>	<i>p</i>
Vowel Neighbor	1.707	10.696	0.160	< 0.8732

## Experiment 2: Positional Specificity of Online VOT Enhancement

Baese-Berke & Goldrick (2009) found VOT lengthening in the initial segment of a target word presented with an on-screen neighbor differing in the voicing of its initial segment. This experiment tested to see if any kind of neighbor can induce this enhancement effect, as might be expected if online effects lack specificity in the way that offline effects do. Target words were presented in the context of neighbors that differed only in onset (a replication of the Baese-Berke & Goldrick study using voice-differing neighbors), vowel, or coda positions. Different neighbor types were matched for frequency (pairwise paired t-tests, all  $p > 0.3$ ).

Table 3: Table of conditions for Experiment 2.

Target	Onset	Vowel	Coda	Filler
CAP	GAP	CUP	CAT	DOLL

Participants (N=24) produced each of 48 target words twice in one of the four conditions, so that each word appeared in all conditions every four subjects. Results are shown in Figure 2 and Table 4. Only onset-differing neighbors appear to cause a significant VOT enhancement effect over fillers. This result suggests that online enhancement effects depend at least on position-level sublexical processing and are thus more *specific* than offline effects.

Table 4: Experiment 2: Statistical results.

Condition	Coeff	SE	<i>t</i>	<i>p</i>
Onset Neighbor	2.07000	0.80555	2.570	< 0.0102*
Vowel Neighbor	0.03449	0.80555	0.043	< 0.9659
Coda Neighbor	0.54367	0.80555	0.675	< 0.4998

Interestingly, the effects found seem to be limited to the first production of each target word. Second productions show no VOT difference across conditions, suggesting a strong effect of repetition in this experiment. Furthermore, as shown in Figure 3, the effects found are limited to cases when the target word begins with /p/ or /t/. This may be due to a ceiling effect associated with the /k/-initial targets used in the experiment, as /k/-initial words are known to have long base VOTs that participants may find it difficult to lengthen further.

Figure 2: Experiment 2: Comparison of mean VOT across experimental conditions.

Figure 3: Experiment 2: VOT broken down by target onset phoneme and condition.

## Experiment 3: Featural Specificity of Online VOT Enhancement

The goal of this follow-up experiment, consisting of two subexperiments, was to determine if online VOT enhancement involves an even lower level of sublexical processing. In particular, we tested to see if only certain kinds of onset neighbors can induce VOT enhancement. In the first subexperiment, we looked for an enhancement effect in the context of place-differing neighbors. Different neighbor types were matched for frequency (pairwise paired t-test,  $p > 0.8$ ).

Table 5: Table of conditions for Experiment 3A.

Target	Voice	Place	Filler
CAP	GAP	TAP	DOLL

Participants (N=22) produced each of 33 target words

twice in one of the three conditions. Results are shown in Figures 4 and 5 and Table 6. There is a significant VOT enhancement effect of place neighbors, and the effect is consistent across /p/, /t/, and /k/-initial targets.

Table 6: Experiment 3A: Statistical results.

Condition	Coeff	SE	<i>t</i>	<i>p</i>
Voice Neighbor	2.1361	0.9329	2.290	< 0.0222*
Place Neighbor	1.8506	0.9333	1.983	< 0.0476*

It is interesting that the VOT of /p/ lengthens in the context of /k/ and /t/, given that /k/ and /t/ tend to have longer average VOT than /p/, and thus VOT lengthening might make /p/ initial words more similar to their competitors. However, aspiration also contains spectral cues for place of articulation (e.g., labial /p/ vs. coronal /t/ or dorsal /k/; (Suchato & Punyabukkana, 2005)), and lengthening VOT may strengthen these cues.

Figure 4: Experiment 3A: Comparison of mean VOT across experimental conditions.

In the second subexperiment we looked for an effect of neighbors differing in the manner of the onset. We attempted to choose neighbors that differed minimally from the targets with respect to manner, but were constrained by the phoneme inventory of English. The /p/-initial targets were paired with /f/-initial neighbors, which differ in manner and a minor place feature (labial vs. labiodental); /t/-initial targets were paired with /s/-initial neighbors, which differ in manner and stridency; and /k/-initial neighbors were paired with /h/-initial neighbors, which differ in both manner and place. Different neighbor types were matched for frequency (pairwise paired t-test,  $p > 0.8$ ).

Participants (N=22) produced each of 36 target words twice in one of the three counterbalanced conditions. Results are shown in Figures 6 and 7 and Table 8. There appears to be no overall significant effect of manner neighbors on VOT enhancement. However, the breakdown of the results

Figure 5: Experiment 3A: VOT broken down by target onset phoneme and condition.

Table 7: Table of conditions for Experiment 3B.

Target	Voice	Manner	Filler
PUN	BUN	FUN	DOLL
KILT	GUILT	HILT	DOLL
TEEM	DEEM	SEEM	DOLL

by target onset (Figure 7) indicates that there is an enhancement effect for /p/ onsets in the context of /f/ initial neighbors ( $p < 0.0225$ ). Since /p/ is likely more similar to /f/ than /k/ is to /h/ (differing in a major place feature) or /t/ is to /s/ (differing in stridency)<sup>1</sup>, it may be that online VOT enhancement may only occur in the context of neighbors that are sufficiently similar to the target word — about one major phonological feature away.<sup>2</sup>

Table 8: Experiment 3B: Statistical results.

Condition	Coeff	SE	<i>t</i>	<i>p</i>
Voice Neighbor	3.2236	0.9293	3.469	< 0.0005
Manner Neighbor	1.4489	0.9293	1.559	< 0.1192

## Explaining Online Variation as Listener-Orientation: Modeling Speech Perception

It has been hypothesized that language is designed to facilitate effective communication between speakers and listeners

<sup>1</sup> Although /p/ and /f/ tend to pattern together as a natural class more often than /k/ and /h/ or /t/ and /s/, the effects found might not be due to their apparent similarity; instead, they may be a property of /p/-initial targets. It is difficult to disentangle this question using English stimuli, since another stop/fricative pair as similar as /p/ and /f/ does not exist in the phoneme inventory.

<sup>2</sup> All of the place neighbors in experiment 3A differ from the target in just one place feature.

Figure 6: Experiment 3B: Comparison of mean VOT across experimental conditions.

Figure 7: Experiment 3B: VOT broken down by target onset phoneme and condition.

(e.g., Lindblom 1990, Genzel & Charniak 2002, Levy 2006, Jaeger 2010, Frank 2008). This suggests that speakers may alter their speech in an effort to aid the recognition accuracy and speed of listeners.

This section presents a preliminary computational model of speech perception intended to help explain the specificity of online hyperarticulatory effects by allowing a comparison of the efficacy of different speech modifications in aiding listeners. The model is an extension of Norris’s Shortlist B (Norris & McQueen, 2008). It assumes that word recognition is a Bayesian process (Norris & McQueen, 2008; Feldman, Morgan, & Griffiths, 2009) that modifies a posterior distribution over possible input words as an acoustic signal unfolds. The word with maximum posterior probability after a certain amount of input is recognized. The ratio of the recognized word’s probability to that of its competitors determines how robust the match is — how likely it is to remain error-free

given noisier input. It is this ratio of posterior probabilities that expresses the concept of competition between alternatives in the model.

The posterior probability of each possible input word ( $W_t$ ) is equivalent to the likelihood that the word generated the signal seen so far ( $S$ ), multiplied by the prior probability of the word, divided by the total probability of the signal being generated by any word:

$$P(W_t|S) = \frac{P(S|W_t)P(W_t)}{\sum_i P(S|W_i)P(W_i)}$$

The likelihood function  $P(S|W_t)$  is equal to the likelihood that some prefix of the sequence of phonemes that make up the word ( $PP_t$ ) generated the signal seen so far:

$$P(S|W_t) = \sum_i P(S|PP_{ti})$$

Unlike Shortlist B, the present model does not assume a fixed amount of time per phoneme (see also Scharenborg, 2009).  $P(S|PP_t)$  can be broken down into a sum over possible segmentations ( $SS$ ) of the signal into phonemes.

$$P(S|PP_t) = \sum_i P(SS_i)$$

The likelihood that a particular phoneme generated a portion of the signal in a segmentation is a function specified for the model, and is intended to be empirically realistic (e.g., the likelihood that a voiced phoneme like /g/ generated a large amount of aspiration is low).

As an example, the model can be used to simulate the results found in Experiment 2. It receives input incrementally in 5ms frames, each containing one feature: C for closure, A for aspiration, and V for vowel (e.g. *gap* would be represented as [CAA...C]). In addition, the model only needs to distinguish between a target word and its on-screen competitor, resulting in a collapsed prior distribution over words (e.g.  $P(\text{cap}) = P(\text{gap}) = 0.5$ ). Simulation using this model indicate that when the target word is *cap* and it is pronounced in the context of *gap*, the ratio of posterior probabilities monotonically improves in its favor as VOT increases.

Overall, the model has certain formal properties that make it suitable for explaining the experimental results presented. First, the posterior odds in favor of a target word can’t be improved by hyperarticulating those parts of the word that are identical to its competitors. Doing this would equally increase the likelihood that the signal was generated by the target and its competitor. Second, the improvement in posterior odds gained by hyperarticulating the differing parts of the target is minimal if the target and its competitor are not sufficiently similar to each other, since in that case the likelihood that the competitor generated the signal,  $P(\text{signal}|\text{competitor})$ , remains near zero throughout the recognition process, and consequently so does the competitor’s posterior probability. In other words, if the target and competitor are different enough it would take a signal that is

very unlikely to have been generated by the target for it to be even slightly likely to have been generated by the competitor. Together, these two properties predict the specificity of online effects found experimentally. Speakers only seem to hyperarticulate when there is sufficient utility gained from the extra effort (Lindblom, 1990).

## Conclusions and Future Research

In summary, the experiments presented here indicate that offline and online effects of phonetic enhancement may *not* share the same underlying mechanisms. Not all offline effects appear to have online analogues, as evidenced by the apparent lack of a significant online vowel space expansion effect. In addition, online effects appear to be more *specific* than offline effects. Online enhancement can be caused only by neighbors in the speech context that are minimally different from the target word (differing by approximately one phonological feature). These findings are compatible with a system in which speakers attempt to aid listener comprehension, with a Bayesian model of word recognition indicating which speech changes are helpful and which aren't.

However, the latter finding opens the possibility that vowels may indeed be subject to online hyperarticulation in principle, but that Experiment 1 did not include competitors that were similar enough to induce this effect. In particular, the vowel neighbors used in the experiment were not controlled to be minimally different from the vowels in the target words (in terms of backness and height features). Experiments 2 and 3 suggest that minimal difference is essential for inducing online effects, and future experiments will explore whether online vowel enhancement can be induced by minimally-different vowel neighbors.

## Running it through the body

David Kirsh (kirsh@ucsd.edu)

Dept of Cognitive Science  
University of California, San Diego

### Abstract

Video data from three large captures of choreographic dance making was analyzed to determine if there is a difference between participant knowledge – the knowledge an agent acquires by being the cause of an action – and observer knowledge – the knowledge an observer acquires through close attention to someone else’s performance. The idea that there might be no difference has been challenged by recent findings about the action observation network and tacitly challenged by certain tenets in enactive perception. We explored why a choreographer ‘riff’s’ when appropriating and evaluating the movements of his dancers. By recruiting his body to help him cognize he is able to understand the possibilities of movement better than observation. He acquires participant knowledge.

**Keywords:** embodied cognition; thinking; choreography.

There is a tacit assumption in situated cognition that performing an action yields a type of knowledge – *participant knowledge* – that is irreducible to knowledge acquired by observing someone else performing the same action – *observer knowledge*. A violinist acquires more knowledge by playing a piece than by listening to someone else. He is embedded more profoundly in the situation. A dancer is able to understand something qualitatively different about a dance phrase by dancing it. Just watching leaves something out.

I present data, from a major study on dance creation that supports this intuitive claim: in dance, using one’s body to explore a dance idea is a better way to understand the idea than watching someone else explore it. This may seem so obvious as to need no justification. But, there is extensive neurophysiological evidence of a close link between action observation and action execution [Viviani, 02; Wilson & Knoblich, 05]. Whenever we observe another person’s goal directed actions we re-enact or mimic that actor’s movements by covertly behaving as if we are performing the action ourselves. [Sebanz, N., & Shiffrar, 07]. Activating the motor resonance system may be comparable to actual performance [Rizzolati & Sinigaglia, 07; Agnew et al, 07; Aglioti et al.].

The idea of a covert action was introduced by Jeannerod [94] to describe the subliminal activation of the motor system by “[intended] actions that will eventually be executed, [and] also [by] imagining actions, recognizing tools, *learning by observation*, or even understanding the behavior of other people”. [Jeannerod 01, emphasis added] Covert action involves motor planning, just as overt action does; and perhaps it involves some level of motor preparation, though probably less than overt action. The real difference is that covert action does not activate muscular control. Yet, the activity in the covert system is nonetheless so strong that

even just watching an action can be as powerful a learning experience as performing the action oneself. [Cross et al., 09]

If it is true that the motor system is activated through observation as powerfully as suggested it is worth asking whether actual execution is required for action understanding and deep processing of action. Maybe observation is indeed enough. What extra does one get by adding overt movement over and beyond what one gets from mentally simulating the same movement covertly?

Exploring this ‘extra’, at least in the dance context, is the topic of this essay. I begin by clarifying what is meant by participant knowledge. I then explain the methodology we used for studying participant knowledge. That section is followed by a presentation of empirical results – observed regularities about when and how a choreographer *runs dance phrases through his body* in order to understand a phrase better – to deep process it. The paper closes with a discussion of the central ideas of bodily mediation, and enactive thinking. Jointly these last two ideas form the basis for an explanation of why authoring an action can lead to a more profound understanding than observing it.

### What is participant knowledge?

If there is something special about participant knowledge, then on those occasions when a violinist – say, Yitzhak Perlman – physically plays a musical piece, he will connect with the piece in a way that is special because he is the one playing. The same holds true for dancers: they will connect in a special way when they take to the floor and perform.

As intuitive as this is it runs contrary to a theory even more general than motor resonance: the theory of internalization. According to Vygotsky [78], whenever Perlman is listening, his internalization of what it is like to play mediates his listening. He will engage violin music as if playing it because, as a result of constant practice, he has internalized the performance mode of interacting with music so deeply that he doesn’t need a physical instrument to participate in music making. He has an inner violin and plays it when hearing others play.

An analogy is private talk. It starts as real talk outside, it is shaped socially by norms and practice, it is internalized and then it is available inside [Vygotsky 86]. After that, we can keep our mouth shut and think entirely in our heads.

In this sense, acquiring mastery of an instrument leads to the internalization of a principle of organization – a way of perceiving the world that comes from having mastered externally a highly structured form of interaction. It is artifact-mediated cognition, but without the artifact. If you play enough, you eventually can simulate playing without an

instrument in your hands. Thus, Perlman understands the meaning structure of a musical piece because of acquired knowledge of music, because he has internalized the way a violinist would approach the music, and because, while listening or watching, his resonant system simulates playing it. [Cisek & Kalaska 04] His vast experience and prior practice grounds his perception sufficiently for him to realize the musical possibilities at each moment.

Despite the allure of motor neuron theories, and despite the importance of recognizing that humans internalize principles of organization I think intuition is against Vygotsky and motor resonance here. Neither dancer nor violinist can mediate their encounter of dance and music to quite the same depth with and without their instrument. Physical performance matters. Whatever Perlman may know about a piece through watching and listening, and it is considerable, he cannot know all that he would feel or register were he playing the piece personally. The difference – the remainder – lies in what it means to be situated and to be an agent; it depends on being the prime cause.

Part of the ‘extra’ that using a physical instrument provides an agent is a consequence of how working with a physical instrument causally shapes what a performing agent understands about the possibilities of a situation. This extra includes a phenomenological sense of freedom and responsibility. By being the person who is creating the music, a violinist has a responsibility to succeed, and during his performance he or she has access to a set of performance specific concepts and experiences unavailable to an observer, even a violinist observer. These concepts are ad hoc [Barsalou 10], situated [Greeno 89, Kirsh 09] and embodied [Barsalou 08], and they permit the agent to project a future that is conceptually and experientially richer than the future projected by an observer. They provide the performer with a framing of decisions at each point: how long to hold a note, how to attack it, its mood and emotionality. These differences are not reducible to the specifics of what it is like to play the violin – to move the bow on a string, to hold the violin under the chin. Those are practical elements that might bear on the moment-by-moment musical decisions that must be made, but many of these mechanical aspects of working with a violin are irrelevant to the performer’s conception of the musicality of the piece. The extra elements of knowledge conferred by participation concern the music itself. Agency is a special mode of making contact with that. The result is that in probing music with his violin, Perlman is able to discover something about the music he himself would miss were he just to listen. He needs the violinistic encounter with the musical composition to activate some of those concepts and sensory experiences. At least that’s the story.

This is a complicated and remarkably strong thesis, one that I believe lurks at the soul of the frameworks of situated and embodied cognition. To my knowledge it has not been closely considered.

## Method

The data for this research comes from two extensive case studies in which we captured the making of new choreographic work created by the celebrated choreographer Wayne McGregor and his contemporary dance company Random Dance. In the course of three periods – the first two occurring in two three-week periods (winter and fall of 2009), the third in a six-week period (fall of 2010) – all the face-to-face encounters between choreographer and dancers, (about 5 hrs/day) as well as all practice sessions involving the dancers and the associate choreographer Odette Hughes, were recorded by six high definition video-cameras. Over thirty 60-90 minute interviews were recorded between the choreographer and author and also with the dancers individually or in small groups. All notebooks, brain storming stimuli and real time notes were collected. Several experiments on marking, mental simulation, imagery ability and movement memory were carried out. Each case study yielded about 20TB of video. All videos had to be transcoded, collated and organized – altogether a massive process that required the help of several teams of students too numerous to thank individually. [Kirsh 10]

Once all materials were organized, work sessions were identified and cursorily annotated. Specific phenomena were then identified for intensive examination. We discuss here our observations and analyses of a process we call ‘riffing’ – an activity the choreographer regularly performs in which he tries out ideas by dancing them himself.

The detailed coding of riffing was performed by three college seniors long involved in this project. Each coder worked on separate days in the corpus and intercoder reliability was measured on 10% of the material done in common yielding .77 using Krippendorff’s alpha measure.

**Riffing off-of-others, the phenomenon studied.** When the dancers we studied are working on an assigned choreographic task, or when working on a duet, trio or quartet, we regularly observed that the choreographer, WM, would observe them closely, and then, if the dancers were to do something interesting or untoward, he would try out their movement himself. He would physically sketch the movement, appropriate what he likes, and then work on the phrase himself, substantially modifying it before sharing it. We call this activity *riffing off-of-others*. Superficially, it is the equivalent of playing a musical piece himself.

When asked in interview why he riffs off-of-others WM said he does it “to feel the moves”, and also “to redo them with [his] own signature”, “to ensure that they are authentic” or to test if they are “consistent with [his] artistic style and the integrity of the piece as a whole”. Executing the movement also lets him see its possibilities, its ability to “support invention”, its potential fertility. We cannot confirm these views on the basis of videographic observation because much of the interest of a movement for WM, he reports, lies precisely in its physical or dynamic novelty, something he recognizes in the movement that is quite different from previous movements he has worked on, owing

perhaps to weight, balance, force, resistance or other attributes that are kinesthetically meaningful but almost impossible to discern visually. This is a key point.

## Empirical Results

Because we have no access to our subject's motor encoding through imaging or otherwise, our empirical study (the non-interview part) involved reviewing nearly a thousand episodes of rifting and measuring about 15% of them. Our goal was to observe when the choreographer riffs, how faithful his riffs are to the target movement he is sketching, how he modifies the movements, and then what he does with these modified movements.

We found that rifting off-of-others follows a common pattern: 1) the choreographer watches a dancer or small group develop a movement idea; 2) he personally sketches or 'marks' their movement, though he also adds or subtracts from their idea by prepending, appending or deleting components in the first pass; 3) he runs through (i.e. he riffs) several more times, each occasion adding, subtracting, or altering more of the phrase as he initially sketched and modified it; 4) he then works with the dancers to share the new idea. The process is very collaborative, though not quite a dialogue, for the dancers do not attend to what WM is doing when he is rifting – they are busy dancing themselves – and WM himself does not seem much concerned to get the dancers' movement exactly right. He does not stop, look again, practice. Instead, he watches, physically sketches and remakes his own versions, all in relatively high speed.

This kind of physical sketching and rifting seems a way for him to pick up ideas he did not originate, and then play with them. He runs someone else's movement through his own body because it is not enough for him to see what others are doing; he needs to appropriate the full structure of the movement to explore how it might be developed, continued. In short, rifting is a way he thinks with his body. He wants 'agentive' knowledge.

Before we look at the data supporting this view, it is worth commenting on how this practice departs from the case where a violinist plays a piece to understand it rather than listening to another violinist playing it. In the musical case, both soloist and listener share a common musical specification: the score. Playing is a better way of appropriating the score. In dance, and most especially in creative dance, there is no prior score and no real-time capture used to 'freeze' a movement. WM never uses a score (or video, though the dancers sometimes do later in the process); and the company makes no effort to transcribe their movements in a dance notation, such as Laban. Understanding must happen on the dance floor and in real time. More importantly, the kind of understanding the choreographer is after is dynamic. He needs to deep process the movement to see its potential. But this does not always mean recreating it exactly. In interviews the choreographer says he wants to appropriate the movements his dancers make. The curious thing is why he does not feel compelled to duplicate their movements more precisely.

**Data.** The data shown in Table 1 are derived from studying the first Make session of the first day of creating a dance made in 2009. Ten sequences of rifting off-of-others were found in this one session. By studying them frame-by-frame we were able to measure the time in seconds of the mean duration of the referent movements – the dancer movements – that WM chose to riff off of, and the timing of his subsequent activity.

Rifting Off-of-Others (measurements in seconds)							
	Referent Move by dancer	Gap 1	Riff 1	Gap 2	Riff 2	Gap 3	Riff 3
Mean Sketch Duration	2.7 secs		2.8s		1.7s		2.4s
Mean gap		0.7s		20.2s		28.1s	
Mean Fidelity	100%		50%		29%		25%
Mean WM-added content			4.1s		3.1s		2.8s
Total			6.9s		4.8s		5.2s

**Table 1. Rifting off-of-others**

Looking at the columns, Gap 1 measures the time between the moment when a dancer performs a movement and the moment WM sketches it. Gaps 2 and 3 measure the time between subsequent riffs. WM-added content is the material he adds that is not found in the referent movement or in his sketch of that movement. It was surprisingly easy to recognize the referent material even though WM's sketch was not perfectly similar to the referent. Our interest was to determine how much of WM's movement was derivative, based directly on a referent, and how much of WM's movement was his own authored content.

In a typical riff, WM observes a referent move he likes and watches it a few times before sketching it in real time, immediately after the next time he sees it. As can be seen in table 1 this delay between seeing the referent and sketching it (after having seen it at least once before) is less than a second. After his first riff he then waits about twenty seconds, either watching other dancers or just standing pensively off stage. He then riffs again, which we call Riff 2; there is a gap again, on average 28 seconds, and then he makes a final riff, Riff 3.

Looking at the values in table 1 we see that on average his first riff is only 50% faithful to the referent. To determine fidelity we graded the quality of a riff along the dimensions of technicality, memory, timing and dynamics, the same dimensions we used in our marking experiment. (See this issue [Kirsh et al] and Kirsh [forthcoming]). Each dimension has four ordinal values: A, B, C, D. Overall fidelity was defined as the averaged score on all three dimensions. To calculate the mean and then return a letter grade for fidelity we converted letters to a percentage in a linear fashion (A=100% faithful, B=75%, ...).

Given his skill at real-time sketching WM's low fidelity suggests that his first riff is more selective than realistic sketching. It may mean that he is interested in appropriating only certain aspects of what another dancer is doing. In this

first riff, we found, further, that on average he adds more than twice as much of his own content to the material he appropriates. After a gap of 20 secs he seems to tighten up the movement by reducing the duration of both derived and WM-made content. Following another delay of 28 secs he increases the duration of the movement. He now has a phrase that contains only 25% of the original 2.7 secs movement he took, making that sketching look less like appropriation and more like inspiration; his own contribution is about the same length. It is this new movement, totaling on average 5.2 secs, that he eventually shows to the dancers in this or a later session.

What does this tell us? First, Table 1 shows that we were wrong in a conjecture we had made. We had assumed that riffs would unfold as a quick sequence of increasingly faithful sketches. WM would fully appropriate the referent phrase before his modifications and divergent sketching. This is typical of the way dancers sketch, when mastering the phrases of others. But it was not the case for WM. On average, WM will riff once, with only moderate fidelity to the referent, and then begin to truncate, add or modify the phrase. Even in his first riff he usually adds more of his own content than the phrase he appropriates.

Second, it suggests that his concern is with only certain aspects of a movement. The obvious analogy is with sketching on paper. An artist inspired by Soutine may sketch one of Soutine's paintings or drawings, hoping for ideas. But the sketch, much like WM's, is rarely faithful to the original and the creativity seems to lie in how the artist departs from the original.

Let us look at the process of choreographic sketching more closely to see if it may illuminate the nature of how physical movement acts as a mediating structure for thought.

**Sketching in Dance** is the process of copying in real-time the movements of another dancer – the referent. The referent dances, produces a target phrase, and the sketcher does her best to duplicate the target phrase herself. Inevitably there are stylistic differences, and most of all, differences owing to variances in dancers' height, weight, body form, strength, and gender. Sketching in this sense is an early shot at mastering a movement the way the referent does it. It is not to be confused with an artist's sketching, or a musician's sketching where often there is no referent – no touchstone of correctness.

If the sketching process in dance follows a normal pattern of structural approximation then the first sketch will be coarse, capturing essential elements of the referent such as emotion, general shape, gross dynamics, key positions, and occasionally sporadic details that they notice or like. What then follows is a trajectory of practice, a sequence of improvements and modifications to the original sketch to improve verisimilitude. The process is remarkably fast for professionals and a phenomenon worthy of study in its own right. After a minute or two, a talented dancer will stop watching the referent and practice on her own.

The majority of sketching we observed among the Random Dancers was real-time sketching. Each time the

choreographer makes a new phrase on one person (or a small group) the rest of the company is expected to learn the movements too. This is expeditious because when crafting phrases for duets and trios it is easiest to 'make' on a referent duo or trio on the assumption that the others, who typically were already doubled or tripled up (usually at WM'S explicit direction) would learn the phrase in their own duo or trio. In this dance company, moreover, the choreographer would sometimes swap dancers, putting a different dancer in the target role in the final piece, so dancers were expected to learn virtually all phrases.

Sketching in dance is a topic of interest because of what it can teach us about how the body is used to manage attention. In my view, a major function of a mediating artifact is to regulate attention and activate priming. A hammer helps us drive nails into wood. It is a purely physical, non-cognitive artifact. [Norman, 91] But when it is in our hand it also coordinates a complex pattern of movement and attention shifts – sensori-motor adaptations and interactions. Some of these are below conscious threshold and involuntary (e.g. grip in mid-swing). Others are fully conscious, but often they too are almost involuntary. For instance, when a hammer glances off a nail imagine how little control we have in seeing where it lands. Our eyes are drawn to it. It is this pattern of action and attention that is hard to duplicate without a physical thing driving it. The physical artifact mediates our knowledge of hammering. It plays an essential role in organizing our hammer'ish interaction with things.

To return to our violinist, we would expect that Perlman can partially simulate his pattern of attention to a musical piece when not physically playing his Stradivarius. He has his inner violin, with all its interaction-organizing principles. Numerous behavioral and imaging studies suggest that when humans mentally rehearse a familiar action they execute some of the same neural operations used during overt motor performance. [Jeannerod 01] When listening, Perlman would have no problem imagining himself playing. And he would engage similar neural and cognitive operations. [Munzart 2009]. But there will be many involuntary, fast paced adjustments to playing for real that would demand his attention physically that simply do not arise during simulated playing, where there can be no direct sensory feedback from the environment. In short, his simulation of playing is at a lower resolution than actual playing.

The special role that a sketch, as mediating structure, may play in dance cognition can be appreciated by analogy with sketching in paleoarchaeology, where Lithic sketching is used to solve a hard problem: distinguishing human made from natural stones in lithic eras.

In figure 1 there is a picture of three stones, any one of them may be from the Paleolithic era, and below them are some drawings made by an expert sketcher following the principles of lithic illustration. According to Addington [86] and Lopes [06] the best method to tell whether a given Paleolithic stone is a cutting tool is to sketch the stone. Not just any form of sketching will do. There is an expert mode of sketching for Paleolithic objects codified in a set of

principles of ‘lithic illustration’. Good archaeological illustrators will draw a lithic stone to reveal the physical ‘problematic’ the tool cutter faced. They will show the “scale; the pattern, sequence, direction, and force of blows to the stone; the bulb and platform of percussion; areas of retouch, snapping, and truncation; areas of grinding, battering, or abrasion; fractures caused by heating; the effects of materials; and pitting and sickle sheen.” [ibid] Potentially

**Figure 1.** Lithic sketches are drawings of stones made according to the strict principles of lithic illustration. The stones in the top picture are either human made – artifactual – or they are nature made and not shaped by humans.

confusing features of the stone such as embedded fossils, variegated coloration, patina, seams, banding, and crystallization are left out of the drawing.

The implication is that expert illustrators, when practicing their craft, are forced to scrutinize stones in a special way. They coordinate hand and eye to interactively probe the stone to reveal knapping related features. The need to draw certain lines drives perceptual inquiry. Attention must be managed, and arguably, without the need to sketch, without the presence of an external structure that the illustrator is creating, attention would not be managed adequately. Of course, this is an exaggeration. Illustrators have professional vision [Goodwin 93] and so can see elements of what they *would* draw without actually drawing. But in drawing, the process of making lines and ensuring they are spaced revealingly, is itself a process that simulates knapping. Using a pencil to draw a curve is physically related to using a knapping stone to flake a chip off a stone. It physically simulates knapping. So, the drawing process can help the illustrator walk through the history of the axehead’s making. The drawing is an external representation, but the process of making this representation is a powerful method for structuring attention. It helps the illustrator figure out what an artifact is by studying ‘the details of its making’ (ibid).

The analogy to riffing should be clear. By riffing, the choreographer is forced to direct his attention to the central aspects of a movement. By running the phrase through his own body WM gets to feel its dynamics, balance, gravity, internal shape. Not as seen in a mirror, but as felt through

movement – he experiences ‘the details of its making’ including the many body decisions the dancer made.

We turn now to what riffing teaches us about the power of using the body to help think about dance; how being the agent of movement offers privileged knowledge of dance.

## Discussion

It is no surprise that dancers physically sketch, explore or probe movement ideas by using their bodies. The question at issue is why, when our choreographer sees an interesting movement performed by one of his dancers, he bothers to mimic it? Given his capacity as a super-expert he ought to be able to attend to enough aspects of the movement by observation alone, or perhaps by inner simulation, making external movement unnecessary. One would suppose that he can think through the possibilities of a movement well enough in his imagination. Observation of the movement ought to give him an adequately precise ‘perceptual blueprint’ [Hodges et al, 07] that he can then imaginatively work with.

Support for the idea of imaginative simulation being sufficient can be found in the idea of enactive perception. [Noe 05] On an enactive account of visual perception, an observer should see the counterfactual futures in the present. He should phenomenologically experience possible ways a phrase may be continued. In this case that would mean anticipating a dancer’s possible movements just before they were made, then saccading, moving the eyes, head, trunk and attending closely to see which of the movements that might have been made do in fact occur, and then revising perceptual expectations appropriately. The enactive process happens during perception, but it grounds an understanding of the movement process that encompasses more than what was literally seen and supports imaginative replay and exploration. [Thomas 99]. It supports projection [Kirsh, 12].

A second reason overt action might be superfluous is that humans have the capacity to improve motor performance by observation alone, without concurrent physical practice, [Torriero et al 08, ibid]. The fact that there are older choreographers (notably Merce Cunningham) who continued making noteworthy pieces after drastically reducing their physical exploration [Nolan, 12] offers further support that physical practice is not necessary for grasping the choreographic potential of a movement; observation and mental simulation may be enough.

For our forty-year old choreographer that is *not* what we found. He regularly runs possible steps and phrases through his own body, and he seems to rely on that process as part of his choreographic practice.

I suggest we view Riffing as a type of enactive thinking. It is not just a way of better activating what vision can supply. It constitutes a more interactive probing. Interaction requires more than simply changing one’s eye, head, trunk and body position to observe; it involves changing the object of inquiry. It is an intervention.

Thus in reply to the question how can thought be partly constituted by bodily movement I have a few answers.

First, since bodily movement is by definition part of the action-perception system it can be harnessed reliably as part of a simulation process as well as ‘mental’ simulation inside cortex. If internal simulation is good enough to ground thought, then why not regard the act of materializing the target process an even better source of grounded thought? Moreover, if nature plays a role in simulation the progression of states will be more detailed and reliable than mentally projecting, imagining, or simulating the next state, which is more error prone. So dancing a phrase ought to be a better way of grasping the possibilities of a phrase than simulating it. And perceiving possibilities is a lot of what understanding is. This leads to the second reply.

Badets et al., [06], showed that physical practice is better than mere observation for learning new movements. This may not always be the case with simple and even moderately complex movements [Cross et al, 09]. Presumably in those cases where physical practice surpasses prolonged action observation something extra is getting in. What is it? In Badets [op cit] the extra is detailed behavioral expertise and its neural basis. But with respect to thought, and not just skilled movement, the extra that comes from overt bodily involvement is an enhanced conceptualization of what the phrase is, a better grasp of what makes a performance *true to the phrase*. In simple dance phrases there is little to grasp or deeply conceptualize. But for complex, choreographically rich phrases this can be a real issue. It means being able to judge when two dancers with different genders, backgrounds and bodies have mastered the phrase ‘correctly’.

Riffing falls into this enhanced conceptualization category because when WM executes a phrase he is making decisions at each moment; he is ‘thinking’ about it. He reports looking for possible lines of development, for novelty, for discovering a point in movement space that is uncharted. In lithic illustration you also feel the decisions: why here, and not there? In dance, part of conceptualizing possibilities means understanding key dynamics like the effect of gravity, balance, force, and bodily tension. These arise through physical interaction and are highly sensitive to momentary physical factors. Observation alone cannot expose these elements. Without agency, intervention and physical engagement, human knowledge is different. Angels can never understand dance as humans can.

## Abstract

We develop and evaluate a preliminary belief-updating model which links intermediate-term (i.e., over several days) syntactic adaptation to the joint statistics of syntactic structures and lexical cues to those structures. This model shows how subjects differentially depend on different cues to syntactic structure following changes in the reliability of those cues, as shown by Fine and Jaeger (2011). By relating syntactic adaptation and cue combination to rational inference under uncertainty, this work links learning and adaptation in sentence processing with adaptation in speech perception and non-linguistic domains.

**Keywords:** sentence processing, adaptation, Bayesian modeling, cue combination, rational analysis

## Introduction

Humans must maintain a stable representation of the environment despite the fact that available sensory input changes across time: for example, over the course of a day, we recognize and grasp objects in a variety of lighting conditions; we execute accurate motor commands despite changes in our own motor systems due to fatigue, over-cafeination, etc.; and during linguistic communication, we process rapidly unfolding acoustic information that varies from talker to talker.

Variability within each of these different modalities changes the correlation between cues—whether visual, haptic, or linguistic—and the things in the world we wish to make inferences about *based on* those cues. How do our brains make use of these cues in spite of variability in the environment? One possibility, suggested by research across a number of domains, is that humans deal with variability in the environment by *adapting to* changes in the statistical properties of the environment (for examples from vision, motor planning, and speech perception, see respectively: Blakemore & Campbell, 1969; Koerding, Tenenbaum, & Shadmehr, 2007; Norris, McQueen, & Cutler, 2003).

While most work on adaptation has been concentrated in perception, the question of whether adaptation is operative in higher level cognition has recently received more attention, particularly in language processing research. For instance, a number of researchers have shown that, when given sufficient experience with a structure initially judged to be ungrammatical, listeners come to subsequently comprehend (Luka & Barsalou, 2005), generalize, and even produce (Kaschak & Glenberg, 2004) that structure. Similarly, recent work has shown that we fine-tune our expectations about which syntactic structures are likely to occur in a given context based on recent experience (Thothathiri & Snedeker, 2008; Farmer, Fine, & Jaeger, 2011).

Thus, behavioral evidence seems to suggest that adaptation, qualitatively speaking, is a very general feature of perception and cognition. A question that arises from all of this previous work is whether adaptation observed across all of these domains can be modeled within a single framework. The goal of this paper is to take a step in this direction. In particular, we model adaptation in syntactic comprehension in terms of Bayesian belief update. Modeling syntactic adaptation in a Bayesian framework is appealing because the same basic computational approach has been successfully pursued in a variety of perceptual and motor domains (e.g. Koerding et al., 2007) and, more recently, in speech perception (Kleinschmidt & Jaeger, 2011; Sonderegger & Yu, 2010).

Moreover, Bayesian belief update is ideally suited to explicitly model the fact that syntactic comprehension involves the combination of multiple cues. This offers the advantage of suggesting a single computational framework for adaptation and cue combination, since Bayesian approaches to cue combination have been successful in a number of domains including visually-guided grasping, audio-visual cue combination, and the weighting of cues to phonetic category. In particular, Bayesian approaches to cue combination in perception have provided a formal means of capturing the fact that humans are able to weight multiple cues (e.g., multiple cues to object depth, such as shading and texture) according to how *reliable* those cues are. We return to the relationship between adaptation and cue combination in the discussion.

The goal of the current study is to ask whether a rational model of adaptation—implemented in the form of Bayesian belief update—can account for behavioral evidence for adaptation in the syntactic domain. Here we model behavioral data originally reported in Fine and Jaeger (2011), which concerns how subjects adjust their expectations about different syntactic structures conditioned on lexical information. Specifically, we exploit temporary syntactic ambiguities as a window onto syntactic expectations. In sentences such as (1), the syntactic assignment of the noun phrase *the judge* is temporarily ambiguous, since it can be parsed as either the subject of a sentence complement (SC) clause, as in (1a), or as the the direct object (DO) of *acknowledged* (as in 1b).

- (1) The lawyer acknowledged the judge ...  
                 disambiguation  
     a. ... {had been} unfair to the defendant.  
     b. ... in the black robe.

The sentence is disambiguated towards the latter reading at

*had been*. A great deal of previous work suggests that reading times at *had been* are a function of subjects' *expectations* about which syntactic structure is likely to occur, based on previous cues in the sentence, such as the verb, the combination of the verb and post-verbal noun phrase (e.g., Garnsey, Pearlmutter, Myers, & Lotocky, 1997), and whether or not the complementizer *that* occurs after the verb (e.g., *The lawyer acknowledged that the judge had been unfair to the defendant*). More recent work has explicitly quantified syntactic expectations in probabilistic terms (Hale, 2001; Levy, 2008). In other words, reading times at the disambiguating region (*had been*) provide information about subjects' subjective beliefs about the relative probability of the SC vs. the DO structures: If reading times are high, this indicates that subjects had assigned a relatively *low* probability to the SC structure; if reading times are low, then subjects had likely assigned a relatively *high* probability to the SC structure.

We model changes in reading times at the point of disambiguation as a consequence of syntactic expectation adaptation. Assuming that reading times in the disambiguating region in sentences such as (1a) reflect subjects' beliefs about the relative probabilities of different syntactic structures, we can interpret *changes* in reading times as changes in subjects' beliefs about the distribution of syntactic structures (at least in the context of the experiment, a point to which we return in the discussion). Syntactic adaptation, construed as the incremental adjustment of the subject's representation of a probability distribution over linguistic events, can therefore be naturally modeled in terms of Bayesian belief update.

In the following section, we briefly describe the behavioral data we set out to model. Next we present a Bayesian belief update model of this behavioral data, and assess the quality of the model's fit to the behavioral data. We conclude by summarizing the model's results and providing a discussion of the implications of this modeling work for our understanding of adaptation and cue combination.

## Methods and Summary of Behavioral Results

The data we use to test the hypothesis that syntactic adaptation can be understood in terms of incremental Bayesian belief update comes from (Fine & Jaeger, 2011). We briefly describe the design of that experiment.

### Experimental Procedure

In a between-subjects, multi-visit self-paced reading experiment, (Fine & Jaeger, 2011) investigated whether comprehenders update their estimates of the probability of the syntactic structures in (1) conditioned on the verb used in the sentence and the presence of the complementizer *that*. The All-SC group received evidence that SC-taking verbs always occur in sentences like (1a), while the 50-50 group was exposed to a 50/50 mix of SC (1a) and DO (1b) structures. For both groups, *that* occurred in 50% of all SC sentences. The experiment consisted of a pre-exposure session, three exposure sessions over at least 6 days, and a final post-exposure session at least 2 days after the last exposure session (cf. Wells,

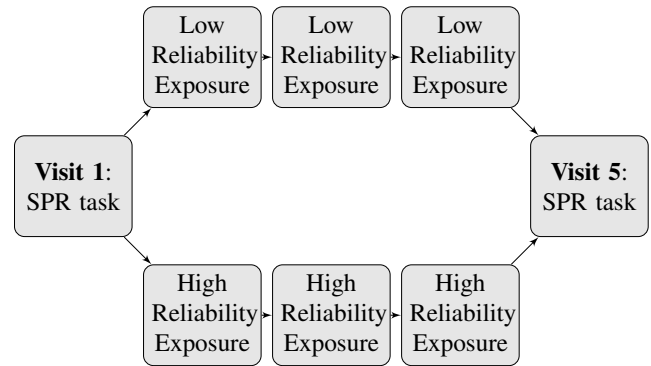

Figure 1: Schematic illustration of experimental procedure

Christiansen, Race, Acheson, & MacDonald, 2009). Subjects in both groups completed identical self-paced reading tasks in the first and final visits. A schematic representation of the experimental procedure is given in Figure 1. Given the design of the experiment, if reading behavior changes from visit 1 to visit 5 differentially across the groups, we can attribute this difference to the distributional properties of the exposure phase within each group.

This experiment allows us to ask two questions. First and foremost, do comprehenders track the distribution of syntactic structures in a given environment? That is, do comprehenders *adapt* to the statistical properties of novel linguistic situations? Second, given the distributional properties of that linguistic environment, do comprehenders *combine* multiple cues to syntactic structure in a way that is rational (i.e., by weighting cues according to their reliability; cf. Bates & MacWhinney, 1987; Anderson, 1990)? Specifically, for subjects in the 50-50 group, all verbs participating in the ambiguity in (1) become—in the experimental context—equally likely to occur with an SC or a DO. Thus the verb becomes, for this group, a very *unreliable* cue to syntactic structure. Qualitatively, according to rational models of cue combination, this should lead subjects in the 50-50 group to depend more on the complementizer *that* in the post-exposure reading task relative to subjects in the All-SC group. That is, the presence of the complementizer should more strongly influence reading times for the 50-50 group. In a regression framework, we therefore predicted a 3-way interaction between time (pre- vs. post-exposure), ambiguity (presence vs. absence of the complementizer *that*), and group (All-SC vs. 50-50). This three-way interaction was significant ( $\beta = 2.4, SE = .9, p < .05$ ), and is visualized in Figure 2 (light bars). This figure shows the decrease in ambiguity effect from pre-test to post-test as a function of training: there is a greater decrease after high-reliability, All-SC training, where subjects do not need to rely on the complementizer as much.

### Modeling framework

In constructing a belief updating model of syntactic adaptation and cue combination, there are two main considerations.

First, how can syntactic expectations be quantified, and second, how are those expectations related to the cues present in the linguistic environment and updated based on linguistic experience? In our model, syntactic expectations are quantified as discrete probability distributions over syntactic structures. In this case, the relevant syntactic structures are possible completions of sentences like (1), which we assume are limited to sentence complement completions (SC) and direct object completions, etc. (DO).

Syntactic expectations are related to relevant cues and in turn to linguistic experience via the conditional probability. SC completions are more common for some verbs than others, and are more common when the complementizer *that* is present. This dependence is captured by the conditional probability of  $p(S = \text{SC}|T, V)$ , where  $T$  indicates the presence or absence of *that* and  $V$  indicates the identity of the main verb of the sentence. The conditional probability of  $S = \text{SC}$  is closely related to the joint probability via the base probability of the various possible combinations of cue values:  $p(S, T, V) = p(S|T, V)p(T, V)$ .

We can model this joint distribution of syntactic structures and cues via a multinomial distribution. A multinomial distribution assigns a probability to a group of observations, each of which is, in our case, a triplet of the form  $S = i, T = j, V = k$ , each with a known probability of  $p(S = i, T = j, V = k) = \theta_{i,j,k}$ . The likelihood of making a group of observations  $X$ , where each outcome occurs  $n_{i,j,k}$  times, is

$$p(X|\theta) \propto \prod_{i,j,k} \theta_{i,j,k}^{n_{i,j,k}}$$

This provides a way of capturing syntactic expectations when the probability of each outcome is known with certainty. However, if the subject is truly certain about the probability of each outcome, then no adaptation should occur. Thus, in order to capture adaptation, or change in expectations, we must capture *uncertain* beliefs about such expectations, via a prior distribution over the probabilities  $\theta_{i,j,k}$ . The most natural choice is the conjugate prior for multinomial probabilities, the Dirichlet distribution:

$$p(\theta) \propto \prod_{i,j,k} \theta_{i,j,k}^{\alpha_{i,j,k}-1}$$

The primary advantage of using this prior distribution is that, after making observations  $X$ , the posterior is also Dirichlet, with parameters  $\alpha_{i,j,k} + n_{i,j,k}$ :

$$p(\theta|X) \propto p(X|\theta)p(\theta) \propto \prod_{i,j,k} \theta_{i,j,k}^{\alpha_{i,j,k}+n_{i,j,k}-1}$$

The parameters ( $\alpha_{i,j,k}$ ) of the Dirichlet prior can thus be interpreted as the number of times each outcome was observed in prior experience. Intuitively, this can be seen just by looking at the equations for the prior and likelihood and noting that  $\alpha$  and  $n$  appear in the same places.

Under this model, the conditional probability of SC, given specific  $V = v$  and  $T = t$  is

$$p(\text{SC}|V = v, T = t, \theta) = \theta_{\text{SC}|v,t} = \frac{\theta_{\text{SC},v,t}}{\theta_{\text{SC},v,t} + \theta_{\text{DO},v,t}}$$

It can be shown that  $\theta_{\text{SC}|v,t}$  (and by definition  $\theta_{\text{DO}|v,t} = 1 - \theta_{\text{SC}|v,t}$ ) follows a Beta distribution with parameters ( $\alpha_{\text{SC},v,t}, \alpha_{\text{DO},v,t}$ ). Marginalizing over the distribution of  $\theta_{i,j,k}$ , the conditional probability of SC given verb  $v$  and complementizer cue  $t$  is:

$$p(\text{SC}|v,t) = \int p(\text{SC}|v,t,\theta)p(\theta|\alpha)d\theta = \frac{\alpha_{\text{SC},v,t}}{\alpha_{\text{SC},v,t} + \alpha_{\text{DO},v,t}}$$

This conditional probability is the major predictor of syntactic expectation and associated comprehension difficulty.

In order to make quantitative predictions from this general framework, it is necessary to specify the parameters of the prior distribution ( $\alpha_{i,j,k}$ ) and likelihood function ( $n_{i,j,k}$ ), and to relate the model output (conditional probability) to the behavioral measure (reading times). These are addressed in the next sections.

### Determining the likelihood

The parameters of the likelihood function are the counts  $n_{i,j,k}$  of how often each unique combination of syntactic structure  $S = i$ , verb  $V = j$ , and complementizer presence/absence  $T = k$  was observed during training, and were set to the counts of the training phase.

### Determining the prior

The prior parameters are the pseudo-counts  $\alpha_{i,j,k}$  which are proportional to the joint prior probabilities. These probabilities are estimated based on a combination of corpus and norming data. The joint probability of syntactic structures, verbs, and complementizer presence  $p(S, T, V)$  can be factored as

$$p(S, T, V) = p(T|V, S)p(S|V)p(V)$$

The verb frequency  $p(V)$  is estimated from the British National Corpus, while the SC-bias of each verb (probability of SC completion)  $p(S|V)$  and *that*-bias (probability of complementizer presence for SC completions of each verb)  $p(T|V, S)$  are estimated based on a sentence-completion norming study (Garney et al., 1997).

Together, these factors provide an estimate of the relative prior frequency of each outcome, and thus the relative magnitudes of the  $\alpha_{i,j,k}$  Dirichlet prior parameters, but say nothing about their absolute magnitude. The absolute magnitude  $A = \sum_{i,j,k} \alpha_{i,j,k}$ , corresponds to the degree of confidence in the prior beliefs: the higher  $A$ , the more the distribution over the modeled probabilities  $\theta_{i,j,k}$  is peaked around the estimated prior frequency, and the less new observations will influence these beliefs. Since there is no way to determine the strength of the prior beliefs *a priori*, we treat  $A$  as a free parameter, which controls the degree of adaptation but does not change

Figure 2: Behavioral results from Fine and Jaeger (2011) (light bars) and corresponding model predictions (dark bars), showing differential effect of high- and low-reliability training on ambiguity effect. Bars show decrease in ambiguity effect (difference in reading times for *that*-present vs. *that*-absent sentences) from pre-test to post-test.

its shape. This is the only free parameter of the model simulations reported here.<sup>1</sup>

## Analysis

To evaluate the predictions of the model against the behavioral data of Fine and Jaeger (2011), we regressed the negative log conditional probability against length-corrected reading times. This measure is known as *surprisal*, and has been shown to be a good predictor of reading times in syntactic comprehension (Levy, 2008; Hale, 2001; Fine, Qian, Jaeger, & Jacobs, 2010).

However, there are many factors which influence reading times, of which syntactic expectation may be just one. This measure explicitly removes the influence of verb frequency and *that*-bias, which independently predict reading times for SCs. Also, reading times decrease in self-paced reading tasks just because subjects become better at “pushing the button”, an effect which will confound any difference in reading times between pre- and post-test due to adaptation.

In order to control for these confounding effects and evaluate their relationship with our model’s predictions about adaptation of syntactic expectations, we fit an increasingly complex series of linear mixed-effects regression models. For each regression model, we compared the baseline, with only the “standard” suite of predictors, with the belief-updating model which additionally includes the surprisal of each item as a predictor. Table 1 shows the factors that were included in each model.

<sup>1</sup>The probability of *that* occurring as a non-complementizer,  $p(T = \text{that} | V, S = \text{DO})$  cannot be determined from the same norming study, and in corpora it varies dramatically between spoken and written English. For the simulations reported here it was fixed at 0.00005, based on the very low but non-zero value observed in the Wall Street Journal corpus. This does not dramatically change the predictions or the best-fitting pseudocount  $A$ .

Model (adds)	Deviance	$\Delta\text{Dev.}$	df	$p(\chi^2)$
(1 Subj)+ (1 Verb)	28066	195	2	<0.0001
Verb Freq.	28059	195	2	<0.0001
Time (pre/post)	27452	25	2	<0.0001
That presence	27448	15	2	0.0006
Verb SC Bias	27438	18	2	0.0001
Training Group	27432	15	2	0.0005
(interactions)	27216	7	2	0.03

Table 1: Results of linear mixed-effects regression analysis of belief-updating model predictions of self-paced reading times. Each row reports the goodness of fit of a model with belief-updating-predicted surprisal and all of the fixed and random effects listed in its row and the preceding rows (that is, the third model includes random intercepts for subjects and verbs, and a fixed effect for verb log-frequency). In the final row, the baseline model has all fixed effects and their interactions, except for the predicted surprisal, which does not interact with any other effects. The deviance (negative two times model log likelihood) is reported for each model, along with the improvement in deviance over the corresponding baseline model, the additional degrees of freedom, and the result of a  $\chi^2$  test.

We found the overall best-fitting parameter values by fitting the whole series of belief-updating regression models using a range of parameter values ( $A = 10^{-3}$  to  $10^4$ ). The parameter value with the best mean normalized goodness-of-fit (across the various regression models) was used for the results below. We compared both  $r^2$  and deviance as measures of regression goodness-of-fit; both measures produce similar relative goodness-of-fit values but we chose to use deviance since it suffers less from ceiling effects in the most complex (and best-fitting) models. The best fitting prior pseudocount, used to generate the predictions evaluated below, was  $A = 2.7$ .

## Results

Qualitatively, the belief-updating model predicts the three-way interaction between group, time, and ambiguity (presence or absence of *that*), Figure 2. The degree to which subjects rely on the complementizer as a cue to SC continuations—i.e., the strength of the effect of the complementizer on RTs—can be measured by the difference in reading times between complementizer-present and -absent sentences. The model predicts (dark bars), as is observed in the data (light bars), that ambiguity effects should decrease more after high-reliability training (All-SC group) and decrease less (if at all) after low-reliability training (50-50 group).

The results from the regression analysis of the belief updating model predictions show that the model predictions generally provide a good fit for reading times in the disambiguating region. First, the model predictions alone (with random intercepts for subject and verb) account for 17% of the variance in reading times. This effect cannot be reduced to any of the other controls we evaluated (verb frequency, time, presence of

*that*, verb SC-bias, and training condition group): the belief-updating predictions still significantly improve the fit of the model even after controlling for all of these fixed effects and all of their interactions ( $\chi^2(2) = 7, p < 0.03$ ).

Of all of these control predictors, time (pre- vs. post-training) has a notably large effect, and Wells et al. (2009) observed a similar global speed-up between pre- and post-test, independent of effects on the form of the test sentences and the type of training the subject received. This speed-up reflects both increased familiarity with the self-paced reading task (demonstrated by the fact that when the Time predictor is added, the deviance accounted for by the belief-updating predictions is reduced) and the effects of simply having seen more SC structures than in typical written English (captured by the belief-updating predictions after some SC exposure; Fine et al., 2010).

Finally, the value of the prior confidence pseudocount parameter  $A$  which best fits the data corresponds to an effective sample size of 2.7 observations for the prior beliefs. This value is very low, but is consistent with results from other belief-updating models of rapid syntactic adaptation and phonetic adaptation (Fine et al., 2010; Kleinschmidt & Jaeger, 2011) and with the larger idea that comprehenders weight prior evidence less in novel situations where rapid adaptation is likely required. Higher values correspond to less adaptation, and produce a worse fit, but interestingly *lower* values produce a worse fit as well. If the good fit of this model were simply due to the qualitative pattern of cue reliability in the exposure statistics, then lower values of  $A$ , which result in post-test reading times which better approximate the exposure statistics, should produce better fits, which is not the case. This supports the idea that post-test reading times reflect a combination of prior knowledge and recent experience.

## Discussion and conclusion

In this paper, we formally characterize syntactic adaptation as the incremental updating of a probability distribution over syntactic structures. We showed that such a model provides a good fit of behavioral data from a previously published study of syntactic adaptation (Fine & Jaeger, 2011). This model is a first step and leaves much open for future work. Because of how it tracks the co-occurrence statistics of cues and syntactic structures, it does not make meaningful predictions on a trial-by-trial basis for how the overall greater prevalence of SC structures in the experiment changes syntactic expectations for verbs not encountered during training (which influences reading times as well, Fine et al., 2010). Such on-line generalization is not in principle beyond the scope of the type of model presented here, but is omitted in favor of presenting a simple model which demonstrates the connections between adaptation, cue-combination, and statistical learning in syntactic comprehension.

Independent of the details of the particular model presented in this paper, characterizing syntactic adaptation in terms of Bayesian belief update is appealing for at least two rea-

sons. First, by modeling syntactic adaptation as incremental Bayesian belief update, we provide a natural, formal connection between previous work on probabilistic models of expectation-based processing (e.g., Hale, 2001; Levy, 2008) and behavioral work on syntactic adaptation (or syntactic priming; e.g., (e.g., Thothathiri & Snedeker, 2008). Second, using this modeling approach has allowed us to take a step towards providing a single computational framework for adaptation phenomena in language processing, since the same approach has been successfully applied in phonetic adaptation (e.g., Kleinschmidt & Jaeger, 2011). Providing such a “common language” is an important step since this provides a way of bridging insights from multiple strands of psycholinguistic research that have previously been pursued in isolation from each other, notably syntactic priming in comprehension (e.g., Thothathiri & Snedeker, 2008) and perceptual adaptation in speech (e.g., Norris et al., 2003).

As we briefly mentioned in the introduction, the model reported here provides a way of formally describing both adaptation and cue combination. Bayesian models of perception have consistently suggested that, when multiple cues are available in a given task, the perceptual system *weights* those cues according to how *reliable* they are, or, more formally, how narrow or wide the variance is over inferences made *based on* those cues (Jacobs, 2002). In the exposure phase of the study modeled here, the reliability of the verb as a cue to syntactic structure is very high in the All-SC group, but very low in the 50-50 group; on the other hand, the complementizer *that* is a consistently good cue across both groups. Our model qualitatively captures the behavioral result that comprehenders in the 50-50 group come to rely *more* on the complementizer *that* in the post- relative to the pre-exposure phase, compared to the All-SC group (see Figure 2). Significantly, this result comes out of the model as a natural consequence of tracking the joint distribution over syntactic structures (DOs vs. SCs) and syntactic cues (complementizers, verbs). The model here therefore suggests a very close relationship between adaptation and cue combination, and provides a formal account for the classic observation that cues are weighted differentially according to their reliability in language acquisition and language processing (Bates & MacWhinney, 1987).

In general, the approach here is conceptually compatible with a sentence processing research emphasizing the role of experience and learning in language comprehension (e.g., MacDonald, 1999). Bayesian models provide a formal framework for capturing the assumption—shared by many experience-based accounts of processing—that comprehenders monitor and constantly integrate new evidence from the input in order to maintain accurate linguistic expectations, and to process language more efficiently (cf., Smith & Levy, 2008).

The results reported here raise a number of interesting questions that we intend to pursue going forward. First, we employ the same modeling framework and find results that

are generally consistent with the modeling results reported in Fine et al. (2010). However, important differences in the experimental design between the two studies leave many questions open. Most significantly, the experiment in Fine et al. (2010) observed changes in reading behavior over a much shorter period of time (one half-hour experimental session) than the current study, which lasted several days. The modeling framework employed here could be extended to examine possible qualitative differences in adaptation over very different time courses, paralleling Bayesian accounts of the time course of adaptation in speech perception (Kleinschmidt & Jaeger, 2011).

Finally, the experiment and model reported here leave open the question of how much the changes in expectations which constitute adaptation *generalize* to novel situations (i.e., did the adaptation effects observed here persist, and influence the way subjects processed language outside the lab?). Rational models of linguistic adaptation generally predict that the extent to which comprehenders generalize adapted expectations should depend on their prior beliefs about the degree of similarity between different situations. This question has been addressed behaviorally in phonetic adaptation (Kraljic & Samuel, 2006, 2007) but remains virtually unexplored in other domains of language processing, and has not been quantitatively modeled. Answering the question of generalization is therefore a high priority for future work on adaptation.

## Abstract

We have previously proposed that incremental belief updating can provide a unified account of the effect of cumulative exposure on phonetic recalibration and selective adaptation (Kleinschmidt & Jaeger, 2011). This model predicts that these are not two distinct phenomena but rather two points on a continuum. We investigate that prediction here using adaptor stimuli intermediate between those which induce recalibration and selective adaptation, and find that the quantitative predictions of the model fit the data well. We also demonstrate that with the proper controls, Mechanical Turk provides a suitable online platform for speech perception experiments.

## Introduction

Language is fraught with variability, and such variability is a particular problem in the mapping from acoustic cues to phonetic categories. Some of this variability is simply random noise, from imprecision in the production and perception systems, but much of it is systematic, reflecting real differences in the way that individual speakers realize phonetic categories.

One of the ways in which the human speech perception system deals with such systematic variability is through rapid recalibration of phonetic categories in response to novel accents (Bradlow & Bent, 2008; Kraljic, Brennan, & Samuel, 2008) and unusual pronunciations of particular phonetic categories (Norris, McQueen, & Cutler, 2003; Vroomen, Linden, Gelder, & Bertelson, 2007). Through repeated exposure to a sound which is acoustically ambiguous between, say, /b/ and /d/, but which is disambiguated via visual or lexical information as a /b/, the listener's categorization behavior will change: they will classify more items on a /b/-to-/d/ continuum as /b/.

Such recalibration is often contrasted with selective phonetic adaptation, where repeated exposure to an *prototypical* /b/ results in exactly the opposite effect on the listener's categorization behavior: they will classify fewer items on the continuum as /b/ (Eimas & Corbit, 1973; Samuel, 1986; Vroomen, Linden, Keetels, Gelder, & Bertelson, 2004; Vroomen et al., 2007). Selective adaptation and recalibration are generally held to be qualitatively distinct, for a number of reasons.

First, recalibration results from repeated exposure to an acoustically ambiguous stimulus, while selective adaptation relies on repeated exposure to an unambiguous stimulus, and

is in fact stronger for more prototypical stimuli (Miller, Conine, Schermer, & Kluender, 1983). Second, despite the fact that both come from repeated exposure to a phonetic category member, they have opposite effects on that category.

Third, selective adaptation and recalibration are thought to reflect different levels of processing. On the one hand, selective adaptation is thought to generally reflect low-level, perceptual processing (Samuel, 1986). On the other, phonetic recalibration (or “perceptual learning for speech”, Norris et al., 2003) seems to reflect reorganization of the phonetic categories themselves (Clarke-Davidson, Luce, & Sawusch, 2008; Maye, Aslin, & Tanenhaus, 2008), is long-lasting (Eisner & McQueen, 2006), and in some cases generalizes to new speakers and phonetic contrasts (Kraljic & Samuel, 2006).

Fourth, the amount of cumulative exposure has a dramatically different effect on selective adaptation and recalibration (Vroomen et al., 2007). Selective adaptation grows stronger with more exposure, while recalibration becomes weaker after an initial rise, to the extent that it is eventually extinguished (Figure 2, left).

Despite these differences, selective adaptation and recalibration have something in common: they are reactions to unusual distributions of acoustic-phonetic cues. Listeners are exquisitely sensitive to such distributional information (Clayards, Tanenhaus, Aslin, & Jacobs, 2008; Maye, Werker, & Gerken, 2002), and we propose that incremental belief updating might provide a unified account of a range of phonetic adaptation phenomena, possibly including selective adaptation (Kleinschmidt & Jaeger, 2011).

This approach suggests that at least in some cases, selective adaptation and perceptual recalibration are better understood as part of a continuum of phonetic adaptation effects, rather than as qualitatively distinct processes, which raises the question of what sort of adaptation effect intermediate adaptors will produce. In this paper, we investigate the quantitative predictions about such intermediate adaptors made by our belief-updating model.

First, we describe how incremental belief updating provides a unifying account of the effects of cumulative exposure on recalibration and selective adaptation (Kleinschmidt & Jaeger, 2011). This model is used to derive quantitative predictions for the effect of cumulative exposure to audiovisual speech stimuli on a continuum between acoustically ambiguous and prototypical. These predictions are tested against human behavior. Finally, we conclude with a discus-

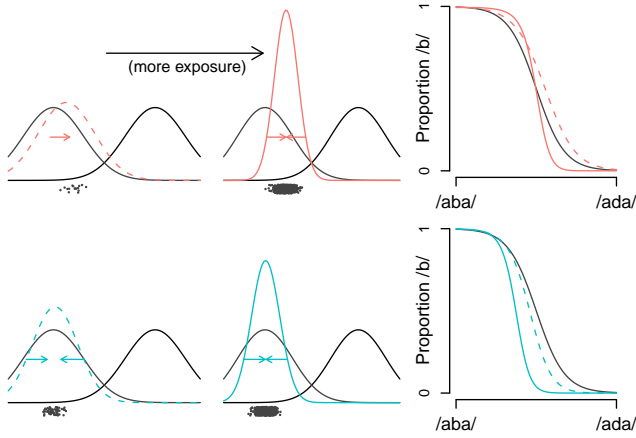

Figure 1: Qualitative predictions of the Bayesian belief updating model for phonetic recalibration (top) and selective adaptation (bottom). Left panels show changes in mean/variance after a small number of adaptor trials, and middle panels show the effect of further exposure. Note that while the adaptor for recalibration is acoustically ambiguous, it is disambiguated (by means of, e.g., a visual /aba/), and thus the percept is biased towards the /b/ prototype. Right panels show corresponding identification curves.

sion of future directions for both the computational modeling and behavioral work.

## Model and predictions

Speech perception can be considered a process of statistical inference: given a set of acoustic-phonetic cues, what is the most likely intended phonetic category (Sonderegger & Yu, 2010; Feldman, Griffiths, & Morgan, 2009; Kleinschmidt & Jaeger, 2011)? This inference critically depends on accurate beliefs about the distributions of acoustic-phonetic cues for each category. If the listener’s expectations about what a /b/ sounds like do not match what the speaker produces then the listener is at risk of mistaking the speaker’s intended phonetic category. Thus, a rational listener must update their expectations based on experience.

Figure 1 shows how such incremental belief updating explains the qualitative differences between recalibration (top) and selective adaptation (bottom) based on the respective distributions of acoustic cues (Kleinschmidt & Jaeger, 2011). Phonetic categories are naturally “wide”, with random variability inherent in perception and production processes. Selective adaptation effects are captured by the fact that in the prototypical-/b/ condition, the unusually tight clustering of acoustic cues from the repeated adaptor stimulus causes the /b/ category to shrink, resulting in fewer /b/ responses to test stimuli from the middle of the continuum.

For recalibration, the initial rise in /b/ responses after exposure to the acoustically ambiguous (but visually or lexically disambiguated) /b/ adaptor is due to a shift in the *mean* of the /b/ category, towards the middle of the continuum. With

more exposure, however, the tight clustering again causes the /b/ category to contract. Because the acoustically ambiguous adaptor is biased towards the prototypical /b/ by the disambiguating (visual or lexical) cue (by a McGurk effect or perceptual magnet effect, etc.), the shrinking of the /b/ category means that, like with selective adaptation, it pulls away from the middle of the continuum, resulting in an eventual decrease in /b/ responses.

This belief-updating model treats the behavioral phenomena of selective adaptation and recalibration as two points on a continuum of phonetic adaptation effects, which is determined by the statistics of the adaptor stimuli. One way of describing these statistics is by the mean and the variance of the adaptor stimuli, and our model makes quantitative predictions about the whole range of adaptors, from prototypical adaptors (which produce selective adaptation) to auditorily ambiguous adaptors (which produce phonetic recalibration), as well as intermediate adaptors, where the adaptor is neither fully auditorily ambiguous nor prototypical.

Specifically, phonetic adaptation with such intermediate audio-visual adaptors should be intermediate in time course and in direction. One simple way of characterizing the time course of phonetic adaptation is the number of exposures at which the direction of the effect of /b/ exposure switches from more /b/ classification to less /b/. In Vroomen et al. (2007, replotted in Figure 2, left), this “switch point” for the ambiguous condition is essentially the end of one full block: /b/-classification is greater after ambiguous /b/ (solid lines) than after ambiguous /d/ exposure (dashed lines) until the very end of the block, at 256 trials, where the two become indistinguishable again. For the prototypical condition, there is less /b/ classification after /b/ exposure from nearly the first adaptor repetition, and so can we say that the switch point is at the beginning of the block. For intermediate adaptors, this switch point will be between the point for fully ambiguous and fully prototypical adaptors, closer to the ambiguous switch point for more ambiguous adaptors and closer to the unambiguous point for less ambiguous adaptors (Figure 3, black curves with arrows showing switch points).

## Model specification

We refer the reader to Kleinschmidt and Jaeger (2011) for full details of the model. This model treats phonetic categories as Normal distributions over acoustic-phonetic cues,  $p(x_i|c_i) \sim \mathcal{N}(\mu_{c_i}, \sigma_{c_i}^2)$ . The listener’s beliefs about these categories are captured by Normal-Gamma probability distributions over the category means and variances,  $p(\mu_c, \sigma_c^2)$ . After exposure to adapting stimuli  $X$  from category  $c$ , the listener’s beliefs are updated via Bayes rule,  $p(\mu_c, \sigma_c^2|X, c) \propto p(X|\mu_c, \sigma_c^2)p(\mu_c, \sigma_c^2)$ . This finds the best compromise between the listener’s prior beliefs and the mean and variance that is most consistent with the data.

The probability of a /b/ response to a stimulus  $x$ ,  $p(b|x)$ , depends on the likelihood of  $x$  under each category  $p(x|b)$  and

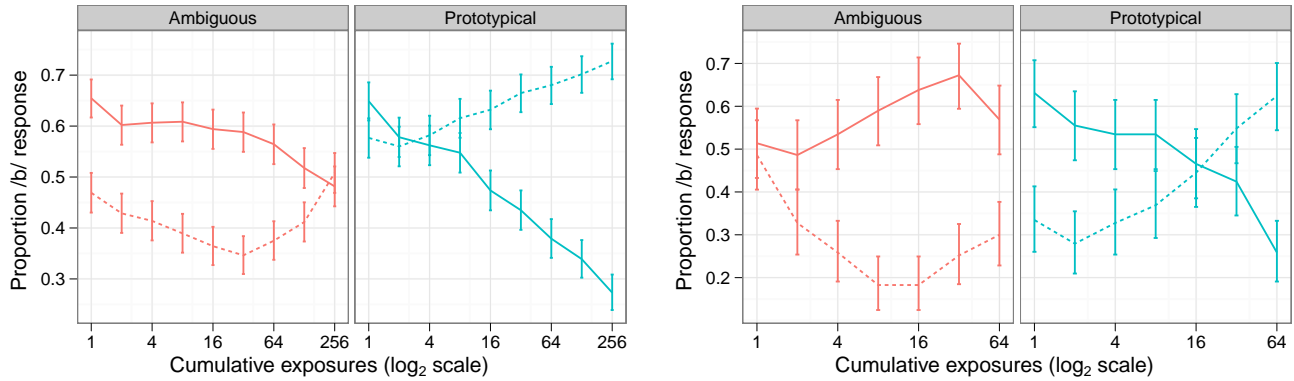

Figure 2: Results from Vroomen et al. (2007), left, and Experiment 1, right: More /b/-classification after ambiguous /b/ exposure (solid lines, left panels) than /d/ exposure (dashed lines). After prototypical-/b/ exposure (solid lines, right panels), less /b/-labeling.

$p(x|d)$ , as well as the prior probability of /b/ and /d/:

$$p(b|x) = \frac{p(x|b)p(b)}{p(x|b)p(b) + p(x|d)p(d)}$$

The predictions of the model depend not only on the mean and variance of the adaptor stimuli (the likelihood function) but also the prior beliefs about the category means and variances. While each subject's most likely means and variances can be determined based on their pre-test classification data, the confidence in these beliefs must be treated as free parameters (Kleinschmidt & Jaeger, 2011).

Here we incorporate a few minor improvements over our original model. Instead of fitting the after-effect measure used by Vroomen et al. (2007) (the difference between /b/ and /d/ exposure), here the model is fit to the /b/-classification rate curves for each individual condition. This requires accounting for asymmetry in the prior probability of /aba/ vs. /ada/, which was fixed to  $p(b) = 0.7$ , based on the English biphone probabilities of /aba/ and /ada/ (Vitevitch & Luce, 2004).<sup>1</sup> The free parameters are fit via MCMC sampling (rather than a grid-search) based on the binomial likelihood of the responses (using a weakly-informative prior).

We next describe experiments which test the predictions of this model. These are extensions of the paradigm of Vroomen et al. (2007), which we have adapted to run on a novel web-based platform. The first experiment replicates Vroomen et al. (2007) to validate this platform, and the second investigates the effect of cumulative exposure on adaptation to intermediate adaptors.

## Experiment 1

Our first experiment is a replication of Vroomen et al. (2007). This is important both to verify the findings of Vroomen et

al. (2007) with English speakers but also to verify our web-based platform for running audio-visual phonetic adaptation studies.

## Participants

24 participants were recruited and run via Amazon's Mechanical Turk service. An additional 4 subjects were excluded by the criteria described below.

## Procedure

Our procedure is adapted from Vroomen et al. (2007), and our stimuli are identical in order to maximize similarity to the original study for purposes of replication (we thank Jean Vroomen for graciously providing them). These stimuli consist of a 9-item /aba/-to-/ada/ continuum synthesized by manipulating F2 locus in equal steps on a log-frequency scale. Audio-visual adaptor stimuli were created by combining a video of a speaker producing /aba/ or /ada/ with one continuum item, according to the condition.

Subjects first did a pre-test and calibration phase, where they classified items from the audio continuum as /b/ or /d/. The point of maximum ambiguity was found via logistic regression for each subject. Subjects who mis-classified any of the two most prototypical stimuli on each end (less than 70% accuracy) were excluded, as were any subjects whose maximally ambiguous stimulus was not one of the three middle continuum items 4, 5, or 6. Three subjects (11%) were excluded by these criteria and replaced.

During the main phase, in each of four blocks subjects saw 64 repetitions of an adaptor stimulus. This stimulus was visually either /b/ or /d/, and auditorily either a *prototypical*, unambiguous rendition of the visual category (continuum item 1 or 9, respectively), or auditorily *ambiguous* (that subject's most ambiguous continuum item as determined during pre-test). These four blocks were presented in latin-square order across subjects. Audio-only test stimuli were interspersed throughout each block in sets of six (two repetitions of each

<sup>1</sup>When the prior probability of /b/ vs. /d/ is treated as a free parameter, the best-fitting value is 63% chance of /b/, very close to the corpus-derived value.

of the three most ambiguous stimuli) after 1, 2, 4, 8, 16, 32, and 64 exposures.

To ensure that subjects were paying attention to the videos, catch trials were randomly interspersed, where a small white dot flashed for one frame below the nose of the speaker. Subjects who failed to respond to at least 80% of these trials (or missed more than 50% in one block) were excluded; only one subject was excluded by these criteria and replaced. Besides this subject, accuracy was 95% (compared to 93% in Vroomen et al., 2007).

## Results

Because subjects were not run in the laboratory, there is some uncertainty about the conditions under which our subjects are doing the task. As one control for this, we compared their performance on the pre-test calibration task with the performance of the subjects in Vroomen et al. (2007) using a logistic mixed-effects regression model, with predictors for stimulus and group (web vs. lab) and with the maximum random effects structure justified by the data. Web and lab subjects did not differ in the slope of their category boundaries ( $\beta = 0.07$ ,  $SE = 0.14$ ,  $p = 0.60$ ). The category boundary (point of maximum ambiguity) was on average about one half to one continuum step closer to the /b/ end of the continuum compared to the lab subjects ( $\beta = -1.15$ ,  $SE = 0.27$ ,  $p < 10^{-4}$ ).

Our results from the main phase replicate Vroomen et al. (2007) as well (Figure 2). In the prototypical (selective adaptation) condition, subjects classify fewer test items as /b/ after /b/ exposure, and this effect grows stronger with further exposure. In the ambiguous (recalibration) condition they classify *more* as /b/ after /b/ exposure, but this effect eventually begins to weaken. Because our subjects only saw 64 exposure trials in each block, versus 256 in Vroomen et al. (2007), recalibration does not completely dissipate by the end of the block, but it does begin to weaken.

The most notable difference between our findings and those of Vroomen et al. (2007) is that in the prototypical, selective adaptation condition of our experiment, /b/-exposure initially produces *more* /b/-classification (as in the ambiguous, recalibration condition). There are two possible explanations for this. First, the “prototypical” stimuli we use correspond to natural productions of /aba/ and /ada/ by Dutch speakers, and may not be fully prototypical to English listeners, which, as we will see in Experiment 2, can produce recalibration-like effects with small amounts of exposure. Second, adaptation could carry over from one block to the next, producing baseline shifts. Such carry-over effects are observed in the data of Vroomen et al. (2007) as well, but are effectively confined to earlier blocks of their experiment (each of their subjects did a total of 16 blocks, versus only four here) and thus do not show up as strongly in the averaged data. In addition, at the end of the ambiguous (recalibration) blocks there is a bigger difference between /b/ and /d/ exposure in our data than in Vroomen’s et al., which would magnify any carry-over effects on the prototypical blocks (which are preceded two-thirds of the time by an ambiguous block).

## Experiment 2

The second experiment tests the predictions of our belief-updating model about the effect of cumulative exposure to adaptor stimuli intermediate between the prototypical and auditorily ambiguous stimuli used in the previous experiment. This also serves as another replication of Vroomen et al. (2007) using our web-based approach.

## Participants

A total of 126 participants were recruited, run, and paid through Amazon’s Mechanical Turk service as in Experiment 1. Six (5%) were excluded for poor catch trial performance, eight (6%) for misclassifying too many prototypical pre-test stimuli, and 18 (14%) for unusual category boundaries (as above).<sup>2</sup> After these exclusions, 94 subjects remained.

## Procedure

The procedure was similar to that from Experiment 1, except that there were four ambiguity conditions rather than two, and they were distributed between subjects rather than within. In addition to the prototypical (selective adaptation) and ambiguous (recalibration) conditions from Experiment 1, there were two intermediate conditions. In the intermediate-ambiguous condition, the audio component was one step towards the visual category prototype from the maximally ambiguous stimulus, and in the intermediate-prototypical condition it was two steps.

Each subject performed two blocks: one /aba/ and one /ada/ of one of the four ambiguity conditions, in order to minimize the effects of carry-over between blocks. Each block was 128 exposure trials, with test trials as in Experiment 1.

## Results

Figure 3 shows the results from all four conditions. As predicted by the belief-updating model, as the auditory component of the adaptor is less and less ambiguous, the switch point between recalibration-like and selective adaptation-like behavior moves closer and closer to the beginning of the block (Figure 4).

The quantitative predictions of the model are also a good match for the observed data. The predictions of the model are shown in black. These predictions correspond to the free parameters which best fit the ambiguous and unambiguous conditions. As in Kleinschmidt and Jaeger (2011), the model predictions provide a good fit for the behavior in the ambiguous and unambiguous blocks ( $r^2 = 0.67$ ). More importantly, without refitting, the model predictions match just as well on the two intermediate conditions ( $r^2 = 0.66$ ). That is, the model does not merely fit but quantitatively *predicts* the time course of adaptation to the intermediate adaptors.

<sup>2</sup>The large number of subjects excluded for unusual category boundaries could be attributed either to variability in listening equipment and environment, or to the fact that our listeners are English speakers but the continuum was generated based on Dutch productions of /aba/ and /ada/.

Figure 3: Model predictions and results from each subject’s first block. Left to right shows fully ambiguous, intermediate-ambiguous, intermediate-prototypical, and prototypical. Solid lines are for visual-b exposures and dashed are visual-d. Colored lines are average /b/ response rate, and error bars are 95% confidence intervals on the mean. Black lines are model predictions based on best-fitting parameters to only ambiguous and unambiguous blocks, and shaded regions are 95% confidence intervals based on MCMC sampling of model free parameters with a weakly informative prior.

Figure 4: Predicted and actual recalibration-to-selective-adaptation switch points. The x-coordinate of each point is the predicted switch point (black curves/arrows in Figure 3), and the y-coordinate is the observed point (colored curves/arrows).

## Discussion and conclusion

We have proposed that incremental belief-updating can provide a unified account of selective adaptation and phonetic recalibration, and have tested a model based on that principle against existing data on the effect of cumulative exposure on these two effects from Dutch listeners (Kleinschmidt & Jaeger, 2011). In this study we have first replicated this data (Vroomen et al., 2007) with American English listeners, using a novel, web-based platform, and second, extended the original study to test a key prediction of the model that existing data does not address.

It is generally argued that selective adaptation and recal-

ibration are qualitatively distinct effects (e.g., Vroomen et al., 2004). However, our model suggests that they both result from adaptation to changes in the statistics of the linguistic environment, and can be understood as two points on a continuum of phonetic adaptation phenomena. The data we present here shows that intermediate audio-visual adaptors produce adaptation which is intermediate in time course and direction in a way that is quantitatively consistent with the model predictions.

There is, of course, a large body of work which highlights the differences between selective adaptation and recalibration, and this study addresses only one such difference. We cannot, and do not, on the basis of this study claim that selective adaptation and recalibration *are*, in a mechanistic sense, the result of the same process. Rather, our approach offers some insight into these seemingly distinct adaptation phenomena by considering how the two behavioral patterns are related to the statistics of the linguistic environment.

Consider the alternative explanation of our results in terms of separate processes of selective adaptation (a decrease in /b/ responses after /b/ exposure) and recalibration (an increase in /b/ responses after /b/ exposure). Selective adaptation is stronger for more prototypical adaptors (Samuel, 1982; Miller et al., 1983), and so more the more selective adaptation-like time course of adaptation with increasingly prototypical adaptors might be explained simply by an interpolation between the time courses of recalibration and selective adaptation. However, this explanation leaves unanswered the question of why selective adaptation should be involved at all in recalibration, especially considering the fact that selective adaptation has been claimed to only be a function of the *audio* component of an AV stimulus (Saldaña & Rosenblum, 1994) and there is little-to-no selective adaptation observed for boundary stimuli (Miller et al., 1983).

Treating selective adaptation and recalibration as rational reactions to changes in the linguistic environment makes the intuitive idea about interpolating between the two time courses precise and quantitative, but more importantly *why*. As the listener encounters different speakers and different listening conditions, their linguistic environment is constantly changing, often in unpredictable ways. The listener needs to be able to cope with such changes and so must update their beliefs (and behavior) in response to their recent experience. However, while the reasons for such adaptation may be the same, the mechanisms by which it occurs could differ, with recalibration resulting, mechanistically, from higher-level language processing and selective adaptation occurring at a lower, perceptual level (Samuel, 1986).

The major goal of this work is to formulate a learning model for phonetic adaptation and use that model to guide experimental investigation of the whole range of phonetic adaptation phenomena. While this program emphasizes the similarities between different sorts of adaptation, it also aims to uncover even finer-grained empirical distinctions, in part to further the use of adaptation as a window on language processing, generally.

The model we have evaluated here is a first step and makes many simplifying assumptions. Still, it is a Bayesian model which, via data-determined priors and known processes—like sensitivity to category variance and the McGurk effect—provides a unified theoretical explanation for a puzzling interaction between the behavioral effects of selective adaptation and phonetic recalibration. More importantly, it makes fine-grained and testable predictions about the time course of behavior, some of which we have verified here.

Future work will focus on exploring the relationship between this rational model and boundedly rational implementations like exemplar models and particle filters. We will also, via structured, hierarchical extensions of this simple model, focus on resolving the apparent conflict between rapid adaptation to new speakers and the long-term stability of the linguistic system. Finally, and most importantly, we will use the predictions of these models to continue to systematically probe the space of phonetic adaptation behavior in order to inform and constrain the modeling work.

## Abstract

ERP (Event Related Potential) measurement using the violation paradigm of Japanese verb conjugation was conducted in order to investigate the mental and neural mechanisms involved in the processing of different conjugation patterns. A LAN-like component followed by a P600 was elicited for the anomaly of using a tense-bearing form with the negative ending, while only P600 was observed for the anomaly of using an infinitive form in the same environment. The non-application of morpho-phonological changes of verb roots (“onbin”) yielded an N400 component and a P600. The P600 components observed in all types of errors reflect the cost of processing morphological and/or syntactic anomalies, while the difference in the negativities suggest that two different mechanisms of rule-based computation and lexical memory are involved in the processing of Japanese verb conjugation.

**Keywords:** verb conjugation; inflection; N400; LAN; P600; Dual Mechanism Model; rule; memory

## Introduction

The aim of the present study is to elucidate the mental and neural mechanisms involved in the word-level language processing, exploiting the technique of ERP (Event Related Potential) measurement. More specifically, we investigated the processing of Japanese verb conjugation by recording ERP responses to different types of errors in the conjugation patterns. In doing so, we addressed the question of whether verb inflection involves more than one mechanism of processing in a language typologically different from European languages.

There has been heated debate since 1980’s concerning the mental mechanisms involved in word-level processing, with the focus on inflectional morphology in European languages. On the one hand, Dual Mechanism Model (Pinker 1999, Ullman 2001, among others) argues that two qualitatively different mechanisms, namely, rule-based computation and associative memory, are involved; English “regular” *-ed* past forms, for instance, are dealt with by the former, while “irregular” forms like *sing/sang* are by the latter. On the other hand, Single Mechanism Model (Joanisse and Seidenberg 1999, among others) contends that one and the

same mechanism can deal with both “regular” and “irregular” inflection.

Few studies have been conducted on Japanese in this context: a notable exception is Hagiwara et al. (1999), who argue for the Dual-Mechanism processing in Japanese derivational morphology. The present study places its focus on the processing of Japanese inflectional morphology, which has so far attracted little attention (cf. Vance 1991, Yu et al. 2011).

## ERP Components Related to Language Processing

Three components, N400, LAN, and P600 are known to be related to language processing.

The N400 is a negativity which peaks at around 400 ms after the onset of stimuli with wide, often posterior-centered distribution (Kutas and Hillyard 1980). The component is known to reflect semantic or pragmatic anomaly. It is likely to be related to the search of lexical memory as well, since its amplitude is known to reflect the frequency of the stimulus word (Kutas & Federmeier 2000), and it is observed in word-specific argument structure violation, namely, anomaly with respect to lexical information (Friederici & Frisch 2000, Friederici and Meyer 2004).

The LAN (Left Anterior Negativity) component is also a negativity observed at around 300-500 ms after the onset of stimuli: it is distinguished from the N400 in its distribution, which is limited to the left anterior region. This component is known to reflect morpho-syntactic anomalies like agreement errors (Coulson, King and Kutas 1998, among others).

The P600 is a positive component observed at around 600 ms after the onset of stimuli. Both anterior and posterior distributions have been reported. This component has been claimed to reflect the process of reanalysis or repair in face of morpho-syntactic or syntactic violations of various types (Osterhout and Holcomb 1992 and Hagoort et al. 1993, among others).

ERP studies on regular and irregular inflection have yielded somewhat varied results. The general tendency is that inappropriately attached or omitted regular inflectional suffixes (as in *bringed* instead of *brought*, or in *wip* instead

of *wipped*) tend to elicit a LAN, while modifications of irregular inflection (as in *pept* instead of *peeped*) tend to yield an N400-like component (Newman et al. 2007).

## Conjugation of Japanese verbs

Japanese verb roots can be divided into two types in terms of their conjugation patterns. The verb roots ending with vowels (/e/ or /i/) take various inflectional endings without any phonological change on the root.

(1) vowel-ending root: *tabe* ‘eat’

- a. non-past      *tabe-r-u*
- b. negative      *tabe-nai*<sup>1</sup>
- c. infinitive    *tabe* (-*masu* ‘polite form’, -*owar* ‘finish’)
- d. past          *tabe-ta*
- e. continuative *tabe-te*

The infinitive (ren’yoo) form (1c) takes the polite ending -*masu* and various aspectual verbs. When the endings start with a vowel, a consonant /r/ is inserted (1a).

In contrast, with consonant-ending roots, a vowel /a/ is inserted in the negative form and /i/ in the infinitive form (2b,c). In addition, the root-final consonants go through morpho-phonological changes called “onbin” in traditional Japanese grammar. Past tense ending -*ta* and continuative -*te* takes infinitive forms in both vowel-ending and consonant-ending verbs, but “onbin” takes place in consonant-ending verbs, as shown in (2d,e).

(2) consonant-ending root: *shaber* ‘chat’

- a. non-past      *shaber-u*
- b. negative      *shaber-a-nai*
- c. infinitive    *shaber-i* (-*masu* ‘polite’, -*owar* ‘finish’)
- d. past          *shabe?-ta*
- e. continuative *shabe?-te*

The onbin forms are conditioned by the final consonants of the roots, as summarized below.

(3) morpho-phonological changes (onbin)

- a. r,t,w→? (glottal stop):  
    *shaber* ‘chat’ / *shabe?-ta*; *kat* ‘win’ / *ka?-ta*
- b. k,g→i: *kak* ‘write’ / *kai-ta*; *kag* ‘smell’ / *kai-da*
- c. b,m,n→n: *tob* ‘fly’ / *ton-da*; *yom* ‘read’ / *yon-da*

As illustrated in (3b,c), the initial consonant /t/ of the ending is voiced after /b, m, n, g/. The roots ending with /s/ do not undergo “onbin” (*tas* ‘add’ /*tas-i-ta*).

It should be noted here that these morpho-phonological changes occur only with /t/-initial inflectional endings, but not with /t/-initial derivational suffixes. For instance, an agent nominal suffix -*te* does not trigger similar changes on the root: *kaki-te* ‘writer’ cf. *kai-te* ‘write (continuative)’ (Tagawa 2008). This confirms our assumption that these are not purely phonological changes, but are morpho-phonologically conditioned.

## Stimuli and Predictions

We focused on two aspects of Japanese conjugation. First, various vowels are added to consonant-ending verb roots as shown in (2a)-(2c): /a/ in Neg-form selecting a negative-ending -*nai* (2b), and /i/ in an infinitive form (2c), while the tense-marking morpheme /u/ yields a non-past form (2a), constituting minimal triplets with the same number of morae. We constructed our stimuli by adding the negative ending -*nai* to such triplets, resulting in one well-formed negative conjugation (4a) and two different illicit forms (4b,c).

- (4) a. *shaber-a-nai* (Neg-form + -*nai*)
- b. \**shaber-i-nai* (infinitive form + -*nai*)
- c. \**shaber-u-nai* (non-past form + -*nai*)

Insertion of these vowels to yield the forms (2a-c) is perfectly regular with consonant-ending verb roots, and hence we can hypothesize that these involve rule-based computation.

It should also be noted that the two types of illicit forms have different types of anomaly. (4b) contains a simple morphological ill-formedness, where a wrong non-tensed form (i.e., infinitive instead of Neg-form) is chosen. (4c), on the other hand, involves a phrase-structure violation, where the tense morpheme (non-past -*u*) is added before the negative ending, yielding the ungrammatical phrase structure where Tense is adjoined to V below the NEG node: [[[ *shaber* ]<sub>V</sub> -*u* ]<sub>T</sub> -*nai* ]<sub>NEG</sub> (the correct configuration would be: [[[ ]<sub>V</sub> ]<sub>NEG</sub> ]<sub>T</sub> ).

Consideration of the nature of unacceptability of these forms, together with the nature of ERP components surveyed above, leads us to predict that these illicit forms (4b, c) will elicit computation-related components (LAN and/or P600) when compared to the well-formed counterparts. Also, it can be expected that the two different illicit forms exhibit some difference in ERP responses.

The second aspect we focus on is onbin-forms exemplified in (2d,e). Although onbin-forms are determined by each root-final consonant as described in (3), there are some exceptions: the past form of *ik* ‘go’ is not *ii-ta*, but *i?-ta*, and the past form of *tow* ‘ask’ is not *to?-ta*, but *tow-ta*. It is also reported by Vance (1991) that native speakers experience difficulty in producing the past form of a novel verb. These facts suggest that onbin forms are lexically memorized. We constructed illicit forms by replacing onbin forms with the forms without onbin, namely infinitive forms (root+/i/), as shown in (5b). These forms can be predicted to elicit a memory-related ERP component N400 compared to the well-formed forms (5a).

- (5) a. *shabe?-ta* / *ka-i-ta* / *ton-da*
- b. \**shaber-i-ta* / \**kak-i-ta* / \**tob-i-ta*

## Method

**Participants** A total of 21 (15 males and 6 females) Japanese right-handed undergraduate students at the University of Tokyo participated in the experiment.

<sup>1</sup> The ending -*nai* in (1b) is the non-past form of the negative ending, which we will represent as one element for expository purposes.

**Stimulus Sentences** The target sentences were created on 162 consonant-ending verbs. For 90 verbs, we constructed illicit forms with violation of negative conjugations, and for 72 verbs, we constructed illicit forms with violation of onbin forms (See “Stimuli and Predictions”). Three experimental lists were created according to a Latin square design, so that each list contained 30 sentences in each of the three negative conjugation error conditions and 36 sentences in each of onbin error conditions. A total of 252 sentences, 162 target and 90 filler sentences, were presented. Half of these sentences were well-formed. All sentences used in this experiment had the structure [NP-adjunct-NP-V-X]. An additional element X, nominal + copula or Auxiliary predicate, was added after the verb where we manipulated the conjugation, so that the sentences do not end with the critical word.

**Procedures** Electroencephalogram (EEG) signals were recorded while the participants read to themselves the stimulus sentences shown automatically on the PC screen phrase by phrase. They were asked to refrain from blinking their eyes or moving their bodies until the end of the sentences. Each sentence had 5 phrases, and each phrase appeared on the screen for 600 ms with a 200 ms blank between each phrase. The critical word, i.e. the verb in all conditions, is the fourth phrase in the stimulus sentences. Following the presentation of a sentence, participants were instructed to make a grammaticality judgment (yes/no decision) by clicking a computer mouse. The 252 sentences were divided into 3 blocks, and within the blocks, sentences were randomized. The participants took a short break between each block.

EEG signals were recorded from 64 Ag/AgCl electrodes mounted in an elastic cap (Quikcap, NeuroScan) according to the International 10–20 system. To control the

participants’ horizontal and vertical eye movements, a bipolar electroencephalogram (EOG) was also recorded using four electrodes. All the EEG and EOG channels were digitized at a 250 Hz sampling rate using a Neuroscan Synamp2s amplifier with a band-pass between DC and 70 Hz. Recordings were referenced to the electrode located between Cz and CPz and then re-referenced offline to the average of the left and right mastoids. Electrode impedance was kept below 10 kOhm. ERP averages were computed with a 100 ms baseline and an 800 ms ERP time window. In the ERP analysis, 9.19% of the trials were rejected because of eye blinks or movement artifacts (the EOG rejection criterion was 70  $\mu$ V).

## Results

### Data analysis

Participants showing high rates of artifacts or error responses to yes/no questions (greater than 20% in the two types of trials combined) were excluded from the analysis. Six participants were excluded and the data from the remaining 15 participants (11 males and 4 females) were analyzed.

Since the visual inspection revealed a negativity with the focus in the left temporal area for (6c) compared with (6a), the following two regions of interest (ROIs) were used in the ANOVAS for the left-lateralized negativity: left-temporal (T7, C5, CP5, and P7) and right-temporal (TP8, C6, CP6, and P8). For statistical analyses of the N400 effect, four regions of interest (ROIs) are derived by crossing two factors; hemisphere (HEMI: left vs. right) and region (REGION: anterior vs. posterior). The ROIs are defined as follows: left-anterior (F5, F3, F1, FC5, FC1, C5, and C1); left-posterior (CP5, CP1, P5, P1, PO7, PO5, and PO3); right-anterior (F2, F4, F6, FC2, FC6, C2, and C6); and right-posterior (CP6, CP2, P6, P2, PO8, PO6, and PO4).

For statistical analyses of the P600, four regions of interest (ROIs) are derived by crossing two factors; hemisphere (HEMI: left vs. right) and region (REGION: anterior vs. posterior). The ROIs are defined as follows: left-anterior (F5, F3, F1, FC5, FC3, FC1, C5, C3, and C1); left-posterior (CP5, CP3, CP1, P5, P3, P1, PO7, PO5, and PO3); right-anterior (F2, F4, F6, FC2, FC4, FC6, C2, C4, and C6); and right-posterior (CP6, CP4, CP2, P6, P4, P2, PO8, PO6, and PO4).

### Negative conjugation error

Figure 1 shows the grand average ERPs for the critical verb, in correct, infinitive, and non-past form conditions.

**correct vs. illicit (infinitive+nai)** As shown in Figure 1, a positivity around 500–800 ms after the onset was elicited by the infinitive form, in comparison with the correct form. The latency and the distribution suggest that it is a P600 component, which is supported by the statistical analysis as follows: The analyses for the time window 500–800 ms revealed a significant main effect of condition,

$F(1,14)=21.98, p<.001$ . The infinitive form condition was more positive going than the correct. No other ERP components besides the P600 were observed in the comparison of the correct form and the infinitive form conditions ( $ps>.05$ ).

**correct vs. illicit (non-past+nai)** The non-past form condition, when compared with the correct form condition, elicited a negativity in the left temporal region at the time range of 300-400 ms and a positivity around 500-800 ms. The analyses for the time window 300-400 ms revealed a significant interaction between HEMI and the correct form vs. the non-past form,  $F(1,14)=4.54, p<.05$ . The non-past form condition was more negative going than the correct form condition in the left-temporal sites ( $F(1,14)=3.76, p=.066$ ), but not in the right-temporal sites. The latency and the distribution of the positivity suggest that it is a P600 component, which is supported by the statistical analysis as follows: The analyses for the time window 500-800 ms revealed a significant main effect of condition,  $F(1,14)=25.80, p<.001$ . The non-past form condition was more positive going than the correct form.

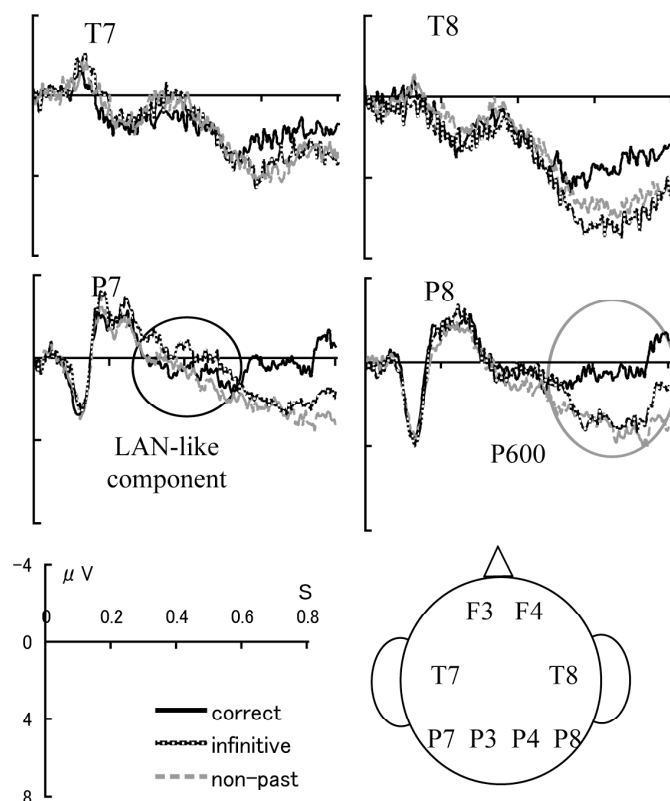

Figure 1: Grand average ERPs at selected electrodes at the position of the target verb (onset at the vertical bar) for the correct form vs. the infinitive form vs. the non-past form. Negativity is plotted upwards.

## Onbin error

Figure 2 shows the grand average ERPs for the critical verb, in the onbin and the infinitive form conditions. The illicit infinitive form condition, when compared with the correct onbin form condition, elicited a negativity at the time range of 200-500 ms with a focus in posterior sites, and a positivity around 600-800 ms. The latency and the distribution suggest that the negativity is an N400 component, which is supported by the statistical analysis as follows: The analyses for the time window 200-500 ms revealed a marginally significant interaction between REGION and the onbin form vs. the infinitive form,  $F(1,14)=3.47, p=.08$  and a significant main effect of condition,  $F(1,14)=5.17, p<.05$ . The infinitive form condition was more negative going than the onbin form condition in the posterior sites ( $F(1,14)=8.36, p<.01$ ), but not in the anterior sites. The latency and the distribution of the positivity suggest that it is a P600 component, which is supported by the statistical analysis as follows: The analyses for the time window 600-800 ms revealed a significant main effect of condition,  $F(1,14)=35.36, p<.001$ . The infinitive form condition was more positive going than the onbin.

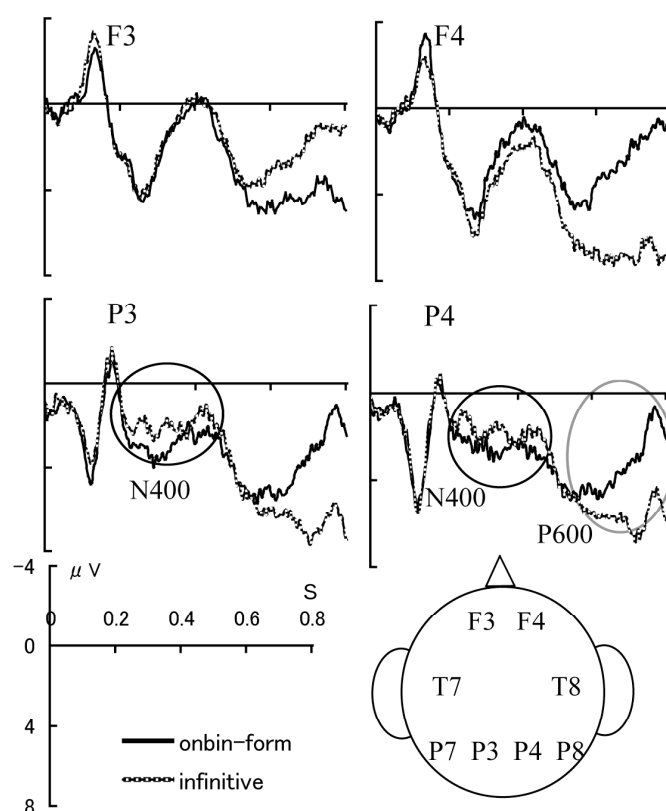

Figure 2: Grand average ERPs at selected electrodes at the position of the target verb (onset at the vertical bar) for the onbin-form vs. the infinitive form. Negativity is plotted upwards.

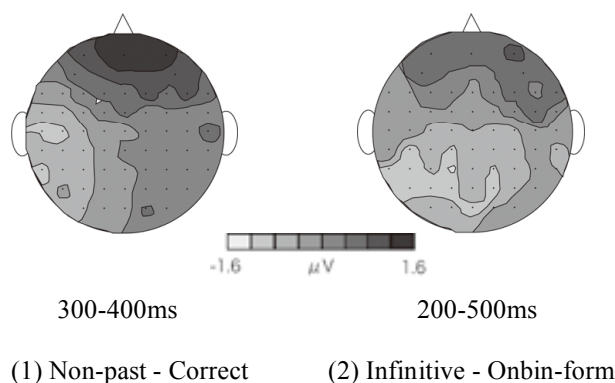

Figure 3. The topographical potential maps display the distribution of the negativities, (1) for the illicit non-past form as compared to the correct form and (2) for the illicit infinitive form as compared to the correct onbin form in the time window used for the statistical analysis. Lighter shading indicates more negative potential differences.

## Discussion

The above results are compatible with what our hypotheses predict: both conditions in negative conjugation errors elicited a P600, while a negative component was observed only in the non-past+*nai* condition, but not in the infinitive+*nai*. The onbin errors elicited an N400 component followed by a P600. We will discuss these results, focusing on what each component can be interpreted to reflect.

### Negative components

First, the negative component observed in negative conjugation errors (6c) and the one observed in onbin errors (7b) were clearly different in their distribution, and hence can be judged to be different components. Secondly, the negativity in negative conjugation errors was observed only for the non-past+*nai* condition, and not for the infinitive+*nai* condition.

The negativity elicited by the illicit infinitive form without onbin (7b), although not so robust in its amplitude, was judged to be an N400, given its distribution with centro-parietal focus and no hemispheric lateralization (Figure 3 (2)). This suggests that detecting this anomaly involved accessing of lexical memory. As has been discussed in the literature (e.g. Kutas and Federmeier 2000), difficulty in lexical access is one of the factors reflected in N400. Thus, this result is in accordance with our hypothesis that onbin does not involve computation by rule but the onbin forms for each verb root are memorized in the lexicon, hence application or non-application of onbin for a specific verb root with the past tense ending *-ta* must be checked against the lexicon.

The negativity elicited by the illicit non-past forms (6c) in comparison with the well-formed control (6a) has clearly different distribution from the N400 component, in that it was limited to the left hemisphere, as supported by the significant difference between the two hemispheres (Figure 3

(1)). Even though its distribution is also different from the classic LAN component in that its focus is in the temporal sites, it is similar in distribution to a left-lateralized negative component reported as a LAN by Rodriguez-Fornells et al. (2001) for Catalan overregularization of stem formation rule. Thus, it is not implausible to consider the negativity observed in our non-past condition as a LAN-like component. This component can be interpreted as reflecting the parser's detection of a phrase-structure violation of (6c), where the tense morpheme is placed below the Neg node. Thus the illicit non-past forms exhibited the biphasic pattern of the LAN-like negativity followed by a P600, which is in accordance with the literature reporting a LAN-P600 pattern for phrase structure violations (Friederici and Meyer 2004).

It is consistent with our prediction that there was a difference concerning negative components between the illicit infinitive forms (6b) and the illicit non-past forms (6c) in negative conjugation errors. It calls for some explanation, however, that a LAN-like component was not observed in (6b). In previous studies on morpho-syntactic anomalies, anterior negative components (LAN or AN) followed by a P600 are reported for agreement errors or case violations, which require syntactic computation of subject-verb or verb-object relation (e.g., Osterhout and Mobley 1995, Coulson et al. 1998). These errors are similar in nature to our non-past condition (6c). In contrast, our infinitive condition (6b) involves a purely morphological error, as mentioned above in "Stimuli and Predictions". Thus, even though our hypothesis holds that (6b) as well as (6c) involves rule-based computation, the violation in (6b) is, in a sense, much simpler, and hence it is conceivable that the cost of detecting the ill-formedness is too weak to elicit a statistically significant LAN-like component. In this vein, it is significant that the illicit infinitive forms did not elicit an N400 component, which supports our contention that the detection of the anomaly in (6b) does not involve lexical memory.

### Positive components

We observed late positive components, which can be judged to be a P600, in all the three illicit conditions (infinitive+*nai* (6b), non-past+*nai* (6c), and infinitive+*ta* (7b)) when compared to the well-formed counterparts. As discussed above, we contend that different mechanisms are involved in the processing of the negative conjugation and onbin forms. And yet, a P600 was observed across all three illicit conditions, which suggests that this component reflects the cost of dealing with conjugation errors, irrespective of their nature, namely, whether purely morphological (6b), morpho-syntactic (6c), or morpho-phonological (7b), and whether rule-based (6b,c) or memory-based (7b).

## Concluding Remarks

These findings taken together suggest the following points on the processing of Japanese verb conjugation. First, conjugation of Japanese roots with a specific vowel for each ending involves rule-based computation. On the other hand,

the morpho-phonological change (onbin) that takes place on the final consonant of some subclasses of the verb roots in the environment of certain ending forms such as past and continuative requires lexical memory. It can be thus concluded that Japanese verb conjugation involves two different mental mechanisms, rule-based computation and lexical memory, depending on the type of conjugation and particular set of endings. Hence our findings are consistent with the Dual Mechanism Model.

As mentioned in “ERP Components Related to Language Processing”, the ERP responses to regular/irregular inflection so far reported are rather varied, especially on negative components. While a LAN is observed for over-application of regular morphology in studies on English and German for instance (Morris and Holcomb 2005, Penke et al. 1997), it is also reported in Morris and Holcomb that the over-regularized irregulars (*bringed*) elicited an N400 when presented in a word-list format (in contrast to a LAN observed in a sentential context). Similarly, Gross et al. (1998) reports an N400-like negativity for overregularized Italian irregulars in a word-list format, where difference between stem-based inflection and affixal inflection is suggested to be relevant. In other words, a number of factors including methods of stimuli presentation and differences in inflectional systems between languages seem relevant, and hence more investigation is obviously needed. Our study has shown that different inflectional processes within one language can involve different mental mechanisms and thus induce different ERP components in the violation paradigm, indicating the importance of studying languages typologically different from European languages.

## Abstract

How do observers perceptually organize the events of individual agents when observing interactions among them? Do they readily perceive all events? Do they selectively perceive some events but not others? Do they see events overlooked by observers focusing on the individual agents? To explore these questions, participants viewed the Heider and Simmel (1944) animation, which shows three moving figures and elicits strong impressions of interacting agents. Participants in the default condition segmented the animation into meaningful events. Those in focus conditions did likewise, but focusing on one of the figures. Results indicate that participants in the default condition disregarded many events identified in the focus conditions, but identified only one event missed by focus-condition participants. These findings suggest that observers of interactions do not encode all events or gain additional insight by “seeing the big picture”; rather, they selectively perceive some events at the cost of overlooking others.

**Keywords:** Social perception; event segmentation; unit formation; perspective taking; movement cues; animation.

## Introduction

Much research has centered on how observers perceive and understand the actions of individual agents. In a typical experimental task, participants view an activity such as washing dishes and mark when, in their judgment, a meaningful event ends and another begins. These marked time points are referred to as *breakpoints*, and participants substantially agree about their placement (e.g., Zacks, Tversky, & Iyer, 2001). Breakpoint placement is not an arbitrary consequence of the segmentation task. Brain activity selectively occurs during mere observation at the same time points that participants identify as breakpoints during a subsequent segmentation task (Zacks, Swallow, Vettel, & McAvoy, 2006). These findings suggest that event segmentation reflects the perceptual structure of events.

Other research on how observers perceptually segment the events of animations of *multiple* interacting figures

finds that motion cues are strongly correlated with breakpoints (Hard, Tversky, & Lang, 2006). Indeed, simple computational models can use seven motion cues to identify agentic motives in animations of two moving figures with accuracy levels similar to those of human observers (Blythe, Todd, & Miller, 1999). Absolute and relational motion cues can be quite complicated in such stimuli, which sometimes have three figures moving in relation to one another and the background context. We wondered how human observers incorporate information from each agent when viewing stimuli of multiple agents interacting. In order to address this question, we had participants in a *default condition* segment into meaningful events a multiple-figure animation previously shown to elicit compelling perceptions of social interactions (Heider & Simmel, 1944). Other participants in *focus conditions* segmented the same animation but only for events meaningful for the figure specific to the condition. We compared participants’ segmentation patterns across conditions to test whether observers by default process all events relevant for all agents. Alternatively, perhaps by default observers systematically miss events that are important for some agents or notice events that would be overlooked when focusing on any one agent. We now consider evidence that suggests each of these is plausible.

Research in which participants segment perceived events for animations of moving figures suggests that movement features such as sudden acceleration elicit the perception of event boundaries (Hard, et al., 2006; Zacks, 2004). For such stimuli, participants even indicate breakpoints at similar time points when viewing multiple-agent animations both forward and backward, and these time points strongly correlate with objective movement features (Hard, et al., 2006). Such findings provide support for the notion that observers incorporate all movement cues when perceiving events, which we label the *objective movement hypothesis*. According to this hypothesis, observers perceive ongoing interactions in terms of all movement

cues from all figures. This would lead to the prediction that participants in the default condition should generate a segmentation that includes all, and no more, of the breakpoints identified across all focus conditions.

Zacks and Tversky (2001) note that for both event segmentation and object perception observers must organize parts into wholes. Heider (1958) suggested that an analogous process – unit formation – occurs during social perception wherein multiple agents, such as those interacting, are perceived as a perceptual unit. If observers perceptually group agents, the action of one agent (e.g., hitting) might be subsumed as a lower-level component of a larger schematic interaction (e.g., fighting), and thereby be disregarded. The *unit formation hypothesis* thus postulates that when observers parse ongoing events in terms of interactions they sometimes neglect agents' individual actions. This hypothesis predicts that participants in the default condition, when viewing a highly salient interaction, will sometimes miss events identified by participants in the focus conditions when the events pertain to a figure that *is part of* that interaction.

Heider (1958) also suggested that unit formation might result in observers attending to the interaction unit as the focal point of perception (the “figure”), with agents outside the interaction receiving little attention (the “ground”). The *distraction hypothesis* therefore postulates that observers attending to an interaction will sometimes fail to notice events meaningful to agents who are not part of the interaction. This hypothesis predicts that participants in the default condition, when viewing a highly salient interaction, will sometimes miss events identified in the focus conditions when the events pertain to a figure that *is not part of* that interaction.

Other research has shown that perspective-taking can interfere with an objective evaluation of events. For example, in one study people from each side of a conflict perceived a media report of an event as biased against their own side (Vallone, Ross, & Lepper, 1985). Similarly, fans of each team in an important football game, when viewing identical tapes of the game, reported events that diverged from each other (Hastorf & Cantril, 1954). This research is complemented by experiments suggesting that adults sometimes have difficulty taking another's perspective even though all of the relevant information is available to them (Keysar, Lin, & Barr, 2003). To our knowledge, perspective-taking has not been evaluated using animated figures. Nonetheless, we embody these ideas in the *perspective-taking hypothesis*, which postulates that focusing on the perspective of one figure interferes with the overall perception of events. It seems plausible that events noted by participants in the default condition but not in any focus condition could be the result of difficulty

participants experience as they attempt to focus on or take the perspective of one figure. This hypothesis predicts that events perceived by participants in the default condition sometimes will be missed by participants in all of the focus conditions.

## The Current Study

We designed a study to test these four hypotheses. In it participants segmented the Heider and Simmel animation (1944) into meaningful events. The animation shows a house-like rectangle and three moving figures: a large triangle, a small triangle, and a circle (*T*, *t*, & *c*). Observers tend to describe the animation as a bully attacking two innocent passersby (Heider & Simmel, 1944). By comparing the default segmentation with those provided for focal agents, we evaluate how observers normally view the animation: whether perception of the whole is equal to, greater than, or less than the sum of its parts.

## Method

**Participants** Participants were 74 female and 51 male American workers on Amazon Mechanical Turk, a crowdsourcing marketplace service, who received US\$ 0.90 for participating. Their mean age was 32.50 years (*SD* = 11.47).

**Stimulus Animations** For the experimental task we modified a version of the Heider and Simmel (1944) animation downloaded on 3 September 2010 from Carnegie Mellon University at [http://anthropomorphism.org/img/Heider\\_Flash.swf](http://anthropomorphism.org/img/Heider_Flash.swf). We increased its frames per second rate from 10 to 30 to make it smoother, keeping it 74 seconds long. For the practice task we created a Flash version of the hide-and-seek animation used in Hard, et al. (2006). It is 84 seconds long and depicts two squares and a circle moving as if they were playing hide and seek in their environment, which has wall-like lines. Both animations were prepared in Adobe Flash and were monochrome, 550 pixels wide by 400 pixels high, but viewed dimensions depended on participants' monitor displays.

**Design** Participants were randomly assigned to one of four conditions, which differed only in their segmentation instructions. In the *default condition* (*n* = 39) participants segmented the animation with no instructions to focus on any specific figure. Thus, their segmentations were potentially based on events for all of the figures. In each of the three focus conditions, the instructions were to segment the animation with a focus on the events for a specific figure, that is, for the big triangle (*n* = 30), the little triangle (*n* = 20), or the circle (*n* = 29).

**Procedure** Participants completed the study over the internet. They provided consent and demographic information and then read instructions indicating that (a) they would see two short animations depicting geometric figures in motion, (b) while watching the animation they should press the spacebar whenever one meaningful event ended and another began, and (c) they would briefly describe each animation after watching it. The instructions also displayed pictures of the figures. Participants then watched and concurrently segmented the practice animation (i.e., hide and seek). Once it ended, participants described what happened in each one-second interval bin for which they had pressed the spacebar. While providing descriptions, participants could review the animation but they could not add or remove markers. The instructions clarified that participants should try to provide their initial impression of the animation (at the time of the spacebar press). Once participants submitted descriptions for each marker, they could continue to the experimental task.

The procedure for the experimental task was the same as that for the practice task, except for different segmentation instructions in the focus conditions. All participants viewed the Heider and Simmel (1944) animation and instructions that indicated that the animation has three moving geometric figures, a large triangle, a small triangle, and a circle, with pictures of all figures. In the default condition, the segmentation instructions were the same as for the practice animation. The circle-focus condition included the following additional instructions: “However, this time do so only for the circle. That is, press the spacebar whenever, for the circle, a meaningful event ends and another begins.” Similar instructions were added to the focus conditions for the big triangle and the small triangle. A blue arrow also pointed at the picture of the focal figure. Participants segmented the animation according to their condition’s instructions, provided descriptions as in the practice task, logged their MTurk ID into the system, and were debriefed.

## Results

If a participant pressed the spacebar during a one-second bin we counted that bin as containing a breakpoint (for similar approaches see, e.g., Hard, et al., 2006; Massad, Hubbard, & Newtonson, 1979). Since only *T* is visible at the start and end of the experiment animation, all results exclude the first 4 and last 12 bins, leaving 58 bins for analysis. We also excluded the data of five participants who indicated one or zero breakpoints while doing the experimental task and that of two who indicated no breakpoints in the practice task.

**Overall Segmentation** We evaluated whether focusing on one figure affected the number of one-second bins participants marked as containing a breakpoint. The objective movement hypothesis predicts that the default

Figure 1. Proportions of participants who selected each one-second interval bin as containing a breakpoint in the default and *t*-focused conditions. The proportions for the *t*-focused condition are shown as negative to facilitate visual comparison.

condition should contain the breakpoints present in all three focus conditions. If this is the case, participants in the default condition should indicate more breakpoints than participants in the focus conditions (assuming segmentation patterns differed across focus conditions, and correlations shown below indicate they did). A one-way between-subjects ANOVA on the number of breakpoints did not indicate a difference across conditions ( $M = 8.96$ ,  $SD = 5.11$ ),  $F(3, 114) = 1.05$ ,  $p = .373$ ,  $\eta_p^2 = .03$ . This lack of a difference cannot be explained by a ceiling effect; participants on average indicated only 15.45% of bins as including breakpoints. Instead, these results suggest, counter to the objective movement hypothesis, that participants in the default condition did not segment based on the objective movements of all three figures. Rather, these results suggest that participants in the default condition may have neglected some events noticed in the focus conditions, consistent with the unit formation and distraction hypotheses. Because focus-condition participants may have noticed some events missed in the default condition, but missed others noticed in the default condition, these results provide no clear evidence regarding the perspective-taking hypothesis.

**Agreement about Event Timing** To gain further insight into how participants perceptually integrate information of individual agents when perceiving them interact, we compared across conditions which one-second interval bins participants tended to indicate as containing breakpoints. For these analyses, we calculated for each 58 one-second bin the proportion of participants in each condition who indicated that the bin contained a breakpoint. Figure 1 presents the segmentation histogram for the default condition and, for comparison, the *t*-focused condition. We correlated the segmentation histogram of the default

Table 1. Correlation coefficients across conditions among segmentation histograms (proportions of participants who indicated a breakpoint in each one-second bin).

Condition	Default	Big T.	Small T.	Circle
Default	1	.61*	.48*	.53*
Big T.	-	1	.41*	.22
Small T.	-	-	1	.38*

\*  $p < .01$ . Note: T. = triangle.

condition with that of each focus condition (see Table 1). All three Pearson correlation coefficients were positive and significant; however, all fell short of the lower bound of the 95% confidence interval of the estimated correlation coefficient for participants within the default condition (estimated using bootstrap aggregation, i.e., sampling 2000 groups of  $n = 20$  from the 39 default condition participants then calculating 58 bin means for each group and pairing groups to calculate 1000 correlation coefficients across bins; mean  $r = .78$ , median  $r = .79$ , 95% CI: .62, .90). This range was estimated to specify the approximate optimal correlation that we could expect between the default histogram and that of any other condition. The finding that the focus condition histograms were less than optimally correlated with the default condition histogram suggests that our manipulation was successful in that participants in the focus conditions were not simply responding to events involving any figure, but instead when focusing on one figure they perceived events differently.

The differences in magnitude across the three correlation coefficients were not significant (maximum  $z = 1.14$ ,  $p = .254$ , using the method suggested by Meng, Rosenthal, & Rubin, 1992), but their relative magnitudes suggest that default-condition participants' segmentation may have been influenced most by  $T$ , then  $c$ , and the least by  $t$ . To further evaluate this possibility, we did a multiple regression analysis wherein we predicted the segmentation histogram from the default condition by the segmentation histograms from all three focus conditions. The results suggest that  $T$  provided a large unique contribution to the perception of the animation,  $b = .47$ ,  $p < .001$ , 95% CI = .27, .67,  $c$  had a medium sized unique contribution,  $b = .31$ ,  $p < .001$ , 95% CI = .15, .47, but  $t$  did not contribute any information above and beyond that provided by  $T$  and  $c$ ,  $b = .16$ ,  $p = .194$ , 95% CI = -.08, .40 (the intercept did not differ significantly from zero,  $b = -.01$ ,  $p = .746$ , 95% CI = -.05, .04). This regression's multiple correlation coefficient (multiple- $R = .74$ ,  $F(3,57) = 22.10$ ,  $p < .001$ ) fell within the 95% CI for the estimated correlation coefficient within the default condition, suggesting that this regression performed near optimally. This suggests that participants in the focus conditions indicated many if not most of the breakpoints identified in the default condition; that is, these analyses provided no support for the prediction of the perspective-

Figure 2. Mean (+/- SE) number of times each participant mentioned the figures, by condition.

taking hypothesis that events would be missed if focusing on a specific figure. We note that exploratory regression analyses including all two-way interactions and the three-way interaction indicated no additional significant predictors,  $ps > .226$ .

**Analyses of Breakpoint Descriptions** We coded which figures participants mentioned in their breakpoint descriptions. As Figure 2 shows, participants in the focus conditions mentioned their focal figure significantly more than participants in any other condition, minimum  $F(3,114) > 10.84$ ,  $p < .001$ ,  $\eta_p^2 = .22$ . This suggests that our manipulation was successful. Participants in the default condition did not mention the three figures an equal number of times,  $F(2, 76) = 8.32$ ,  $p = .001$ ,  $\eta_p^2 = .18$ . Uncorrected post hoc tests indicated that default-condition participants mentioned  $T$  more than  $t$ ,  $t(38) = 5.86$ ,  $p < .001$ ; they mentioned  $T$  marginally more than  $c$ ,  $t(38) = 2.02$ ,  $p = .051$ ; but they mentioned  $c$  and  $t$  about equally,  $t(38) = 0.16$ ,  $p = .124$ . These findings suggest that  $T$  was the most salient figure for the default-condition participants.

**Disagreement across Conditions** We also calculated for each bin a difference score equal to the proportion of participants in the default condition identifying the bin as containing a breakpoint minus the maximum such proportion among the three focus conditions (see Figure 3). Most strikingly, nearly all difference scores were negative. Indeed, a binomial test ( $p = .005$ ) indicated fewer positive scores than expected by chance given a .25 probability that each of the four conditions would have the largest proportion. Our earlier analysis indicated no significant difference in the number of breakpoints across conditions, whereas the current finding indicates that, when comparing bin-by-bin, for almost all bins participants in one of the focus conditions were more likely to indicate a breakpoint

Figure 3. Difference in proportion in the number of participants indicating a breakpoint for each one-second interval bin in the default condition with the maximum proportion doing so from any of the focus conditions.

than participants in the default condition. This suggests that for observers in the default condition some events had reduced salience as compared to observers who focused on a particular figure, consistent with the unit formation and distraction hypotheses. By contrast, almost all events that are salient in the default condition remain so in the focus condition for at least one of the figures, contradicting the perspective-taking hypothesis. Indeed, setting a .2 difference in proportions as a cutoff to identify clear-cut differences in event salience, only one bin has a more salient event in the default condition as compared to any of the focus conditions. By contrast, 15 bins had events that were more salient in at least one of the focus conditions as compared to the default condition (see Table 2). Corroborating our previous findings that for default-condition participants the figures were of unequal salience, the three figures were not equally likely to be part of a reduced-salience event: *T* was in 3 such events, *c* in 5, and *t* in 8, multinomial test,  $p = .017$ .

Why did these 15 events have reduced salience for participants in the default condition? To determine the likely source of the reduced salience for each of these events we examined which figures were mentioned in participants' event descriptions across conditions. For convenience, we use the term "overlooked figure" to refer to the figure whose event had reduced salience in the default condition. Let us first consider which figures are mentioned in descriptions from the focus condition for the overlooked figure. If they predominantly mentioned the overlooked figure and one other figure, this suggests that the overlooked figure appeared to interact with the other figure and therefore that the reduced salience was due to unit formation. If these descriptions instead predominantly mentioned only the overlooked figure, but descriptions from the other focus conditions did not mention the overlooked figure but did mention the other two figures, this suggests that the other figures had a salient interaction that distracted default participants from noticing the

Table 2. Reduced-salience events, that is, events for which the discrepancy in the proportion of participants who indicated a breakpoint was greater by at least .2 in any focus condition (boldface) as compared to the default condition. The table reports the proportions by condition, the coded explanation for the difference (source: dist. = distraction, unit. = unit formation), and the ongoing overall event.

Bin	Proportion P. by condition				Source	Ongoing overall event

Note: Def. = Default condition

overlooked figure. However, if descriptions from the focus condition for the overlooked figure predominantly mentioned the overlooked figure, but the other conditions had very few descriptions, we looked to recent bins for clarification. If descriptions from recent bins across conditions suggested a two-figure interaction, we coded the reduced salience as due to unit formation if the overlooked figure was part of that interaction or as due to distraction otherwise. Finally, two reduced-salience events had characteristics suggesting both unit formation and distraction. That is, descriptions from the default condition and the focus condition for the overlooked figure predominantly mentioned the overlooked figure and one other figure, suggesting the overlooked figure was interacting with the other figure and was thereby perceived as a unit with it. On the other hand, descriptions from the other two focus conditions predominantly mentioned both the other two figures but not the overlooked figure, suggesting their interaction distracted default condition participants from seeing the overlooked figure. Using these criteria, from 58 bins we clearly associated 7 with unit formation, 6 with distraction, and 2 with characteristics of both. These findings provide fairly direct support for the unit formation hypothesis and the distraction hypothesis.

## General Discussion

We investigated how observers perceptually organize the events that are meaningful for individual agents while observing them interacting with one another. Our results support the notion that observers selectively perceive some events and not others. Moreover, our results suggest that this sometimes occurs because observers link individual agents into larger perceptual units with the consequence that the salience of events at the unit-level sometimes dominates the salience of events for agents within the unit. At other times observers appear to have missed events important for one agent because their attention was focused on more salient interactions between other agents. These findings provide some empirical support for Heider's (1958) idea of unit formation. They also replicate the findings of Massad, et al. (1979) that observers selectively perceive some events and disregard others, although in their study selective perception resulted from pre-information about what would happen in the Heider and Simmel animation. Previous research has noted the importance of movement features for event segmentation, but our findings suggest that observers do not normally perceive interaction events in terms of all movement features for all agents. This finding suggests a caveat to the idea that observers use all motion information. Future research will be required to more fully determine when and why observers fail to incorporate some motion features. Our results suggest that participants were able to focus on one figure as instructed, and that doing so resulted in little difficulty due to perspective-taking. Indeed, to the extent to which participants in the focus conditions engaged in perspective-taking, our findings suggest this is not always a difficult process (cf. Keysar, et al., 2003), but can occur in a rather effortless fashion. In fact, the results indicate a greater cost, in terms of missed events, of engaging in the default rather than an agent-focused perspective.

The current study compared how observers segment events when focusing holistically on all agents to how they do so when focusing on individual agents. A future study could more completely separate information regarding single agents from the whole by removing all other figures from the animation, leaving a single, isolated figure. We could then compare segmentations of the animated solo figures with those of default and focus conditions. This would allow us to evaluate the relative importance for perceptual segmentation of context-free movement cues versus relational movement cues. Such a comparison might provide a more direct test of the unit formation hypothesis (Heider, 1958). We also note that participants in the default condition may have perceived events that they failed to report, but why they would do so more than participants in the focus conditions is unclear. We leave such problems

and further questions about the perception of interactions to future research.

## Acknowledgments

We thank Barbara Tversky and Bridgette Hard for providing their hide and seek animation. We thank Barbara Tversky and three anonymous reviewers for insightful comments on earlier drafts of this paper. We also thank Swati Gupta and William Chandra Tjhi for assistance with statistical analyses.

## Abstract

Intentional harms are typically judged to be less forgivable than accidental harms. This difference depends on mental state reasoning (i.e., reasoning about beliefs and intentions), supported by a group of brain regions, the ‘theory of mind’ network. Prior research has found that (i) interfering with activity in this network can shift moral judgments away from reliance on mental state information, and (ii) high-functioning individuals with Autism Spectrum Disorder (ASD) rely significantly less on mental state information to make moral judgments than matched neurotypical (NT) participants. Across three experiments, we find using multi-voxel pattern analysis (MVPA) that, in NT adults, (i) one key region of the ToM network, the RTPJ, shows reliable and distinct spatial patterns of responses across voxels for intentional versus accidental harms, and (ii) individual differences in this neural pattern predict individual differences in moral judgment. By contrast, (iii) in ASD adults, the difference between intentional and accidental harms is not encoded in the voxel-wise pattern in the RTPJ or any other region, and (iv) higher symptom severity scores are predictive of diminished pattern discriminability. We conclude that MVPA can detect features of mental state representations and that these features are behaviorally and clinically relevant.

**Keywords:** morality, harms, theory of mind, autism, fMRI, multivoxel pattern analysis (MVPA)

## Introduction

Intentional harms are usually judged to be morally worse than the same harms caused by accident (Cushman, 2008; Knobe, 2005; Malle & Knobe, 1997; Piaget, 1965; Singer et al, 2004; Young & Saxe, 2011). The capacity to distinguish between intentional and accidental harms depends on the capacity to represent another person’s mental states, a cognitive function associated with a specific and selective group of brain regions (the ‘theory of mind network’). Prior research has revealed that moral judgments of harmful actions depend on one region in particular, the right temporo-parietal junction (RTPJ). For example, individual differences in moral judgments of accidental harms are correlated with RTPJ activity (Young & Saxe, 2009), and disrupting RTPJ activity interferes with these judgments (Young et al, 2010).

Recent evidence suggests that moral judgments may provide a sensitive measure of enduring impairments in ToM in high-functioning individuals with Autism Spectrum Disorders (ASD). Children with ASD are disproportionately impaired on tasks that require them to consider the beliefs and intentions of other people (Peterson et al, 2005; Baron-Cohen, 1995). Although children with ASD distinguish between moral and conventional transgressions (Blair et al, 1996), and between good actions and bad actions (Leslie et al, 2006), they are delayed in using information about innocent

intentions to forgive accidents (Grant et al, 2005). In a recent study, Moran et al. (2011) found that high-functioning adults with ASD show the same pattern, delivering less forgiveness and more blame for accidents than neurotypical (NT) adults.

These findings suggest that the RTPJ should encode the difference between accidental and intentional harm. Puzzlingly, however, we find that the average mean signal – a standard way of measuring neural involvement in a task – in RTPJ and the other theory of mind regions is not different for intentional versus accidental harmful actions in NT participants. One possibility is that this key dimension can be detected, not in the magnitude of response across a brain region, but in the pattern of responses across voxels.

A complementary approach to traditional neuroimaging analyses (which rely on average response magnitude) is to look at the pattern of activity across voxels within a region, using a technique called multi-voxel pattern analysis. If a different tasks, stimulus categories, or stimulus features are processed by (partially) different subpopulations of neurons within a brain region, the difference may not be detectable in the region’s average response, but may nevertheless produce systematic and distinct patterns of activity across neighboring voxels within the region (Normal et al, 2006; Haynes et al, 2006; Kriegeskorte & Bandetti, 2007). A key advantage of this technique is that these patterns can be used to ‘decode’ information from the neural response not otherwise detectable in the overall magnitude (e.g., object category in ventral temporal regions, Haxby et al 2001). Thus MVPA can reveal how stimulus categories are processed within a functional region (Peelen et al, 2006; Haynes & Rees, 2006).

Given the importance of intentions for moral judgments of accidental and intentional harms, we predicted that one or more brain regions in the ToM network would explicitly encode this feature of others’ mental states, in neurotypical (NT) adults. That is, we predicted that (i) while participants read about a wide range of harmful acts, we would be able to decode whether the described harm was intentional or accidental based on the spatial pattern of activity within ToM brain regions. We tested this prediction in three experiments. We also investigated (ii) whether the robustness of the spatial pattern information within individuals would predict those individuals’ moral judgments, and (iii) whether high-functioning adults with ASD, who make atypical moral judgments of accidental harms, would show correspondingly atypical patterns of neural activity.

## Methods

### Participants

**Experiment 1:** Sixteen right-handed members of the MIT community (aged 18-50, 7 women). **Experiment 2:** Eighteen

right-handed college undergraduate students (aged 18-25 years, 8 women). **Experiment 3:** Fourteen right-handed college undergraduate students (aged 18-25 years, 8 women).

**Experiment 4:** Twelve individuals diagnosed with Autism Spectrum Disorder (aged 25-43 years, 2 women). Participants were recruited via advertisements placed with the Asperger's Association of New England. All participants were prescreened using the Autism Quotient questionnaire (AQ; Baron-Cohen et al., 2001). ASD participants then underwent both the Autism Diagnostic Observation Schedule (ADOS) (Lord et al 2000, 2002) and impression by a clinician trained in both ADOS administration and diagnosis of ASD. All ASD participants received a diagnosis of an Autism Spectrum Disorder based on their social ADOS score ( $6.2 \pm 0.6$ ), communication ADOS score ( $3.5 \pm 0.4$ ), and total ADOS score ( $9.6 \pm 0.8$ ) and on clinical impression based upon the diagnostic criteria of the DSM-IV (APA, 2000). The matched NT (Exp. 1) and ASD (Exp. 4) groups did not differ in age (NT (mean  $\pm$  SEM)= $27.1 \pm 2.3$ ; ASD= $31.8 \pm 2.1$ ;  $t(28)=1.4$ ,  $p > 0.17$ ) or IQ [NT:  $118.1 \pm 2.8$ ; ASD:  $121.0 \pm 3.8$ ;  $t(27)=0.60$ ,  $p > 0.55$ ]. No participant had higher language than social scores, suggesting no specific language deficits.

All participants participated for payment, were native English speakers, had normal or corrected-to-normal vision and gave written informed consent in accordance with the requirements of Institutional Review Board at MIT. Data from Experiments 2 and 3 have previously been published, analyzing the magnitude but not the pattern of response in each region, in Young et al. (2008) and Young & Saxe (2009).

### fMRI Protocol and Task

**Experiment 1 & 4:** Participants were scanned while reading 60 stories: 12 intentional harm violations, 12 accidental harm violations, 24 stories with other types of moral violations, and 12 neutral scenarios. Stories were presented in the second person, using present tense, and displayed in four cumulative segments: 1. Background (6s), 2. Action (4s), 3. Outcome (4s), 4. Intent: Good (Accidental Harm) or Bad (Intentional Harm) (4s). In the scanner, after each story, participants made moral judgments of the action from "not at all morally wrong" (1) to "very morally wrong" (4), using a button press. For example stimuli, see [http://mit.edu/jorie/www/CogSci2012/Koster-Hale\\_CogSci2012\\_supp.pdf](http://mit.edu/jorie/www/CogSci2012/Koster-Hale_CogSci2012_supp.pdf).

Stories were presented in a pseudorandom order; condition order was counterbalanced across runs and subjects, and no condition was immediately repeated. Participants never saw both intentional and accidental versions of the same scenario. Word count was matched across conditions. Ten stories were presented in each 5.5 min run; the total experiment, six runs, lasted 33.2 min. Rest blocks of 10 s were interleaved between each story. Stories were projected onto a screen via Matlab 5.0 running on an Apple MacBook Pro in 40-point white font.

**Experiments 2 & 3:** Participants were scanned while reading 48 stories. Experiment 2 included 12 intentional harms, 12 accidental harms, and 24 non-harm stories. All harms were physical harms, resulting in someone's death. Stories were presented in cumulative segments: 1. Background (6s) 2.

Foreshadow (6s, only in Experiment 2), 3. Intent: Good (Accidental Harm) or Bad (Intentional Harm) (6 s), 4. Outcome (6s). Half of the stories in each run were presented with foreshadow before intent; the order was reversed in the other half. After each story, participants made moral judgments of the action on a 3-point scale, from "forbidden" (1) to "permissible" (3), using a button press.

Experiment 3 included 8 intentional harms, 8 accidental harms, and 32 other non-harm stories. Participants delivered a non-moral judgment, answering a true/false question about the content of the final sentence.

Stories were counter balanced and matched as in Experiment 1. Rest blocks of 14 s were interleaved between each story. Stories were projected onto a screen via Matlab 5.0 running on an Apple G4 laptop in 24-point white font.

**Theory of Mind Localizer task:** In all four experiments, participants also saw 4 runs of a theory of mind localizer task, contrasting stories requiring inferences about mental state representations (e.g., thoughts, beliefs) versus physical representations (e.g., maps, signs, photographs), which are similar in their meta-representational and logical complexity but differ in whether the reader is building a representation of someone else's mental state. See Saxe & Kanwisher (2003) and Dodell-Feder et al (2010) for further discussion; stimuli and presentation from Saxe & Kanwisher 2003, Exp. 2.

### Acquisition and Preprocessing

fMRI data were collected in a 3T Siemens scanner at the Athinoula A. Martinos Imaging Center at the McGovern Institute for Brain Research at MIT, using a 12-channel head coil. Using standard echoplanar imaging procedures, we acquired blood oxygen level dependent (BOLD) data in 26 near axial slices using  $3 \times 3 \times 4$  mm voxels (TR=2 s, TE=40 ms, flip angle=90°). To allow for steady state magnetization, the first 4 seconds of each run were excluded.

Data processing and analysis were performed using SPM8 (Experiments 1 & 4) and SPM2 (Experiments 2 & 3) and custom software. The data were motion corrected, realigned, normalized onto a common brain space (MNI template), spatially smoothed using a Gaussian filter (FWHM 5 mm kernel) and subjected to a high-pass filter (128 Hz).

### fMRI Analysis

All fMRI data were modeled using a boxcar regressor, convolved with a standard hemodynamic response function (HRF). The general linear model was used to analyze the BOLD data from each subject, as a function of condition. The model included nuisance covariates for run effects, global mean signal, and an intercept term. A slow event-related design was used. An event was defined as a single story, the event onset was defined by the onset of text on screen, and offset as the end of the story presentation.

**Functional Localizer: Individual ROIs** Based on prior research, functional regions of interest (ROIs) were defined in right and left temporo-parietal junction (RTPJ, LTPJ), medial precuneus (PC), and dorsal medial prefrontal cortex (DMPFC), for each participant. Using a pre-defined

hypothesis space for each ROI, each subject's contrast image (Belief > Photo) was masked and the peak voxel that occurred in a cluster of 10 or more voxels significant at  $p < 0.001$  was selected. All voxels contiguous with the peak voxel, individually significant at  $p < 0.001$ , within a 9mm radius, were defined as the ROI.

**Group ROIs:** To compare NT participants from Experiment 1 and ASD participants from Experiment 4, we also identified independent group-level ROIs, using data from a previous set of theory of mind localizers ( $n=477$  NT participants, 260 women). Pattern analyses for both groups were then conducted within these group ROIs. Selecting the same voxels across participants and group ensured that any differences found between the NT and ASD group are due to differences in the pattern itself, rather than any differences in the ROI selection method, across populations.

**Within-ROI Magnitude Analysis:** We measured the response to each condition in each ROI. The percent signal change (PSC) relative to baseline was calculated for each time point in each condition, averaging across all voxels in the ROI and across all blocks in the condition, where  $PSC(t) = 100 \times (\text{average BOLD magnitude for condition } (t) - \text{average BOLD magnitude for fixation}) / \text{average BOLD magnitude for fixation}$ . We averaged the PSC across the entire presentation – offset 6s from presentation time to account for hemodynamic lag – to get a single PSC for each condition, in each ROI, in each participant (Poldrack, 2006).

**Within-ROI Pattern Analysis:** In all experiments, we conducted within-ROI pattern analyses. Following Haxby et al. (2001), each participant's data were divided into even and odd runs ('partitions') and then the mean response (beta value) of every voxel in the ROI was calculated for each condition. The "pattern" of response was the vector of beta values across voxels within the ROI. To determine the within-condition correlation, the pattern in one (e.g., even) partition was compared to the pattern for the same condition in the opposite (e.g., odd) partition; to determine the across-condition correlations the pattern was compared to the opposite condition, across partitions.

For each individual, an index of classification was calculated for each condition pair as the z-scored within-condition correlation minus the z-scored across-condition correlation. A region successfully classified a category of stimuli if, across individuals, the within-condition correlation was higher than the across-condition correlation, using a Student's T complementary cumulative distribution function.

## Results

### Localizer

Replicating many studies using a similar functional localizer task (e.g., Saxe & Kanwisher, 2003), we localized four theory of mind brain regions showing greater activation for false belief stories compared to false photograph stories in the majority of participants (uncorrected,  $p < 0.001$ ,  $k > 10$ ): **Exp 1-3 (NT):** RTPJ 46/48, LTPJ, 44/48, PC 47/48, DMPFC

41/68; **Exp 4 (ASD):** RTPJ (12/12 participants), LTPJ (12/12), PC (11/12) and DMPFC (5/12).

### Behavioral Results

**Experiment 1:** Participants judged intentional harms ( $3.31 \pm 0.10$ ) to be worse than accidental harms ( $1.62 \pm 0.11$ ;  $t(14) = 15.1$ ,  $p < 0.0001$ ), both of which were judged to be worse than neutral stories ( $1.03 \pm .02$ ,  $t(14) = 18.1$ ,  $p < 0.001$ ).

**Experiment 2:** Replicating the results in Experiment 1, participants judged intentional harms ( $2.9 \pm .03$ ) to be worse than accidental harms ( $1.9 \pm .11$ ;  $t(12) = 8.24$ ,  $p < 0.0001$ ).

**Experiment 4:** Behavioral data were available for only 7 participants with ASD (remaining data were lost due to a coding error and due to theft of experimental equipment). When making moral judgments, ASD participants, like NT participants from Experiment 1, ASD participants judged intentional harms ( $3.5 \pm 0.12$ ) to be worse than accidental harms ( $1.85 \pm 0.21$ ;  $t(6) = 8.9$ ;  $p < 0.0001$ ), both of which were judged to be worse than neutral stories ( $1.09 \pm .04$ ;  $t(6) = 13.9$ ;  $p < 0.0001$ ).

**Group Comparison:** A mixed effects ANOVA crossing Group (NT in Exp 1, ASD in Exp 4) by Condition (neutral, accidental, intentional) yielded a main effect of condition and no interaction ( $F(2,36) = 284.4$ ,  $p < 0.0001$ ). Post-hoc t-tests revealed that ASD adults assign more blame for accidental harms than NT adults ( $t(19) = 1.7$ ,  $p < 0.05$ ), but there was no difference between NT and ASD judgments of intentional harms (Moran et al., 2011).

### fMRI - Magnitude Analysis

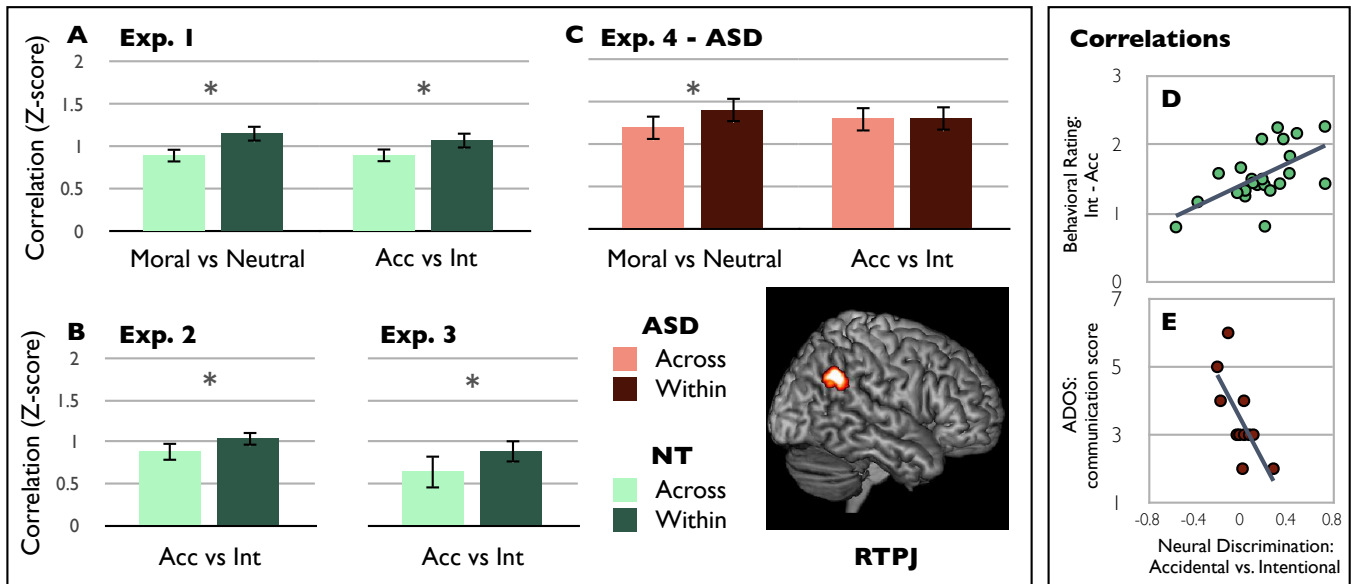

**Experiment 1-4** In all three experiments with NT adults, and in the final experiment with ASD adults, all four ROIs (RTPJ, LTPJ, PC, DMPFC) showed a higher BOLD response for moral violations than for neutral acts. However, none of the regions showed a significant difference between accidental and intentional harms (all  $p > .2$ ).

### fMRI - Pattern Analysis

**Experiment 1 Moral vs. Neutral:** Multi-voxel pattern analyses revealed reliably distinct patterns of neural activity for moral violations versus neutral acts in all four ROIs: RTPJ, LTPJ, PC, DMPFC. The pattern generated by stories within a category (moral or neutral) were more correlated with other stories in the same category compared to stories in the opposite category (RTPJ: across condition correlation = 0.90 (.1), within condition correlation = 1.16(.1),  $t(15) = 2.6$ ,  $p = 0.02$ ; LTPJ: across = 1.5(.07), within = 1.6(.06),  $t(14) = 2.3$ ,  $p = 0.019$ ; PC: across = 0.86(0.13) within = 1.2(0.12),  $t(14) = 3.1$ ,  $p = 0.005$ ; DMPFC: across = 1.1(0.13), within = 1.2(0.11),  $t(12) = 1.9$ ,  $p = 0.04$ ). Group ROIs yielded the same results.

**Accidental vs. Intentional:** In only the RTPJ, the pattern of response distinguished between accidental and intentional harms (across condition correlation = 0.91(.1), within condition correlation = 1.08(.11),  $t(15) = 2.6$ ,  $p = 0.01$ ). No other regions showed distinct patterns of response to intentional versus accidental harms (all correlation differences  $< 0.1$ , all  $p > 0.1$ ). Group ROIs yielded the same results, (**Figure 1-A**).

**Figure 1:** (A) MVPA results from Experiment 1: neurotypical adults ( $n=16$ ) show pattern discrimination for moral vs. neutral actions, and for accidental vs. intentional harms in RTPJ, (B) a finding replicated across Experiments 2 and 3 ( $n=18,14$ ). (C) Adults with ASD ( $n=12$ ) show neutral discrimination of moral vs. neutral actions in RTPJ, but not of intentional vs. accidental harms. (D) Individual differences in pattern classification predict individual differences in behavior in NT adults ( $n=23$ ). (E) In ASD adults ( $n=12$ ), symptom severity is negatively correlated with neural discrimination of accidental and intentional harms.

**Experiments 2 & 3:** Experiments 2 and 3 replicate Experiment 1. In RTPJ, but no other region, MVPA analyses revealed that accidental harm and intentional harm elicited reliably distinct neural patterns (Exp 2 RTPJ: across condition correlation=0.76(.13), within=1.1(.11),  $t(15)=2.6$ ,  $p=0.01$ ; Exp 3 RTPJ: across=0.65(.21), within=0.89(.14),  $t(13)=1.8$ ,  $p=0.04$ ; all other regions: correlation differences  $<0.1$ ,  $p>0.1$ ).

**Combining Experiments 1, 2, & 3:** Pooling the data across all three experiments allowed us to increase our power to detect results in neural regions beyond RTPJ. Again, MVPA analyses revealed distinct neural patterns for accidental and intentional harms in RTPJ (RTPJ: across=0.78(0.09), within=1.0(0.08),  $t(45)=3.9$ ,  $p=0.0002$ ) and no other region (all differences  $<0.1$ ,  $p>0.1$ , Figure 2); repeated measures ANOVAs crossing Region by Pattern yielded a significant interaction between RTPJ and each of the three other regions (all  $F > 8$ , all  $p < 0.007$ ), and no interactions between any of the other regions (however, see Smith et al., 2011 for caution in interpreting differences in discriminability across regions).

**Behavioral and Neural Correlation:** In Experiments 1 and 2, NT participants provided moral judgments of each scenario in the scanner, allowing us to determine whether behavioral responses were related to the spatial pattern of the neural response in RTPJ or any other region. For each participant, we calculated the difference between moral judgments for intentional versus accidental harms. We tested whether this difference score was correlated, across participants, with the index of classification in each region (intentional vs. accidental, within-condition correlation minus across-condition correlation). In both experiments we found that only in the RTPJ the difference between intentional and accidental harms in individuals' moral judgments correlated

with the neural classification index (Exp 1:  $r^2(12)=0.38$ ;  $p=0.03$ ; Exp 2:  $r^2(11)=0.40$ ;  $p=0.03$ ). The correlation was also significant after combining the data from both experiments ( $r^2(23)=0.35$ ,  $p=0.003$ ; **Figure 1-D**).

**Experiment 4 (ASD) Moral vs. Neutral:** As in NT controls, pattern analyses revealed a separation in the pattern of response for moral violations and neutral scenarios in ASD adults. Using individual ROIs, significant discrimination was found in RTPJ and LTPJ (RTPJ: across=1.2(0.18), within=1.4(0.16),  $t(11)=3.2$ ,  $p=0.005$ ; LTPJ: across=1.3(0.12), within=1.5(0.11),  $t(11)=2.3$ ,  $p=0.02$ ; see Figure 1); there was a trend in the same direction in the PC. DMPFC was found in only 5 of 12 individuals so we did not have sufficient power to test for pattern discriminability. However, using group ROIs, we found significant discrimination in DMPFC as well (across=1(0.12), within=1.2(0.10),  $t(11)=3$ ,  $p=0.007$ ).

**Accidental vs. Intentional:** Pattern analysis within both group and individual ROIs revealed no pattern discrimination between accidental and intentional harms in any ToM region, in participants with ASD (all differences  $<0.1$ ,  $p>0.1$ ).

**Group Comparison Moral vs. Neutral:** A Group (ASD, NT)  $\times$  Pattern (within, across) ANOVA revealed that NT and ASD participants show equally robust neural discrimination in response to moral violations versus neutral actions in their RTPJ, with a main effect of Pattern ( $F(2,51)=12.4$ ,  $p=.002$ ), no effect of Group ( $F(1,51)=1.07$ ,  $p=.3$ ), and no interaction ( $F(2,51)=.13$ ,  $p=.7$ ).

**Accidental vs. Intentional:** In contrast, NT participants discriminated between accidental and intentional harms to a greater extent than ASD participants, reflected in a significant

Group x Pattern interaction ( $F(2,51) = 5.1, p = .03$ ), and no main effects (**Figure 1-C**).

**Symptom Severity and Neural Correlation:** In ASD participants, we found no significant correlation between neural pattern and behavior in any region. However, we found, in RTPJ and no other region, a significant inverse correlation with symptom severity: individuals with higher ADOS (Lord et al, 2000, 2002) scores showed less neural discriminability between intentional and accidental harms ( $r^2(12)=0.51, p=0.01$ , **Figure 1-E**). No symptom severity score correlated with moral versus neutral discrimination.

## Discussion and Conclusion

### Moral Judgments: Neurotypical adults

A central aim of this study was to ask whether the difference between accidental and intentional harms could be decoded from the pattern of response within theory of mind brain regions. Across three experiments with neurotypical (NT) adults, using different stimuli, paradigms, and participants, we found converging results: stories about intentional versus accidental harms elicited spatially distinct patterns of response within the right temporo-parietal junction (RTPJ). Moreover, this neural response mirrored behavioral judgments: individuals who showed more distinct patterns in the RTPJ also made a larger distinction between intentional and accidental harms in their moral judgments.

The convergence across experiments provides strong evidence that intentional and accidental harms can be discriminated, using MVPA, in RTPJ. Designed to test a series of separate questions, the three experiments differed in the story content, voice of the narrative (2nd or 3rd person), the order of information provided, the length of the stories, the number of stories per condition, and the participants' explicit task. Perhaps most importantly, the information indicating that the harmful action was accidental or intentional was provided by different cues. In Experiment 1, the same mental state content (e.g., your cousin's allergy to peanuts) was described as known or unknown (e.g., "you had no idea" vs. "you definitely knew"). By contrast, in Experiments 2 and 3, sentences with the same syntax and mental state verbs were used to describe beliefs with different content (e.g., "Steve believes the ground beef is safe / rotten"). Nevertheless, the spatial pattern of response was reliable and distinct for intentional versus accidental harms, and only in the right TPJ. The generalizability of the pattern discriminability indicates that, rather than being driven by specific stimulus features or task demands, the discriminable neural patterns reflect an underlying distinction in the representation of accidental and intentional harms.

In Experiments 1 and 2, participants made moral judgments in the scanner. In both experiments, individuals differed in the amount of blame they assign to accidental harm, some weighing intent more strongly (and thus were more forgiving) and some weighing outcome more strongly (and thus were more condemning), (Young & Saxe, 2009). These individual differences in moral judgment were predicted by individual

differences in pattern discriminability in the RTPJ. While Experiment 1 used a blameworthiness scale ("How much blame should you get?") and Experiment 2 used a permissibility scale ("How permissible was Steve's action?"), we found the same result in both studies: individuals who showed more sensitivity to the dimension of intent in their neural pattern – those who processed accidental and intentional harms most differently in their RTPJ – were also those who showed the most forgiveness to characters who accidentally harmed someone.

As in prior work, the average magnitude of RTPJ response did not distinguish between intentional and accidental harms. This observation fits in a larger pattern emerging in the literature: while the RTPJ is selective for the cognitive process of mental state reasoning – and not, for example, generic attentional processes (Scholz et al., 2008; Young et al., 2010b; see also Decety and Lamm, 2007) – the average RTPJ response is unaffected by changes in the specific features of mental states, such as whether beliefs are true or false (Jenkins and Mitchell, 2009; Young, et al, 2010b), justified or unjustified (Young et al., 2010c), positively or negatively valenced (Kliemann et al., 2008), plausible or crazy (Young et al., 2010b), "constrained" or "open-ended" (Jenkins and Mitchell, 2009), attributed to friends or enemies (Bruneau & Saxe in press), or first-order or higher-order (Koster-Hale & Saxe, 2011).

These findings left open the question of whether and how the RTPJ or any other neural substrate encoded specific mental state features, like the dimension of intent. A key contribution of the current study then is to reveal that the dimension of intent is encoded in the voxel-wise pattern of the RTPJ, and specifically for the evaluation of harm.

### Moral Judgments: ASD adults

A group of high functioning adults with Autism Spectrum Disorders showed a different response profile: the response of the RTPJ showed a reliable spatial pattern of response across moral stories, compared to neutral stories, but did not distinguish between intentional and accidental harms. Moreover, we found that symptom severity on the ADOS was predictive of decreased neural discrimination in RTPJ: those individuals with more severe diagnoses showed a less distinct neural response to accidental and intentional harms. Thus, the neural pattern mirrored the behavioral performance previously observed in participants with ASD (Moran et al 2011): compared to NT controls, participants with ASD judged accidental and intentional harms to be more similar in moral permissibility (though note that, in the current sample, the group by condition interaction was not replicated, likely due to lack of power).

One possible mechanism of reduced pattern information in ASD might be more noisy or heterogeneous neural responses. However, both the strong discrimination between moral violations and neutral stories, and the high overall pattern correlations speak against this alternative. Rather ASD participants seem to show a less sensitive neural response: accidental and intentional harms appear to be processed by the same neural sub-populations within the RTPJ.

Multivoxel pattern analysis may therefore be a successful way of measuring behaviorally-relevant neural differences in ASD. Note that due to the demands of the task and scanning environment, the ASD participants in this study (as in previous task-oriented neuroimaging studies) are extremely high functioning, which may limit the generalizability of the results to lower-functioning individuals. Nevertheless, the individuals in the current study do have disproportionate difficulties with social interaction and communication, and the current results may provide a window on the neural mechanism underlying these difficulties.

## Conclusion

In summary, MVPA allows us to determine (i) that features of mental state representations that are not observable in the mean neural signal, including the behaviorally relevant difference between accidental and intentional harms, are encoded in the *pattern* of neural activity; (ii) that these mental state features elicit both stable and distinct patterns of neural activity in RTPJ, a region implicated in mental state reasoning; (iii) that individual differences in neural discrimination predict individual differences in moral judgment; and (iv) that atypical behavioral patterns in ASD are reflected in atypical neural patterns, which (v) are more atypical with increasing symptom severity.

## Abstract

Consonants and vowels differ in the extent to which they are perceived categorically. We use a Bayesian model of speech perception to explore factors that might cause this difference. Simulations show that perception of vowels, fricatives, and stop consonants can all be captured under a single model in which listeners use their knowledge of phonetic categories to infer the sound that a speaker intended. This suggests that the differences in the way we perceive vowels and consonants, when viewed at the computational level, can be explained as parametric variation within a single framework.

**Keywords:** perceptual magnet effect; categorical perception; Bayesian modeling; computational linguistics

Phonetic categories influence perception of speech sounds, with stimuli belonging to different categories being easier to discriminate than stimuli from a single category (Lieberman, Harris, Hoffman, & Griffith, 1957; Kuhl, 1991). However, different types of sounds differ in the degree to which they are perceived categorically. At one end of the spectrum, perception of stop consonants is strongly categorical. Discrimination is little better than would be expected if listeners used only category assignments to distinguish sounds, and between-category differences are extremely pronounced (Lieberman et al., 1957). At the other end of the spectrum, vowel perception is much more continuous, with some even arguing that vowels display no categorical effects at all (Fry, Abramson, Eimas, & Liberman, 1962).

Researchers have used various mechanisms underlying speech perception to explain these differences. For example, differences have been proposed to stem from the way each type of sound is stored in memory (Pisoni, 1973) and to be related to innate auditory discontinuities that seem to influence stop consonant perception (Pisoni, 1977; Eimas, Siqueland, Jusczyk, & Vigorito, 1971). However, the qualitative similarity of categorical effects in consonants and vowels suggests that in some ways these are also instances of the same phenomenon. This raises the possibility that perceptual differences among different classes of sounds are quantitative rather than qualitative.

In this paper we explore these similarities and differences at Marr's (1982) computational level, looking at the optimal solution to the problem of inferring speakers' intended productions from the available acoustic information. We adapt a Bayesian model from Feldman, Griffiths, and Morgan (2009), in which listeners use their knowledge of phonetic categories to recover the sound a speaker intended. We show that an extended version of this model can account for perceptual data from stop consonants and fricatives as well as vowels. This

suggests that differences in the degree to which vowels and consonants are perceived categorically can be explained as parametric variations in a single underlying model.

Our paper is organized as follows. First, we review evidence concerning categorical effects in consonants and vowels, giving an overview of the types of explanations that have been proposed to account for these data. We then describe the model from Feldman et al. (2009) in detail, focusing on their results for vowel perception. In the subsequent section, we present simulations testing our extended model on two types of consonants, stop consonants and fricatives, to determine whether a model built for vowels can also account for patterns in consonant perception. We conclude by summarizing our findings and discussing implications for theories of speech perception.

## Categorical Effects in Speech Perception

Categorical perception in stop consonants was first described by Liberman et al. (1957) as consisting of a sharp change in the identification function between different consonants, as well as a peak in the discrimination function at the location of the identification boundary. The authors proposed a model in which participants used only category assignments to determine whether sounds were the same or different. If the sounds belonged to different categories, then participants would respond *different*; otherwise, they would respond *same*. By examining participants' identification functions, Liberman et al. could use this model to predict the extent to which participants should be able to discriminate each pair of sounds. Participants' actual discrimination performance exceeded the model's predictions only by a small amount, and the authors took this as evidence of a strong categorical component in stop consonant perception. Liberman et al.'s experiment focused on stop consonants that differed by place of articulation, but similar findings have been obtained along the voice onset time (VOT) dimension as well (Wood, 1976).

Descriptions of categorical effects in vowels have focused primarily on the *perceptual magnet effect* (Kuhl, 1991). This effect was originally proposed as a within-category phenomenon, characterized by sounds near category centers being more difficult to discriminate than sounds near category edges, with an accompanying correlation between goodness ratings and discriminability. There is disagreement over whether categorical perception and the perceptual magnet effect are separate phenomena or different variants of the same phenomenon (e.g. Lotto, Kluender, & Holt, 1998). Some characteristics of the perceptual magnet effect are similar to

pure categorical effects, such as reduced discriminability near category centers. Data from Iverson and Kuhl (2000) suggested that discrimination peaks near category boundaries are separable from correlations of discrimination and goodness ratings, whereas more recent studies have found that these two effects cooccur (Tomaschek, Truckenbrodt, & Hertrich, 2011). Regardless of terminology, however, categorical effects in vowel perception are much weaker than those found in consonant perception.

In addition to stop consonants and vowels, it is natural to consider categorical perception of another major class of speech sounds, fricatives. In this paper, we consider categorical perception of sibilant fricatives. There has been some disagreement over the degree of categorical perception in fricatives in previous research. Repp (1981) showed that fricatives follow patterns similar to the categorical perception found for stop consonants. However, in the same study, a subset of participants seemed to have perception that was more continuous, which Repp attributed to a choice between two processing strategies, acoustic and phonetic. Others have found that fricative perception is much less categorical than stop consonants (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Healy & Repp, 1982; Repp, 1984). Another more recent study showed identification patterns consistent with categorical perception together with a neural signature indicative of something like perceptual warping near category centers (Lago, Kronrod, Scharinger, & Idsardi, 2010).

These data set up a continuum ranging from nearly completely categorical perception of stop consonants to much more continuous perception of vowels, with fricatives falling somewhere in between. However, this continuum is not as clear cut as it may seem, as neural and behavioral evidence suggests that listeners attend to phonetic detail when perceiving stop consonants (Pisoni & Lazarus, 1974; Blumstein, Myers, & Rissman, 2005), and the degree of categorical perception in both consonants and vowels can be influenced by task-related factors (Pisoni, 1975; Repp, Healy, & Crowder, 1979). Nevertheless, the differences between consonant and vowel perception are robust. In what follows, we use a model to account for the variability in these effects within a single framework, identifying aspects of category structure that might contribute to differences in categorical effects across consonants and vowels.

## Model Overview

Our model is an extension of the model from Feldman et al. (2009). The model assumes that listeners are trying to recover phonetic detail about the speaker's intended production as well as category information. It differs from traditional models of categorical perception in that it recognizes two different sources of within-category variability: meaningful variability (also referred to as category variance) and noise variance. The category variance  $\sigma_c^2$  is assumed to arise from processes that yield information useful to listeners, such as coarticulatory effects that allow listeners to predict the iden-

tity of upcoming sounds (Gow, 2001). Once a speaker selects a target production,  $T$ , from the category, there is assumed to be additional articulatory, acoustic, and perceptual noise  $\sigma_s^2$  that further distorts this sound. This process results in a speech sound  $S$  that is heard by listeners.

Listeners are trying to infer the target production through the noisy speech signal. To do this, listeners can use their knowledge that speakers tend to produce sounds near category centers. Hence, they rely both on category knowledge and on acoustic cues to recover the phonetic detail of a speaker's target production. If listeners encounter little noise and the category allows a large amount of meaningful variability (e.g., coarticulation), then listeners attend more to acoustic detail in perceiving sounds; however, in situations with high noise and low meaningful variability, they rely more on their knowledge of phonetic categories. This relationship between category variance and noise plays an important role in determining the degree to which perception is biased toward category centers, and it thus has the potential to account for differences in the degree to which vowels and consonants are perceived categorically.

Feldman et al.'s (2009) original model relied on a simplifying assumption that all categories considered by a listener have equal category variance. While this assumption might be adequate for vowels, other sound categories do not necessarily reflect this simplification, particularly voiced and voiceless stop consonants which have been shown to have substantial differences in VOT variance (Lisker & Abramson, 1964). Hence, we extend the original model proposed by Feldman et al. (2009) to allow for unequal category variances. This section gives an overview of our extended model; full derivations are omitted due to space limitations, but are parallel to those in Feldman et al.

The model assumes phonetic categories are Gaussian distributions of sounds along the relevant auditory dimensions, so that a speaker's target production is normally distributed around the category mean,  $T|c \sim N(\mu_c, \sigma_c^2)$ . Noise in the speech signal causes the stimulus heard by listeners to be normally distributed around the target production,  $S|T \sim N(T, \sigma_s^2)$ . We can integrate over all possible target productions  $T$  to get an expression relating the perceived sound directly to the underlying categories,

$$S|c \sim N(\mu_c, \sigma_c^2 + \sigma_s^2) \quad (1)$$

In identification tasks, listeners recover a category given the sound  $S$ , which corresponds to computing the posterior distribution over category membership  $p(c|S)$  in the model. They can compute this by applying Bayes' rule,

$$p(c|S) = \frac{p(S|c)p(c)}{\sum_c p(S|c)p(c)} \quad (2)$$

If we limit ourselves to two categories but relax the assumption that these have equal category variances, we need two means ( $\mu_{c_1}$  and  $\mu_{c_2}$ ) and category variance parameters ( $\sigma_{c_1}$  and  $\sigma_{c_2}$ ). We derive the identification function by substituting

Simulation	Means		Variances			Category:Noise Variance Ratio
	$\mu_{c_1}$	$\mu_{c_2}$	$\sigma_{c_1}^2$	$\sigma_{c_2}^2$	$\sigma_S^2$	
Vowels (Equal Variance)	F1=224 Hz F2=2413 Hz	F1=423 Hz F2=1936 Hz	5,873	5,873 (Mels)	878	6.69
Stop Consonants (Unequal Variance)	60 ms	-0.3 ms	253.9	14 (ms)	82.3	/p/: 3.09, /b/: 0.17
Fricatives (Unequal Variance)	19.0 Barks	15.99 Barks	0.5992	0.5772 (Barks)	0.3098	/s/: 1.93, /f/: 1.86

Table 1: Best fitting model parameters for vowels (Feldman et al., 2009), stop consonants, and fricatives.

Equation 1 into Equation 2 and following a parallel derivation to that in Appendix B from Feldman et al. (2009), yielding

$$p(c_1|S) = \frac{1}{1 + \sqrt{\frac{\sigma_1^2}{\sigma_2^2}} \times \exp \frac{(\sigma_2^2 - \sigma_1^2)S^2 + 2(\mu_{c_2}\sigma_1^2 - \mu_{c_1}\sigma_2^2)S + (\mu_{c_1}^2\sigma_2^2 - \mu_{c_2}^2\sigma_1^2)}{2\sigma_1^2\sigma_2^2}} \quad (3)$$

where  $\sigma_1^2 = \sigma_{c_1}^2 + \sigma_S^2$  and  $\sigma_2^2 = \sigma_{c_2}^2 + \sigma_S^2$ .

The model assumes that listeners recover the phonetic detail of a speaker’s target production in addition to category information when perceiving a speech sound, and that they use this information when performing a discrimination task. Perceiving phonetic detail corresponds to computing the posterior distribution on target productions,  $p(T|S)$ . Applying Bayes’ rule, where the prior  $p(T)$  is a mixture of Gaussians and the likelihood  $p(S|T)$  is Gaussian, we obtain a posterior distribution whose form is a mixture of Gaussians and whose mean is

$$E[T|S] = \sum_c p(c|S) \frac{\sigma_c^2 S + \sigma_S^2 \mu_c}{\sigma_c^2 + \sigma_S^2} \quad (4)$$

(see Feldman et al., 2009 for a full derivation). Each category makes a contribution to this posterior mean with magnitude proportional to the posterior probability of the sound belonging to that category,  $p(c|S)$ . The specific contribution of each category is to bias perception toward the category mean. The strength of the bias is controlled by the relationship between parameters  $\sigma_c^2$  and  $\sigma_S^2$ , which represent the amount of meaningful variability and the amount of noise. Notice that the contribution of the category mean,  $\mu_c$ , is weighted by the noise variance,  $\sigma_S^2$ . This means that when there is more noise, listeners will rely more on their underlying knowledge of the categories. In contrast, the acoustic information,  $S$ , is weighed by the meaningful variance parameter,  $\sigma_c^2$ , such that when there is a lot of meaningful variability in the underlying category, listeners will pay more attention to the acoustic data. It is this relationship that will be critical to modeling differences in perception between different categories of sounds.

Feldman et al. (2009) applied their model to vowel perception (continuum from /e/ to /i/), obtaining a close fit to the multidimensional scaling data from Iverson and Kuhl (1995) (Figure 1). However, in analyzing their own data from an AX

discrimination experiment, the patterns they found suggested that multidimensional scaling was distorting the perceptual patterns, and that the noise parameter needed to capture experimental data directly was much lower than they initially found.<sup>1</sup> Thus, the “Vowels (Equal Variance)” section of Table 1 shows the values they derived on the basis of their experimental data. As might be expected for relatively continuous vowel perception, these parameters showed high meaningful category variance relative to noise variance, indicating that the bias toward category centers was small. We use these parameters as a baseline for comparison in our consonant simulations.

Figure 1: Figure from Feldman et al. (2009) showing inter-stimulus distances from Iverson and Kuhl’s (1995) multidimensional scaling solution and the fitted model.

<sup>1</sup>In our simulations below, we select data that use the distance measure  $d'$  rather than multidimensional scaling data in order to avoid this type of discrepancy.

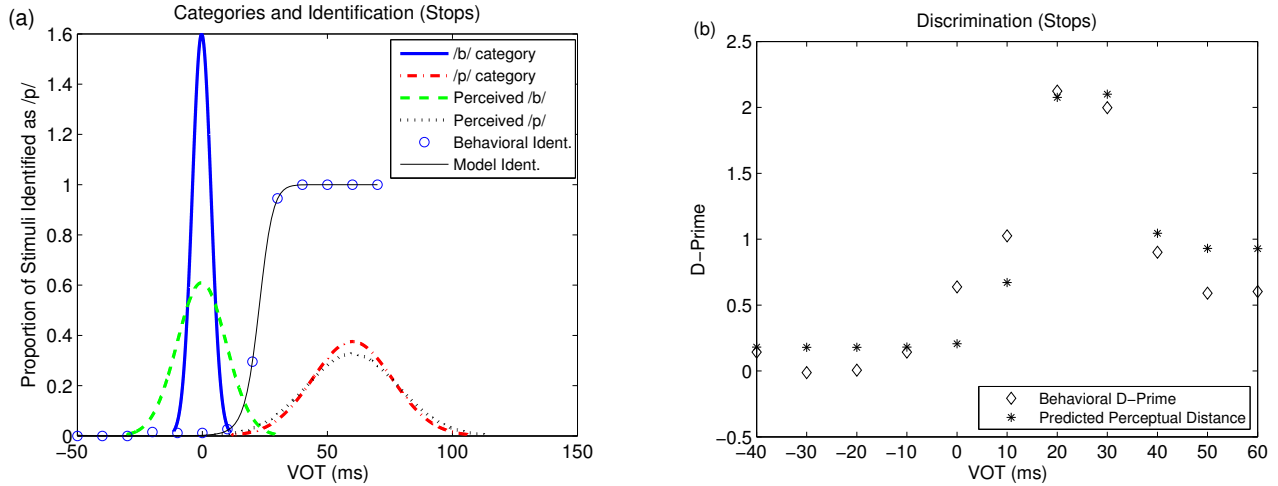

Figure 2: Stop consonants: (a) Underlying categories, perceived distributions, and identification curve in the model, together with behavioral identification data; (b) Interstimulus distances predicted by the model, together with behavioral  $d'$  data.

## Simulations

We applied this model to data from stop consonants and sibilant fricatives, deriving parameters on the basis of experimental data in order to determine whether categorical effects in each type of sound can be explained as the result of optimally inferring the phonetic detail of a speaker’s target production. Examining the resulting parameters then allows us to assess the degree to which those parameters are adequate with regard to existing data, as well as examine the relationship between the two variance parameters and the degree of observed perceptual warping. Following Feldman et al. (2009), our general strategy for fitting our parameters was as follows:

1. Set  $\mu_{c_1}$  on the basis of production data.
2. Determine  $\mu_{c_2}$ ,  $\sigma_1^2$ , and  $\sigma_2^2$  from identification data using Equation 3.
3. Determine the ratio of category variances,  $\sigma_{c_1}^2$  and  $\sigma_{c_2}^2$ , to noise,  $\sigma_s^2$ , by fitting acoustic differences between percepts,  $E[T|S]$ , in the model (Equation 4) to a distance measure such as  $d'$ .

We need to set one of the means in order to obtain a single identifiable set of parameters. The model is then fit to identification data, allowing us to derive the other mean as well as both sums of variances (one corresponding to each category). Note that the only parameter being fit directly to the discrimination data is the ratio of meaningful category variance to noise variance, which is the parameter of interest for examining the degree of bias toward category centers exhibited by each class of sounds. In effect, the discrimination data provide a general test of the model’s fit to behavioral data from each class of sounds.

## Stop Consonants

We first consider behavioral data from identification and discrimination experiments on stop consonants, which have been found to exhibit much stronger categorical effects in perception than vowels. Under our account, this difference might stem from low category variance relative to noise variance, such that listeners rely more on category information. If we are able to account for stop consonant perception with our model, then that would suggest that it may not be necessary to posit qualitative differences in the types of computations performed by listeners when perceiving consonants and vowels. It is not obvious that our model should be able to explain stop consonant data, however, as other factors such as innate phonetic boundaries (Eimas et al., 1971) or auditory discontinuities (Pisoni, 1977) might retain their influence on stop consonant perception even after phonetic learning is complete.

For this simulation we used identification and discrimination data from Wood (1976), who examined perception of /p/ and /b/ along a voice onset time (VOT) continuum. The continuum consisted of synthetic stimuli ranging from -50 to +70 ms VOT. A forced identification task as well as both a 10-ms and 20-ms difference AX discrimination task were administered. We used 20-ms discrimination data for our simulations. On the basis of data from Lisker and Abramson (1964), we set  $\mu_{/p/}$  at 60 ms VOT and derived the remaining parameters from the identification and discrimination data. The identification fit produced an estimated value of -0.3 ms for the mean  $\mu_{/b/}$ , which was a close match to production data found in Lisker and Abramson (1964). The full set of parameters is found in section “Stop Consonants (Unequal Variance)” of Table 1, and the resulting identification curve and category distributions are shown in Figure 2(a). The fit between model and data is very close: the model is even able to predict the reduced within-category discriminability of voiced stops compared to voiceless stops that is observed in the empirical data.

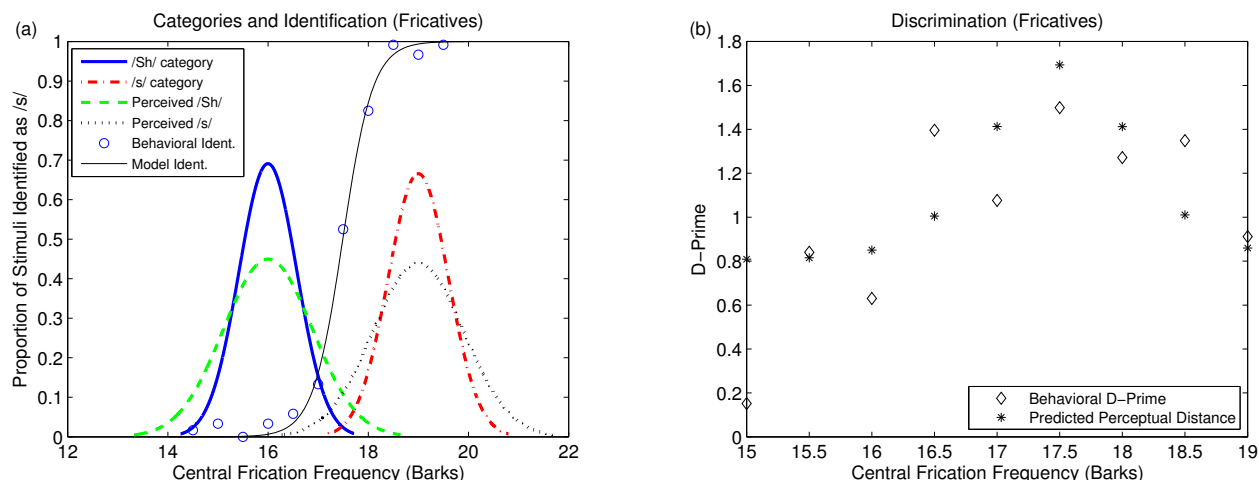

Figure 3: Sibilant fricatives: (a) Underlying categories, perceived distributions, and identification curve in the model, together with behavioral identification data; (b) Interstimulus distances predicted by the model, together with behavioral  $d'$  data.

This can be seen in Figure 2(b), where the perceptual distance between stimuli toward the left side of the continuum is lower than that toward the right side of the continuum.

As predicted, the ratio of category variance to speech signal noise was lower than that obtained for vowels for both categories of stop consonants, voiced and voiceless. These findings suggest that stop consonants have less meaningful within-category variance relative to noise variance than vowels, leading the listener to rely on prior category knowledge in inferring the speakers' target production. This causes a greater pull toward category centers and hence stronger categorical perception. Perceptual bias is particularly strong in voiced stops due to their low category variance.

### Sibilant Fricatives

The previous simulation indicates that the model provides a good account for stop consonants as well as vowels. We next apply our model to sibilant fricatives. Sibilant fricatives are obstruents (like stop consonants), but their characteristic noise components at higher frication frequencies show some similarity to the higher formant structures of vowels. As discussed above, there has been conflicting evidence on the strength of categorical effects they exhibit. These factors make fricatives an interesting modeling target.

For this simulation we used identification and discrimination data along the /s/-/ʃ/ continuum from Lago et al. (2010). The continuum consisted of 11 tokens with central frication frequencies varying from 14.5 to 19.5 Barks. A forced identification task as well as a 2-step AX discrimination task were administered to 12 participants. For our model, we fixed the value of  $\mu_{/s/}$  to 19.0 Barks based on natural productions by an adult male participant and derived values for the remaining parameters by fitting the model to behavioral identification and discrimination data. The resulting parameter values are given in the “Fricatives (Unequal Variance)” entry in Table 1.

Figure 3(a) shows the identification data and the identification curve used in our model, together with the underlying and perceived category distributions that correspond to the parameters used in our simulation. Figure 3(b) compares the model predictions to the observed discrimination measures. The fit is not perfect, due in part to noisy data from the original experiment, but both data and model show the peak in discrimination at the same location as the inflection point in the identification data.

Given that fricatives tend to be perceived more categorically than vowels but less so than consonants, we might expect the category variance to noise ratio to be smaller for fricatives than for vowels, leading to a larger perceptual bias toward category centers, but larger than that for stop consonants, indicating more attention focused on acoustic cues. As predicted, the ratios for the sibilant fricatives are reduced compared to the parameters estimated for vowels (1.93 and 1.86 compared to 6.69). Additionally, we see that they are close to the ratio for the voiceless stops but much higher than that of the voiced consonants, suggesting that they may be closer to the stop consonant end of the spectrum in terms of their degree of bias toward category centers.

### Discussion

This paper used a Bayesian model to investigate the relationship between categorical effects in consonant and vowel perception. Our results suggest that these effects can be explained at Marr's (1982) computational level by the same underlying principles: Listeners use their knowledge of phonetic categories to optimally infer a speaker's target production through a noisy speech signal, and this causes their perception to be biased toward category centers. The model accounts for differences in the strength of categorical effects by assigning consonants less meaningful variability, compared with noise variance, than vowels.

Our analysis is reminiscent of an analysis pursued by Pisoni (1973), Liberman et al. (1967), and others. Their account proposes that speech perception incorporates a phonetic mode of perception, i.e., categorical perception, and an auditory mode of perception, i.e., continuous perception. Pisoni (1973) argued that differences between consonant discriminability and vowel discriminability could be accounted for by assuming that listeners have less access to auditory short-term memory when hearing consonant stimuli than when hearing vowel stimuli. This distinction between phonetic and acoustic modes of perception is parallel to the weighted average in Equation 4, where acoustic information is weighted by the category variance and the category mean is weighted by the noise variance. When noise variance dominates over category variance, listeners rely more on the category mean rather than acoustic information (i.e. phonetic mode). Otherwise, acoustic information receives more weight and within-category discriminability increases (i.e. auditory mode). Looking at ratios of category variance to noise variance across consonants and vowels we see that for vowels category variance exerts much more influence than noise variance and therefore listeners' perception is drawn less towards the category center, causing within-category discriminability to increase (i.e. continuous perception). For consonants the ratio is smaller, coinciding with a decrease in within-category discriminability (i.e. categorical perception).

Our findings suggest that perception of three types of sounds – vowels, stop consonants, and fricatives – adheres to the same abstract computational principles. Importantly, however, the idea that listeners are performing the same computation at an abstract level does not necessarily mean that the underlying mechanisms are identical. Our analysis simply suggests that perception of each type of sound has been optimized to allow listeners to recover the sound intended by a speaker. Bias toward category centers may be implemented differently across different classes of sounds, and separate mechanisms are almost certainly necessary for extracting the various cues we have used as input to our model (formant frequencies for vowels; voice onset time for stop consonants; and central frication frequencies for fricatives). In future work we hope to explore these issues by considering perception of a fourth class of speech sounds, nasals, and by linking our computational approach with descriptions of sound perception at the algorithmic and implementational levels.

**Acknowledgments** We thank Sol Lago, Mathias Scharinger, and Bill Idsardi for sharing behavioral data from their experiments with fricatives. We also thank the Computational Psycholinguistics group, the PFNA Sounds group, and the Language Science Lunch group for valuable discussion and feedback. Finally, we thank Bill Idsardi and four anonymous reviewers for their insightful commentary and suggestions on earlier versions of this paper. This work was supported in part by NSF IGERT grant DGE-0801465.

## Abstract

This article presents the results of an online creativity experiment ( $N = 81$ ) that examines the effect of example timing on creative output. In the between-subjects experiment, participants drew animals to inhabit an alien Earth-like planet while being exposed to examples early, late, or repeatedly during the experiment. We find that exposure to examples increases conformity. Early exposure to examples improves creativity (measured by the number of common and novel features in drawings, and subjective ratings by independent raters). Repeated exposure to examples interspersed with prototyping leads to even better results. However, late exposure to examples increases conformity, but does not improve creativity.

## Introduction

Examples are considered “a cornerstone of creative practice” (Herring et al., 2009). Leveraging examples of prior work is an established technique in design (Buxton & Buxton, 2007), and many design programs encourage students to use examples of existing designs (Schön, 1985). However, the strategies employed by designers to seek and use examples is largely ad-hoc (Newman & Landay, 2000).

Frequently, these strategies differ in timing—in an informal survey we conducted among designers around Stanford University, one respondent described inspirational examples as “huge parts of my initial steps. I need to know as much as I can about the topic before I feel comfortable moving forward.” In contrast, another said that “I don’t do this [look at examples] at the very beginning because it gets your mind stuck in one way of thinking.” This fear of conformity was echoed by other participants, and one went on to say that he looked for inspiration only when “facing a creative block.”

These different strategies suggest that examples may modify the creative process differently depending on the point in the design process at which they are presented. This leads to the practical question: what are the tradeoffs of looking at examples earlier or later in the design process? Furthermore, even if there is an “ideal” time to view examples, some designers feel ubiquitous information access and their own “thirst for knowledge” bombards them constantly with examples (Herring et al., 2009). How does this repeated exposure to examples affect the creative process?

This article presents the results of an online creativity experiment we conducted on Amazon Mechanical Turk. Participants in the experiment generated drawings of alien creatures as a creative task. The pervasive use of sketches to develop and communicate conceptual designs in the creative fields (Suwa & Tversky, 1997), and the use of similar tasks in prior work Ward (1994) inspired the choice of the drawing task. Focusing on drawings of alien figures makes this task

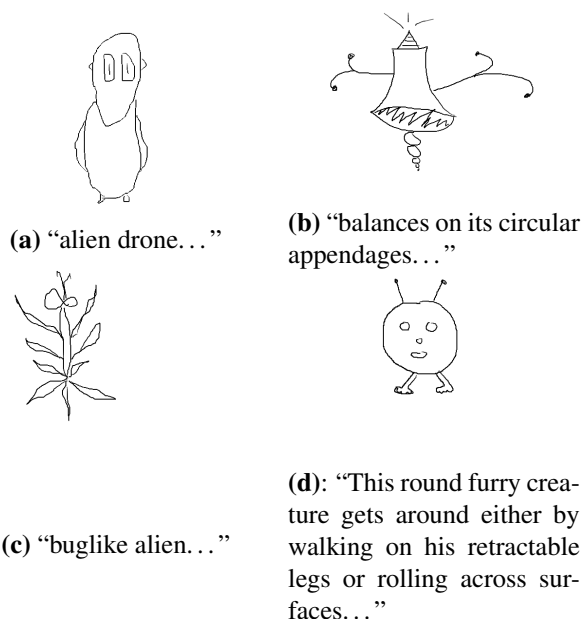

Figure 1: Sampling of drawings created in our experiment, with excerpts of participant-provided descriptions

readily accessible to non-designers (see Figure 1 for a sampling of drawings created by participants). Participants were randomly assigned to one of four conditions: examples early, examples late, examples early and late, or a control condition without examples. This study’s creativity measures were the number of uncommon and novel features in the drawings and Likert-scale ratings by condition-blind raters. Conformity was measured by the number of critical features (features that were directly copied from examples).

This paper’s experimental results suggest that while exposure to examples increases conformity, such exposure early in the creative process improves the creativity in the output, while later exposure provides no such benefit. Furthermore, exposure to examples followed by prototyping and subsequent re-exposure to the same examples improved creative output even more. This finding may allay some fears of example bombardment. Lastly, in our experiment, participants exposed to examples created fewer drawings, so these example driven quality improvements may come at the cost of a lower quantity of creative work.

## Related work

**Examples:** Bringing existing solutions to mind is crucial for creative generation (Smith et al., 1993). The Structured Imag-

ination theory by Ward (1994) describes creativity as a multi-step process: in the *recall* step, people bring to mind existing solutions and constructs. Then, in the *modification* step, these constructs are altered in novel ways. Similar analogical processes are found in other areas of cognition such as analysis and learning (Gentner & Colhoun, 2010).

Designers often incorporate features from examples directly into their work (Marsh & Bower, 1993, “inadvertent plagiarism”); but examples also “ultimately alter the nature of the creative product” in more subtle ways (Marsh et al., 1996). Lee et al. (2010) found that designing with examples generally improves the quality of creative work. These findings have also led to tools for discovering, storing and retrieving examples (Kerne et al., 2008; Ritchie et al., 2011).

The current work is an extension of Marsh et al. (1996) (itself an extension of Smith et al., 1993), so we describe Marsh et al.’s experiment in more detail. In their experiment, participants generated drawings of non-Earth-like creatures to inhabit an alien planet similar to Earth. In the example conditions, experimenters provided participants example drawings of aliens at the start of the experiment. Example drawings all had certain attributes, or *critical* features, in common—four legs, antennae and a tail. The proportion of these critical features incorporated into participants’ own drawings was used as a measure of conformity. The proportion of other, non-critical, features was used as a measure of creativity. These non-critical features were classified as either *novel* (not commonly found on animals, such as speakers or propellers), *uncommon* (such as a pouch or tentacles), or *common* (such as a nose, mouth or two legs).

Participants exposed to examples incorporated more critical features in their drawings, but not at the expense of novel and uncommon features. Instead, their drawings contained fewer *common* features. This suggests that while examples increase conformity by increasing activation of critical features, they do not block retrieval of original ideas (such as novel and uncommon features).

We use Marsh et al.’s feature-based evaluation metric, and extend their work by examining how the example timing affects creative output. In addition, we study the effects of repeated exposure to examples in the creative process.

**Research methods** Our experiment uses a task (drawing sketches of alien figures) that has previously been employed to study creativity in a context of no prior training (Marsh & Bower, 1993; Ward, 1994). Drawing tasks have also been demonstrated to be appropriate for online experiments (Yu & Nickerson, 2011).

This experiment was run on Amazon Mechanical Turk ([www.mturk.com](http://www.mturk.com)), a web-based crowdsourcing platform. This platform has been used for experiments on affect and creativity (Lewis et al., 2011). Mechanical Turk workers have also been employed to provide perception responses (Heer & Bostock, 2010), objective labels (Deng et al., 2009; Snow et al., 2008), and subjective ratings (Dow et al., 2011).

<b>Early</b>	Examples	Think
<b>Late</b>	Think	Examples
<b>Repeated</b>	Examples	Examples

Table 1: Experimental conditions

## Experiment

Our experiment had two goals. First, we wanted to see if exposure to examples at the start of a creative process leads to a different quality of creative output in contrast to exposure when the creative process is underway. Second, we wanted to investigate the role of repeated exposure to examples.

Our initial hypothesis was that exposure to examples later in the creative process would have the same creative benefits but lower conformity than exposure at the start. This hypothesis was motivated by Weisberg (1999), who observed that creative failures are more often explained by the absence of relevant information than the presence of irrelevant information. Furthermore, the presence of one’s own ideas would inhibit the adoption of sub-optimal ideas from late exposure to examples (mirroring the intuitions of some designers).

In the case of repeated exposure, the activation account would predict that, similar to showing more examples at once, this would result in greater degree of conformity due to higher activation of features present in examples.

## Participants

We solicited US-resident participants on Mechanical Turk with a compensation of US\$1.00. 81 participants responded (27 male, 54 female; median age 34). All participants reported a high-school diploma or a higher degree. This between-subjects experiment randomly assigned participants to one of four conditions.

## Procedure

The experiment comprised two drawing sessions, each lasting 7 minutes. Participants were asked to create as many drawings as they could during the drawing session. To encourage this (and discourage participants from spending time perfecting only a few drawings), the experimental platform included a clear-canvas tool but no line-eraser tool (Figure 2).

Each session was preceded by a condition-specific task in which participants were either exposed to examples, or asked to think about the aliens they planned to draw in the next session (Table 1).

At the start of the experiment, all participants saw a Web page with instructions adapted from Marsh et al. (1996) to account for two drawing sessions and a break (see [hci.stanford.edu/example/aliens](http://hci.stanford.edu/example/aliens) for actual prompts used).

For the **Example** task, participants were shown three example alien drawings for 90 seconds (see Figure 4). We used drawings from (Marsh et al., 1996), p. 672. Using the prompt

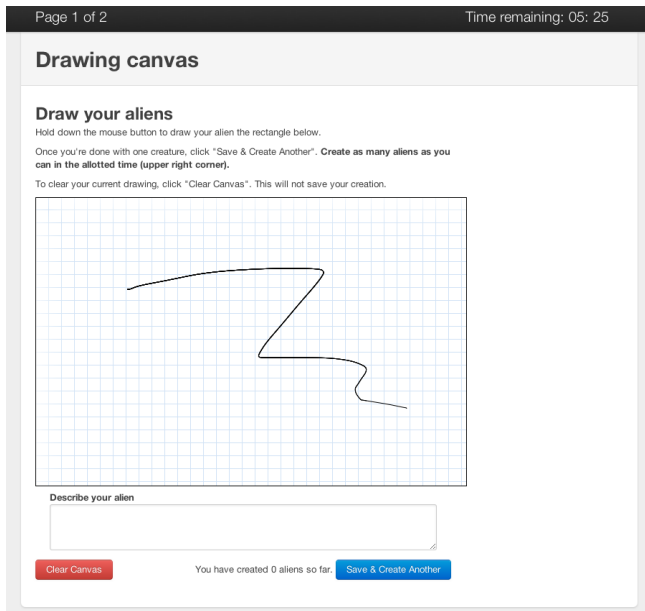

Figure 2: Drawing canvas with time remaining (top right), and an option to clear the canvas (bottom left, red)

of Marsh et al. (1996) (and Smith et al., 1993), participants were instructed that examples were only shown to help them create their original creations, and that we did not want them to copy the examples in any aspect. For the **Think** task, participants were asked to “think about aliens” they planned to draw in the next session for 90 seconds. In the Repeated Examples condition, participants saw the same three examples before both drawing sessions.

After the second drawing session, participants filled out a survey that covered demographics, artistic interest and ability and the thought-process they followed while drawing.

### Labeling features in drawings

Participants generated a total of 543 drawings. Each drawing was labelled with the features it incorporated from the feature set of Marsh et al. (1996) (Appendix). Drawings were annotated on Mechanical Turk, since the features were well-defined. All workers were US resident and at least 18 years of age, and were compensated US\$0.50 for the task. Workers who participated in the experiment were disallowed from the annotation task (and vice-versa). All annotators were blind to experimental condition.

Workers were trained using a drawing from a pilot participant (Figure 3). Then, each worker annotated a set of seven randomly assigned drawings. Workers also rated how creative they found the drawing on a 7-point Likert scale (each annotator saw at least one drawing from each condition). Lastly, annotators could flag offensive (or non-alien) drawings. Upon review, 34 flagged drawings were discarded by the authors. Each drawing was annotated by two workers. Disputes in annotation were resolved by the authors.

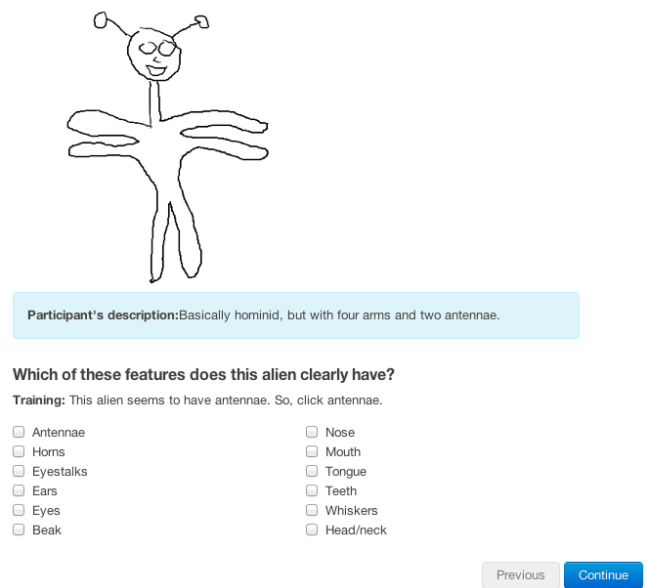

Figure 3: Training interface for annotators. The training interface shows what features to label (“click antennae”). The actual annotation is performed on an identical list of features.

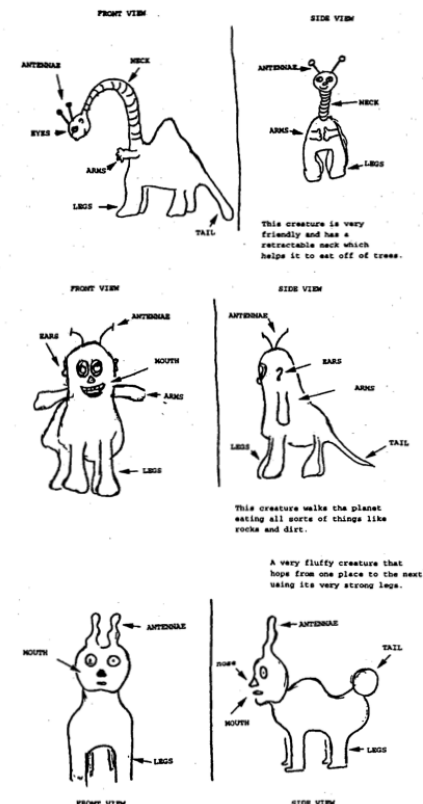

Figure 4: Example drawings provided to participants. All examples contain critical features—four legs, antennae, and a tail.

Condition	Critical	Common	Uncommon	Novel	Total	Drawings per session	Likert Rating
Control	0.39	4.21	0.95	0.47	6.03	4.00	3.71
Early	<b>0.57</b>	3.91	<i>1.15</i>	0.40	6.04	<b>3.00</b>	<b>4.10</b>
Late	<b>0.52</b>	3.82	0.78	0.45	5.57	<b>3.68</b>	3.43
Repeated	<b>0.64</b>	4.20	<b>1.21</b>	0.54	6.60	<b>3.00</b>	<b>4.22</b>

Table 2: Table of means. Means that differed from control at  $p < 0.05$  are **bold**, those marginally significant ( $p < 0.1$ ) are in *italics* (p-values from the post-hoc analysis using mixed models, see section Results).

## Results

We analyze data using a mixed-effects linear model. Since participants drew multiple drawings per drawing session, unless noted, we consider the participant as a random effect with a fixed intercept; and experimental condition, drawing session (first or second), and an interaction term as fixed-effects in all our analysis below. Reported p-values are from a Monte-Carlo (MCMC) simulation (Baayen et al., 2008).

### Examples increase conformity

Following Smith et al. (1993), conformity was measured as the number of critical features incorporated per drawing. Without controlling for the drawing session, examples shown at the start of the experiment increased the number of critical features that were incorporated into drawings ( $t(507) = 2.06$ ,  $p < 0.05$ ), consistent with results from (Smith et al., 1993; Marsh et al., 1996). Participants in the Late Examples condition show higher conformity in the second drawing session (*i.e.* post-exposure) [ $t(419) = 1.83$ ,  $p = 0.07$ ].

### Early exposure increases uncommon features

The number of uncommon features per drawing increased in the Early Examples condition ( $t(419) = 1.61$ ,  $p = 0.06$ ), and in the Repeated Examples condition ( $t(419) = 1.72$ ,  $p < 0.05$ ), but not in the Late Examples condition ( $t(419) = -0.45$ ,  $p = 0.649$ ) (Figure 5). The number of novel features did not vary significantly across condition. Participants in the Late exposure condition created drawings with marginally fewer common features ( $t(419) = -1.33$ ,  $p = 0.09$ ) and fewer total number of features ( $t(419) = -1.30$ ,  $p = 0.09$ ).

### Early and Repeated exposure leads to higher subjective ratings

Annotators rated drawings in the Early Examples and the Repeated Examples conditions higher ( $t = 2.24$ ,  $p < 0.05$  and  $t = 2.65$ ,  $p < 0.01$ , respectively). Intra-class correlation amongst raters (average, random raters) was 0.54 ( $F(508, 508) = 2.2$ ,  $p < 0.001$ ).

### Examples reduce number of drawings

Unlike Marsh et al. (1996), participants created fewer drawings per session in all example conditions<sup>1</sup> [Early:  $t(149) = -2.50$ ,  $p < 0.05$ ; Late:  $t(149) = -2.14$ ,  $p < 0.05$ , Repeated:

Figure 5: Participants in early and repeated exposure conditions included more uncommon features compared to Late exposure/control conditions.

$t(149) = -2.63$ ,  $p < 0.05$ ] (Figure 6). Participants in the Late Examples condition created fewer drawings after exposure to examples ( $\mu_{before} = 4.10$ ,  $\mu_{after} = 3.13$ ,  $t(149) = 1.91$ ,  $p_{interaction} < 0.05$ ).

## Discussion

### Example timing affects creative output

These results suggest that exposure to examples at any time increases conformity. However, early exposure increases the number of uncommon features and subjective ratings of creativity, while late exposure provides no such benefits. This runs counter to both our initial hypothesis and the intuitions of many designers who delay looking at examples in an effort to reduce fixation and think “out of the box” (Jansson & Smith, 1991).

One possible explanation for these effects is that early exposure to examples aids the designer in understanding the scope of acceptable solutions to a problem, and helps form an initial representation of the creative concept (Heit, 1992). Prototyping results in subsequent abstraction and refinement of the initial representation (Lim et al., 2008). Without initial exposure to examples, the refined representation may dif-

<sup>1</sup>Since the number of drawings is not a repeated measure, analysis uses a fixed-effects model with interaction, the experimental condition and the type of session being independent variables.

Figure 6: Participants drew fewer drawings when examples were shown (in the Late examples condition, participants drew fewer drawings in the second session).

fer widely from the one embodied in examples, which would make it harder to map concepts from the example to one's own representation. When exposure is only for a short duration (90s in our experiment), it is possible that only concepts with high enough activation, such as critical features in our experiment, are transferred (motivated by Boroditsky, 2007).

Another counter-intuitive experimental result is that repeated exposure to the same examples led to higher creative quality. This may also be explained by a seeding-and-transfer account. Initial exposure to examples prevents the refined representation formed by prototyping from diverging greatly from the one embodied in the examples. This refined yet similar representation would then allow the designer to learn different concepts on re-exposure to the same example.

In essence, the crucial ingredient that allows repeated exposure to improve creativity might be the prototyping that occurs between exposures.

### Why did examples yield fewer drawings?

Examples play a dual role in design— first, they inspire different solutions and ways of thinking. Second, they help form expectations about what characteristics a solution needs to have (Herring et al., 2009). The decrease in the number of drawings created may be due to this second role. Seeing examples may have signaled a higher threshold for “acceptable” drawings, resulting in participants spending more time on each drawing, and creating fewer drawings overall.

Our data suggest that this expectation-setting role has a different behavior than the inspirational role. While the number of drawings created decreased nearly uniformly post-exposure, changes in creativity measures (uncommon features and subjective ratings) were non-uniform. Therefore, while examples may set expectations any time they are pre-

Figure 7: Participant-provided description: “An ambush predator that does move very much, but lures prey into its mouth using scent to make them think there is food there. It only occasionally shifts using the pads on its bottom, which can also suck up nutrients from the ground or water for emergencies.” Rated highly creative by our raters, this drawing has no novel or uncommon visual features, and uses a non-visual feature (scent).

sented (including late in the design process), their inspirational value may be time-dependent.

### Multiple Measures of Creativity

Results from both the feature-counting measure of creativity from prior work and the Likert-scale ratings provided by annotators are largely consistent. While the Likert ratings are subjective, they better capture the creativity in some drawings that combine common or critical features in a novel way, or use a non-visual feature (for *e.g.* see Figure 7). Using both together provides a better characterization of creativity.

### Conclusions and future work

This work demonstrates the benefits of early and repeated exposure to examples on creative work. In addition, it suggests that conformity may be the price one pays for these gains, regardless of when examples are seen. Hopefully, these results will encourage designers to seek examples early and often in the design process, when they are most useful.

This experiment also demonstrates a replication (and extension) of creativity studies in an online crowdsourced environment. Crowdsourced experiments often offer a lower cost, have a faster time to completion, and provide access to wider populations (Heer & Bostock, 2010). This paper's experiment and the labeling tasks took one week on Amazon Mechanical Turk. This was possible because the labeling scheme from Marsh et al. (1996) provided this study with a clear taxonomy of features that could be easily labeled by non-experts. We suggest crowdsourcing as a viable platform both for experiments that do not need participants with specialized skills or background (or modification per participant) and for analysis/labeling tasks that easily verifiable.

This work also raises a number of questions. First, the results of the repeated-exposure experimental condition indicate that the processes of prototyping and learning from examples may be intertwined in a creative task. Further empir-

ical studies could characterize the precise nature of this interaction. Second, this work shows that repeated exposure to examples is beneficial. How does the frequency of (or interval between) such exposures affect this result? Third, designers often spend years acquiring skills and specific domain knowledge. How do such skills and knowledge affect their interaction with examples? Furthermore, similar to cross-cultural effects of prototyping (Kim & Hinds, 2012), are effects of examples different in different cultures? Finally, how can the results of this work inform the design of tools that support creative work?

## Abstract

Sense of agency refers to the sense of authorship of a given action. While the phenomenon seems too obvious to demand further investigation, pathological conditions such as delusions of control suggest the requirement of further investigation into the phenomenon of sense of agency. The traditional view point regarding the role of intention in sense of agency is complemented by computational models of motor control. Accordingly, we hypothesized and tested the role of error monitoring mechanisms in the sense of agency by manipulating the feedback given independent of the responses of the participant while performing a Flanker task. The results point out the potential role of error monitoring mechanisms by modulating the forward model predictions to experience a sense of agency for unintended actions.

**Keywords:** sense of agency; motor control; forward model; error monitoring mechanisms; Flanker task; error feedback; action intention.

## Introduction

In day-to-day life, we encounter various sensorimotor events, in which sensory perception and action are intertwined. A chain of events including intention to act, movement preparation, generating motor commands and sensory feedback are part of the underlying components of our sensorimotor experience (Haggard et al., 2002). The sense of agency for a given action refers to the sense that an agent has that s/he is the author of that action (Pacherie, 2007b). In other words, the sense of agency is a pre-reflective experience which enables the sense of authorship of one's own thoughts and actions. The sense of agency also critically contributes to a sense of self in terms of experiential immediacy (Tsakiris & Haggard, 2005). Though actions are found to be accompanied by a sense of agency, not much is known in terms of its underlying mechanism or set of processes responsible for this experience.

Different prevailing views have explained regarding the mediators between sense of agency and action (see David et al., 2008 for a review). One view proposed by Haggard et al. (2002) is that the intention of an agent, i.e. "intentional binding" has an important role on the sense of agency (Haggard et al., 2003; Tsakiris & Haggard, 2003), that contributes significantly to action awareness. Pacherie (2007a, b), on the other hand, claims that the sense of agency contains not only an experience of intentional causation, but a sense of initiation and control. Disturbance

in any phase can cause disruption in the sense of agency. Yet another view is based on established models of motor control (Wolpert, 1997) as explained below.

Computational models of motor control (Blakemore et al., 2001, 2002) have an alternative suggestion about the mechanisms responsible for the sense of agency. The computational view is that the sensorimotor loop consists of an inverse model, which identifies the motor commands required to achieve a certain desired state and a forward model, which predicts the sensory consequences of motor actions. These models are represented within the central nervous system in the form of internal models. According to Frith (1992), internal forward model is principally responsible for the sense of agency because it generates an efference copy, which predicts the sensory consequences of motor commands in advance. Predicted sensory information is matched against subsequent sensory information. If predicted and sensed information match, then the sensory events are self-generated, and the subject will experience sense of agency for those events. If there is mismatch, then the sensory information registers it as an external event, and therefore the sense of agency is absent. This model has been used to explain the perceptual attenuation of self-generated stimuli (Blakemore et al., 2000), and pathological experiences, such as delusions of control found in Schizophrenia. For example, Blakemore et al. (2002) have suggested that the misattribution of action shown in patients experiencing delusions of control can be explained by a deficit in the internal forward model (Frith, 1992).

Simulation theory of agency suggests that in understanding or predicting other's action we use our own experiences to simulate those of others (Goldman, 1989). Sebanz et al. (2005) found that subjects within the autism spectrum did not show deficits in representing another person's action but exhibited mentalizing deficits. David et al. (2007) showed autistic subjects show deficits in perspective taking which has been explicitly linked to simulation (Gallese & Goldman, 1998; Langdon & Coltheart, 2001). Children with autism have also shown reduced error monitoring (Vlamings et al., 2008) and altered cerebellar feedback projection (Catani et al., 2008).

Another explanation for experienced agency for unintentional actions is suggested by recent studies on error

monitoring mechanisms (Yordanova et al., 2004; Van Schie et al., 2004). It is well known that after an erroneous action is selected, internal monitoring mechanisms give the feedback that one has committed an error. Such error signals are based on the detection of a conflict that occurred while choosing between several action alternatives, rather than on the comparison between the predicted and actual consequences of a specific action selected for execution. Agency for erroneous actions could be experienced because an error-monitoring signal is used to readjust the system. The readjustment could serve as a direct indication of agency or it could influence post-hoc evaluations of performed actions (Knoblich & Natalie, 2005).

Experiments by Sato and Yasuda (2005) suggest that motor prediction contributes to the experience of agency. Their findings show that agency is experienced not only for intended, but also for erroneous/unintended actions. This result supports the view that the experience of agency depends on the discrepancy between predicted and actual sensory consequences regardless of whether an action was intended or unintended (Fournier et al., 1998; Sato & Yasuda, 2005).

Present study aims to investigate the role of error monitoring mechanism in the attribution of sense of agency. We propose that error monitoring mechanisms can update the ‘forward model’ efferent prediction to match the actual sensory outcome. The activation of error monitoring mechanisms can cause the online or real time alteration in predictions by forward model. This modulation in prediction can occur before assimilating the actual sensory outcome which can influence the sense of agency. We hypothesized that the feedback should modulate the sense of agency, more particularly when the feedback is inconsistent with the actual responses of the participant. We argue that, this online modulation of forward model prediction through error monitoring mechanisms can explain the sense of agency in unintentional action.

## Materials and Methods

### Participants

15 undergraduate students (Mean age = 19.4 years) have participated in the study. All participants were right-handed having normal or corrected to normal vision. Participants provided informed consent and were paid for participation.

### Design

We have used some of the designs proposed by Sato & Yasuda (2005) to examine the role of error monitoring mechanism and to explore the possibility of modulation of the forward model predictions. Participants performed an Eriksen Flanker task (Eriksen & Eriksen, 1974), which is a forced choice reaction time task in which the target letter is flanked by distracter letters (either congruent or incongruent

letter). When participants are asked to respond quickly to the flanker array, they tend to make errors and have low reliability on their responses. To activate error monitoring mechanisms, we have given an immediate feedback after the response which could be right (correct feedback) or wrong (incorrect feedback). If wrong feedback can alter the attribution of agency (refer table 1) then it might be possible that error monitoring mechanisms are capable to modulate the efferent predictions of forward model before assimilating the actual sensory outcome.

Thus, the experiment consisted of two within-subjects factors (a) Type of sensory outcome (Congruent tone or incongruent tone with prediction), and (b) type of feedback (Wrong feedback & Right feedback). Notably the error feedback was manipulated independent of the actual response.

Table 1: Prediction of sense of agency in different conditions.

Response → Condition ↓	Correct	Incorrect
Wrong Feedback-Congruent Tone	No	Yes
Wrong Feedback-Incongruent Tone	Yes	No
Right Feedback-Congruent Tone	Yes	No
Right Feedback-Incongruent Tone	No	Yes

### Procedure

Upon entering the laboratory, participants were seated in front of a computer screen with a pair of headphones. Prior to the experiment, participants performed 300 learning trials. On each trial, 1000ms after fixation onset, the target stimulus (i.e., “H” or “N”) was presented for 250ms on the center of the screen. Participants were told to press the left button with the left index finger as quickly and accurately as possible whenever an “H” appeared on the center of the screen and the right button with the right index finger whenever an “N” appeared on the screen. After each button press, a certain tone was immediately presented for 200ms through in-ear headphones: a 600 Hz tone or a 1000 Hz tone. The assignment of stimuli and tones to buttons was consistent for each participant and counterbalanced across participants. Participants were explicitly told that each button pressing would evoke a certain tone. Tones were identical in duration and sound pressure throughout the experiment.

In the main experiment, participants performed the Flanker task for 200 trials. Each trial started with the onset of centrally presented fixation sign. After the 1000ms of fixation onset, a five-letter array (i.e., HHHHH, NNNNN, HHNHH, or NNHNN) was presented for 250ms. Participants were instructed to respond to one of the two target letter (central H or N) with one finger and to the other letter with the other finger as quickly as possible and not to correct their responses even if they made errors. The assignment of responding finger to target letter was the

same as the learning session. After the response was made, an immediate feedback was provided on the screen for 200ms which could be right (congruent with response) or wrong (incongruent with response). After 200ms of offset of feedback a tone was presented through headphone for 200ms either congruent or incongruent with prediction. Then participants were asked for their rating regarding the sense of agency using a question “I was the one who produced the tone”. The responses could be one of the three options in the form of ‘Yes’, ‘No’ and “Maybe”. To prevent demand effects and any other possible biases in responses such as motor preparation, the question was randomly alternated with a second question “I was the one who was listening to the tone”. Further, the options Yes and No were counterbalanced across trials. The experiment was designed using Psychophysics toolbox (Brainard, 1997) in MATLAB (Mathworks Inc.) (See figure 1).

Figure 1: Trial procedure for an experimental trial

## Data Analysis

We present the results for the sense of agency, as this is the main hypothesis of our experiment. We have also analyzed the reaction time data to check our manipulation effect of flanker task. For quantitative analysis we have transformed the ratings into numerical values. Now ‘Yes’ is represented as 1, ‘No’ is represented as 0 and ‘Maybe’ lies in between as 0.5. These ratings of sense of agency were analyzed using 2x2 repeated measures ANOVA separately for correct and incorrect response trials (see results).

## Results

To check the manipulation effect of flanker task, we have analyzed the reaction time to target letter for correct and incorrect trials in both practice and experimental session. We have found that in practice session participants were significantly faster [ $t(14) = 2.97, p = 0.01$ ] in incorrect responses [Mean = 0.32 Sec, SD = 0.15] than correct responses [Mean = 0.53 Sec, SD = 0.18]. In experimental session, participants were significantly slower [ $t(14) = 3.34, p > 0.01$ ] when they made incorrect responses [Mean = 1.3 Sec, SD = 0.5] in comparison to correct responses [Mean = 0.75 Sec, SD = 0.06]. These results suggest that participants face internal conflict between various alternatives of actions in experimental session (target letter was flanked by congruent/incongruent letters) which in turn delayed the response and end up in incorrect action.

The rating scores on sense of agency were analyzed separately for correct-response trials and incorrect-response trials using repeated measure analysis of variance with two factors: Tone congruency (2 levels – Congruent & Incongruent Tone) X Type of feedback (2 levels – Wrong & Right Feedback). For correct responses, this analysis revealed the main effect of tone congruency [ $F(1,14)=12.86, p < 0.01$ ], but there was no significant main effect of feedback [ $F(1,14)=1.02, p=0.32$ ]. More crucially, we have found significant interaction between tone congruency and type of feedback [ $F(1,14)=353.0, p < 0.01$ ]. Further post-hoc analysis revealed that under congruent tone condition sense of self-agency was significantly reduced ( $p < 0.01$ ) in wrong feedback condition (Mean=0.25, SD=0.08) in compare to Right feedback condition (Mean=0.81, SD=0.04). It also revealed that sense of self-agency was significantly increased ( $p < 0.01$ ) under wrong feedback condition (Mean=0.68, SD=0.10) than in right feedback condition (Mean=0.18, SD=0.15) when tone was incongruent with prediction (See figure 2).

Figure 2: Sense of self-agency for correct responses

For incorrect response, repeated measure analysis of variance revealed that neither tone congruency [ $F(1,14)=0.12, p=0.73$ ] nor feedback [ $F(1,14)=2.6, p=0.12$ ] had a significant main effect on rating of sense of agency.

But there was significant interaction between tone congruency and type of feedback [ $F(1,14)=35.40$ ,  $p<0.01$ ]. Post-hoc analysis revealed that in the Congruent tone condition sense of self-agency was significantly increased in wrong feedback condition (Mean=0.63, SD=0.41) from sense of self-agency in right feedback condition (Mean=0.24, SD=0.16). It also shown that under the Incongruent tone condition, sense of self-agency was reduced when wrong feedback (Mean=0.11, SD=0.12) was given instead of right feedback (Mean=0.75, SD=0.31) (See figure 3).

Post-hoc analysis also has shown the magnitude of manipulation effect. For Correct responses, reduction of sense of self-agency in Wrong feedback – Congruent tone condition is up to level of self-agency in Right feedback – Incongruent tone ( $p=0.15$ ), but manipulation effect is not that much strong in Wrong feedback – Incongruent tone condition because sense of self agency in this condition is significantly lesser from self-agency in Right feedback – Congruent tone condition ( $p<0.01$ ).

Figure 3: Sense of self-agency for incorrect responses.

These results point towards the potential role of interaction between the feedback and tone congruency on sense of agency.

## Discussion

In this study, we manipulated the effect of error monitoring mechanisms on sense of agency. Participants performed a Flanker task and the error feedback was manipulated orthogonal to the actual responses. Accordingly, we found a differential but consistent behavior between the correct and incorrect responses. For both the correct and incorrect responses, a significant interaction was observed for tone congruency and type of feedback. Consistent with our hypothesis, when participant made a correct choice but the feedback was falsely incorrect, the sense of self-agency increased. In contrast, when participant made an incorrect choice and the feedback was falsely correct, the sense of self-agency decreased. However, a

main effect for tone congruency was observed only for correct but not for incorrect responses. These results point out the role of error monitoring mechanisms in attribution of sense of agency.

Previous studies have suggested (Blakemore et al., 2001, 2002) the profound role of forward model prediction in the attribution of agency to self or an external agent. Forward model predictions are based on motor program which in turn are based on our intentions guided by motor planning. However, forward model of attribution of agency is not able to explain the self-agency attribution for unintended actions – actions which are not congruent with the intentions or motor plan. This incongruency in action could occur because of multiple causes such as (a) action slips due to internal noise (Wolpert & Ghahramani, 2000) in the transformation from motor signal to actual action, (b) the conflict in choosing an action between various alternatives as in a forced choice task. Unintentional action through internal noise or conflict activates the error monitoring mechanisms, and this activation of error monitoring mechanism can play a significant role in attribution of agency by modulating the forward model predictions in real time.

We have found that by activating error monitoring mechanisms by external feedback after the action (but before the actual sensory outcome) alters the attribution of agency. For the correct responses, when forward model prediction was congruent with actual sensory consequences, wrong/falsely incorrect feedback (a cross sign) after the action causes the attribution of agency to an external agent. Similarly, when prediction and actual sensory consequences were not congruent, participants tend to attribute the agency to themselves when their actions were followed by wrong/falsely correct feedback. In contrast, when participant made an incorrect response and the feedback was wrong/falsely correct, the sense of self-agency get decreased when consequence of the action is also incongruent with the actual sensory consequences. Similarly, when prediction and actual sensory consequence were congruent, sense of self-agency get increased when actions were followed by wrong/falsely correct feedback.

Previous experiments on error monitoring mechanisms show that cerebellum is involved in error monitoring and optimizing the system (Kawato & Gomi, 1992; Dreher & Grafman, 2002; Menon et al., 2001). Cerebellum is also responsible for predicting the sensory consequences of action (Blakemore et al., 2001). Synofzik et al. (2008) showed that in a motor learning task cerebellum updates predictions about the visual consequences of one's behavior. These findings suggest that error monitoring mechanisms play more profound role in generating sense of agency than just influencing the post-hoc evaluation or serving as direct indicator of agency. Our findings are also in support with the previous findings that cerebellum updates the

predictions of forward model. Since, the sensory consequences of actions vary as a result of changes of the effector's efficacy, internal predictions need to be updated continuously, our findings suggest that cerebellum as an error monitoring mechanism serves as a device which updates predictions of forward model in real time before assimilating any actual sensory consequences.

Alternatively, our results can also be explained by simulation approach to sense of agency. In this line, alteration in attribution of agency can be the result of activation of error monitoring mechanisms which can be used as a signal to navigate within shared representations. Our results also suggest that misattribution of agency in schizophrenia may not be based on imprecise predictions (Synofzik et al., 2010); they misattribute the agency might be because of failure in real time update in predictions by forward model.

These results of alteration in attribution of agency by activating error monitoring mechanisms suggest that forward model predictions are being modulated in real time as soon as they come to know that performed action was not correct. This modulation in prediction before actual sensory consequences helps them to experience a sense of agency for unintended/erroneous actions.

## Abstract

Drawing on insights from recent work on phonetic adaptation, we examined how listeners interpret prosodic cues to two opposing pragmatic meanings of the phrase “It looks like an X” (e.g., “It looks like a zebra (and it is one)” and “It LOOKS like a zebra (but its actually not)”. After establishing that different prosodic contours map onto these meanings (Experiment 1), we demonstrated that prosodic interpretation is shifted by inclusion of another alternative (Experiment 2); the reliability a speaker’s use of prosody to signal pragmatic alternatives (Experiment 3); and most importantly by the distribution of cue values along a continua (Experiment 4). We conclude that listeners derive linguistically meaningful categories from highly variable prosodic cues through rational inference about assumptions that are shared in the conversational context and adaptation to distributional characteristics of prosodic cues.

**Keywords:** Prosody, contrastive accent, Gricean pragmatics, speech adaptation, rational inference

## Introduction

In a famous scene in the movie *Taxi Driver*, Robert DeNiros character repeatedly utters, *You talkin’ to me*. As he changes pitch contours, the intended meaning of the utterance shifts from a question to a challenge. As the example illustrates, prosody carries information about a speakers intentions. However, the acoustic features of prosodic alternatives, as well as the mappings between prosodic patterns and intended meanings vary considerably across speakers. For example, although rising boundary tones can distinguish between questions and assertions in many languages, many questions in fact do not end with a rising boundary tone. Also speakers who use “up-talk” often end assertions with a rising boundary tone. Likewise, a pitch accent preceded by an initial drop (fall-rise: often annotated as L+H\* in the ToBI convention (Silverman et al., 1992)) can signal the presence of contrast. However, characterizing the acoustic properties that signal this contrast in natural speech is far from straightforward. L+H\* and a simple rise (H\*) have overlapping interpretations that are highly dependent on utterance context (Itô & Speer, 2008; Watson, Tanenhaus, & Gunlogson, 2008).

How, then, do listeners navigate the lack of invariance in prosodic cues to pragmatic meaning? We propose that listeners solve the variability problem for prosody in the same way as they solve the variability problem for phonetic features, namely by *adaptation*. Just as prosodic contours vary according to both random and systematic factors, phonetic features of speech contain massive variability, which presents a challenge to listeners who are to derive discrete phonemic categories. It has been suggested that the speech perception system deals with the lack of invariance in two ways. One is to store separate, speaker-, group-, and context-specific representations of tokens from the same categories (Goldinger,

Figure 1: Waveforms (top) and pitch contours (bottom) of the utterance “It looks like a zebra”. The affirmative interpretation *It is a zebra* is typically conveyed by the pattern on the left, while the negative interpretation *It is not a zebra* is conveyed by the pattern on the right.

1998). The other is to adapt phonetic categories to the distributional characteristics of the acoustic input. For example, Clayards, Tanenhaus, Aslin, and Jacobs (2008) provided evidence that listeners adapt their perceptual categories according to the mean and the variance of a bimodal distribution along a VOT continuum (e.g. /b/-/p/).

Importantly, the way listeners integrate different kinds of information in speech perception is compatible with the hypothesis that they make rational inferences (Kleinschmidt & Jaeger, 2011). Listeners can weight different kinds of information according to their reliability, adjust phonetic categories based on more reliable information, and ignore deviation from the expected patterns when there is an ad-hoc source for the unfamiliar pronunciations (Kraljic, Brennan, & Samuel, 2008).

The current study draws on these insights to explore the hypothesis that listeners navigate prosodic heterogeneity by adapting their interpretations through rational inference. We focus on the construction “It looks like an X”, which can evoke different pragmatic meanings depending on its prosodic realization. A canonical accent placement (as illustrated in Figure 1, left panel, henceforth *noun-focus prosody*) typically elicits an affirmative interpretation (e.g. *It looks like a zebra and I think it is one*). When the verb “looks” is lengthened and emphasized with a contrastive accent (L+H\*) and the utterance ends with a L-H% boundary tone (Figure 1, right, *verb-focus prosody*), it can trigger a negative interpretation (e.g. *It LOOKS like a zebra but its actually not one*; see also Dennison & Schafer, 2010).

We explored the adaptation hypothesis in four rating experiments. Experiment 1 established that listeners systematically derive different pragmatic interpretations based on noun- and verb-focus prosodic contours. Experiments 2 and 3 demonstrated that pragmatic interpretations are systematic-

cally modulated by speaker-specific use of particular prosodic contours in different linguistic contexts and the reliability with which a speaker signals pragmatic contrasts prosodically. In Experiment 4, we exposed listeners to affirmative- and negative-interpretation tokens with different distributions of constituent duration and fundamental frequency ( $f_0$ ) values, sampled from a continuum of noun- and verb-focus prosodic contours. Consistent with the adaptation hypothesis, listeners' judgments shifted according to the distributional properties of the input. Taken together, our results provide novel evidence that listeners make optimal use of speaker and context-specific information to derive pragmatic meaning from contrastive prosody.

## Experiment 1

We elicited listeners' interpretations of "It looks like an X" in two types of rating tasks to establish that the proposed prosodic contours result in different pragmatic inferences.

### Methods

**Participants** We used an online crowd-sourcing platform (Amazon's Mechanical Turk) for the experiment. We posted 65 separate HITs (Human Intelligence Tasks: experimental tasks for participants to work on) and received 63 HITs from distinct individuals. Participants were all self-reported native speakers of American English. They received \$0.80 for completing the task and the mean task duration was 11 minutes.

**Stimuli** 24 imageable high-frequency nouns were embedded in the sentence frame "It looks like an X". Two tokens of each item with noun-focus and verb-focus prosodic patterns were recorded by a native speaker of American English.

**Procedure** Participants were first presented with a cover story in which a school teacher described animals and objects in an encyclopedia with pictures that were not directly accessible to his students. In response to a question from a child about what he saw on the page, the teacher said, "It looks like an X" (e.g., *It looks like a zebra*). The participants' task was to judge whether the teacher was referring to a picture of the target noun (e.g., a zebra) or something else.

For each item, participants first heard one of the two target prosodic patterns, and rated how likely it is that the teacher is looking at a picture of the target noun or a picture of something else. Likelihood was indicated using a 100-point scale (0 = something else, 100 = a picture of the noun referent). Next, they heard the same item produced with the other prosodic pattern and answered a 3-alternative forced choice question: If the teacher had used the second intonation pattern, the likelihood of the picture depicting an exemplar of X (e.g. a zebra) would be (a) greater, (b) the same, or (c) less.

### Results and Discussion

Figure 2a plots responses in the 100-point-scale rating task. Participants rated items with noun-focus prosody higher than those produced with the verb-focus prosody, indicating that they were more likely to derive the affirmative interpretation

Figure 2: a) The likelihood estimation based on a 100-point scale by prosodic patterns. The crosses within the boxes indicate the mean values. b) Proportions of the responses given in the 3AFC questions [1 = MORE likely to be an X, 2 = no difference, 3 = LESS likely to be an X. The solid line and the dotted line represent the responses based on the noun-focus prosody and the verb-focus prosody, respectively.

(i.e., it is an X) based on the noun-focus prosody. A mixed effects regression analysis (Gelman & Hill, 2006) confirmed that the difference was statistically significant after controlling random effects of subjects and items ( $\beta = -13.38$ ,  $p < .001$ ). Notice, however, that mean values for both prosodic patterns (indicated by the crosses in Figure 2-a) were above 50%. Judgments were thus strongly biased towards the affirmative interpretation.

Figure 2b plots responses in the 3-alternative forced choice task. The difference between the prosodic patterns was significant ( $\beta = .41$ ,  $p < .001$ ): When participants first heard the verb-focus prosody, the noun-focus prosody was rated as more likely to refer to a denotation of the noun (61%) compared to 28% for the verb-focus when it followed the noun-focus prosody.

Overall, participants made distinct pragmatic interpretations based on the two prosodic patterns. However, the judgments were far from categorical and strongly biased towards the affirmative reading. Taking this as our point of departure, we evaluated the adaptation hypothesis by manipulating factors which we predicted would shift listeners' judgments.

## Experiment 2

The adaptation hypothesis posits that noun-focus and verb-focus prosodic contours are not directly mapped onto two distinct pragmatic meanings. Rather, these pragmatic interpretations are obtained through inference based on linguistic and non-linguistic information shared in a particular discourse context. Grice (1989) proposed that utterance meanings are derived through comparison among potential expressions that could have been used in the same situation. We hypothesized that "It looks like an X" would elicit more negative interpretations when the set of sentences produced by the speaker also included a stronger statement (e.g., *It is an X*), on the grounds that the speaker would have simply used this stronger statement to express the affirmative meaning.

Figure 3: Proportions of competitor pictures chosen in the target and the control conditions in Experiment 2. Error bars represent standard error of the mean.

## Methods

**Participants** We posted 50 separate HITs and received 48 HITs from distinct individuals.

**Stimuli** An additional 24 stimuli in the form of “It is an X” (e.g. “It is a zebra”) were recorded by the same speaker as in Experiment 1. Two lists were created based on the items from Experiment 1 and these newly added items. In the *control condition*, all items were in the form of “It looks like an X”: 12 with verb-focus prosody and 12 with noun-focus prosody. In the *target condition*, 8 of the 12 noun-focus items were replaced by tokens of “It is an X”. Each participant was randomly assigned to the control or test condition.

**Procedure** Participants were presented with the same cover story as that in Experiment 1 and instructed to select an intended referent of an X out of two pictures: a *target picture* (e.g. a zebra) and a *competitor* (e.g. an okapi, a four-legged animal with black and white stripes only on its legs) after listening to each sentence. Participants completed 24 consecutive trials with no feedback.

## Results and Discussion

Analyses were conducted on the items that were common to the two conditions (i.e., we excluded responses to “It is an X” in the target condition and the corresponding sentences in the control condition). Figure 3 illustrates the proportion of a competitor picture chosen in each condition. A mixed logit regression (full factorial; maximum random effects (Jaeger, 2008)) confirmed that there were significant main effects of prosody ( $\beta = 1.9$ ,  $p < .0001$ ) and conditions (target vs. control,  $\beta = 1.18$ ,  $p = .061$ ) as well as a significant interaction term between them ( $\beta = 0.83$ ,  $p < .05$ ), with verb-focus prosody eliciting more competitor responses in both conditions.

Crucially, when the stronger statements were added, participants were more likely to select a competitor picture (indicating a negative interpretation) for both the noun-focus and verb-focus contours. This suggests that the pragmatic interpretation of prosody is not solely determined by the acoustic characteristics of utterances, consistent with the predictions of the adaptation hypothesis. Expectations based on context- and speaker-specific knowledge modulate pragmatic interpretations of contrastive prosody.

## Experiment 3

The adaptation hypothesis predicts that listeners are more likely to adapt to cues that are used reliably and systematically. Experiment 3 manipulates the overall reliability with which particular prosodic contours are associated with particular pragmatic meanings.

## Methods

**Participants** We posted 80 separate HITs and received 76 HITs from distinct individuals.

**Stimuli** 26 items of “It looks like an X” (16 training and 10 test items) were recorded in each of the two target prosodic patterns. For each of the training items, two continuation phrases were recorded to disambiguate the intended meaning. One continuation supported the affirmative interpretation (e.g., “It looks like a zebra because it has black and white stripes all over its body”). The other pattern supplied feedback confirming the negative interpretation (e.g., “It looks like a zebra but it’s not; it has stripes only on its legs”).

**Procedure** Participants were presented with a cover story in which a mother and a child were naming animals and objects in a picture-book. The exposure phase included 16 trials in which participants heard the mother tell the child, “It looks like an X”. Their task was to choose the likely referent of N between a target and competitor picture (e.g. a zebra and an okapi). They then heard a continuation phrase disambiguating the intended referent.

Each participant was randomly assigned to one of two conditions. In the *reliable-speaker condition*, items with noun-focus and verb-focus prosody (8 items each) were invariably associated with affirmative and negative continuations, respectively. In the *unreliable-speaker condition*, half of the items with noun-focus prosody were followed by negative continuations and half of the items with verb-focus prosody were followed by affirmative continuations.

The test phase was identical across conditions. In this phase, participants made 10 additional judgments in the same format without any feedback. For each item, they were also asked to rate confidence in their judgment on a 7-point scale.

## Results and Discussion

As illustrated in Figure 4, the verb-focus prosody systematically biased judgments towards competitor pictures ( $\beta = 1.78$ ,  $p < .0001$ ) in both conditions. Crucially, we also found a significant negative interaction term between prosody and

Figure 4: Proportions of competitor pictures chosen in the target and the control conditions in Experiment 3. Error bars represent standard error of the mean.

speaker reliability: In the unreliable-speaker condition, the effects of prosody on judgments, and particularly on negative interpretations of contrastive prosody, were weaker overall ( $\beta = -1.07$ ,  $p < .004$ ). That is, participants down-weighted the contrastive accent as a cue to a competitor object after exposure to a speaker who did not use the cue systematically.

Confidence rating data exhibited the same pattern. Confidence ratings were lower overall for utterances with verb-focus prosody ( $\beta = 0.3$ ,  $p < .001$ ), whereas speaker reliability did not significantly affect confidence ratings ( $p > .2$ ). We also found a significant negative interaction between these two factors ( $\beta = -.2$ ,  $p < .0001$ ). When exposed to an unreliable speaker, participants gave responses based on verb-focus prosody with diminished degree of confidence.

In sum, participants take into account prosodic features idiosyncratic to a particular speaker when deriving pragmatic meanings from prosodic contours. They down-weight prosodic information when it is an unreliable cue to intended meaning.

## Experiment 4

Experiment 4 was designed to provide a stronger test of one of the central assumptions of the adaptation hypothesis. If listeners are sensitive to the probabilistic nature of prosodic cues in the input, they should adapt their pragmatic interpretations according to the distribution of tokens in the input. Using resynthesized 12-step continua between noun-focus and verb-focus prosodic contours, we examined how different distributions of prosodic patterns in an initial exposure phase affect listeners' interpretation of utterances in the test phase.

## Methods

**Participants** We posted 360 separate HITs and received complete responses from 324 individuals.

Figure 5: The responses in the confidence rating questions in Experiment 3.

**Stimuli** The stimuli created for Experiment 3 were divided into six regions corresponding to each of the four initial words (i.e. ① it ② looks ③ like ④ a) and the portions of the final word associated with each of the two tonal targets (i.e. the H\* and L-L% in the noun-focus contour and the L- and H% in the verb-focus contour). The turning point in the f0 contour within the final word was used to delineate the final two regions (e.g., ⑤ zeb ⑥ ra, as illustrated in Figure 1). The f0 of each region was sampled at 20 equally spaced time points, and measures from each time point were aggregated across items to derive mean f0 contours for noun-focus and verb-focus utterances, following (Isaacs & Watson, 2010). Likewise, the durations of each region were averaged across items by contour type. Twelve-step continua for each item were derived from these mean f0 contours and durations by interpolating between values within each region and then manipulating the F0 and duration of each recording to match the interpolated values using the pitch-synchronous overlap-and-add algorithm implemented in Praat (Moulines & Charpentier, 1990; Boersma & Weenink, 2008).

These items (12 steps \* 26 words) were normed by 50 people using the same 2AFC picture-selection paradigm as in Experiment 3 without feedback. The results of this norming study are summarized in Table 1. Items from most of the continuum steps were more likely to elicit affirmative responses. The items at Step 10 were judged to be the most ambiguous as to the pragmatic interpretations. Based on these norming responses, we postulated that the prosodic cue values for the Noun-focus and the Verb-focus stimuli form distributions with different means and variance, as schematically shown in Figure 6a. The distribution of cue values for the affirmative interpretation (solid line) has a mean value close to the midrange of the continuum and has relatively high variance. In contrast, the distribution for the negative interpretation (dashed line) is considered to have a mean value closer to

Table 1: Proportion of a target picture chosen at each step in the norming study.

Steps	1	2	3	4	5	6	7
Percentages (%)	84	79	80	80	75	77	78
	8	9	10	11	12		
	60	60	48	37	37		

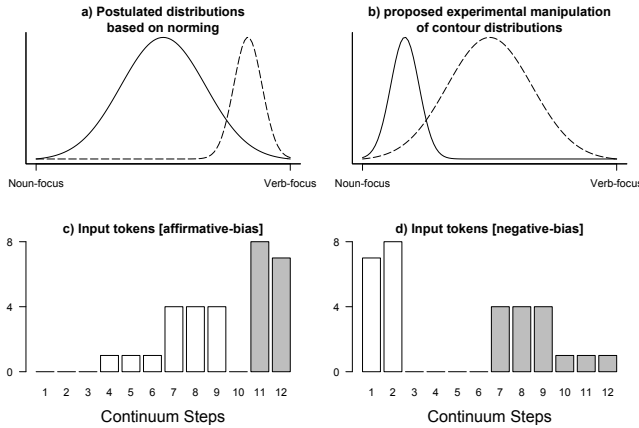

Figure 6: a) A schematic representation of distributions of prosodic cue values postulated based on the norming data. b) Proposed experimental manipulation of contour distributions. c) and d) Input frequencies of tokens sampled from each step of the continuum in the training phase of the affirmative-bias in the negative bias conditions. X-axis: continuum steps. Y-axis: Token frequencies of input utterances. Tokens indicated as white bars were disambiguated as affirmative interpretation and those indicated as shaded bars were disambiguated as negative interpretation.

the higher end of the continuum, with relatively low variance.

Based on these assumptions, we created two sets of exposure items for the current experiment. In the **affirmative-bias condition**, the distributions of the exposure items were meant to approximate the distributions observed in the norming study. Participants heard items sampled from Steps 4-9 with affirmative continuations and items from Steps 11 and 12 with negative continuations (Figure 6c). On the other hand, in the **negative-bias condition**, we tried to reverse this pattern and provided input in the distribution patterns, which are schematically illustrated in Figure 6b. In this condition, listeners heard items from Steps 1 and 2 with affirmative continuations and items from Steps 4-9 with negative continuations. Notice that in either of the conditions participants heard the same number of items from Steps 7-9 while they are identified as items from different categories (Figure 6d).

The adaptation hypothesis predicts that exposure to these affirmative-bias and negative-bias distributions should result in recalibration of the categorization function. Figure 7a plots the proportions of target pictures chosen at each step along the continuum in the norming study. We hypothesized that

Figure 7: a) Proportions of target pictures chosen (affirmative interpretation) in the norming study. X-axis: Continuum steps (1 = prototypical noun-focus prosody, 12 = prototypical verb-focus prosody). Solid line represents lowest smoothing and dashed line indicates where the stimuli elicit most ambiguous responses (50% chance of a target picture chosen); b) A hypothesized pattern of category recalibration in the negative-bias condition in Experiment 4.

participants' categorization functions would shift towards the negative interpretation, as illustrated in Figure 7b.

**Procedure** The procedure of the experiment was nearly identical to Experiment 3. Participants were exposed to tokens of "It looks like an X" and selected either a target picture or a competitor picture as the more likely referent. In the exposure phase, they heard 30 items: 15 with affirmative continuations and 15 with negative continuations. The distribution of items sampled from a 12-step continuum differed across conditions, as illustrated in Figure 6c and 6d. In the test phase, which was identical across conditions, participants completed 12 trials in the same format without feedback.

## Results and Discussion

Responses are plotted in Figure 8. In the affirmative-bias condition, as predicted, participants' judgments did not deviate from those in the norming study. Items from most of the steps were associated with the affirmative interpretation and the items from Step 10 was judged to be most ambiguous as to their pragmatic meanings.

In the negative-bias condition, however, a wider variety of items were assigned the negative interpretation (i.e., *it is not an X*). As shown in Figure 8, the proportion of affirmative interpretations drops to 50% around Step 7. Items that had been normed to be highly ambiguous (i.e., those from Steps 10) were more reliably assigned the negative interpretation. These results lend strong support for the adaptation hypothesis: Pragmatic interpretation of contrastive prosody does not result from an invariant mapping between sound and meanings. Depending on the patterns of input, participants can rapidly and flexibly adjust their classification criteria so that they can make optimal use of the incoming input.

Figure 8: Percentages of target pictures chosen in the test phase [Experiment 4]. Dotted, solid, and dashed lines represent responses from the norming, the affirmative-bias, and the negative-bias conditions, respectively. X-axis plots the continuum steps. Step 1: prototypical noun-focus prosody; Step 12: prototypical verb-focus prosody.

## General Discussion

Our results provide novel evidence about how listeners navigate variability in prosodic information to make inferences about an intended meaning of an utterance. We first confirmed that listeners derive affirmative and negative interpretations for “It looks like an X” based on two distinct prosodic patterns (noun-focus and verb-focus contours). The pragmatic inference associated with the contrastive interpretation, however, is affected by the range of linguistic contrasts provided in the context: Introducing a stronger statement (“It is an X”) increases the proportion of contrastive implicatures for the “It looks like an X” construction. Listeners also rapidly adjust to speaker-specific use patterns of prosodic cues to pragmatic meanings. Finally, listeners optimize pragmatic interpretations based on probabilistic distributions of prosodic cue values. After hearing 30 tokens of input, listeners adjusted their classification criteria to reflect the properties of the distribution to which they were exposed.

These results provide strong support for the adaptation hypothesis: Listeners take into account the reliability of the mapping between prosodic patterns and intended meanings for a particular speaker when evaluating whether a prosodic contour provides evidence for a contrastive inference. Also, in order to effectively process noisy input, listeners integrate multiple acoustic cues as well as information idiosyncratic to a particular context. In future research we plan to extend our approach to a wider range of constructions and prosodic contours in order to further evaluate the hypothesis that adaptation to prosody can be understood within a rational inference framework.

## Abstract

For designing effective and tailored instruction, valid instruments that measure the level of expertise are necessary. We propose a graph-oriented approach for in-depth analyses of knowledge structures. Therefore, four measures of integration and encapsulation of knowledge structures were validated in an experiment. Participants (six experts and six intermediate students) recalled and explained the symptoms and laboratory data of a medical case description in the domain of cardiology. The results showed that the graph-oriented measures were more discriminative towards expertise-related differences than classic measures. Thus, our graph-oriented measures offer a more adequate and a more fine-grained analysis of knowledge structures.

**Keywords:** expertise, graph theory, knowledge encapsulation, knowledge integration.

## Introduction

“Experts are made, not born” (Schraw, 2009). This citation nicely illustrates that the way from a novice to an expert can be characterized as a bumpy road of deliberate practice and effort (Ericsson, 2006). For supporting novices in developing their skills and knowledge, good and accurate shock absorbers, such as effective instructional explanations, are necessary. Thus, a deep understanding of expertise and its unique differences to novices’ knowledge structures as a target state of novices’ development is crucial for designing effective instruction (Nückles, Wittwer, & Renkl, 2005). Cognitive science provides a comprehensive picture about the patterns of knowledge structures that constitute expertise: the main findings suggest that experts primarily differ from novices in the nature of their knowledge structure; more specifically in the extent to which their domain knowledge is integrated and compiled. Knowledge integration can be described as principled knowledge, which is characterized as coherent and well-integrated domain knowledge (Chi, Feltovich, & Glaser, 1981). More specifically, novices tend to organize their knowledge around literal, superficial features, while experts organize their knowledge around abstract principles lying underneath the superficial features. These abstract principles allow for the integration of obviously divergent concepts and subcomponents into a coherent, tightly connected schema. As novices and intermediates do not come up with these abstract principles, they have more difficulties in recognizing patterns that fit together, as, for example, it is easier for a medical doctor to ascribe divergent symptoms

like a loss of vision and a collapsing pulse to bacterial endocarditis, whereas novices and intermediates would not be able to intuitively ascribe these symptoms to a specific disease and would rather tend to “store” such details unconnectedly in long-term memory (Schmidt & Rikers, 2007).

The second distinctive feature of experts’ knowledge is the degree of compilation. Knowledge compilation refers to the process by which persons transform declarative knowledge into productions and automate these productions by combination of these productions to larger units (Anderson, 1981). For instance, compared to intermediates, in order to medicate a flu, a medical doctor does not need to reason on the detail-level of pathophysiology, but rather operates on the macro-level of automated clinical knowledge, like “if the patient has symptoms A,B,C, then she has...“, which allows the expert to omit reasoning steps when solving routine tasks (Koedinger & Anderson, 1990). But how does this compilation change the expert’s knowledge structure? Boshuizen and Schmidt (1992) suggested that knowledge compilation resulted in the “subsumption of lower level, detailed propositions under higher level [...] propositions.” This reorganization of the knowledge structure is called knowledge encapsulation. For example, Rikers, Schmidt, and Boshuizen (2002) found that experts’ knowledge structures were less detailed and they contained more encapsulated concepts compared to intermediates. In sum, developing expertise can be illustrated by progressing through a number of transitory stages that are characterized by the degree of integration and the degree of encapsulation of the knowledge structure (Schmidt & Rikers, 2007). To support learning, accurate and valid assessment strategies of these stages of knowledge structures are needed as a prerequisite for the design of effective and tailored instruction.

## Measurement of Knowledge Integration and Knowledge Encapsulation

To have experts and intermediates elicit their knowledge, we used the classic procedure by Patel and Groen (1986) that consists of the following elements: 1) Participants are provided with a medical case description, 2) they accomplish a free recall task of the medical case description, 3) explain the underlying processes that cause the disease, and 4) provide a diagnosis for the case description. Whereas the free recall protocol allows for an insight into a

participant's problem representation, the explanation captures the conceptual understanding of underlying patterns and the logical and semantic relations of the subject domain (Chi, 2006). For the analysis, the recall protocols and explanations were segmented into propositions, consisting of one relation and an ordered set of two concepts, containing the elementary idea units of the referring text base (Kintsch, 1988).

### Classic indicators of knowledge encapsulation and knowledge integration

Based on the propositional segmentation of the recall protocols and the explanations, Rikers et al. (2002) used three different measures of knowledge encapsulation and knowledge integration. Knowledge encapsulation was measured by the number of *high-level inferences* a participant made during the recall of the case description. A high-level inference is a statement that compiles several reasoning steps into one statement. Therefore, each statement in the recall protocol was coded as a 1) literal, 2) paraphrased, 3) low-level inferred, or 4) high-level inferred proposition of the case description. Low-level inferences were based just on one statement in the case description, whereas high-level inferences merged several propositions of the case description into one inferential proposition. Consider the following propositional segmentation of a case description and a fictitious participant's recall (cf. figure 1). In this case, the participant merged seven propositions of the case description to one proposition and solely recalled that the man has endocarditis. Therefore, the proposition was coded as high-level inference.

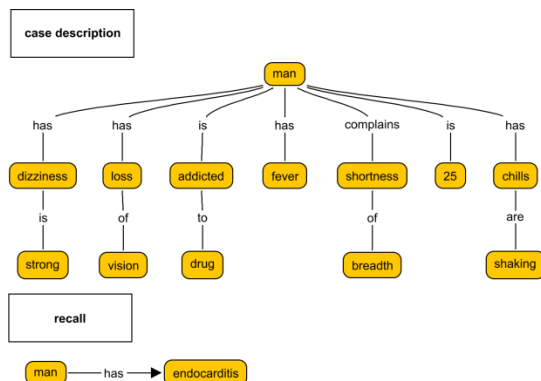

Figure 1: Example for the coding of high-level inferences

The second indicator, *encapsulated concepts*, was measured by the number of matching concepts between the participant's explanation and a reference model that included encapsulated concepts of the subject domain. For instance, the match between the graphs in figure two and three would have four matching encapsulated concepts. Thus, the participant would have used four encapsulated concepts.

For the knowledge integration, Rikers et al. used the number of mentioned *concepts* and *relations* in the explanations. For instance, the graph depicted in Figure 2

would have a detailedness index of four concepts and three relations.

### Limitations of the classic indicators

Although the measure *high-level inferences* provides a fine-grained analysis on the level of inferences in the recall protocols, the analyses of the participants' explanations imply some shortcomings: The measurement of the use of encapsulated concepts and detailedness were solely based on the computation of frequencies of concepts and relations. However, structural dependencies, like inter-relations between concepts, were not investigated and thus lack validity. In order to properly measure knowledge encapsulation, what must be demonstrated is the reorganization of the knowledge structure, more precisely how participants subsume their knowledge of details under higher-level concepts (Boshuizen & Schmidt, 1992). In a similar vein, measuring knowledge integration requires both structural indicators for the connectedness and the fragmentation of the knowledge structures. Therefore, an in-depth analysis of structural properties is necessary for validly measuring knowledge integration and knowledge encapsulation.

### A Graph-Oriented Approach for Measuring Knowledge Integration and Knowledge Encapsulation

The purpose of this paper was to improve existing measures in order to increase the reliability and validity of knowledge encapsulation and knowledge integration measures. Therefore, to capture key latent variables of knowledge encapsulation and knowledge integration, we developed four measures that were strictly based on graph theory (Sowa & Shapiro, 2006). The analysis of knowledge structures with graph-oriented measures has two main methodological advantages. First, they are capable of directly tracking structural differences, which heightens the validity of our methodology. More precisely, with graph-oriented measures, subsumption and integration processes can be captured in the graphical structure. Second, due to the mathematical formalization of knowledge encapsulation and knowledge integration, our graph-oriented measures could easily be automated, which increases objectivity and efficiency.

Figure 2: Example for a conceptual graph

Mathematically, an explanation segmented into single propositions can be interpreted as a directed simple graph (Sowa, 2006). A graph  $G$  is an abstract representation of a finite set of nodes  $V$  that are connected by edges  $E$ , mathematically as  $G = (V, E)$ . Nodes represent concepts, whereas edges represent relations between the concepts.

## Knowledge Integration

For the analysis of knowledge integration, we used two different measures. *Connectedness* was computed by the proportion of the sum of edges  $e$  and the sum of nodes  $v$ , formally as:

$$\frac{\sum_{i=1}^n e_i}{\sum_{i=1}^n v_i}$$

This expression describes the average relatedness of concept to concept and can take values between 0 and 1, where 0 represents a non-connected graph and 1 means that all concepts are directly related to each other. Figure 2 shows an example of a graph consisting of three relations and four concepts. The connectedness for the example graph would be .75.

The second indicator for integration is *fragmentation* of the knowledge structure. Fragmentation was computed as the number of isolated knowledge units. A knowledge unit is represented as a disconnected component in a graph, indicating a subgraph that is not connected to the rest of the graph. Formally, we define fragmentation as the number of components  $C_n$  which are subsets of the graph  $G$ , where each node  $v \in V$  has no edge connection to the set of nodes  $v$  of the complement of  $G \setminus C_n$  (Sowa & Shapiro, 2006). Our example graph would have a fragmentation index of 1, because there are no disconnected subcomponents in the graph.

## Knowledge Encapsulation

For the analysis of the encapsulation of the knowledge structures, we used two different measures. The *omission of concepts* is an indicator of how many inferential steps a participant skips while explaining a phenomenon. The more encapsulated a knowledge structure is, the more concepts a participant omits. For the identification of the inferential steps, a reference model is needed. This reference model must include all causal relations to sufficiently understand the phenomenon under investigation. Thus, the reference model depicts an accurate causal representation of the phenomenon. The omission of concepts is computed as the number of concepts that are in the set of the reference model ( $rm$ ), but not in the participant's model ( $pm$ ), formally as:

$$rm \setminus pm = \{x \in rm \mid x \notin pm\}$$

The more omission a participant made the less accurate was her explanation. Figure 3 shows an example for a reference model. Located in the reference model are the concepts 5, 6 and 7 that do not appear in the participants' model in figure 2. In this case, we would have an omission of 3, because in this case the participant would have omitted three concepts in her explanation.

A second indicator concerning knowledge encapsulation is the length of the *inference path*. It describes the shortest path between the most distinct concepts and is an indicator for the average length of inferences in the experts' explanation (Dijkstra, 1959). It is computed as the shortest

distance between the most distant nodes and can take values from 1 to  $N$ . A low index in the inference path indicates high encapsulation, whereas high  $N$  indicates a very detailed description of the phenomenon. In our example, the most distant nodes would be *Node 6* and *Node 7*, and the shortest path would include 4 edges; therefore the inference path would be 4.

Figure 3: Example for a reference model

## Research Questions and Hypotheses

The main purpose of the experiment was to test, if our graph-oriented measures were more sensitive when investigating expertise-related differences of knowledge encapsulation and knowledge integration compared to the classic measures (Boshuizen & Schmidt, 1992; Patel & Groen, 1986; Rikers, Schmidt, & Boshuizen, 2002). In more detail, we examined, if our graph-oriented measures were more capable to detect differences concerning knowledge encapsulation and knowledge integration compared to the classic measures. Furthermore, we validated our graph-oriented measures with the classic measures. For this purpose, we, analogically to previous experiments, asked cardiology experts and intermediate medical students to recall and explain the signs and symptoms of a clinical case description of a fictitious patient who had bacterial endocarditis, taken from Patel and Groen (1986).

Based on these theoretical considerations, we addressed the following research questions.

### Predictions Regarding Structural Differences between Experts and Intermediates

For the classic indicators, in accordance with Rikers et al. (2002), we hypothesized that experts would make more *high-level inferences* and would use more *encapsulated concepts* compared to intermediates. For knowledge integration, analogically to Rikers et al., we assumed that experts' explanations would be less *detailed* (less concepts and less relations) compared to intermediates.

For the graph-oriented measures, we expected the following effects: Generally, we assumed that experts would subsume specific concepts under encapsulated concepts, which would result in *shorter inference paths* and more *omissions of concepts* in their explanations compared to intermediates. With regard to knowledge integration, we expected that experts' knowledge structures should be more *tightly connected* and less *fragmented* compared to intermediates (Chi et al., 1981).

## Predictions Regarding the Validity of the Graph-Oriented Measures

In order to test concurrent validity of the graph-oriented measures, we examined whether the classic measures were correlated with the graph-oriented measures. More importantly, we tested whether our graph-oriented measures would be able to discriminate between experts' and intermediates' explanations. More specifically, we hypothesized that our graph-oriented measures would be more discriminatory with regard to differences related to expertise, because they would be better able to measure structural differences.

## Method

### Participants

Six experts and six intermediates participated in the experiment. Experts were recruited from a German cardiology hospital. All were medical specialists who had a mean work experience of 19.5 years and board certification in their specialty of cardiology. They were, on average, 49.75 years old ( $SD = 6.24$ ). Intermediates were advanced medical students in the clinical block of their study program. They were on average 25.83 years old ( $SD = 1.72$ ). Their average number of semesters in the medical program was 10.83 semesters ( $SD = 1.17$ ) and they had attended at least one special course in cardiology.

### Design

A quasi-experimental between subjects design was used, with expertise as the independent variable. Dependent variables encompassed measures of knowledge integration and knowledge encapsulation.

### Materials

The materials were merged into one booklet, containing a demographic questionnaire about the participants' age, prior knowledge and experience in the area of cardiology. The main component was a clinical case description of a fictitious patient who had bacterial endocarditis (an inflammation of the inner layer of the heart). This description was used in several previous studies (Patel & Groen, 1986; Rikers et al., 2002). The clinical case description included context information, central findings of laboratory data, and descriptions of symptoms. Furthermore, we included two blank sheets for the recall task and the explanation.

### Procedure

The entire experiment lasted approximately 40 minutes. First, the participants completed the demographic questionnaire (5 minutes). Second, they read the case description (5 minutes). Third, in the recall task, participants wrote down everything they could remember (5min). Fourth, the participants provided an explanation for the signs and symptoms of the case description, in full

sentences (20 minutes). They were asked to write an intelligible and comprehensive explanation. Fifth, participants provided a diagnosis and suggested possible therapies (5 minutes).

## Analysis of the Knowledge Structures

We used our graph-oriented measures, described above, to examine differences between experts and intermediates regarding their knowledge structures. For the cross-validation of our graph-oriented measures, we used the classic measures by Rikers et al. (2002) as well. To heighten reliability, we implemented a computer program which automatically calculated all mathematically formalized measures for knowledge integration and knowledge encapsulation, except for the number of high level inferences. Latter was coded by two independent raters that were blind to the experimental conditions. Interrater agreement as determined by Cohen's Kappa was very good ( $\kappa = .77$ ) and differences were resolved by discussions.

## Results

There were no significant differences between experts and intermediates regarding the number of propositions in the recall protocol,  $F(1, 10) = 3.44$ ,  $p = .09$ , partial  $\eta^2 = .26$ , and the number of propositions in the explanations,  $F(1, 10) = 3.01$ ,  $p = .11$ , partial  $\eta^2 = .24$ . Furthermore, as all of our participants were knowledgeable in the domain of cardiology, all participants correctly diagnosed that the patient had bacterial endocarditis, and proposed broad antibiotic mediation as first treatment. The means and standard deviations for all the dependent measures as well as for the propositions can be seen in table 1.

## Predictions Regarding Structural Differences between Experts and Intermediates

### Classic indicators

Concerning *knowledge integration*, our analyses showed that intermediates' explanations contained more *concepts*,  $F(1, 10) = 6.23$ ,  $p = .03$ , partial  $\eta^2 = .38$ , but did not significantly differ with regard to the number of *relations*,  $F(1, 10) = 3.04$ ,  $p = .11$ , partial  $\eta^2 = .23$ . Concerning *knowledge encapsulation*, there was no significant difference between experts and intermediates regarding the number of high-level inferences,  $F(1, 10) = 2.43$ ,  $p = .15$ , partial  $\eta^2 = .20$  and in the use of encapsulated concepts,  $F(1, 10) = .06$ ,  $p = .82$ , partial  $\eta^2 = .01$ .

### Graph-Oriented Measures

With regard to *knowledge integration*, intermediates' knowledge structures were significantly more fragmented than experts' knowledge structures,  $F(1, 10) = 6.58$ ,  $p = .03$ , partial  $\eta^2 = .40$ . Concerning connectedness, there was no significant difference between experts and intermediates,  $F(1, 10) = 2.83$ ,  $p = .12$ , partial  $\eta^2 = .22$ .

With regard to *knowledge encapsulation*, experts' inference paths were significantly shorter than those of intermediates,  $F(1, 10) = 4.40$ ,  $p = .05$ , partial  $\eta^2 = .33$ . Furthermore, experts omitted more relevant concepts in

their explanations compared to intermediates,  $F(1, 10) = 7.50$ ,  $p = .02$ , partial  $\eta^2 = .43$ .

Table 1: Means, standard deviations and effect sizes for knowledge integration and encapsulation.

Variables	Intermediates	Experts	$\eta^2$
Propositions RC <sup>a</sup>	33.33 (5.99)	27.50 (4.85)	.26
Propositions EX <sup>b</sup>	44.67 (8.59)	34.50 (11.31)	.24
<i>Classic measures of knowledge integration</i>			
Concepts	50.83 (9.45)	35.83 (11.29)	<b>.38</b>
Relations	44.50 (8.46)	34.33 (11.52)	.23
<i>Graph-oriented measures of knowledge integration</i>			
Connectedness	.88 (.05)	.96 (.11)	.22
Fragmentation	6.5 (1.98)	3.5 (2.07)	<b>.40</b>
<i>Classic measures of knowledge encapsulation</i>			
High-level	1.17 (1.17)	5.33 (6.44)	.20
Inferences			
Encapsulated concepts	7.50 (1.87)	7.17 (2.93)	.01
<i>Graph-oriented measures of knowledge encapsulation</i>			
Inference path	10.83 (3.06)	7.17 (2.64)	<b>.33</b>
Omission of concepts	2 (1.10)	4 (1.41)	<b>.43</b>

Note. Differences with  $p < .05$  are in boldface.

<sup>a</sup> mean number of propositions in the recall protocols.

<sup>b</sup> mean number of propositions in the explanations.

## Predictions regarding the Validity of the Graph-Oriented Measures

Table 2 presents the correlations between the classic and the graph-oriented measures. With regard to *knowledge integration*, we found high correlations between the classic measure of detailedness and the graph-oriented measure of fragmentation.

For *knowledge encapsulation*, we found high correlations between the classic measure of high-level inferences and the graph-oriented measure of inference path. Correlations between high-level inferences and omission of concepts were not significant. As the effect sizes (table 1) indicated, the best indicator of knowledge integration was our fragmentation measure; for knowledge encapsulation, our omission of concepts measure.

To test if our graph-oriented measures discriminated better between experts and intermediates as compared to the classic measures, we conducted a discriminant analysis (step-wise). All variables both of the classic and the graph-oriented measures were entered into the analysis. The method of minimizing Wilks' lambda was used for inclusion of the variable, and the criterion F to enter was set to 4. The stepwise discriminant heuristic selected as relevant predictors *omission of concepts* and *fragmentation*, canonical  $R^2 = .62$ , which significantly discriminated all the cases into the expert's and intermediate's condition,  $\Lambda = .39$ ,  $\chi^2(2) = 8.58$ ,  $p = .01$ . The discriminant heuristic solely selected graph-oriented measures, but none of the classic measures was selected.

Table 2: Correlations of the dependent measures ( $N=12$ )

	1	2	3	4	5	6	7
<i>Classic measures</i>							
1 Concepts	-						
2 Relations	<b>.95</b>	-					
3 High-level Inferences	-.43	-.46	-				
4 Encapsulated Concepts	.24	.05	.25	-			
<i>Graph-oriented measures</i>							
5 Connectedness	-.35	-.04	-.20	<b>-.65</b>	-		
6 Fragmentation	<b>.64</b>	.41	-.06	.55	<b>-.78</b>	-	
7 Inference Path	<b>.68</b>	<b>.63</b>	<b>-.62</b>	.30	-.18	.45	-
8 Omission of concepts	-.54	-.49	.14	-.19	.24	-.34	-.26

Note. Correlations with  $p < .05$  are in boldface.

## Discussion

In this paper, we proposed four graph-oriented indicators for measuring knowledge integration and knowledge encapsulation. Based on graph theory, these indicators allow for an in-depth analysis of the structure of knowledge integration and encapsulation. The results from our study can be summarized as follows:

Overall, our results showed the validity of our graph-oriented measures with regard to knowledge encapsulation and knowledge integration by detecting structural differences between experts' and intermediates' knowledge structures.

For the classic measures by Rikers et al. (2002), the only statistically significant expertise-related difference occurred in regard to the number of concepts, indicating that experts' explanations were less detailed than intermediates' explanations. For the other classic knowledge encapsulation measures, that is, the number of high-level inferences and the number of encapsulated concepts, no significant differences between experts and intermediates were found. However, we concede that our sample of experts and intermediates was very small. Thus, given the considerable effect sizes for the classic measures, it can be assumed that with a larger sample size, those differences would have also reached statistical significance.

Our graph-oriented measures of encapsulation, namely the omission of concepts and the length of the inference path, significantly differed between experts and intermediates. Additionally, for knowledge integration, we found significant differences with regard to the fragmentation of the explanations, indicating that experts' explanations were less fragmented (i.e. more integrated) than intermediates' explanations. However, connectedness did not differ significantly between experts and intermediates. Generally, the largest effects in our study resulted for the graph-oriented indicators: analyses showed that the most discriminative indicator of knowledge integration was fragmentation. Similarly, regarding knowledge encapsulation, the omission of concepts was the most discriminative predictor. Hence, the graph-oriented

indicators were more sensitive towards differences between experts and intermediates, that is, the graph-oriented indicators were better able to discriminate between experts and intermediates. Further evidence for the validity of our graph-oriented measures can be found in the high correlations between the classic measures by Rikers et al. (2002) and our graph-oriented measures. They seem to measure the construct of knowledge encapsulation and knowledge integration related to the classic measures, but due to the granularity of the graph-oriented measures in a more sensitive and discriminative way.

Despite the promising results of our experiment, there are also limitations and open questions that need to be addressed. One limitation refers to the small sample size in the experiment. Although we showed that the graph-oriented measures were more discriminative compared to the classic measures by Rikers et al., the small sample size limited test power and therefore results should be interpreted with caution. As our experts were cardiologists with around 20 years of work experience, it proved to be difficult to convince a large number of them to participate in our study. Additionally, in using only one task, namely to explain the reasons of bacterial endocarditis, the scope of our experiment was rather restricted. Therefore, additional tasks should be included to map a more integrated representation of the domain of cardiology. Apart from the scope, it should also be acknowledged that assessing participants' knowledge structures by analyzing written recall protocols and written explanations is a rather indirect measure of participants' knowledge structure. Therefore, it should be examined whether our results can also be replicated using a more direct elicitation technique, such as think-aloud protocols. Beside these methodological issues, there remains the question, if the graph-oriented indicators are able to model the development of expertise. Therefore, novices should be included in future studies.

In conclusion, we see our methodology as a promising starting point for future research. The results showed that our graph-oriented indicators are well suited to detect differences between different expertise levels concerning the encapsulation and integration of knowledge structures. Graph-oriented indicators proved to be more sensitive and therefore more valid measures of structural differences, compared to the classic measures that solely rely on frequencies of concepts and high-level inferences. Likewise, due to the formalization of the measures, they can be easily automated, which heightens objectivity and reliability and offers a more efficient way of measuring knowledge structures. It is up to further research to explore these possibilities.

## Abstract

Human concept learning is particularly impressive in two respects: the internal structure of concepts can be representationally rich, and yet the very same concepts can also be learned from just a few examples. Several decades of research have dramatically advanced our understanding of these two aspects of concepts. While the richness and speed of concept learning are most often studied in isolation, the power of human concepts may be best explained through their synthesis. This paper presents a large-scale empirical study of one-shot concept learning, suggesting that rich generative knowledge in the form of a motor program can be induced from just a single example of a novel concept. Participants were asked to draw novel handwritten characters given a reference form, and we recorded the motor data used for production. Multiple drawings of the same character not only produced visually similar drawings, but they also showed a striking correspondence in their strokes, as measured by their number, shape, order, and direction. This suggests that participants can infer a rich motor-based concept from a single example. We also show that the motor programs induced by individual subjects provide a powerful basis for one-shot classification, yielding far higher accuracy than state-of-the-art pattern recognition methods based on just the visual form.

**Keywords:** concept learning; one-shot learning; structured representations; program induction

The power of human thought derives from the power of our concepts. With the concept “car,” we can classify or even imagine new instances, infer missing or occluded parts, parse an object into its main components (wheels, windows, etc.), reason about a familiar thing in an unfamiliar situation (a car underwater), and even create new compositions of concepts (a car-plane). These abilities to generalize flexibly, to go beyond the data given, suggest that human concepts must be representationally rich. Yet it is remarkable how little data is required to learn a new concept. From just one or a handful of examples, a child can learn a new word and use it appropriately (Carey & Bartlett, 1978; Markman, 1989; Bloom, 2000; Xu & Tenenbaum, 2007). Likewise, after seeing a single “Segway” or “iPad,” an adult can grasp the meaning of the word, an ability called “one-shot learning.” A central challenge is thus to explain these two remarkable capacities: what kinds of representations can support such flexible generalizations, and what kinds of learning mechanisms can acquire a new concept so quickly? The greater puzzle is putting them together: how can such flexible representations be learned from only one or a few examples?

Over the last couple of decades, the cognitive science of concepts has divided into different traditions, focused largely on either the richness of concepts or on learning from sparse data. In contrast to the simple representations popular in early cognitive models (e.g., prototypes; Rosch, Simpson, & Miller, 1976) or conventional machine learning (e.g., support vector machines), one tradition has worked to develop

more structured representations that can generalize in deeper and more flexible ways. Concepts have been characterized in terms of “intuitive theories,” which are mental explanations that underly a concept (e.g., Murphy & Medin, 1985), or “structural description” models, which are compositional representations based on parts and relations (e.g., Winston, 1975; Hummel & Biederman, 1992). In the latter framework, the concept “Segway” might be represented as two wheels *connected* by a platform, which *supports* a motor, etc. Most recently, research in AI and cognitive science has emphasized rich *generative* representations. Concepts like “house” can vary in both the number and configuration of their parts (windows, doors, balconies, etc.), much like the variable syntactic structure of language. This has lead researchers to model objects and scenes using generative grammars (Wang et al., 2006; Savova, Jakel, & Tenenbaum, 2009; Zhu, Chen, & Yuille, 2009) or programs (Stuhlmüller, Tenenbaum, & Goodman, 2010).

A different tradition has focused more on rapid learning and less on conceptual richness. People can acquire a concept from as little as one positive example, contrasting with early work in psychology and standard machine learning that has focused on learning from many positive and negative examples. Bayesian analyses have shown how one-shot learning can be explained with appropriately constrained hypothesis spaces and priors (Shepard, 1987; Tenenbaum & Griffiths, 2001), but where do these constraints come from? For simple prototype-based representations of concepts, rapid generalization can occur by just sharpening particular dimensions or features, as described in theories of attentional learning (Smith, Jones, Landau, Gershkoff-Stowe, & Samuelson, 2002) and overhypotheses in hierarchical Bayesian models (Kemp, Perfors, & Tenenbaum, 2007). From this perspective, prior experience with various object concepts may highlight the most relevant dimensions for whole classes of concepts, like the “shape bias” in learning object names (as opposed to a “color” or “material bias”). It is also possible to learn new features over the course of learning the concepts (Schyns, Goldstone, & Thibaut, 1998), and recent work has combined dimensional sharpening with sophisticated methods for feature learning (Salakhutdinov, Tenenbaum, & Torralba, 2011).

Despite these different avenues of progress, we are still far from a satisfying unified account. The models that explain how people learn to perform one-shot learning are restricted to the simplest prototype- or feature-based representations; they have not been developed for more sophisticated representations of concepts such as structural descriptions, grammars, or programs. There are also reasons to suspect that these richer representations would be difficult if not impos-

sible to learn from very sparse data. In linguistics, for instance, grammar induction is typically studied in the limit as the number of examples goes to infinity; why should we expect learning a grammar that describes instances of houses, or cars, to be possible from just one example? Theoretical arguments (e.g., the bias/variance tradeoff; Geman, Bienenstock, & Doursat, 1992) imply that representationally rich concepts should generally require more data to learn, not less. The work of Winston (1975) and Lovett, Dehghani, and Forbus (2007) might be the closest to human-level concept learning, where they learned relational schemata for simplified notions of “arches,” “houses,” “stoves,” and “fireplaces” from short sequences of examples. But a fully human-like, one-shot learning ability was beyond their scope.

Even with these gaps in our understanding, we believe that the power of human concepts will be best explained by bringing these two traditions together. By doing so, we hope to explore the extent to which people can learn representationally rich concepts from very sparse data, and we also hope to explain this ability in computational terms. These are the long-term goals of our work. Here we take a first step with a large-scale empirical study of one-shot concept learning, using a domain of handwritten characters from the world’s alphabets (see Figure 1). These objects are not nearly as complex as many object concepts such as “house,” “dog,” or “Segway,” but they still offer a vast number of novel, high-dimensional, and cognitively natural categories with important relational structure. They are much richer than the highly oversimplified artificial stimuli used in previous laboratory studies of one-shot learning (Feldman, 1997; Kemp & Jern, 2009). Yet characters are still simple enough for us to hope that tractable computational models can represent all the structure people see in them – unlike natural images.

What is the right structural representation for these simple visual concepts? The generative process for any handwritten character is a motor program, which is a set of instructions, in the mind of the drawer, that can be sent to the motor effectors such as an arm or a hand. These programs are complex compositions of pen strokes (the “parts” or the “sub-routines” of the program), which might vary in their number, order, and style across drawers. Despite these various degrees of freedom, human drawing is noted for its regularity, which has been likened to a “grammar of action” (Goodnow & Levine, 1973). Thus it seems fruitful to explore a generative approach based on motor programs, especially since people have the generative capacity for drawing. There are also well-developed, feature-based alternatives from psychology (Grainger, Rey, & Dufau, 2008) and machine learning, especially “deep learning” models which have achieved some of the best results on handwritten digit classification (0, 1, 2, ..., 9) (e.g., Salakhutdinov & Hinton, 2009). Thus it will be important to compare multiple computational approaches, with the goal of better understanding the psychological processes and also improving one-shot learning in machines.

To begin exploring these questions, we ran a large-scale

Figure 1: The top row shows example characters from our dataset, in the original printed form. Below are three example drawings from participants.

online study where participants drew novel character concepts after seeing just a single example. We refer to this task as “one-shot category production,” drawing inspiration from numerous studies that have used the generation of category exemplars as a window into conceptual representation (e.g., Battig & Montague, 1969; Rosch et al., 1976; Feldman, 1997). We see one-shot category production as a special case of “one-shot learning,” which includes classification and other types of generalization from just one example. Our large-scale study produced about 32,000 images of characters across a set of 1,600 concepts, and the on-line drawing trajectories were recorded for each image. From the production data, we analyzed the extent to which people can infer a robust motor program representation from a single example. We also compared humans and multiple computational approaches on a one-shot classification task, using methods based on either the motor data or just the visual forms.

## Category production experiment

The 1,600 character concepts were collected from 50 alphabets, including current or historic scripts (e.g., Bengali, Sanskrit, and Tagalog) and invented scripts for purposes like sci-fi novels. The characters were taken from [www.omniglot.com](http://www.omniglot.com) in printed fonts, and several originals and their subsequently drawn images are shown in Fig. 1. This dataset was previously used to compare models of one-shot classification (Lake, Salakhutdinov, Gross, & Tenenbaum, 2011).

The drawing experiment was run through Amazon Mechanical Turk, and participants were asked to draw at least one entire alphabet. For each template image, they were asked to “draw each character as accurately as you can.” An alphabet’s printed characters were displayed in rows on a webpage, with an associated drawing pad below each image. Participants could draw by holding down a mouse button and moving the mouse, and we also included “forward,” “back,” and “clear” buttons. Some participants made minor image adjustments with small mouse movements, and we tried to mitigate this inconsistency by excluding strokes that were very short in time and space from the analysis.

## The structure of the motor programs

When people perceive a new character, in what sense do they infer a new concept? While this mental representation might be just a bundle of features, the concept might also include richer structure in the space of motor programs. To investigate this possibility, we analyzed how multiple drawers produced a particular concept during the drawing task. We rea-

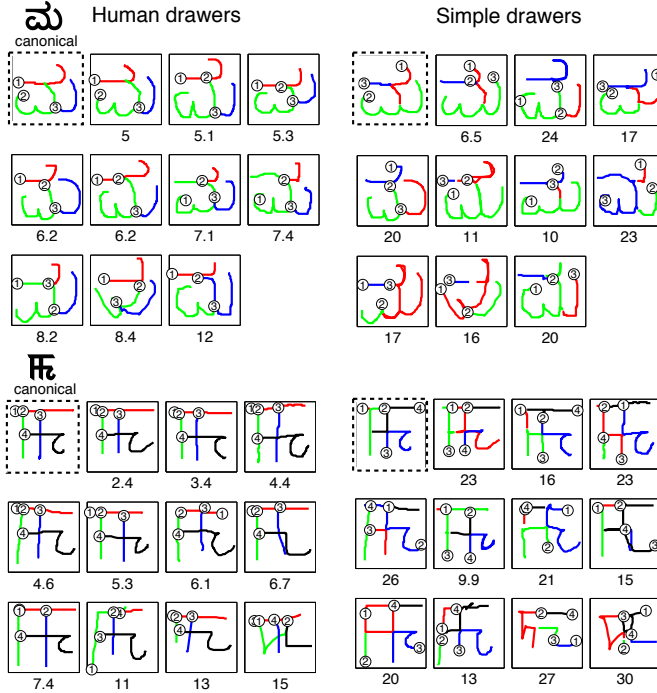

Figure 2: For two concepts (out of the 1600 total), each box shows the motor data produced by human drawers (left) or simple drawers (right). “Canonical” drawers are in the dotted boxes, and their distances (Eq. 1) to the other examples are the numbers below each frame. Stroke color shows correspondence to the canonical, circles indicate the beginning of each stroke, and numbers inside circles denote stroke order.

soned that in order to do this task, participants must infer a novel motor program, which will be reflected in the time course of drawing. Consistency in the structure of these drawings would provide evidence for two interlinked claims: people seem to grasp the same underlying concept from one example, and this concept includes a highly structured generative program. To measure consistency for a particular character, we quantitatively analyzed the number, shape, direction, and order of the parts (strokes) in the motor data.

### The number of parts

This analysis (and subsequent ones) used just 20 of the alphabets in the dataset, excluding the six most common as determined by Google hits. The remaining alphabets were needed to train the alternative models in the later classification experiment. The simplest statistic to analyze was the number of parts. For each character, we investigated whether the drawers clustered around a common number of parts (the mode number across participants). Aggregating across each drawing in the dataset, the histogram in Fig. 3A (red) shows the absolute difference between the actual number of strokes and the mode number of strokes from all of the drawings of that character. Although this distribution is guaranteed to peak at zero, a strikingly large percentage of drawers used exactly the modal number (66%). As a control, a null dataset was created by replacing each number of strokes by a uniform draw (1 to 6 here, but other values are similar). This distribution was not nearly as peaked around the mode (Fig. 3A blue).

### The shape of the parts

The parse of a character into parts (strokes) is at the core of each drawing. When people look at a new concept, do they perceive the same parts? This is difficult to analyze, since the number and length of the strokes can differ between images. A similarity measure should also be invariant to the order and direction of the strokes. Despite these challenges, we found that it was possible to analyze consistency in the shape of the strokes, and we discuss our method in the section below.

**Shape-based distance in motor space.** Since most drawers (66%) used the modal number of strokes, we restrict this and subsequent analyses to only these modal drawings. With this simplification, the strokes in two images can be matched in correspondence (one-to-one and onto). Our approach also matches the sub-structure within two strokes, finding an alignment between the points in the two trajectories (onto but not one-to-one). Given an optimal matching at both levels, the overall shape distance is roughly the mean distance between all of the aligned trajectory points. Before computing distance, characters were also transformed to be translation and scale invariant.<sup>1</sup> Examples of the distance are illustrated in Fig. 2, where the number below each drawing is the distance to the drawing in the dotted box.

The details of the distance measure are as follows. Consider two drawings  $S_1, \dots, S_k$  and  $R_1, \dots, R_k$  with  $k$  strokes each. Each stroke is a sequence of positions  $S_i = [S_{i1}, \dots, S_{in}]$  with arbitrary length, where  $S_{ij} \in \mathbb{R}^2$ . The overall distance between the characters is defined as

$$\min_{\pi} \frac{1}{k} \sum_{i=1}^k \min [dtw(S_i, R_{\pi(i)}), dtw(S_i, F(R_{\pi(i)}))], \quad (1)$$

where  $\pi(\cdot)$  is a permutation on the stroke indices  $1, \dots, k$  (a bijective function from the set  $\{1, \dots, k\}$  to  $\{1, \dots, k\}$ ), and the flip function  $F(S_i) = [S_{in}, \dots, S_{i1}]$  reverses the stroke direction to provide direction invariance. The distance  $dtw(\cdot, \cdot)$  between two trajectories is calculated by Dynamic Time Warping (DTW; Sakoe & Chiba, 1978), which fits a non-linear warp such that each point in one trajectory is aligned with a point in the other. The DTW distance is then the mean Euclidean distance across all pairs of aligned points.

**The simple drawer model.** Upon visual inspection of the stroke matches  $\pi(\cdot)$  chosen by the outer minimization in Eq. 1, there is a striking consistency across drawers in the inferred parts for a character. We show two characters in Fig. 2, where color denotes the stroke matches (left panels). The plots for the entire dataset are available online.<sup>2</sup> While this qualitative correspondence may reflect richly structured motor processes, there could be a more simplistic explanation. The consistency could be a consequence of selection bias, since we selected drawers that used the modal number of strokes,

<sup>1</sup> This transformation subtracts the center of gravity and rescales, such that the range of the largest dimension is 105.

<sup>2</sup> <http://web.mit.edu/brenden/www/consistency.html>

Figure 3: A histogram analysis of the consistency in the motor data, comparing human drawers (red) with a parallel dataset of simple drawers (blue) designed as a null hypothesis. Humans are strikingly consistent across a range of statistics compared to the simple model. As labeled, some histograms pool data from characters with different numbers of strokes (e.g.,  $\{2,3\}$  includes 2- and 3-stroke characters).

and there will be fewer degrees of freedom available to a  $k$ -stroke drawer for any given  $k$ . In the special case of  $k$  disjoint segments (like in Braille), there may only be one production option. To explore the degrees of freedom and to provide a baseline for the observed consistency, we devised a “simple drawer” model that is likely to mimic human drawers when the space is highly constrained, but otherwise it more freely explores the potential motor space.

The simple drawer is given access to the same set of points as a real drawer traversed in the motor data, but without the sequential information. It then tries to draw the same character as efficiently as possible using the same number of strokes. It must visit every point exactly once, while minimizing the distance traveled while ink is flowing. Given a real drawing with strokes  $S_1, \dots, S_k$ , the simple drawer’s interpretation  $Q_1, \dots, Q_k$  is defined by the problem

$$\operatorname{argmin}_{Q_1, \dots, Q_k} \sum_{i=1}^k \sum_{j=1}^{|Q_i|-1} \|Q_{ij} - Q_{i(j+1)}\|_2, \quad (2)$$

where  $|\cdot|$  is the number of points in the stroke sequene, and  $\|\cdot\|_2$  is Euclidean distance. Each point  $S_{ij}$  in the original drawing is equal to exactly one point  $Q_{ab}$  in the new drawing. This formulation encourages smooth strokes, but it also leads to creative parses (Fig. 2 right panels), in part because there are multiple optima. A drawback of the model is that it sometimes draws paths where no ink exists. To reduce this problem, the simpler drawer is not allowed to travel large distances between adjacent points, where the upper bound is the maximal adjacent distance in the corresponding real drawing. For optimization, we can reformulate the problem as the well-known traveling salesman problem (TSP) by inserting  $k$  cost-free “points” to indicate the stroke breaks. Inspired by efficient approximate solvers for the TSP

problem, we optimized using simulated annealing with alternating Metropolis-Hasting node swaps and Gibbs sampling (Rubinstein & Kroese, 2008).

**Results.** The simple drawer was used to re-sketch each image, creating an entire parallel dataset for comparative analysis. The shape-based consistency of a character is the mean distance (Eq. 1) between each pair of drawings of that character. Fig. 3B shows histograms of this consistency measure for the human drawers (red) and the simple drawers (blue). The aggregate histogram (right) for characters with two to five strokes shows a large difference in the consistency of the parts. The histogram for characters with one stroke (left) shows a closer correspondence between participants and the simple drawer, due to the limited degrees of freedom.<sup>3</sup> These results suggest that people inferred motor programs that were based on a characteristic set of strokes.

### The direction of the parts

Do different drawers infer the same stroke directions? For each character, a single canonical drawer was chosen to minimize the sum shape-based distance across all other drawers of that character (Eq. 1). Example canonical drawers are shown in the dotted boxes in Fig. 2 (left). For each person’s drawing compared to the canonical drawing, the chosen value of the inner minimization in Eq. 1 indicates whether each stroke, or that stroke in reverse direction ( $F(\cdot)$ ), is a better match to the corresponding stroke in the canonical drawer. Aggregating across each stroke in the dataset, Fig. 3C (red) displays the proportion of times the modal stroke direction was picked, using the canonical drawer as the reference point. The dataset

<sup>3</sup>Some single stroke characters can still be drawn in a number of ways, such as choosing the starting location of an “O.” People tend to start at the top, while the simpler drawer is agnostic.

of simple drawers (blue) provides a direction-agnostic baseline. By comparison, people’s inferred programs clearly have preferred directions.

### The order of the parts

Is stroke order also consistent across drawers? As in the analysis of direction, and the canonical drawers were used as the reference points, from which stroke order was defined. For any person’s drawing compared to the canonical drawing of that character, the chosen permutation  $\pi(\cdot)$  from the outer minimization in Eq. 1 defines a relative ordering of the strokes. Aggregating across each drawing, Fig. 3D shows the proportion of times the modal stroke order was picked. Like the other statistics, stroke order was also highly consistent across characters. Unsurprisingly, consistency was less pronounced as the number strokes increased.

### One-shot classification

The previous analyses suggest that people can infer rich motor-based concepts from just a single example. If the same perceptual inferences occurred in the context of categorization, would these representations prove useful for one-shot classification? We investigated this question by using the motor data to classify characters by type, based on the shape-based distance measure (Eq. 1). The model received 20 random characters with just one example each. Test examples (2 per class) were classified as the best fitting category. All 20 categories used the same (modal) number of strokes. This classification task was repeated 20 times with different characters, and the mean percent correct is shown in Fig. 4.

We used several baselines for comparison. The simplest method picked the closest image in pixel space, using Euclidean distance. We also tested Deep Boltzmann Machines (DBMs; Salakhutdinov & Hinton, 2009) as a representative feature-based model. DBMs learn a hierarchy of distributed feature representations for the raw pixels, without using a priori knowledge about the geometry of images. DBMs have obtained state-of-the-art performance on handwritten digit recognition when trained with thousands of digits, and we pre-trained it on the 30 alphabets that were not used for classification (about 19,000 images). For one-shot classification, new items were represented in feature space and classified based on cosine similarity across all hidden layers (two with 1000 units each). We also tested a model that infers latent stroke-like parts from the raw images (Lake et al., 2011), as well as the simple drawing model, which uses the same motor data but without the strong structural consistency.

Performance was measured across a range of different numbers of strokes (Fig. 4). Chance performance is 5% correct, and pixel distance performed at 20% correct on average (“pixels” in Fig. 4). Next was the DBM at 37% (“features”), the inferred parts model at 48%, and then the simple drawer at 50%. The real stroke data was far better than all of the other methods, with an average performance of 83% correct. We also tried to include stroke order and direction information in the classification cost function, but performance did

Figure 4: Classification performance based on one example of 20 different characters. Test instances were compared to each class, and the best match was selected.

not improve significantly. Finally, human one-shot classification performance was 96%, as measured behaviorally in a 20-way classification task (“human-level” in Fig. 4; see footnote for experimental setup).<sup>4</sup> Overall, the motor data was by far the most effective means for one-shot classification.

### Discussion

Our category production experiment produced over 32,000 images of handwritten characters. Each of the roughly 1,600 characters was drawn by 20 different participants, and we found a strong correspondence in the structure of their inferred motor programs. On the whole, the number, shape, order, and direction of the parts (strokes) was highly consistent across participants. Also the motor data provided a powerful basis for one-shot classification. These results suggest that when people look at a new character, they can infer a richly structured motor program. This motor program is capable of both synthesizing new examples and classifying new instances with high discriminative accuracy.

How can these motor programs be learned from just one example? This ability clearly depends on prior experience, but how does this translate into constraints on the formation of these programs? There are various possibilities. Prior knowledge might come in the form of shared sub-programs or shared strokes, like our preliminary model in Lake et al. (2011). From their general writing and drawing experience, people might learn sub-routines like “circles, diagonal lines, or S-shapes,” and then they could parse novel characters into this rich set of parts. But prior knowledge could come in many other forms, including more general constraints and biases (learned or otherwise) in human drawing and motor capabilities. Researchers have found a number of rules that usefully characterize drawing: start drawing at the top-left, draw horizontal strokes left-to-right, draw vertical strokes top-to-bottom, and minimize the number of strokes (Goodnow & Levine, 1973; Van Sommers, 1984). In a preliminary analysis, we have observed strong versions of these effects in our dataset of natural alphabets. Thus, it is possible that

<sup>4</sup>This study was run on Amazon Mechanical Turk with 15 participants and 50 trials. Each trial consisted of a single test image, and participants were asked to pick one of the 20 other images that looked the most similar. This was the same task that the models performed, except that characters with different numbers of strokes were intermixed and a different set of alphabets was used.

some of the richness of these newly acquired concepts (including shape, direction, and order) is a consequence of relatively simple, low-level principles. But it is also unclear how these directives should be combined when they conflict, or how they might interact with other forms of prior knowledge. Computational models are well-suited to help answer these questions, and we hope that future work will clarify how prior knowledge can support such rapid program induction.

Finally, although our work has focused on handwritten characters, we expect that similar phenomena and computational accounts are relevant more broadly. Characters share interesting structure with other kinds of symbols used for communication, including spoken words and gestures. Characters are produced by a sequence of strokes, and likewise, spoken words are produced as a sequence of phonemes. Characters, spoken words, and gestures are also “embodied,” since the mind and body can both generate and perceive concepts in these domains (e.g., Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Freyd, 1983). All of these concepts must also be learnable from one or a few examples, in the context of efficient communication and social learning. One-shot program induction may also be possible in learning very different kinds of natural concepts, such as trees or ferns that have distinctive branching patterns and unique leaf shapes. One-shot learning could be possible here for a different reason: not because of the strong priors imposed by motor constraints or previous learning, but because a single example is highly complex and contains extensive repeated structure. We hope that future work will explore a fuller range of rich representations for concepts, while explaining how these same concepts can be learned from just one or a few examples.

**Acknowledgements** We gratefully acknowledge Jason Gross for developing the experimental interface and for collecting the data. We also thank John McCoy for helpful comments, and Dan Ellis for making his DTW code available.

### Abstract

Previous research (Heit & Rotello, 2010; Rips, 2001; Rotello & Heit, 2009) has suggested that differences between inductive and deductive reasoning cannot be explained by probabilistic theories, and instead support two-process accounts of reasoning. We provide a probabilistic model that predicts the observed non-linearities and makes quantitative predictions about responses as a function of argument strength. Predictions were tested using a novel experimental paradigm that elicits the previously-reported response patterns with a minimal manipulation, changing only one word between conditions. We also found a good fit with quantitative model predictions, indicating that a probabilistic theory of reasoning can account in a clear and parsimonious way for qualitative and quantitative data previously argued to falsify them. We also relate our model to recent work in linguistics, arguing that careful attention to the semantics of language used to pose reasoning problems will sharpen the questions asked in the psychology of reasoning.

**Keywords:** Reasoning, induction, deduction, probabilistic model, formal semantics.

Suppose that you have learned a new biological fact about mammals: whales and dogs both use enzyme B-32 to digest their food. Is it now *necessary* that horses do the same? Is it *plausible*, *possible*, or *more likely than not*? Expressions of this type—known as *epistemic modals* in linguistics—have played a crucial role in recent work that argues for a sharp qualitative distinction between inductive and deductive modes of reasoning. In the paradigm introduced by Rips (2001) and extended by Heit and Rotello (2010); Rotello and Heit (2009), participants are divided into two conditions and are either asked to judge whether a conclusion is “necessary” assuming that some premises are true, or whether it is “plausible”. The former is identified with the deductive mode of reasoning, and the latter with the inductive mode.

These authors asked participants in both conditions to evaluate a variety of logically valid and logically invalid arguments. An example invalid argument might be “Cows have sesamoid bones; Mice have sesamoid bones; therefore, Horses have sesamoid bones”. An example valid argument might be “Mammals have sesamoid bones; therefore, horses have sesamoid bones.” They found that there was a non-linear relationship between the endorsement rates of arguments depending on condition: participants in both conditions generally endorsed logically valid arguments, but participants in the deductive condition were much less likely to endorse invalid arguments than those in the inductive condition. These results are interpreted as a challenge to theories of reasoning which rely on a single dimension of argument strength and interpret deductive validity as simply the upper extreme of this dimension (Harman, 1999; Johnson-Laird, 1994; Oscherson, Smith, Wilkie, Lopez, & Shafir, 1990). In particu-

lar, Rips and Heit & Rotello argue that non-linearities cannot be accounted for by probabilistic theories of reasoning, which identify the strength of an argument with the conditional probability of the conclusion given the premises (Heit, 1998; Kemp & Tenenbaum, 2009; Oaksford & Chater, 2007; Tenenbaum, Griffiths, & Kemp, 2006). On the other hand, they claim that the results are consistent with two-process theories of reasoning (Evans & Over, 1996).

We argue that the manipulation involving “necessary” and “plausible” hinges not on a qualitative distinction between two reasoning processes, but rather on facts about the semantics of these words which can be modeled using a single underlying scale of argument strength—conditional probability. We propose a semantically motivated model of reasoning with epistemic concepts which predicts non-linear response patterns depending on the choice of modal similar to those observed in previous work, and makes detailed quantitative predictions about response patterns in invalid arguments.

We test the claim that the modal word is the crucial factor using a new paradigm that isolates its effects. Our arguments had the same form as the examples above, except that we placed the modal word of interest in the conclusion:

**Premise 1:** Cows have sesamoid bones.

**Premise 2:** Mice have sesamoid bones.

**Conclusion:** It is {plausible/necessary/possible/likely/probable/certain} that horses have sesamoid bones.

We will refer to configurations such as “It is plausible/possible/etc. that *C*” as a **modal frame**. If varying the modal frame gives rise to a non-linear pattern of responses similar to the one found in previous work, this would indicate that an explanation of these results should be framed in terms of the meaning of these modal words.

Together, the model and experimental evidence indicate that the negative conclusions of previous work regarding one-dimensional theories of argument strength are not warranted: it is possible to explain non-linear response patterns with a probabilistic account of argument strength.

### Previous Work

Rips (2001) conducted a reasoning experiment designed to investigate the traditional distinction between deductive and inductive reasoning. Participants in two groups were asked to judge arguments either according to whether the conclusion was *necessary* (assuming that the premises were true) or whether it was *plausible*. Most participants in both conditions accepted logically valid arguments and rejected invalid arguments whose conclusion was not causally consistent with the

premises, such as “Car X strikes a wall, so Car X speeds up”. However, participants differed by condition in whether they rejected non-valid arguments which were causally consistent with the premises: those in the inductive condition generally accepted arguments such as “Car X strikes a wall, so Car X slows down”, while those in the deductive condition did not. Rips argued that this result falsifies theories of reasoning in which argument strength is a one-dimensional quantity such as conditional probability: “[i]f participants base all forms of argument evaluation on the position of the argument on a single psychological dimension, then induction and deduction judgments should increase or decrease together” (p.133).<sup>1</sup>

Heit and Rotello (2010); Rotello and Heit (2009) extended Rips’ paradigm in a number of ways. Their core finding was that  $d'$ , a standard measure of sensitivity in Signal Detection Theory (SDT), was significantly higher in the deductive condition across a variety of arguments types and manipulations.  $d'$  is defined as  $z(H) - z(F)$ , the difference between the  $z$ -scored hit rate  $H$  and false alarm rate  $F$  (Macmillan & Creelman, 2005). This difference means that participants in the inductive condition were more sensitive to argument validity than participants in the deductive condition (see Table 1).

Table 1: Acceptance rates and  $d'$  in Experiment (1a) of Rotello and Heit (2009) (three-premise arguments only).

	Deduction	Induction
Acceptance, valid	.94	.95
Acceptance, invalid	.06	.17
Sensitivity ( $d'$ )	3.31	2.56

Differential sensitivity indicates that the difference between conditions is not simply a shift in response criterion in the presence of two equal-variance Gaussians representing signal and noise. Thus we cannot fit a one-dimensional SDT model to such results. In accord with Rips, Rotello and Heit (2009) argue that the non-linear relationship between validity and condition is a challenge to probabilistic theories of reasoning. They argue that the results are better captured by a two-dimensional SDT model with possibly orthogonal dimensions of inductive strength and deductive validity, in which the response criterion can vary in two dimensions.<sup>2</sup>

<sup>1</sup>Rips (2001) also found a crossover effect in which participants in the “necessary” condition were slightly more likely to endorse valid arguments that were inconsistent with causal knowledge than participants in the “plausible” condition, but the reverse was true for arguments consistent with causal knowledge. Heit & Rotello’s work did not find any analogous effect, nor did we in our experiment reported below, and we do not consider it further. However, it is possible that the effect is real and attributable to one of the various detailed differences in materials and instructions between the experiments.

<sup>2</sup>Heit and Rotello (2010); Rotello and Heit (2009) also introduced a number of further manipulations involving e.g. constrained response time, number of premises, and readability which we will not discuss in detail for reasons of space. See the concluding section for a brief consideration of two of these manipulations, however.

## A Probabilistic Model

In contrast to Rips and Rotello & Heit, we do not see these results as strong support for a two-process theory. Instead, we will argue that these results are also compatible with a probabilistic account of inductive reasoning once the semantics of the modal words used in the experiment is taken into account. In this section we propose a model of the relationship between the probability on the one hand and epistemic concepts such as certainty, necessity, and plausibility on the other. The latter are treated as non-linear functions of the former determined by a single parameter per item. This model, inspired by recent work in formal semantics, predicts non-linear response patterns and variation in  $d'$  depending on the modal used, and makes a number of fine-grained predictions that we will later evaluate against the results of an experiment.

Our probabilistic model of reasoning with epistemic modals is intended to capture the following intuitions. A maximally strong conclusion  $C$  remains maximally strong whether you ask if it is *possible*, *plausible*, *likely* or *necessary*; a maximally weak conclusion remains maximally weak under the same conditions; but there is much more flexibility around the middle of the probability scale depending on which question is asked. If  $C$  has a probability of .4, it presumably will count as *possible* and perhaps as *plausible*, but it would not seem to be *likely* and surely not *necessary* or *certain*. Thus the effect of an epistemic modal on a conditional probability should be a transformation that preserves the minimum value 0 and the maximum value 1.

Perhaps the simplest way to capture the behavior just described is to suppose that each modal  $M \in \{\text{possible, plausible, likely, probable, certain, necessary}\}$  is associated with a parameter  $\alpha_M \in \mathbb{R}^+$  which, in combination with the conditional probability  $pr(C|P)$  of conclusion  $C$  given premises  $P$ , determines the probability of *It is M that C* given  $P$ . We propose that  $\alpha_M$  relates these two probabilities by a power-law:

$$pr(\text{It is } M \text{ that } C|P) = pr(C|P)^{\alpha_M} \quad (1)$$

We model arguments with no modal as also being governed by some  $\alpha_M$  as in (1) (rather than directly reflecting the conditional probability of the conclusion given the premises).

We assume that participants’ responses to a modalized question  $Q$  are governed by (1) plus a noise parameter  $\epsilon$  (interpreted as the proportion of trials in which participants choose a response at random).

$$pr(\text{“yes”}|P, Q = \text{Is it } M \text{ that } C?) = pr(C|P)^{\alpha_M} (1 - \epsilon) + \frac{\epsilon}{2} \quad (2)$$

Depending on  $\alpha_M$  we get a variety of possible curves, a few of which are sketched in figure 1b (setting  $\epsilon = .1$  for illustrative purposes). This model captures the behavior just described: in the limits  $\alpha_M$  does not influence the response probability, but there is significant variation in response probabilities in the middle range depending on  $\alpha_M$ . This feature leads to a prediction that the choice of modal will have less influence on response rates for arguments with very high strength (e.g., valid arguments) than those with intermediate strength.

Figure 1: (a): Predicted response probability for various settings of  $\alpha_M$ . (b): Example of relation between  $\alpha_M$  and  $d'$ .

We also predict that  $d'$  will vary depending on  $\alpha_M$ . Suppose for illustration that the mean conditional probability of logically invalid arguments in some sample is .5, and that the conditional probability of valid arguments is 1. The  $d'$  statistic estimated from this data should then be (on average)

$$\begin{aligned} d' &= z(1^{\alpha_M}(1-\epsilon) + \epsilon/2) - z(.5^{\alpha_M}(1-\epsilon) + \epsilon/2) \\ &= z(1-\epsilon/2) - z(.5^{\alpha_M}(1-\epsilon) + \epsilon/2) \end{aligned} \quad (3)$$

If  $\epsilon = .1$ , we expect the observed  $d'$  to be related to  $\alpha_M$  as in figure 1b. This illustrates the fact that the value of the  $d'$  statistic is not predicted to be constant in our probabilistic model, but should depend on the choice of  $M$ . Thus, a model with one dimension of argument strength (conditional probability) is able to predict non-linearities of the type previously claimed to be problematic for probabilistic accounts.

The model also makes strong quantitative predictions about the relationship between different modal frames. That is, we predict a systematic (though non-linear) relationship between the response rates to the same argument in the modal frames *It is  $M_1$  that  $C$*  and *It is  $M_2$  that  $C$* . If  $M_1$  is associated with parameter  $\alpha_1$  and  $M_2$  with  $\alpha_2$ , for any argument with premises  $P$  and conclusion  $C$  there is some positive  $r$  such that

$$\begin{aligned} pr(Is\ it\ M_1\ that\ C|P) &= pr(C|P)^{\alpha_{M_1}} \\ &= pr(C|P)^{(r \times \alpha_{M_2})} \\ &= pr(Is\ it\ M_2\ that\ C|P)^r \end{aligned} \quad (4)$$

The prediction that every pair of modals should be related by a power-law allows us to evaluate model fit using a variety of arguments which, although not logically valid, vary widely in intuitive strength. It also shows that our model predicts that the strength of any two arguments should be related monotonically (though non-linearly) across modal frames.

## Experiment

Our experiment tested the hypothesis that non-linear response patterns can be attributed to the semantics of the modal expressions used. The main innovation was to manipulate the choice of modal  $M$  within the stimulus sentence:

*Non-valid:*

Cows have enzyme X.  
Seals have enzyme X.  
So, it is  $M$  that horses  
have enzyme X.

*Valid:*

Horses have enzyme X.  
Cows have enzyme X.  
So, it is  $M$  that horses  
have enzyme X.

This minimal manipulation allowed us to isolate the effect of the modal frame on acceptance rates both for valid vs. invalid arguments and for invalid arguments of varying strengths. We also used a larger set of epistemic modal expressions than were used in previous work, including *possible*, *plausible*, *likely*, *probable*, *necessary*, and *certain*.

## Methods

**Participants** 507 participants were recruited using Amazon’s Mechanical Turk platform, with a restriction to participants located in the United States. They were compensated for their participation.

**Materials** Participants saw 21 valid and invalid arguments with two premises and a conclusion. 18 of these included one of the 6 modal words listed above (3 for each modal), and 3 did not include a modal word. The properties used in the arguments were chosen from a list of unfamiliar biological and pseudo-biological properties. In every case, the animal in the conclusion was “horses” (Osherson et al., 1990). The arguments seen were randomly selected from a total of 63 arguments tested. 36 were non-valid arguments, in which the premise animals were chosen from the set {cows, chimps, gorillas, mice, squirrels, elephants, seals, rhinos, dolphins}. 27 were logically valid arguments with one of two forms, following (Rotello & Heit, 2009): one premise involved a mammal and the other was an *identity* premise (stating that horses have the property) or an *inclusion* premise (stating that mammals or animals have the property).

**Procedure** Participants were instructed to answer each question according to whether they agreed with the conclusion, assuming that the premises were true. For each question participants were asked to select “agree” or “disagree” and to give a confidence rating on a five-point scale.

Figure 2: (a): Valid and invalid endorsement rates by modal frame with 95% CIs; (b):  $d'$  by modal frame with 95% CIs.

## Results

We analyzed data from the 485 participants who reported that their native language was English, for 10,185 total judgments. No systematic differences emerged between identity and inclusion arguments, and we group them together as valid.

Our results replicated the crucial finding of (Heit & Rotello, 2010; Rotello & Heit, 2009) showing that sensitivity to argument validity is greater when participants are asked to judge whether a conclusion is “necessary” than when they are asked whether it is “plausible” (Table 2). The difference in  $d'$  values is significant at the  $p < .05$  level.

Table 2: Acceptance rates and  $d'$  in our experiment (*plausible* and *necessary* only), with 95% confidence intervals.

	<i>Necessary</i>	<i>Plausible</i>
Acceptance, valid	.82	.94
Acceptance, invalid	.41	.82
Sensitivity ( $d'$ )	1.15 ± .19	0.63 ± .27

Comparing Table 1 with Table 2, there are two clear differences between our results and those of Rotello and Heit (2009): our participants rejected valid arguments with *necessary* more often than with *plausible*, and they accepted invalid arguments at much higher rates. These factors contributed to lower  $d'$  in both conditions. The first difference suggests that participants in our experiment judged some logically valid arguments as strong but not maximally strong. The second is plausibly due to the use of different materials in our experiment: Rotello & Heit used the same predicate “have property  $X$ ” in all arguments, using the variable  $X$  in the stimuli and instructing participants to treat property  $X$  as a novel biological property. The use of more natural biological predicates in our experiment may have encouraged participants to have greater confidence in their guesses, particularly if they had general background knowledge about e.g. enzymes and bones.

The fact that  $d'$  differed significantly for “necessary” and “plausible” suggests that our within-participants manipulation successfully captured the core features of between-participants manipulations in previous work. That is, the dif-

ference previously reported can be elicited by a difference of a single modal word, and so appears to be triggered by semantic properties of the modal words.

**Assessing Model Fit** As pointed out in introducing the model, our account predicts three general trends. First, it predicts that acceptance rates should vary less across valid arguments than across invalid arguments (Figure 1a). This is indeed what we find (Figure 2a). Second, it predicts the possibility of a continuous gradient in  $d'$  values (Figure 1b). Our results confirm this prediction as well (Figure 2b). Third, it predicts that the acceptance rate of argument  $A$  in any two modal frames  $M_1$  and  $M_2$  should be related by a power-law. This is the quantitative prediction that we now set out to test.

We fit the model to our results using the acceptance rates of each argument in the no-modal condition as a baseline. Note that we do not believe that acceptance rates in this condition are an estimate of the true probability of the conclusion given the premises. However, our model predicts that the choice of baseline condition should not affect predictions (cf. equation 4). In accord with this prediction we found no systematic effect on  $R^2$  by varying the choice of baseline. The primary effect of the choice of baseline condition, then, is that estimates of  $\alpha_M$  given for the other conditions are up to multiplication by  $\alpha_0$ , the parameter which determines the probability of arguments in the baseline condition.

Figure 3 plots the endorsement rate of each argument in the unmodalized condition against the endorsement rate for the same argument in various modal frames. We calculated the best-fit  $\alpha_M$  for each condition. For each graph in Figure 3 the curve determined by equation (2) is superimposed, with the overall best-fit noise parameter  $\epsilon = .12$ . As the  $R^2$  values in Figure 3 and Table 2 show, this model captures much of the variance in the data, but not all of it.

In order to discern whether the remaining variance was due to systematic factors that our model does not capture, we performed a split-half reliability test, randomly dividing the data into equal-sized halves 10,000 times and testing the correlation between the two halves on the same measure that

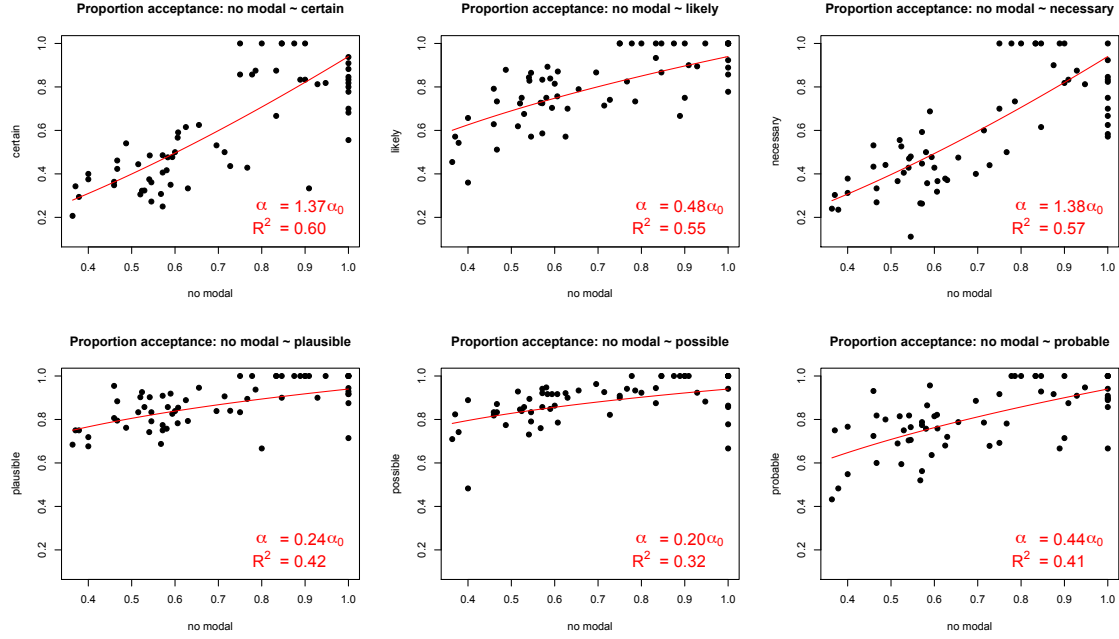

Figure 3: Endorsement rates by argument and modal frame. Curves represent model predictions using (2) and the best-fit  $\alpha$ .

was used to fit our model: acceptance rate by argument and modal. The model correlations were overall very close to the split-half correlations (Table 3). This suggests that the model captures most of the true structure in the data, though a good deal of noise remains that we cannot expect to explain.

Recall that the model predicts a consistent order in the endorsement rates of arguments across modal frames (see equation 4). In order to test this prediction we considered two tests, a permutation test and a model-based simulation. The average value of Spearman’s rank-order correlation for all pairwise comparisons between modal frames in our experiment was .53. A 10,000-sample permutation test revealed that this correlation was highly significant,  $p < .0001$ .

For the model-based test, we simulated 1,000 data sets with the same dimensions as our data using the best-fit model predictions as binomial proportions for each argument and modal frame. Equation 4 entails that all rank-order correlation in the model predictions are 1, and so this test gives us an opportunity to observe what correlations we should expect to see in a data set of this size if the prediction of a perfect underlying rank-order correlation is correct. The result was consistent with the observed rank-order correlation of .53, with 95% of the model-generated correlations falling between .49 and .64 (mean = .57). This result suggests that the model’s

monotonicity predictions fit the data well, providing further support for our claim that argument strength is based on a single scale which is manipulated by modal expressions.

## Relation to Formal Semantics

Epistemic modality has been the subject of much investigation in formal semantics (Kratzer, 1991; Egan & Weatherson, 2011). This paper has been concerned with a subtype of epistemic modals whose grammatical features indicate that they are *gradable adjectives*. This means that, like other gradable adjectives, they can be used in comparative and degree modification structures: for example, conclusion  $C$  might be *more plausible* than  $C'$  given some evidence, or  $C$  might be *very likely* or *almost necessary*. This corresponds to the fact that person  $x$  can be *taller* than person  $y$ , and a glass of water might be *very large* or *almost full*. Gradable expressions are generally treated in formal semantics as functions which map objects to points on a *scale* and compare them to *threshold values* (Kennedy, 2007). Recent empirical and formal work on gradable epistemic modals suggests that a scalar analysis is appropriate for them as well, and that probability is a good choice for the underlying scale (Lassiter, 2010; Yalcin, 2010).

Although our model is superficially different from linguistic models, there is in fact a straightforward translation between the two. Linguistic models assume that the location of the threshold is typically uncertain, a fact which is closely related to the problem of vagueness. If the uncertain location of the threshold for gradable expressions is modeled probabilistically as in (Frazee & Beaver, 2010; Lassiter, 2011; Schmidt, Goodman, Barner, & Tenenbaum, 2009), our model can be seen as describing the cumulative distribution of this threshold. Letting  $p_M(\theta)$  be the probability density of the unknown threshold associated with modal  $M$ , the cumulative distribu-

Table 3: Model correlations vs. split-half reliability results.

Modal	model $R^2$	mean split-half $R^2$
<i>certain</i>	.60	.66
<i>likely</i>	.55	.57
<i>necessary</i>	.57	.70
<i>plausible</i>	.42	.37
<i>possible</i>	.32	.34
<i>probable</i>	.41	.47

tion is given by (5), which — plugging in (1) — gives us (6).

$$pr(It\ is\ M\ that\ C|P) = \int_0^{pr(C|P)} p_M(\theta) d\theta \quad (5)$$

$$pr(C|P)^{\alpha_M} = \int_0^{pr(C|P)} p_M(\theta) d\theta \quad (6)$$

Using the fundamental theorem of calculus we can derive from equation (6) a simple formula linking  $p_M(\theta)$  to  $\alpha_M$ .

$$p_M(\theta) = \alpha_M \theta^{\alpha_M-1}, \quad 0 \leq \theta \leq 1. \quad (7)$$

This relationship allows us to interpret our model as an implementation of scalar semantics for gradable epistemic modals closely related to recent work in formal semantics.

## Conclusion

We have shown that non-linearities in responses to valid and invalid arguments can be explained by a simple probabilistic model, and thus are not evidence against a probabilistic account of reasoning. Our experimental manipulation involved the difference of a single word (an epistemic modal), and uncovered a gradation of non-linearities as a function of the specific modal used. Our model predicts a particular functional form for these differences, a power law in conditional probability, which we found in our data. This shows that it is possible to account for different patterns of results in reasoning experiments without assuming that everyday reasoning makes use of two (or more) qualitatively different types of reasoning. Rather, our model utilizes a single type of reasoning — probabilistic inference — together with a number of different but related linguistic mechanisms for talking about the results of inferential processes. This indicates that a one-dimensional theory of argument strength, coupled with an explicit formal semantics for epistemic modals, can account for a variety of patterns of reasoning in a parsimonious and explanatory way. This does not rule out a qualitative distinction between inductive and deductive reasoning, but it does call into question previous efforts to show that such a distinction is necessary to account for everyday human reasoning, suggesting instead that a single process may underlie both.

The probabilistic approach also suggests accounts of several related phenomena. For instance, the fact that argument length tends to affect plausibility judgments more than necessity judgments (Rotello & Heit, 2009) may be attributable to the fact that, in a probabilistic theory, we expect that adding premises of the type used in these experiments will usually increase the probability of the conclusion given the premises (Heit, 1998). The non-linearities predicted by equation 2 lead us to expect that the same change in probability will have different effects depending on the modal used.

Our probabilistic theory leaves open the psychological process by which people evaluate arguments. One possibility is that people are only able to *sample* possible worlds in accord with the distribution implied by the premises (Vul, Goodman, Griffiths, & Tenenbaum, 2009), and evaluate the truth of the

conclusion in these sampled worlds. If people take several samples and respond “yes” when the conclusion is true in each sampled world, we recover a power law. If the average number of samples depends on the modal, we recover the probabilistic model described above. For instance, we would posit that people tend to take more samples to evaluate “necessary” conclusions than “plausible” conclusions. This process-level implementation predicts that under time pressure, when people can take fewer samples, “necessary” would begin to look more like “plausible”. Indeed, this is exactly the finding of Heit and Rotello (2010).

We have illustrated an approach to reasoning based on an overall probabilistic view of inference, together with careful attention to natural language semantics. We believe that this approach will prove fruitful in studying a wide variety of phenomena related to human reasoning.

## Abstract

A cornucopia of dimensionality reduction techniques have emerged over the past decade, leaving data analysts with a wide variety of choices for reducing their data. Means of evaluating and comparing low-dimensional embeddings useful for visualization, however, are very limited. When proposing a new technique it is common to simply show rival embeddings side-by-side and let human judgment determine which embedding is superior. This study investigates whether such human embedding evaluations are reliable, i.e., whether humans tend to agree on the quality of an embedding. We also investigate what types of embedding structures humans appreciate *a priori*. Our results reveal that, although experts are reasonably consistent in their evaluation of embeddings, novices generally disagree on the quality of an embedding. We discuss the impact of this result on the way dimensionality reduction researchers should present their results, and on applicability of dimensionality reduction outside of machine learning.

**Keywords:** dimensionality reduction; unsupervised machine learning; psychophysics

## Introduction

There is an evaluative vacuum in the dimensionality reduction literature. In many other unsupervised machine learning fields, such as density modeling, evaluation may be performed by measuring likelihoods of held-out test data. Alternatively, in domains such as topic modeling, human computation (Ahn, Maurer, McMillen, Abraham, & Blum, 2008) resources such as Amazon’s Mechanical Turk may be employed to exploit the fact that humans are phenoms in evaluating semantic structure (Chang, Boyd-Graber, Gerrish, Wang, & Blei, 2009). Human evaluations have also been used to assess image segmentation techniques (Martin, Fowlkes, Tal, & Malik, 2001). The field of dimensionality reduction, however, lacks a standard evaluation measure (Venna, Peltonen, Nybo, Aidos, & Kaski, 2010), and is not as obvious a target for human intuition. Two or three dimensional embeddings can be visualized as scatter plots, but on what intuitive basis can we judge a 200 to 2-dimensional reduction to be good? In addition, Gestalt effects or simple rotations may bias human evaluations of scatter plots. Nevertheless, with no broadly agreed upon embedding quality measure (though a few have been proposed, see below), human judgment is often explicitly and implicitly solicited in the literature. The most common form of this solicitation consists of placing a scatter plot of the preferred embedding next to those of rival embeddings and inviting the reader to conclude that the preferred embedding is superior (e.g., (Maaten & Hinton, 2008)). If one is interested in applying a dimensionality reduction algorithm to visualize a dataset, is this a valid way to select from the

wide range of techniques?<sup>1</sup> To answer this question, we need to evaluate whether humans are good at evaluating embeddings. As there is no external authority we can appeal to, this is a daunting task. However, it is relatively easy to find out whether human data analysts are at least consistent in their evaluations, which is the first aim of this study. Consistency, across individuals and across a wide range of inputs, is a reasonable prerequisite for evaluation.

Beyond investigating whether human data analysts are consistent when they evaluate embeddings, the second aim of this study is to investigate what humans are doing when they evaluate embeddings. Such information could be useful for determining whether humans are appropriate for an evaluation task with a known structure (e.g. if they naturally prefer embedding characteristics appropriate to the structure), or for developing techniques that are tailored towards producing results that humans will find helpful (e.g. algorithms that selectively emphasize informative data structure). We can to some extent infer human strategies from the algorithms humans prefer, but we can also investigate those strategies by correlating embedding characteristics with human evaluations.

Motivated by the two aims described above, we solicit embedding quality judgments from both novice and expert subjects in an effort to determine whether they are consistent in their ratings, and which embedding characteristics they find appealing. For the novice subjects, we manipulate dataset knowledge—half read a description and see samples from each dataset, and half do not. We hypothesize that providing dataset information will increase consistency, as it should if the evaluative process is principled. The study consists of two experiments. The first presents subjects with a selection of embeddings derived from nine distinct dimensionality reduction algorithms; the second uses embeddings from a single algorithm with several different parameter settings for a more controlled comparison between “clustered” and “gradual” embeddings.

## Dimensionality reduction techniques

Dimensionality reduction techniques can be subdivided into several categories: linear or non-linear, convex or non-convex, parametric or non-parametric, etc. (Lee & Verleyesen, 2007). Whilst many new techniques have been proposed over the last decade, data analysts still often resort to linear, convex, parametric techniques such as PCA to visualize their

<sup>1</sup>Moreover, one should note that dimensionality reduction comprises only a small part of the “visualization zoo” (Heer, Bostock, & Ogievetsky, 2010).

data. Non-linear, convex, non-parametric manifold learners such as Isomap (Tenenbaum, Silva, & Langford, 2000), LLE (Roweis & Saul, 2000), and MVU (Weinberger, Sha, Zhu, & Saul, 2007) are also frequently used for visualization purposes (Jain & Saul, 2004; Lewis, Hull, Weinberger, & Saul, 2008; Mahecha, Martínez, Lischeid, & Beck, 2007), even though it is unclear whether these techniques produce superior results (Maaten & Hinton, 2008).

As described in the introduction, one of the key problems of dimensionality reduction is that it lacks a widely agreed upon evaluation measure (Venna et al., 2010). In fact, it is very unlikely that there will ever be such an evaluation measure, as it would imply the existence of a *free lunch* (Wolpert, 1996): the “optimal” dimensionality reduction technique would be the technique that optimizes the measure. Also, there is a lot of debate within the field on what a good objective for dimensionality reduction is: for instance, a latent variable model approach to dimensionality reduction suggests one should focus on preserving *global* data structure (Lawrence, 2005), whereas a manifold learning viewpoint deems preservation of *local* data structure more important (Roweis & Saul, 2000). The lack of an evaluation measure and the ongoing debate within the field motivate the use of a more anthropocentric approach.

In our study, we investigate nine dimensionality reduction techniques, selected for their importance in the literature: (1) PCA, (2) projection pursuit, (3) random projection, (4) Sammon mapping, (5) Isomap, (6) MVU, (7) LLE, (8) Laplacian Eigenmaps, and (9) t-SNE. PCA and projection pursuit find a subspace of the original data space that has some desired characteristic. For PCA, this subspace is the one that maximizes the variance of the projected data. For projection pursuit (Friedman & Tukey, 1974), the subspace maximizes the non-Gaussianity of the projected data. Random projections are linear mappings that mostly preserve pairwise distances in the data due to the Johnson-Lindenstrauss lemma (Bingham & Mannila, 2001). Sammon mapping constructs an embedding that minimizes a weighted sum of squared pairwise distance errors, where distances are weighted in inverse proportion to their magnitude (Sammon, 1969). Isomap constructs an embedding by performing classical scaling on a geodesic distance matrix that is obtained by running a shortest-path algorithm on the nearest neighbor graph of the data (Tenenbaum et al., 2000). MVU learns an embedding that maximizes data variance, while preserving the pairwise distances between each data point and its  $k$  nearest neighbors, by solving a semidefinite program (Weinberger et al., 2007). LLE constructs an embedding that preserves local data structure by minimizing a sum of squared errors between each map point and its reconstruction from its  $k$  nearest neighbors in the original data (Roweis & Saul, 2000). Laplacian Eigenmaps try to minimize the squared Euclidean distances between each points corresponding to its  $k$  nearest neighbors in the original data, while enforcing a covariance constraint on the solution (Belkin & Niyogi, 2002). t-SNE embeds points

by minimizing the divergence between two distributions over pairs of points, in which the probability of picking a pair of points decreases with their pairwise distance (Maaten & Hinton, 2008).

## Experimental setup

We perform two experiments with our human subjects. The first experiment uses stimuli generated from the dimensionality reduction algorithms described above to determine whether humans are consistent in their evaluations when the embeddings are fairly distinct (the first aim of the study). The second experiment uses stimuli that are all generated by t-SNE, but with different parameter settings that affect how clustered the resulting embedding appears. This helps us determine what type of structure humans generally prefer in embeddings (the second aim of our study).

### Experiment 1

In the first experiment, we divided subjects into (1) an expert group with detailed knowledge of dimensionality reduction and information on the underlying datasets presented in written and pictorial form, (2) a novice group with no knowledge of dimensionality reduction and no information on the visualized data, and (3) a group of similar novices but with the same information on the underlying datasets given to the experts. The dataset information we presented to groups 1 and 3 constituted of an intuitive description of the data, as well as images representing the underlying data (e.g., the Swiss roll, or handwritten character images).

Thirty one undergraduate human subjects were recruited for this study as the novice group, 16 female and 15 male, with an average age of 19.1 years. None of the novice subjects had any specific knowledge of dimensionality reduction techniques. Our expert group consisted of five subjects—three graduate students and two faculty members. The expert subjects were drawn from the same institution and represent two different departments. Amongst the five expert subjects there are four distinct academic backgrounds at the graduate level. The informed novice group had 15 subjects and the uninformed novice group 16. We generated two-dimensional point-light stimuli (see Figure 1 for a visualization of all the stimuli) by running the nine dimensionality reduction techniques discussed in Section on seven different high-dimensional datasets, comprising a variety of domains. We ran each technique for a reasonable range of parameter settings, and we selected the embedding that was best in terms of the trustworthiness<sup>2</sup> (Venna & Kaski, 2006) for presentation to the subjects.

Each trial consisted of nine different embeddings of the same dataset arranged randomly per trial in a  $3 \times 3$  grid. The datasets were shown as scatter plots with white points on a black background to reduce brightness-related eye fatigue. For novice subjects, trials were organized into three blocks

<sup>2</sup>The trustworthiness measures the ratio of  $k$  nearest neighbors in the data that is still among the  $k$  nearest neighbors in the maps.

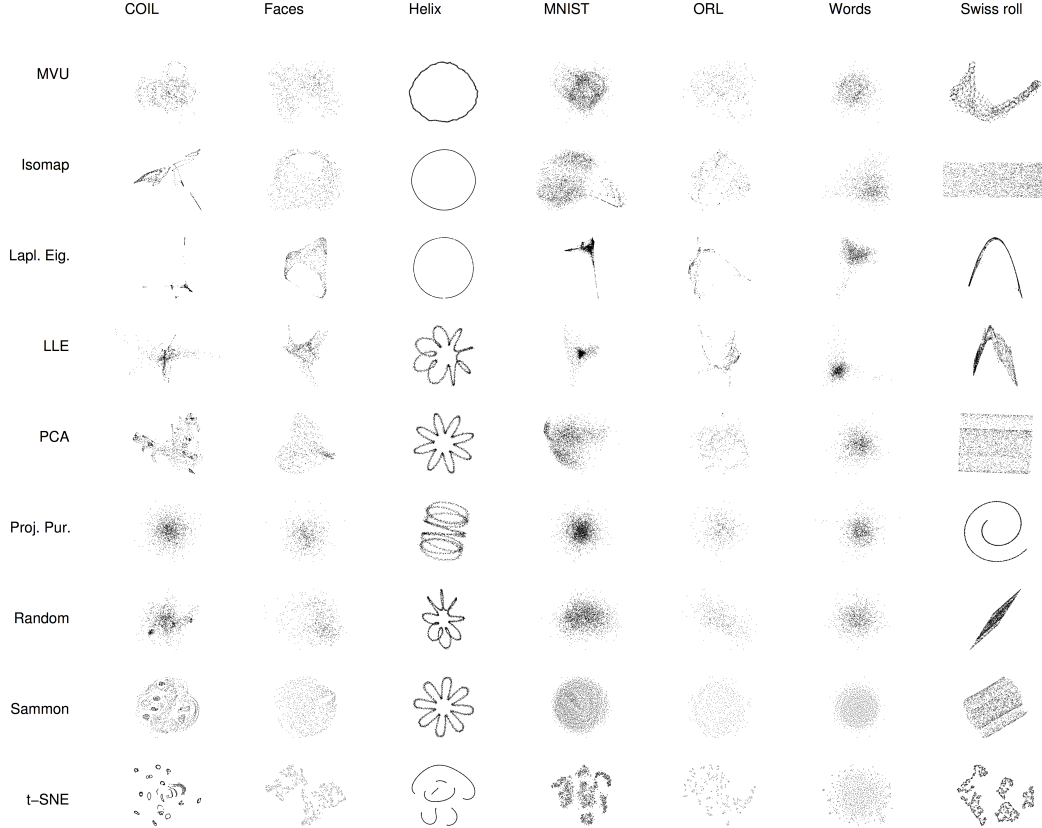

Figure 1: All stimuli from experiment 1. Methods are in rows; datasets are in columns.

of seven, where each dataset appeared once per block and the order of the datasets within each block was randomized. Expert subjects were tested on one block. We instructed subjects to choose the two most useful displays and the one least useful display from the nine available on every trial. After describing what a scatter plot is and emphasizing that each set of nine plots is a different perspective on the same dataset, we gave subjects the following instructions: *For each trial, please examine all the scatter plots and choose the two that you find most useful and the one that you find least useful. The task in the second part of this experiment will be much faster and easier if you choose useful scatter plots. Do the best you can to choose useful plots based on whatever criteria you deem appropriate.* We intentionally left the task ambiguous so as not to bias subjects towards particular evaluation criteria<sup>3</sup>, and the fictitious “second part” of the experiment existed solely for increasing subject motivation.

We analyzed our novice subjects for internal consistency of their positive and negative ratings across blocks and found that even our least consistent subject was more consistent than expected by chance. Hence, we did not exclude any subjects due to internal inconsistency. To analyze consistency across subjects (the first aim of this study) we use Fleiss’  $\kappa$  (Fleiss,

1971) and include neutral responses. Fleiss’  $\kappa$  measures the deviation between observed agreement and the agreement attributable to chance given the relative frequency of ratings, and normalizes for the number of raters. Neutral ratings are twice as frequent as non-neutral, and positive ratings are twice as frequent as negative ratings, so the compensation for relative frequency in Fleiss’  $\kappa$  makes it well-suited to our data.

We also measured the following six characteristics of our embedding stimuli: (1) variance, (2) skewness, (3) kurtosis, (4) clusteredness, (5) visual span, and (6) Gaussianity. The variance, skewness, and kurtosis were measured per dimension in a map that was scale-normalized such that  $\mathbf{y}_i \in [0, 1]^d$  (preserving the aspect ratio of the maps), and averaged over the  $d$  dimensions of the map. We measured clusteredness by constructing  $k$ -nearest neighbor graphs in the map with  $k = 3, \dots, 12$ , and measuring the maximum clustering coefficient of the resulting graphs (Watts & Strogatz, 1998). The clustering coefficient computes the ratio of connections between the adjacent vertices of map point  $i$ , averaged over all map points. The visual span of each map was measured by fitting a Parzen kernel density estimator with Gaussian kernels on the map (the variance  $\sigma$  of the Gaussians was optimized on a small validation set). Subsequently, we measure the ratio of the map surface that has a density of at least 10% of the max-

<sup>3</sup>For instance, defining a classification task would bias subjects to embeddings that show separated clusters.

imum density of the density estimate. The Gaussianity of the maps was determined by averaging the results of Lilliefors tests (Lilliefors, 1967) performed on 5,000 one-dimensional random projections of the map<sup>4</sup>. We analyze the relationships between novice informed ratings, novice uninformed ratings, expert ratings, and the six quantitative measures by calculating the Pearson’s correlation coefficient  $\rho$  between ratings and measures (after normalization within trial).

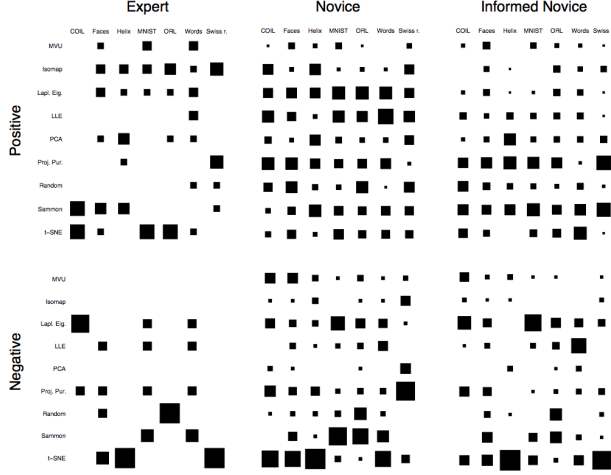

Figure 2: Human responses to the embeddings in experiment 1. Positive responses in the first row, negative in the second row. Experts (left), novices (center) and informed novices (right) by column. Algorithm and dataset ordering are the same as in Figure 1 within each block.

## Experiment 2

The second experiment was run directly following experiment 1 on the same subject pool using the same methods, save stimulus design. In experiment 2, the nine stimuli in each trial are obtained by running t-SNE with nine different degrees of freedom  $v$  (viz.  $v = 0.5, 0.8, 1.0, 1.2, 1.5, 2.0, 2.5, 3.0, 4.0$ ) on the seven datasets. The degrees of freedom in t-SNE determine to what extent the visualizations are “clustered” (Maaten, 2009). Sample stimuli are shown in Figure 3.

## Results

### Experiment 1

For the first experiment, the Fleiss’ kappa consistency measure  $\kappa$  for experts is 0.39, for uninformed novices is  $-0.28$ , and for informed novices is  $-0.40$ . Fleiss’ kappa  $\kappa$  ranges from  $-1$  to  $+1$ , with  $-1$  representing complete disagreement,  $+1$  representing complete agreement and  $0$  representing the amount of agreement expected by chance. Though there is no standard significance test for Fleiss’ kappa, based on the Landis and Koch scale (Landis & Koch, 1977), experts exhibited fair to moderate agreement, while both groups of novices

<sup>4</sup>Note that if the distribution of points in the embedding is Gaussian, the point distribution in each of the random projections has to be Gaussian as well.

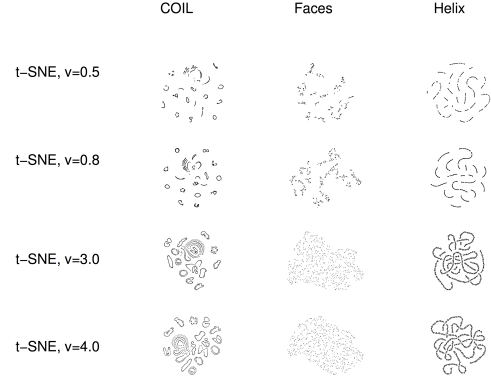

Figure 3: Sample stimuli from experiment 2. Parameter values are in rows; datasets are in columns.

exhibited poor agreement. Hence, the consistency measures reveal that, whereas experts tend to agree with each other on the quality of an embedding, novices strongly disagree with each other in their evaluations (they disagree more than if the evaluation was done randomly). Surprisingly, novices who received information on the underlying data disagree more strongly with each other than novices who had no information about the underlying data (counter to our hypothesis but interpretable, see below).

Table 1: Correlation coefficients between human responses and dataset characteristics. Text in bold if  $p < .0036$  after Bonferroni correction for  $n = 14$  comparisons per subject group and  $\alpha = .05$ .

$\rho$	Lilliefors	Skewness	Kurtosis	Variance	Visual Span	Clusteredness	Trustworthiness
Ex. Pos.	.26	-.01	-.19	.34	.17	.22	<b>.41</b>
Ex. Neg.	-.08	.17	.19	-.14	-.17	.08	-.08
Nov. Pos.	.07	-.03	<b>.50</b>	-.18	-.29	.01	-.08
Nov. Neg.	.00	.17	-.10	.22	.10	-.03	.24

Inf. Neg.	.03	.31	.19	.10	-.19	.20	.19

In Figure 2, we depict the raw ratings (averaged over each group) as a collection of Hinton diagrams. In the figure, a large square indicates that a relatively large number of subjects gave a positive or negative evaluation of the embedding of the corresponding dataset, constructed by the corresponding technique. The top row of diagrams represent positive responses and the bottom negative, so if subjects are in disagreement about a stimulus, there will be a large box in its corresponding location in both rows. The diagrams reveal that informed novices exploit dataset knowledge in specific

instances to differ significantly from uninformed novices. For example, the t-SNE embedding of the Swiss roll dataset (a relatively clustered embedding) is rated much more negatively by novices when they know that the data are gradual. Experts tend to rate t-SNE positively or negatively depending on the dataset and show a relatively consistent rating for Isomap. Informed novices consistently rated Sammon mapping and projection pursuit positively while generally rating manifold learners such as Isomap and LLE negatively. Uninformed novices are all over the map with the exception of (like all other subjects) rating MVU as not notable in either a positive or negative sense.

Table 1 shows correlation coefficients between the six embedding characteristics and the evaluations by the three human groups. We also present the correlation between the evaluations and the trustworthiness, which gives an indication of the quality of the embedding (in terms of local neighborhood preservations). The significant correlations are in bold type, after a Bonferroni correction for multiple comparisons (14 comparisons per subject group,  $\alpha = .05$ ). Notably, expert positive ratings are the only ratings that correlate significantly and in the correct direction with trustworthiness. Another correlation that stands out is visual span: it appears to play a substantial role in informed novice ratings (they apparently surmise an embedding should fill up the available space), whereas it plays little role in expert ratings.

## Experiment 2

For the second experiment, the consistency measure  $\kappa$  for experts is 0.35, for uninformed novices is  $-0.32$ , and for informed novices is  $-0.26$ . The results of the second experiment thus reveal a similar trend: experts have fair agreement on the quality of embeddings, whereas novices give ratings have poor agreement. The ratings reveal that, whereas experts selectively rate more clustered or more continuous embeddings positively depending on the dataset, novices overwhelmingly rate the more clustered embeddings as negative. On the other hand, for positive ratings the novices tend to choose embeddings at either end of the spectrum while avoiding the moderate values of  $v$ . Moderate values of  $v$  might be avoided since subjects want to classify displays closest to the prototypical clustered or graded display (Rosch, 1975). Using the same set of correlations from Experiment 1 we find that experts ratings do not strongly correlate with any of the characteristics (including trustworthiness), but both groups of novices show a correlation between negative ratings and those stimuli with low kurtosis and high clusteredness.

## Discussion

In both experiments, experts show themselves to be more consistent than chance and much more consistent than novices in either condition. This is reassuring, and indicates that the idea of having experts evaluating embeddings is not flawed to begin with. In the first experiment, novice subjects actually get less consistent with each other if they are informed. While this seems troubling at first, it actually makes

some sense after closer consideration. Comparing the Hinton diagrams between novices and informed novices, one can plainly see that informed novices are converging on a smaller selection of techniques for both positive and negative ratings. The issue for the informed novices, however, is that they are not sure whether these stimuli should be rated as positive or negative. As a result, there is often energy for the same cell in both diagrams. Since the base rate of positive and negative ratings is low compared to the neutral ratings, the  $\kappa$  consistency measure interprets this as substantial disagreement and thus the negative numbers. Importantly, the informed novice  $\kappa$  is further from chance level than the novice  $\kappa$ . In Experiment 2, uninformed novices actually differ more from chance but the effect is about half the size, and experts remain consistent.

Expert ratings are laudable in that they correlate in the correct direction with trustworthiness and have a context-dependent appreciation of clusteredness. Both novice groups rate clusteredness negatively regardless of context and are more influenced by elementary characteristics such as visual span. The substantial difference in strategy between novices and experts indicates that novices could really benefit from training on the task of evaluating embeddings (unlike evaluating results from topic modeling, image segmentation, or object recognition).

## Conclusion

With respect to the first aim of our study (determining whether humans are consistent in rating embeddings), we conclude that dimensionality reduction experts are indeed reasonably consistent judges of embedding quality. This supports the practice of soliciting expert judgment for embedding evaluations, as nowadays is common in the literature on dimensionality reduction. However, we also conclude that novices are very inconsistent with one another in terms of their rating of an embedding, even when they have detailed information on the dataset the embedding is visualizing. In fact, novices even correlate negatively with a measure of embedding quality.

With respect to the second aim of our study (determining what types of structure humans appreciate in embeddings), we conclude that humans do not appear to have overwhelmingly strong *a priori* preferences, although novices appear to appreciate gradual embeddings that span a large portion of the space. Experts can adapt their preference for gradual vs. clustered depending on the dataset.

Overall, our results discourage free-form solicitation of human computation approaches à la (Chang et al., 2009) and (Martin et al., 2001) to the evaluation of dimensionality reduction techniques. Moreover, the novices' lack of consistency lends worry to the prospect of naïve dimensionality reduction-based analysis. Most data analysts seeking to apply dimensionality reduction are not very familiar with the field. As a result, they are likely to be susceptible to the favorable visualizations presented in many dimensionality re-

duction papers. To ensure that dimensionality reduction techniques are applied wisely, authors should strive to explicate the dataset characteristics that favor their algorithms (e.g., t-SNE is useful if the data is expected to have cluster structure, Isomap if the data lie on a convex manifold). Authors could also cover usage scenarios appropriate to their algorithm (e.g., if a researcher is interested only in visualizing points that are most different then PCA would suffice and other techniques would be overkill), including guidelines for interpreting the relationship between the high and low dimensional spaces (sometimes this relationship will be very clear, as in PCA; other times, as in MVU, there is not a clear relationship). In addition, data analysts should be encouraged to use sanity checks such as the trustworthiness measure in order to prevent them from basing analysis on interesting, but flawed, embeddings.

## Abstract

Like many other cognitive processes, the perception of music involves processes and structural considerations that are highly relational in nature. To date, no physiologically plausible model has been used to simulate and explain how infants perceive melodic content. Here we used DORA (*Discovery Of Relations by Analogy*; Doulas et al., 2008), a domain-general symbolic-connectionist model of relational learning, to simulate melodic perception and categorization by infants (Chang & Trehub, 1977; Trehub et al, 1984), and to provide an account of the mechanism for melodic processing in infants. Given four input semantic features for each note in the melodic stimuli sequence (two of which could be internally obtained from the other two via a comparator), DORA's performance matched the behavioral data from the infant studies. Furthermore, the ability of our model to simulate infants' behavior is evidence that structured representations of relational musical properties can be bootstrapped from unstructured feature representations.

**Keywords:** Melodic perception; relative pitch; relational learning; symbolic connectionist; DORA.

## Introduction

While there are many defining characteristics of music (e.g., harmony, rhythm, timbre, pitch, etc.), one of the most fundamental and salient aspects is the melody. Indeed, simple melodies were likely the earliest form of music to have been created and transmitted, and have been (and still are) prevalent in all documented cultures past and present (Sachs, 1943).

Simple melodies consist of discrete units or notes, with each note characterized by a pitch, or fundamental frequency. Importantly, there are several ways in which the pitch sequence of a melody can then be encoded and stored. The two most well documented forms of encoding are *absolute* or *relative* pitch. Absolute pitch encodes and stores a melody using the fundamental frequencies of each pitch, while relative pitch (or intervallic) encodes the melody in terms of the *relations* (or specific frequency differences) between each note. Notably, processing melodies in terms of the relative pitch information (or intervallic patterns) is considered to be the strategy most humans use to

characterize and store familiar melodies (Attneave & Olson, 1971). Another characteristic upon which melodies can be categorized, however, is according to the contour (general shape, or sequence of up and down movements in frequencies from note to note). Given the existence of these various characteristics, there has been considerable research and speculation on the extent to which these categorizations contribute to a listener's mental representation of a melody, and how they may interact.

## Relative pitch and melodic contour

The properties of relative pitch (or intervallic patterns) are most commonly used in long term musical storage and recall (Page, 1994). For example, when listening to the melody of a song, such as *Happy Birthday*, what makes the song immediately recognizable is the unique intervals between each of the notes in the song. That is, the song is recognizable whether it initially starts on a low or high note due to the unique intervallic pattern between all subsequent notes. There is much evidence on the use of relative pitch information in adults through both behavioral studies (Dowling, 1978, 1984, 1988) as well as neuroimaging studies (Fujioka, Trainor, Ross, Kakigi, & Pantev, 2004; Trainor, McDonald, & Alain, 2002).

It is worth noting that while a melody with an identical contour to *Happy Birthday*, but with a different intervallic sequence would sound like a completely different tune, it would still have the same general "shape", or up and down pattern. Although the intervallic pattern may be the most overtly salient feature of a melody, studies have shown that human adults are also sensitive to absolute pitch and melodic contour in the short term (Bartlett & Dowling, 1980; Dowling, 1978). And while there is evidence that infants may also be sensitive to intervallic information (Trehub, Bull, & Thorpe, 1984), numerous experiments with infants suggest that they may primarily encode melodies using contour information (for review, see Trehub, 2001; Trehub, Trainor, & Unyk, 1993).

Even though intervallic and contour properties may characteristically differ in the type of information they

carry, what is perhaps more important is the fact that the nature of the information they carry are both fundamentally relational in nature. That is, this information depends on the relationship (whether it is the precise intervallic distances or the general contour shape) between each pitch, and not on the actual pitch frequencies themselves. And it is within this capacity that melodic perception can be said to share a cornerstone property with many higher-level cognitive tasks (and arguably certain “lower” level processes such as pattern recognition as well).

### Relational processing

The ability to explicitly represent and reason about relational properties has been proposed as a fundamental mechanism underlying a wide range of cognitive phenomenon, including analogy-making (Gentner, 1983; Gick & Holyoak, 1980; Holyoak & Thagard, 1995), language (Kim, Pinker, Prince, & Prasada, 1991), detection of perceptual similarities (Medin, Goldstone, & Gentner, 1993), and the application of rules in novel situations (Lovett & Anderson, 2005). Given that melodic processing appears to require extracting relational information from melodies, it is reasonable to assume that the same mechanisms used in other relational tasks might also operate when processing musical information. That is, common to both of the main approaches used by adults and infants (intervallic and contour) to encode melodic information is that the underlying structure of the melody is represented as the relations between the individual notes. The strength of relational reasoning is in the ability to reason about the roles that objects play rather than the literal features of those objects (see Doumas, Hummel, & Sandhofer, 2008). Similarly, the ability to recognize a melody (or its shape) rests on appreciating the relationship between the pitches, and not the specific frequencies of each note. To evaluate the similarity between relational reasoning and music processing, we modeled melodic perception using a neurally plausible domain-general model of relational cognition.

### The LISA/DORA models

LISA (*Learning and Inference with Schemas and Analogies*; Hummel & Holyoak, 1997, 2003) is a symbolic-connectionist model of analogy and relational reasoning. DORA (*Discovery Of Relations by Analogy*; Doumas et al., 2008) is an extension of LISA that learns structured (i.e., symbolic) representations of relations from unstructured inputs. That is, DORA provides an account of how the structured relational representations LISA uses to perform relational reasoning can be learned from examples. At present, DORA accounts for over 30 phenomena from the literature on relational learning, and cognitive development, and as it learns representations of relations it develops into LISA and can simulate the additional 40+ phenomena in relational thinking for which LISA accounts for (e.g., Doumas et al., 2008). In the following, we provide a very brief description of the LISA/DORA models (for full details, see Hummel & Holyoak, 1997, 2003; Doumas et al., 2008).

**LISAese Representations** In LISA (and DORA *after* it has gone through learning), relational structures are represented by a hierarchy of distributed and localist codes (see Figure 1). At the bottom, “semantic” units (small circles in Figure 1) represent the features of objects and roles in a distributed fashion. At the next level, these distributed representations are connected to localist units (POs) representing individual predicates (or roles) and objects (triangles and larger circles in Figure 1). Localist role-binding units (RBs; rectangles in Figure 1) link object and role units into specific role-filler bindings. At the top of the hierarchy, localist P units (ovals in Figure 1) link RBs into whole relational propositions.

Relational structures (or propositions) are divided into two mutually exclusive sets: a driver and recipient(s). In LISA/DORA, the sequence of firing events is controlled by the driver. Specifically, one (or at most three) proposition(s) in the driver become(s) active (i.e., enter working memory). When a proposition enters working memory, role-filler bindings must be represented dynamically on the units that maintain role-filler independence (i.e., POs and semantic units) to allow for reusability of units and preservation of similarity across different bindings (Hummel & Holyoak, 1997). In LISA, binding information is carried by synchrony of firing (with roles firing simultaneously with their fillers). In DORA, binding information is carried by systematic asynchrony of firing, with bound role-filler pairs firing in direct sequence (for details, see Doumas et al., 2008).<sup>1</sup>

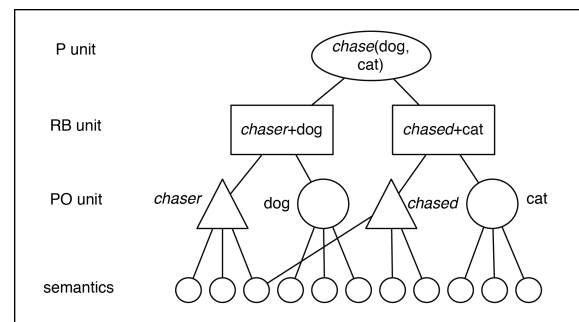

Figure 1. LISA/DORA representation of the proposition, *chase* (dog, cat).

**Relational Learning** In broadest strokes, DORA learns structured representations by comparing objects to isolate their shared properties and to represent these shared properties as explicit structures. More specifically, DORA starts with simple feature-vector representations of objects (i.e., a node connected to set of features describing that object; large and small circles from Figure 1). When DORA compares one object to another, corresponding elements (i.e., shared features) of the two representations fire simultaneously. Any semantic features common to both

<sup>1</sup> Asynchrony-based binding allows role and filler to be coded by the same pool of semantic units, which allows DORA to learn representations of relations from representations of objects (Doumas et al., 2008).

objects receive twice as much input and thus become roughly twice as active as features connected to one but not the other. By recruiting a new PO unit and learning connections between that unit and active semantics via Hebbian learning (wherein the strength of connections is a function of the units' activation), DORA learns stronger connections between the new PO unit and more active semantic units. The new PO thus becomes an explicit representation of the featural overlap of the compared objects and can act as a single place predicate, taking other object representations as arguments to form role-filler pairs (see Doumas et al., 2008). Applied iteratively, this process allows DORA to learn structured explicit single-place predicate representations of any properties compared objects may share. Comparison also allows DORA to learn representations of multi-place relations by linking sets of constituent role-filler pairs into relational structures (i.e., to learn the *chases* relation by linking together representations of the roles *chaser* and *chased*; see Doumas et al., 2008 for details).

**Mapping** For the purpose of analogical mapping, LISA/DORA learns *mapping connections* between units coactive of the same type in the driver and recipient (e.g., between PO units in the driver and PO units in the recipient). These connections grow whenever corresponding units in the driver and recipient are active simultaneously. They permit LISA to learn the correspondences between matching structures in separate analogs. They also permit correspondences learned early in mapping to influence the correspondences learned later.

## Methods

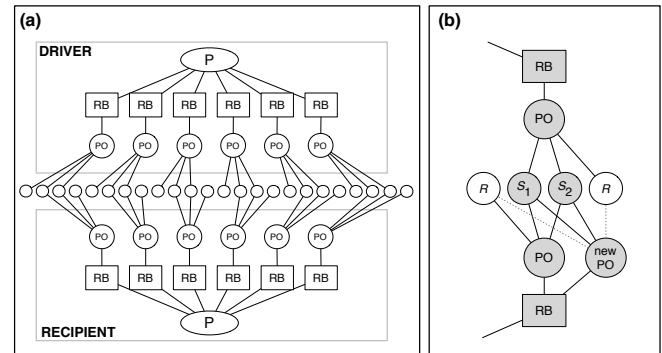

In this section we describe two infant studies (Chang & Trehub, 1977; Trehub et al., 1984), followed by the details and outcomes of DORA's simulation.

### Task 1 description

In an experiment by Chang and Trehub (1977), infants (4.5 to 6 months of age) were tested on their ability to recognize melodies based on either the absolute pitch frequencies or relational properties extracted from these pitches. This between-group experiment was conducted with a set of 15 habituating trials, followed by four novel dishabituation trials, while the infants' heart rates were monitored throughout to determine their expectation and recognition levels for the novel stimuli. The habituation stimuli consisted of randomly constructed six note melodic patterns. The dishabituation stimuli varied depending on which of two groups the infants were in.

Crucially, in the "transposed" group, the novel test stimulus consisted of the same melody transposed to a different key. The novel melody retained the relational information between the individual notes (intervallic sequence), but none of the featural information (specific frequencies) of the individual notes. In the control group, the novel melody was a scrambled version of the original melody. The individual notes' featural characteristics (pitch

frequencies) were retained, while the relational characteristics between the notes were not. Thus, comparing performance between the "transposed" and control groups would indicate whether infants were processing the melodies based on the individual frequencies, or extracting the relational information between notes.

Figures 2. a) The note sequences in the driver and recipient are compared with each other. b) After mapping notes in the sequence, DORA learns a new PO unit from the featural overlap of the mapped notes.  $S_n$  are semantic units, and  $R$  are random units (only two each are shown here).

### Simulation 1

To simulate the training portion of the study, we created a "melody" consisting of 6 object PO units—one PO for each note (see Figure 2a). Each note PO unit was attached to four random semantic units (chosen from a pool of 100 features), one semantic indicating the note's place in the stimuli sequence (1-6), one semantic describing the note's specific frequency (between f1 and f24), one semantic for whether the note was higher or lower than the previous note (the first PO in the sequence was not connected to such a semantic), and one semantic describing the note's distance (i.e., frequency difference) from the previous note. The information the semantic units carried was based on features which infants have been shown to be capable of extracting from melodies to greater or lesser extents. For instance, infants have been shown to be sensitive to sequential order (Thorpe & Trehub, 1989; Thorpe, Trehub, Morrongiello, & Bull, 1988), are sensitive to and can discriminate absolute pitch information under certain conditions (Lynch, Eilers, Oller, & Urbano, 1990; Trehub, Cohen, Thorpe, & Morrongiello, 1986), can process contour information (Trehub et al., 1984; Trehub et al., 1993), and are also sensitive to intervallic differences (Schellenberg & Trehub, 1996a, 1996b). Importantly, the semantic values specifying frequency direction and frequency difference can be generated from the raw frequency values using the comparator mechanism described in Doumas et al. (2008) and adopted from the JIM model of object recognition (Hummel & Biederman, 1992). Finally, each PO was attached to an RB unit, and all the RBs attached to a single P unit, representing that the notes all belonged to a single sequence.

We allowed DORA to compare each note sequence to the previously experienced note sequence, map the two sequences, and learn new predicate POs using the predication learning algorithm described above. The sequence of firing of the PO units in the driver was the same as the order of the notes in the melodic sequence (i.e., the first note in the sequence fired first, the second note second, and so on). More specifically, DORA represented the current note sequence in the driver and the previous note sequence in the recipient (see Figure 2a). Next DORA attempted to map the sequences. Finally, DORA learned new PO units using these mappings (Figure 2b). DORA stored the results of learning in memory.

In previous studies, DORA has successfully been used to simulate frontal lobe maturation by adjusting the level of lateral inhibition between units in the recipient (e.g., Dumas, Morrison, & Richland, 2009, 2010; Morrison, Dumas, & Richland, 2006, 2011). Reflecting the fact that we are simulating infants we used a highly reduced lateral inhibition parameter of 0.5.

After training, DORA's LTM consisted of the 15 sequences of notes it had learned during training. In addition, we created 50 additional sequences of between 2 and 8 notes to serve as distractors in memory (following the assumption that other melodic sequences may have been learned by the infant). In each distracter note sequence each PO from the same sequence was attached to a single RB unit with all RBs from the same sequence attached to a single P unit, indicating all the notes belonged to a single sequence (as with the training items). Each PO was attached to 4 random features as well as one semantic indicating the note and another semantic indicating the interval (frequency difference) from the previous note.

To simulate the test, we created two melodies, each consisting of 6 PO units, each representing a single note. Each note PO unit was attached to four random semantics, one semantic unit describing the note's place in the sequence (1-6), one semantic describing the frequency, one describing frequency difference from the previous note, and another describing the direction of the difference (just as for the melodies created in the training condition). Additionally, as originally conducted by Chang and Trehub (1977), we created a transposed melody that consisted of the same sequence of notes as the training melodies, but in a different key. The control melody consisted of the exact same POs used in training, but in a scrambled order.

We put the test melody (transposed or control) in the driver, and allowed DORA to attempt to retrieve an item from LTM, and attempt to map it to the melody in the driver. If DORA successfully mapped the new melody to one of the sequences it had learned during training, this implied that DORA recognized the new melody. Otherwise, DORA was taken to be surprised by the new melody.

We ran 200 simulations (100 transposed and 100 control), each consisting of 15 training and one test trial (the exact same number of training and test trials used in the original study). DORA's performance was a close qualitative match

to the data from Chang and Trehub's (1977) study. Just like infants in the transposed condition, when presented with transposed melodies, DORA was much more frequently unsurprised (77 of 100 trials). On the other hand, for control melodies, DORA was unsurprised much less frequently (31 of 100 trials). These results indicate, that DORA, like the infants in the original study, could detect and extract regularity in melodic sequences, and generalize that regularity to novel keys.

## Task 2 description

For the second simulation, we used a study by Trehub, Bull, and Thorpe (1984). This study was conducted on infants 8 to 11 months of age, and used a broader range of melodic stimuli to examine the extent to which infants process intervallic, contour, octave transpositions, and range information from melodies. Although the first task (Chang & Trehub, 1977) demonstrated that infants used relational information to categorize melodies, the design did not specifically differentiate between intervallic and contour relations (it is possible that infants could have used either strategy to categorize the melodies).

Figure 3. Three types of transformations applied to test melodies in Trehub, Bull, & Thorpe (1984).

Although a similar paradigm to Chang and Trehub's (1977) study was used by Trehub et al. (1984), the two studies differed in two important aspects. First, the training and testing methodology was different. Whereas the first experiment used a habituation/dishabituation training paradigm and monitored heart-rate during testing, the second experiment used a training procedure that habituated infants to a melodic pattern and also trained them to respond with head turns to melodies that differed in melodic contour and range. Infants were then tested for subsequent discriminations of novel stimuli by monitoring head turns. Secondly, although training and testing stimuli also consisted of six note melodic patterns, several additional melodic properties were examined Trehub et al.'s testing condition. In addition to the transposed melody (as used in Chang and Trehub, 1977), the testing conditions included *contour preserving* and *contour violating* conditions in order to test for octave and frequency range sensitivity. The *contour preserving* condition (see Figure 3) allowed the researchers to test whether infants categorize melodies based on intervallic or contour properties. That is, it was

assumed that if infants recognized only the transposed condition and not the contour-preserving condition, then that would be taken as evidence that they processed the melodies based on intervals. On the other hand, if they recognized both, the most parsimonious explanation would be that they were processing the melodies based on contour alone. Additionally, the *octave change* conditions tested whether infants' were also sensitive to larger changes in intervallic patterns. Crucially, it was found that infants did not discriminate either the transposition or contour preserving melodies, but discriminated the *octave change* melodies.<sup>2</sup> In summary, Trehub et al. found that infants could categorize melodies by contour properties, but were also sensitive to the magnitude of the contour, and therefore could discriminate larger intervals (outside of the general original range) from the smaller intervals of melodies that occurred within the original melodic range.

## Simulation 2

Although there were methodological differences between Task 1 and 2, we simulated Trehub et al. (1984) using the same basic procedure as in Simulation 1. Fundamentally, Task 2 used the same approach by exposing infants to a standard melody and then subsequently observing how they would perceive and categorize novel test stimuli. Accordingly, we created a set of training patterns and trained the model as in Simulation 1.

To test the model, we created transposition melodies just as in Simulation 1. In addition, we created two kinds of contour preserving melodies. Close contour preserving melodies were similar to the training melodies, but with frequencies within 2 units of the training trials. So for example, if the first three notes of the training stimulus were: frequency2, frequency6, frequency8, the first three notes of the test pattern would be frequency2  $\pm$ 2, frequency6  $\pm$ 2, frequency8  $\pm$ 2 (under the constraint that the direction of the note was maintained across training and test patterns—e.g., if the second note of the training melody was higher than the first, the second note of the test melody was also higher than the first). Similarly, the far contour preserving melodies were created in exactly the same manner, but with each note  $\pm$ 6 from the original.

The results followed the same qualitative pattern observed in Trehub et al. (1984). As in the previous simulation, DORA successfully matched transposed melodies. Importantly, DORA also successfully matched close contour preserving melodies the majority of the time (74 of 100 trials), and was surprised on far contour preserving melodies more frequently (63 of 100 trials). In other words, like the infants in Trehub et al.'s study, DORA was sensitive to contour preservation, but under conditions when the contour was preserved but coupled with large changes in

frequency, DORA was more likely to categorize the melody as being different or produce a surprise reaction.

## Discussion

To our awareness, this is the first time a general model of relational cognition has been used to simulate melodic perception, and the results subsequently compared to existing behavioral data from infants.<sup>3</sup> We view these first steps as a very simple beginning, and hope to expand the complexity of the model and the range of future simulations.

The results of both simulations were a good match to their behavioral counterparts, and supported our hypothesis that relational processing might play an important role in music perception. In the first simulation, DORA performed similar to infants in extracting the relational properties of transposed melodies, and also in failing to recognize the scrambled melody. In the second simulation, both DORA and infants categorized the melodies based primarily on relational information of the melodic contours. Furthermore, DORA's ability to discriminate large contour distortions (far contour) in Simulation 2 suggests that infants may be sensitive to certain intervallic properties.

While these simulations provide insights into some of the mechanisms that infants may use when categorizing music, we hope to determine through future studies, when and how children begin to learn the more typically defining feature of melodies: the intervallic sequences, or relative pitch relations between notes. Crucially, this study corroborates existing evidence that infants as young as four months are sensitive to relational features of music and appear to reason about these relational features in a structure sensitive manner (i.e., generalizing relational properties to novel inputs). Another important question that future simulations and studies should attempt to answer is whether this widespread ability to discriminate intervallic sequences in adults is innate, or in fact a learned ability.

Lastly, DORA is currently the only model that learns complex structured relations and that can subsequently "grow up" to reason like an adult (Doumas & Hummel, 2005). Accordingly, we hope to determine through future simulations whether DORA can perhaps also grow up to "appreciate" (or even compose) music like an adult.

<sup>2</sup> There was no evidence that infants processed octave shifts as musical pitches with closely related harmonic properties (as adults generally do), but rather that they only processed them as large shifts in frequency (see Trehub et al., 1984).

<sup>3</sup> We also simulated Task 1 using an Elman neural network with similar inputs to what was given to DORA. With a hidden layer of 24 neurons, the network learned the training melody sequence to a MSE of .01 within 15 iterations, however, after training it failed to systematically generalize to contour preserving melodies even when the intervallic pattern was consistent (performing at chance when predicting the contour). Moreover, this failure occurred even while the Elman network was provided a clean input set (unlike DORA, which was "handicapped" with distractor sets in memory and a highly reduced lateral inhibition parameter).

## Abstract

Taking a test tends to improve the retention of the tested information. Additionally, taking a test often influences the later retention of non-tested information, provided such information is related to the tested information in a specific manner. To illustrate, recent research has demonstrated that multiple-choice tests containing competitive alternatives can improve retention of both tested and non-tested information pertaining to such incorrect alternatives at least over a short delay. The present research investigated whether such improvements in retention would persist with a delay more likely to occur in educational contexts (i.e., 48 hr). Taking an initial multiple-choice test improved retention more than a comparable cued-recall test—for both previously tested and related information—and over both short and long delays. Moreover, misinformation effects seen for the multiple-choice test at the short delay were reduced. These results thus have important implications for the use of multiple-choice tests as learning opportunities.

**Keywords:** Testing; test effects; multiple-choice; retrieval-induced forgetting; retrieval-induced facilitation

## Introduction

Taking a test does more than assess one's knowledge: It can also improve one's long-term retention of the tested information. Not all tests, however, are equally beneficial in this manner. For example, more open-ended tests (e.g., cued-recall), in general, have been shown to improve long-term retention more than multiple-choice tests (see meta-analyses by Anderson & Biddle, 1975; Hamaker, 1986). Moreover, some research has shown that taking multiple-choice tests can actually harm later performance on open-ended tests by exposing the test takers to misinformation in the form of incorrect, but plausible, answer choices, with the consequence of such information sometimes being intruded as incorrect responses to later cued-recall questions—findings referred to as misinformation effects (e.g., Roediger & Marsh, 2005). Thus, multiple-choice tests are often accused of not only being less effective for learning than are more open-ended types of tests, but also to risk negative misinformation effects, bringing their use as learning tools in educational contexts into question.

Although, as indicated, multiple-choice tests can produce misinformation effects on later open-ended tests, research, in general, has shown that the positive effects of multiple-choice testing (as compared to no testing) outweigh any such negative effects they engender. Furthermore, recent

research has indicated that multiple-choice testing may have a benefit for later overall performance that is not produced by the taking of prior cued-recall tests: namely, not only improving the retention of the information tested but also that of non-tested, but related, information—an outcome that would seem to be particularly desirable in educational contexts. When, for example, instructors give quizzes or practice tests to be followed later in the course by a more comprehensive exam, they are likely to ask questions about related information instead of (or in addition to) questions about the specific information tested earlier. Thus, it seems critical that the use of prior testing in educational contexts should help to improve the retention of both types of information.

With respect to the question of how retrieving some information affects the later retention of non-tested related information, previous research has demonstrated that the effects can be negative—that is, answering a cued-recall question can lead to impaired recall of competitive related information on a later test, a finding referred to as retrieval-induced forgetting (Anderson, Bjork, & Bjork, 1994). Even in cases in which retrieval-induced forgetting does not occur, however, the retention of non-tested related information is rarely facilitated as a consequence of a cued-recall test, especially when such non-tested information has a competitive relationship with the tested information. (For exceptions to this finding when tested and non-tested related questions were created to be facilitative, see Chan, McDermott, & Roediger, 2006, and Chan, 2009.)

In contrast to such findings for cued-recall tests, however, Little, Bjork, Bjork, and Angello (in press) recently demonstrated that—in addition to improving retention of previously tested information—taking an initial multiple-choice test, as compared to taking an initial cued-recall test, can improve retention of related information when the answers to the competitive related questions have occurred as incorrect alternatives in the initial multiple-choice test. Although these findings have clear implications for educational practice, particularly how an instructor might construct a practice exam, the procedure used by Little et al. employed a delay that is considered to lack educational realism (e.g., 5 min). Thus, a primary goal of the present research was to assess whether the demonstrated retention benefits (particularly for competitive related information) occurring as a consequence of taking multiple-choice

tests—compared to cued-recall tests—would persist at more educationally realistic delays.

### Retention of Non-tested Related Information

Although the effect of testing on the retention of both tested and related information was thoroughly explored in the 1960s and 70s (e.g., see literature on the use of adjunct questions, Anderson & Biddle, 1975; Frase, 1971; Hamaker, 1986; Rothkopf, 1970), interest in this topic has recently been renewed, not only because of the implications for educational practice, but also, in light of the finding of retrieval-induced forgetting (Anderson et al., 1994), to gain a better understanding of the circumstances under which an initial test might improve or impair retention of related information (e.g., Carroll, Campbell-Ratcliffe, Murnane, & Perfect, 2007; Chan et al., 2006; Chan, 2009; Little, Storm, & Bjork, 2011).

The research by Little et al. (in press), in which they directly compared the effects on later recall of taking an initial cued-recall test versus a multiple-choice test following study of a passage, provides some insight into this issue. Because retrieval-induced forgetting seems to depend upon the occurrence of a competitive relationship between tested and non-tested related information (see, e.g., Storm, 2010), Little et al. specifically constructed related question pairs so that one question in the pair would have a competitive relationship with the other question in the pair. For example, given a passage about Saturn, one question would ask the participant “how long it takes Saturn to revolve around the Sun” to which the correct answer is “30 Earth years,” and the other question would ask “how long it takes Saturn to rotate on its axis” to which the correct answer is “10 Earth hours.” On the initial multiple-choice tests, the answer to the related question appeared as one of the incorrect alternatives (e.g., *How long does it take Saturn to rotate on its axis? a. 10 Earth hours, b. 88 Earth days, c. 176 Earth days, d. 30 Earth years*).

Little et al. hypothesized that the presence of competitive alternatives as answer choices on the multiple-choice question would induce students to think deeply about the question and alternatives—perhaps not only recalling information about why the correct alternative is right, but also why the incorrect alternatives are wrong—with this spontaneous recall of information pertaining to incorrect alternatives serving as a learning event for that information and potentially improving its future recall. In contrast, they hypothesized that a cued-recall test would not afford the opportunity for such beneficial processing of related competitive information; thereby, perhaps making it subject to retrieval-induced forgetting. And, indeed, their findings supported this type of analysis: Whereas the taking of an initial cued-recall test following study of the passage led to impaired later recall of non-tested competitive information (Exp. 1), the taking of a multiple-choice test after reading the passage not only spared such information from forgetting (Exp. 1), but facilitated its retention (Exp. 2).

Although one might wonder if the facilitated retention of related information observed by Little et al. (in press) might have occurred owing simply to the exposure of those answers as incorrect alternatives during the initial multiple-choice test, a study by Little and Bjork (2010) provides evidence that the benefit for the retention of related information would not have occurred for this reason. Little and Bjork manipulated whether the incorrect alternatives were competitive or non-competitive for a given question, with the expectation that alternatives would need to be competitive for facilitation to occur. To illustrate, students answered questions (e.g., *Which outer planet was discovered by mathematical predictions rather than direct observation? Answer: Neptune*) with competitive alternatives (e.g., *Neptune, Uranus, Saturn*) or with non-competitive alternatives (e.g., *Neptune, Mercury, Mars*), and they were better able to answer a later related question (for which *Uranus* or *Mercury*, respectively, were the correct answers) when the answer to that related question had served as a competitive alternative versus as a non-competitive alternative on the initial multiple-choice test. Thus, simple prior exposure to the incorrect alternatives cannot explain the observed results: Competitive alternatives seem to trigger the retrieval processes that support the improved retention of information pertaining to those incorrect alternatives.

The results of the experiment by Little and Bjork (2010), although theoretically informative, do not address the question of concern in the present research: namely, whether such effects persist over educationally realistic durations. On the one hand, the pattern of their results suggests that the presence of competitive alternatives on the initial multiple-choice test induces learners to engage in both deep processing of the choices and spontaneous recall of information pertaining to those choices, both of which might promote long-term retention. On the other hand, the pattern of results observed by Little et al. (in press, Exp. 1) might not persist. Their observation of a benefit of multiple-choice testing over cued-recall testing might reflect, in part, a temporary impairment in the recall of information related to the cued-recall questions, as other research has suggested that such retrieval-induced forgetting does not persist (Chan, 2009; MacLeod & Macrae, 2001). Chan, for example, found that although forgetting occurred as a consequence of an initial cued-recall test when the retention interval was short (i.e., 20 min), forgetting was not observed when the interval was long (i.e., 24 hrs). Furthermore, when forgetting did not occur at a short delay, facilitation emerged at a longer delay. Thus, it is possible that Little et al.’s observed pattern of a benefit of multiple-choice testing over cued-recall testing would be eliminated when retention is assessed at a delay longer than 5-20 minutes.

### Retention of Previously Tested Information

In addition to assessing the effect of initial testing on the later recall of related information, we were also interested in its effect on previously tested information. Specifically, we

also wanted to assess whether the benefit of multiple-choice testing compared to cued-recall testing observed by Little et al. (Exp. 1) would persist over a long delay. If, as has been suggested (e.g., Foos & Fischer, 1988), cued-recall tests involve deeper processing than do multiple-choice tests, then such an outcome would seem unlikely; that is, improved retention of the tested information would seem more likely to persist as a consequence of a cued-recall test than as a consequence of a multiple-choice test (see, e.g., Roediger & Karpicke, 2006), which might lead to a reversal in the direction of the effect.

### **Misinformation: A Negative Consequence of Multiple-choice Testing**

Finally, multiple-choice tests can result in misinformation effects (Roediger & Marsh, 2005) and seem particularly prone to do so when feedback is not provided (Butler & Roediger, 2008). Thus, another goal of the present research was to assess the influence of a longer retention interval on the prevalence of misinformation effects.

### **The Present Experiment**

In summary, Little et al. (in press) claimed that multiple-choice tests should be exonerated—at least from the criticisms involving their use in learning, but they used a retention interval that has limited application for educational purposes. In the present experiment, we assessed whether their observed benefits of taking a multiple-choice test over taking a cued-recall test or no test at all would persist over a longer retention interval. Additionally, we assessed the occurrence of misinformation at these two retention intervals.

## **Method**

### **Participants and Design**

Seventy-two undergraduates at the University of California, Los Angeles, who were all recruited for a two-session study, participated for either partial course credit or payment. Each participant read three passages, followed immediately by two initial tests: a cued-recall test for one passage and a multiple-choice test for another passage (the remaining passage was not tested initially and served as the control condition). After a delay (either 5-min or 48-hr), all participants took a final test that included previously tested questions and previously non-tested related questions (pertaining to multiple-choice questions for one passage and cued-recall questions for another passage), and non-tested questions from the non-tested passage.

### **Materials**

The same materials as used by Little and Bjork (2011, Exp. 3) were employed: Three passages of approximately 800 words each about Saturn, Yellowstone National Park, and stimulant drugs with ten pairs of multiple-choice questions for each passage. The two multiple-choice questions in each pair were semantically related in that both tested the

same topic (e.g., geysers) and had the same four alternatives (e.g., *Old Faithful*, *Steamboat Geyser*, *Castle Geyser*, and *Daisy Geyser*), but different correct answers (e.g., *What is the tallest geyser in Yellowstone National Park?* Answer: *Steamboat Geyser*; and, *What is the oldest geyser in Yellowstone National Park?* Answer: *Castle Geyser*). For each passage, the questions in each pair were randomly assigned to a different 10-item set. Cued-recall questions were the same as the multiple-choice ones, but without alternatives provided.

### **Procedure**

All participants were given 6 min to read each of the three passages in immediate succession, being told to spend the full time reading and studying. After this initial study phase, they were given a 10-item multiple-choice test for one passage and a 10-item cued-recall test for another passage (with each test containing all the items in one of the question sets for that passage). Questions were shown on the computer screen one at a time for 24 s, and participants typed in their responses, being instructed to spend the full time thinking about the question and their answer. Each question was answered twice (as is common in studies of retrieval-induced forgetting) such that participants answered each of the ten questions once, and then answered each question again, but in a different order.

After taking the initial multiple-choice and cued-recall tests, all participants engaged in a non-verbal 5-min distractor task of maze completion. Then, participants randomly assigned to the 5-min delay condition immediately took the final test; those randomly assigned to the 48-hr delay condition were excused, with the instruction to return 48 hrs later.

On the final test, participants answered 60 cued-recall questions, with the questions presented one at a time on the computer screen. Of the 20 final-test questions associated with the passage that received an initial cued-recall test, half were identical to the 10 cued-recall questions initially asked about that tested passage, while the other half consisted of the related questions that had not been presented on the initial cued-recall test (i.e., the remaining questions from the set of 10-paired questions constructed for that passage). Of the 20 final-test questions associated with the passage that received an initial multiple-choice test, half were identical to the 10 multiple-choice questions initially asked about the tested passage (except they were now asked as cued-recall questions without alternatives presented), while the other half consisted of the related questions that had not been presented on the initial multiple-choice test (i.e., the remaining questions from the set of 10-paired questions constructed for that passage). Of the 20 final-test questions related to the non-tested passage, all were previously non-tested and served as baseline control items.

As the later recall of non-tested related information was most crucial to our research questions, the non-tested questions from the tested passages were tested in the first half of the test, along with half of the non-tested control

questions, to which their performance would be compared. Previously tested questions were tested in the second half of the test, along with the remaining non-tested control questions, to which their performance would be compared. The order in which the passages were studied, the passages assigned to the different testing conditions, the order in which the tests were administered, and which 10-item question set was presented during the initial tests were counterbalanced across participants.

## Results

### Initial Test Performance

Participants in the 5-min and 48-hr delay conditions correctly answered 63% ( $SD = 18\%$ ) and 66% ( $SD = 19\%$ ) of the questions on the initial multiple-choice test, respectively. Participants in the 5-min and 48-hr delay conditions correctly answered 40% ( $SD = 21\%$ ) and 39% ( $SD = 18\%$ ) of the questions on the initial cued-recall test, respectively. As would be expected, initial test performance did not differ between the two retention-interval conditions.

### Final Test Performance for Previously Tested Information

Final-test performance for previously tested information and comparable control information is presented in Figure 1. As indicated there, taking an initial test improved performance for those previously tested items on the later test, as compared to not taking an initial test, regardless of the type of initial test taken (cued-recall or multiple-choice) or the delay from initial test to the final test (5 min or 48 hr).

Interestingly, although performance appeared to be lower at a 48-hr delay than at a 5-min delay for questions initially presented in a multiple-choice test and for control questions (i.e., questions not previously tested), no forgetting appeared to occur for those items initially presented in a cued-recall test, suggesting a possible interaction. A  $3 \times 2$  mixed-model

Figure 1: Correct performance percentages for previously tested information (and comparable non-tested control information) as a consequence of the testing condition (cued-recall, multiple-choice, or no-test control) and the retention interval between initial and final test (5 min or 48 hr). Error bars represent  $\pm 1$  SE.

ANOVA, however, did not reveal this apparent interaction between testing condition (cued-recall vs. multiple-choice vs. control) and delay (5 min vs. 48 hr), to be reliable,  $F(2, 69) = 1.97, p > .05$ . A significant main effect of testing condition, however, was obtained,  $F(2, 69) = 43.73, \eta^2 = 0.56, p < .01$ . Most importantly, taking a multiple-choice test was better for retention of previously tested information than was taking a cued-recall test,  $t(71) = 4.32, d = 0.51, p < .01$ .

That performance for questions previously tested with a cued-recall test did not appear to differ when assessed at a 5-min delay versus a 48-hr delay is noteworthy, indicating the effectiveness of cued-recall tests for the retention of tested information and consistent with findings that items successfully retrieved at short delays tend to remain accessible at longer delays (e.g., Halamish & Bjork, 2011; Kornell, Bjork, & Garcia, 2011).

### Final Test Performance for Non-tested Related Information

Results relevant to our primary objective of testing whether the finding that taking a multiple-choice test improves retention of non-tested information more than does taking a cued-recall test with a short retention interval between initial and final tests would replicate, and, if so, to assess whether such benefits would persist with a longer retention interval are shown in Figure 2. As can be seen there, information that was related to questions on an initial multiple-choice test appeared to be better recalled than was information related to questions on an initial cued-recall test or information from the non-tested control passage, both at a 5-min delay and at a 48-hr delay.

Figure 2: Correct performance percentages for non-tested related information (and comparable non-tested control information) as a consequence of the testing condition (cued-recall, multiple-choice, or no-test control) and the retention interval between the initial and final tests (5 min or 48 hours). Error bars represent  $\pm 1$  SE.

Again, a  $3 \times 2$  mixed-model ANOVA did not reveal an interaction between testing condition and delay,  $F(2, 69) = 0.12, p > .05$ , but did reveal a main effect of testing condition,  $F(2, 69) = 5.04, \eta^2 = 0.13, p < .01$ . Overall, taking a multiple-choice test was better for the retention of

related information than was either taking a cued-recall test or not taking a test (control condition),  $t(71) = 2.72$ ,  $d = 0.33$ ,  $p < .01$  and  $t(71) = 2.82$ ,  $d = 0.33$ ,  $p < .01$ , respectively. Importantly, however, no difference in performance for the cued-recall condition versus the control condition was observed, indicating that although taking a cued-recall test did not impair the later recall of related information in the present study, neither did it help it compared to not taking a test at all. Taking a multiple-choice test did, however, and this benefit occurred regardless of the retention interval.

### **Intrusions of Incorrect Information**

As previously mentioned, multiple-choice tests can result in misinformation effects (Roediger & Marsh, 2005; Marsh, Roediger, Bjork, & Bjork, 2007) thought to be a drawback to multiple choice testing as compared to more open-ended types of testing, and, indeed, participants in the present study made such intrusions on the final test in the multiple-choice condition. Because, however, all of the alternatives had appeared in the passages, participants also made such intrusions in the control and cued-recall conditions.

In the present study, there appeared to be more intrusions as a consequence of taking a multiple-choice test ( $M = 24\%$ ,  $SE = 3\%$ ) than as a consequence of taking a cued-recall test ( $M = 12\%$ ,  $SE = 2\%$ ) or having no initial test ( $M = 14\%$ ,  $SE = 2\%$ ) when the final test occurred at a 5-min delay. At the 48-hr delay, however, intrusions as a consequence of taking a multiple-choice test ( $M = 17\%$ ,  $SE = 2\%$ ) appeared to be reduced while intrusions occurring as a consequence of taking a cued-recall test ( $M = 13\%$ ,  $SE = 2\%$ ) or having no test ( $M = 14\%$ ,  $SE = 2\%$ ) did not. Looking specifically at the interaction between the two test types and the delay, a  $2 \times 2$  mixed-model ANOVA revealed an interaction,  $F(1, 70) = 4.24$ ,  $p < .05$ , with an independent samples  $t$ -test demonstrating that multiple-choice alternative intrusions were significantly lower at the 48-hr delay than at the 5-min delay,  $t(70) = 2.14$ ,  $d = 0.50$ ,  $p < .05$ . In considering these results, one should note that while correct performance in the control condition was lower at the 48-hr delay than at the 5-min delay, intrusion rates at the two delays were not different, suggesting that forgetting rates of correct and incorrect responses are not necessarily related. For the multiple-choice condition, however, both correct responses and intrusions were reduced at the 48-hr delay compared to the 5-min delay. Interestingly, in the multiple-choice condition, correct responses and intrusions were negatively correlated,  $r(72) = -.30$ ,  $p < .05$ , suggesting that the more correct answers one recalled, the fewer intrusions one made, in both delay conditions.

### **Discussion**

Taking a multiple-choice test shortly after study appears to have some particularly positive consequences for learning. Doing so not only increases retention of both tested and non-tested related information compared to taking a cued-recall test or no test, but such benefits also persist over a

retention interval that is, by most standards, considered educationally realistic. In the present study, we also found that even misinformation effects, a frequently cited negative consequence of taking a multiple-choice test, become less of a problem at a longer retention interval. Thus, at a longer delay from initial to final test, multiple-choice testing still had the benefits seen at a shorter delay, but with less cost.

The present results can be contrasted with much past research demonstrating that cued-recall tests are better for retention than multiple-choice tests (e.g., Hamaker, 1986). Our finding of a greater benefit for multiple-choice testing than cued-recall testing might have occurred owing to the relatively low performance for cued-recall questions on our initial test: Although participants were unlikely to forget answers to questions that they answered correctly on the initial cued-recall test, the majority of responses on the initial test were incorrect and thus unlikely to be answered correctly later. In contrast, more of the multiple-choice questions were answered correctly on the initial test. Thus, although answering a given multiple-choice question might be less powerful for long-term retention than answering a given cued-recall question (Foos & Fisher, 1988), the greater number of correct responses on the initial multiple-choice test would result in more items having the potential to be recalled correctly later. It should be noted, however, that our use of highly competitive alternatives might also have resulted in our multiple-choice questions being more powerful for retention than those typically used in past research. Even so, perhaps providing feedback, a common practice in educational contexts, would lead to a reversal in our observed effect because feedback provides a second opportunity for the correct answers to incorrectly answered cued-recall questions to be learned (e.g., Kang, McDermott, & Roediger, 2007). Importantly, however, Little et al. (in press) also demonstrated that—although providing feedback did improve performance for information initially tested with a cued-recall test more than for information initially tested with a multiple-choice test, a reversal in final test performance was not realized. Furthermore, performance for related information was not affected as a consequence of whether or not feedback was provided.

Additionally, in the present study, we did not find evidence of retrieval-induced forgetting in the cued-recall condition, which is interesting, particularly at the short delay and given the competitive nature of our question pairs. Although retrieval-induced forgetting has been demonstrated with a variety of materials (see, e.g., Bjork, Bjork, & MacLeod, 2006; Storm, 2011), its occurrence with educational text materials is less consistent, with some studies observing retrieval-induced forgetting (e.g., Carroll et al., 2007; Little et al., 2011) and others not (e.g., Chan et al., 2006). Competition during the initial test, coherence of the to-be-learned materials, and the delay between initial and final tests have been pointed to as predictors of whether or not the effect will occur, but the exact specifications of the boundary conditions for the occurrence, or lack thereof, of retrieval-induced forgetting remain to be determined.

## Concluding Comments

Multiple-choice tests are widely used in educational contexts and elsewhere, but their use—either as instruments of assessment or learning—is frequently disparaged. Although the present research does not directly speak to their potential value as tools of assessment, it does speak to their use as tools for learning. And, in that respect, as tools to reinforce knowledge, for the long as well as the short term, they seem quite useful when constructed with competitive alternatives and, perhaps, uniquely so with respect to the increased learning of competitive related as well as actually tested information.

## Abstract

Expertise in Chinese character recognition is marked by analytic/reduced holistic processing (Hsiao & Cottrell, 2009), which depends mainly on readers' writing rather than reading experience (Tso, Au, & Hsiao, 2011). Here we examined whether simplified and traditional Chinese readers process characters differently in terms of holistic processing. When processing characters that are distinctive in the simplified and traditional scripts, we found that simplified Chinese readers were more analytic than traditional Chinese readers in perceiving simplified characters; this effect depended on their writing rather than reading/copying performance. In contrast, the two groups did not differ in holistic processing of traditional characters, regardless of their performance difference in writing/reading traditional characters. When processing characters that are shared in the two scripts, simplified Chinese readers were also more analytic than traditional Chinese readers. These results suggest that simplified Chinese readers may have developed better analytic processing skills than traditional Chinese readers from experiences with simplified characters, and these skills are transferrable to the processing of shared and even traditional characters.

**Keywords:** Chinese character recognition, holistic processing, reading, writing

## Introduction

Chinese characters are the basic writing units in Chinese orthography. They consist of strokes packed into a square configuration, in contrast to words in most alphabetic languages, which are linear combinations of letters. It has been suggested that Chinese characters have many visual similarities with faces (McCleery et al., 2008). For example, both faces and Chinese characters have a homogenous shape, are recognized at the individual level, and learnt in an upright orientation. However, expertise in face recognition is marked by holistic processing, that is, to perceive features of an object as a whole instead of various parts (Gauthier & Tanaka, 2002); in contrast, expertise in recognizing Chinese characters is marked by reduced holistic processing (Hsiao & Cottrell, 2009). This effect may be due to expert Chinese readers' knowledge about Chinese orthography. Chinese characters are composed of strokes, which combine to form over a thousand different stroke patterns in Chinese orthography (Hsiao & Shillcock, 2006), and stroke patterns are the smallest functional units in Chinese character recognition (Chen, Allport, & Marshall, 1996). For expert Chinese readers, when recognizing Chinese characters, they may be more sensitive to the internal constituent

components and have better ability to ignore some unimportant configural information for recognition, such as exact distances between features (Ge, Wang, McCleery, & Lee, 2006) compared with novices (Ho, Ng, & Ng., 2003; Hsiao & Cottrell, 2009). Consequently, expert readers may process Chinese characters less holistically than novices.

There are currently two Chinese writing systems in use in Chinese speaking regions, namely simplified and traditional Chinese. The simplified script was created during the writing reform initiated by the central government of the People's Republic of China in the 1960s for easing the learning process. Today the majority of Chinese speaking regions including Mainland China, Singapore, and Malaysia use the simplified script, while Hong Kong and Taiwan continue to use the traditional script. The simplification process did not apply to all characters; among the most frequently used 3,500 characters, around 40% were simplified, which have approximately 22.5% fewer strokes than the traditional counterparts (Gao & Kao, 2002); the remaining 60% remained the same in two scripts.

The effects of simplifying the script have aroused some discussion since last decade. For instance, while simplified characters were designed to ease the learning process, many researchers (e.g., Chen, 1999) believe that pure reduction of strokes without standardization of principles may make the characters harder to learn: on one hand, reducing the stroke numbers may make the characters more legible and easier to write for beginners; on the other hand, up to a certain point, characters may become less distinguishable due to high visual similarity among one another as readers' lexicon size expands (Chen, 1999). Consistent with this speculation, McBride-Chang et al. (2005) recently found that visual skills of children who learned simplified characters were significantly better than those of Hong Kong children who learned the traditional script. Peng, Winett, and Wang's (2010) ERP data were also consistent with the finding that simplified character readers have greater visual discrimination skills than traditional character readers in perceiving Chinese characters.

Thus, it is possible that the simplification has significantly increased visual similarity among characters in the Chinese lexicon. Simplified characters may differ from one another in fewer strokes than traditional characters. As the ability to identify these diagnostic features is important for recognition (e.g., Oliva & Schyns, 1997), reading simplified characters may involve more analytic/reduced holistic processing than reading traditional characters. Here we aim

to examine whether native traditional and simplified Chinese readers process Chinese characters differently due to the differences in their scripts. We first examine their perception of characters in either the simplified or the traditional form; we predict that simplified Chinese readers will perceive simplified characters less holistically than traditional readers due to their expertise with the simplified script, and vice versa in the perception of traditional characters. In addition to the characters that have different visual forms in the two scripts, around 60% of the most frequently used characters have the same form in the two scripts, and these shared characters provide us a unique opportunity to test the transfer effect of reading simplified/traditional characters. Because both reader groups are experts in reading shared characters, if the two groups differ in the way they perceive/process the shared characters, it will suggest a transfer effect from their experience with the simplified or traditional scripts.

Tso, Hsiao, and Au (2011) recently examined how writing experience influences holistic processing in Chinese character recognition. They recruited proficient Chinese readers who were skilled in both reading and writing (Writers), and those who had limited writing experience regardless of their proficient reading ability (Limited-Writers). They found that Writers perceived Chinese characters less holistically than Limited-Writers, and holistic processing effect was dependent on writing rather than reading performance. Although simplified Chinese readers may still be able to read traditional characters through their similarity with simplified characters or context information, they generally do not know how to write them (and vice versa for traditional Chinese readers). Thus, similar to Limited-Writers, they may perceive characters in their unfamiliar script more holistically, and this effect may depend on their writing rather than reading performance. To verify this hypothesis, we also measure participants' reading and writing performance in the two scripts and examine whether their (reduced) holistic processing can be predicted by these measures. This study is also the first to investigate holistic processing effects in the two Chinese scripts across two groups of readers.

## Methods

### Participants

24 native simplified Chinese readers (5 males and 19 females) from Mainland China and 24 native traditional Chinese readers (9 males and 15 females) from Hong Kong participated in the study. They were all skilled writers in their own script: all Mainland participants had passed the Chinese test of National Entrance Examination to college, and all Hong Kong participants had passed the Chinese test of Hong Kong Advanced Level Examination. They were all students at University of Hong Kong; all simplified Chinese readers had resided in Hong Kong for less than 1 years (average length of stay was 9.35 months) by the time they were recruited and had limited exposure to traditional

Chinese before<sup>1</sup>. Both groups had similar education background (average years of education, Mainland = 15.46,  $SE = .37$ ; Hong Kong = 15.38,  $SE = .44$ ) and similar age (Mainland average = 22.25,  $SE = .65$ ; Hong Kong average = 22.42,  $SE = .81$ ). All of them had normal or corrected-to-normal vision and were right-handed as measured by the Edinburgh Handedness Inventory (Oldfield, 1971).

### Holistic processing

The complete composite paradigm was used to examine holistic processing effects (Gauthier & Bukach, 2007). The experiment procedure was adopted from Hsiao and Cottrell (2009; Fig. 1). In each trial, participants were presented with a pair of Chinese characters simultaneously, and told to attend to only half of each character and judge whether they were the same or different. In congruent trials, the attended and irrelevant halves of the characters led to the same response (i.e., both were the same or different); in incongruent trials, they led to different responses. The level of holistic processing was assessed by the performance difference between the congruent and incongruent trials.

**Materials** The materials consisted of 480 pairs of low to medium frequency (Kwan, 2001) Chinese characters in Ming font, divided equally into three script types: 160 pairs were simplified characters; 160 pairs were the corresponding traditional version of the simplified characters, i.e., having same meanings and pronunciations and differing in orthography; the remaining 160 pairs were characters shared between the two scripts (i.e., shared characters). Characters of different script types were matched in relative character frequency, and the traditional characters were significantly more complex than the simplified ones ( $t(159) = 6.17, p < .01$ ). In each script type, half of the characters had a top-bottom (TB) configuration, and the other half were left-right (LR) structured<sup>2</sup>, and two groups were matched in complexity and frequency. The 80 character pairs in each script type and character configuration combination were further divided into the four conditions in the complete composite paradigm, with 20 pairs in each condition shown in Fig. 1a. Each character could be divided into two components, horizontally for TB and vertically for LR characters. In either character configuration condition, the attended halves were matched across congruent and incongruent trials (see Fig. 1a for an illustration), and character frequency and visual complexity were also matched across congruent and incongruent trials.

**Design** The design had three within-subject variables: congruency (congruent vs. incongruent), character

<sup>1</sup> Note that the official written languages used in Hong Kong are English and traditional Chinese, and the official language for instruction at University of Hong Kong is English.

<sup>2</sup> We used both TB and LR characters to counterbalance possible influence from character structure; the LR structure is the most dominant structure in Chinese orthography, followed by the TB structure (see, e.g., Hsiao & Shillcock, 2006).

configuration (TB vs. LR), and script type (simplified vs. traditional vs. shared); and a between-subject variable: group (simplified vs. traditional Chinese readers). The dependent variable was discrimination sensitivity measured by  $A'$ , a bias-free nonparametric measure of sensitivity<sup>3</sup>.

**Procedure** All characters were shown in low contrast to avoid ceiling effects. In each trial, participants were presented with a central fixation cross for 1000 ms, followed by a symbol indicating which half of the character (top or bottom for TB characters; left or right for LR characters) they should attend to. They were then presented with a pair of characters above and below the initial fixation respectively for 500 ms, followed by a mask (Fig. 1b). Both characters were about 2.5° of visual angle away from the center, each occupying around 1.5° of visual angle. Participants performed a same-or-different judgment task as quickly and accurately as possible with a response box; their accuracy was collected. There were six blocks of test; each block had 80 trials; characters with different configurations or in different script types were presented in different blocks. The sequence of blocks was counterbalanced across participants. A practice session with characters not used in the materials was given before the test.

Fig. 1: Illustration of stimulus pairs in the complete composite paradigm (a) and trial sequences (b). In (a), the attended components are the bottom halves shaded in grey.

### Reading & Writing Performance

Tasks assessing participants' reading and writing abilities were adopted from Tso et al. (2011). Participants' reading ability was assessed by a character naming task, in which they named the characters in their mother tongue (i.e., Putonghua for Mainland China participants and Cantonese for Hong Kong participants). Their writing ability was assessed by a character copying and a word dictation task.

**Character Naming** The materials consisted of 120 Chinese characters, half with a TB structure and the other half with a

LR configuration. In either configuration, 20 characters were simplified characters, 20 were the corresponding traditional version of the simplified characters, and the remaining 20 were shared characters; these characters were not used in the holistic processing task. All characters were of medium to high frequency (Kwan, 2001); they were matched in relative frequency across the script types. The traditional characters had significantly more strokes than the simplified ones ( $t(39) = 10.92, p < .01$ ). In each trial, after a 500 ms central fixation, participants were presented with a character occupying 1.5° of visual angle at the center of the screen, and they were asked to read it out in front of a microphone. Upon their response, the screen turned blank and the experimenter pressed buttons on a response box to record the accuracy and initiate the next trial.

**Character Copying** Participants copied 60 characters (20 shared, 20 simplified, and 20 traditional) as quickly and as accurately as possible. The characters were randomly selected from those used in the character naming task; half of them had a TB structure whereas the other half had a LR configuration. All characters were of medium to high frequency and were matched in relative frequency across script types. The traditional characters had significantly more strokes than their simplified counterparts ( $t(19) = 8.26, p < .01$ ). In each trial, after a 500 ms central fixation, participants were shown a stimulus at the center of the screen, occupying around 1.5° of visual angle, and were asked to copy it as quickly and as accurately as possible. After they finished copying, they pressed a button on a response box to signal completion and the screen turned blank. Then the experimenter pressed buttons on a response box to record the accuracy and to initiate the next trial. 60 stimuli were presented in a random order in one block.

**Word Dictation Task** 40 characters (20 shared and 20 traditional/simplified) were selected from the character naming task. Each character was concatenated with a second character to compose a two-character word, and these words were used here. Words instead of characters were used to avoid the ambiguity due to the many homophone characters in Chinese. All words were of medium to high frequency (Taiwan Ministry of Education, 1997) and were matched in relative word frequency across different script types. Participants listened to the words presented in a female voice in their native language respectively, i.e., Cantonese for Hong Kong participants and Mandarin for Mainland participants. The audio recordings of the words were presented by a computer in a random order, and participants wrote down each word in their own script first and then in the other script, even if they thought the characters were the same in the two scripts. If they did not know how to write a character, they indicated it by putting a cross on the space. In each trial, after the words "get ready" presented on the screen for 500 ms, participants were presented with a stimulus; they then pressed buttons on a response box to indicate whether they knew how to write it or not. After

<sup>3</sup>  $A' = .5 + \left[ \text{sign}(H - F) \frac{(H - F)^2 + |H - F|}{4\max(H, F) - 4HF} \right]$ , where  $H$  and  $F$  present hit rate and false alarm rate respectively.

writing the word in both scripts, they pressed a button to indicate completion and start the next trial. Their accuracy of writing the first character of each word was assessed (to match the character naming task).

## Results

### Reading and Writing Performances

**Reading Performance** Participants' character naming performance was summarized in Table 1. Repeated measures ANOVA revealed a main effect of script type in accuracy ( $F(2, 92) = 5.40, p < .01$ ) and response time (RT) ( $F(2, 92) = 5.60, p < .01$ ); and an interaction between group and script type in accuracy ( $F(2, 92) = 14.66, p < .01$ ) and RT ( $F(2, 92) = 15.70, p < .01$ ). Simplified Chinese readers were more accurate in naming shared ( $t(46) = 1.51, p < .05$ ; although the difference was only 1%) and simplified characters ( $t(46) = 2.87, p < .05$ ) than traditional Chinese readers, and traditional Chinese readers were more accurate in naming traditional characters ( $t(46) = 3.33, p < .01$ ; these differences were not significant in RT).

Task	Script	Simplified Chinese Readers		Traditional Chinese Readers		Comparison between two groups	
		Acc	RT (ms)	Acc	RT (ms)	Acc	RT
Namin	Shared	1.00	251.05	0.99	327.12	*	
	Simplified	1.00	251.85	0.96	351.36	*	
	Traditional	0.97	286.79	0.99	326.36	*	
Copyin	Shared	0.96	7531.16	0.96	6201.31		
	Simplified	0.98	4815.76	0.94	5834.29	*	
	Traditional	0.65	12251.36	0.94	6173.10	**	**
Dictatio	Shared	0.99		0.97		*	
	Simplified	1.00		0.66		**	
	Traditional	0.20		0.99		**	

Table 1: Summary of participants reading and writing performance  
\*  $p < .05$ , \*\*  $p < .01$

**Writing Performance** Participants' writing performance was summarized in Table 1. In character copying, repeated-measures ANOVA revealed a main effect of script type in both accuracy ( $F(2, 92) = 93.40, p < .01$ ) and RT ( $F(2, 92) = 135.28, p < .01$ ), and an interaction between group and script type in accuracy ( $F(2, 92) = 81.76, p < .01$ ) and RT ( $F(2, 92) = 115.38, p < .01$ ). Traditional Chinese readers were faster ( $t(46) = -7.58, p < .01$ ) and more accurate ( $t(46) = 9.58, p < .01$ ) in copying traditional characters, but less accurate in copying simplified characters ( $t(46) = -3.58, p < .05$ ) than simplified Chinese readers. In contrast, the two groups did not differ in the accuracy or RT of copying shared characters; this suggests that both group had similar level of copying skills in shared characters. In the dictation task, a main effect of script type ( $F(2, 92) = 59.15, p < .01$ ) and an interaction between script type and group ( $F(2, 92) = 171.96, p < .01$ ) were found. Simplified Chinese readers were more accurate in recalling and writing shared ( $t(46) = 2.41, p < .05$ ) and simplified characters ( $t(46) = 6.13, p < .01$ ), but were less accurate in recalling and writing traditional characters ( $t(43) = 21.86, p < .01$ ) than traditional Chinese readers.

### Holistic Processing

In A', repeated measures ANOVA revealed main effects of congruency ( $F(1, 46) = 70.40, p < .01$ ), and character configuration ( $F(1, 46) = 33.79, p < .01$ ). Participants did better in congruent ( $M = .98, SE = .00$ ) than incongruent trials ( $M = .94, SE = .01$ ), and in processing LR ( $M = .97, SE = .02$ ) than TB ( $M = .95, SE = .02$ ) characters. A significant interaction between congruency and group ( $F(1, 46) = 6.60, p < .05$ ) indicated that traditional Chinese readers were more holistic than simplified Chinese readers in general. There was also a three-way interaction between script type, congruency, and group ( $F(2, 92) = 5.027, p < .05$ ), suggesting that the interaction between congruency and group was different across the three script types. To investigate how the two groups differed in processing different script types, we first contrasted their difference in processing simplified vs. traditional characters; we then compared their behavior in processing shared characters to examine how their experience in processing simplified/traditional characters influenced their perception of shared characters.

**Simplified vs. Traditional characters** Repeated-measure ANOVAs revealed main effects of congruency ( $F(1, 46) = 65.55, p < .01$ ) and character configuration ( $F(1, 46) = 33.26, p < .01$ ). There was an interaction between congruency and group ( $F(1, 46) = 5.30, p < .05$ ): simplified Chinese readers perceived both characters less holistically overall; and a three-way interaction between script type, congruency, and group ( $F(1, 46) = 5.11, p < .05$ ), suggesting the interaction between congruency and group was different between the two scripts.

When we examined their performance in processing the two scripts separately, in processing simplified characters, as predicted, the interaction between congruency and group was significant ( $F(1, 46) = 5.74, p < .05$ ): simplified Chinese readers processed simplified characters less holistically than traditional Chinese readers (Fig. 2a), possibly due to their expertise with simplified characters. Nevertheless, in processing traditional characters, there was no interaction between group and congruency ( $p = .76$ ; Fig. 2b). This suggests that the two groups processed traditional characters with a similar level of holistic processing, regardless of their performance difference in reading and writing traditional characters.

Since the two groups differed in some reading and writing performance measures in processing simplified characters (Table 1), to examine whether the difference in holistic processing of simplified characters was dependent on these measures, we put them as covariates in separate ANCOVA tests. Participants' reading performance in traditional and shared characters could hardly explain the holistic processing difference, because the interaction was still significant if we put their shared character reading accuracy ( $F(1, 46) = 5.62, p < .05$ ) or RT ( $F(1, 46) = 6.08, p < .05$ ), or traditional character reading RT ( $F(1, 46) = 5.66, p < .05$ ) as a covariate separately, and it was marginal when

traditional character reading accuracy was put as a covariate ( $F(1, 46) = 3.62, p = .06$ ). Similarly, when putting either their simplified character naming accuracy ( $F(1, 46) = 4.01, p < .05$ ) or simplified character copying RT ( $F(1, 46) = 5.99, p < .05$ ) as covariates the interaction between congruency and group was still significant. When we put their simplified character reading RT ( $F(1, 46) = 3.23, p = .08$ ) or copying accuracy ( $F(1, 46) = 2.71, p = .11$ ), the interaction between congruency and group became marginal. Only when we put simplified character dictation accuracy ( $F(1, 46) = .627, p = .43$ ) as a covariate did the interaction become insignificant. Furthermore, participants' difference between congruent and incongruent trials (the measure of holistic processing) in processing simplified Chinese characters was significantly correlated with their simplified character dictation ( $r = -.39, p < .05$ ) but not with reading or copying performances. These results were consistent with Tso et al.'s (2011) finding that the reduced holistic processing effect in expert Chinese character processing may depend more on writing rather than reading or copying performance.

Fig. 2: Performance of simplified and traditional Chinese readers in the holistic processing task with (a) simplified Chinese characters and (b) traditional Chinese characters.

**Shared characters** A main effect of congruency was found ( $F(1, 46) = 54.96, p < .01$ ). There was an interaction between congruency and group ( $F(1, 46) = 5.01, p < .05$ ): simplified Chinese readers were less holistic than traditional Chinese readers (Fig. 3), even though these characters were shared in the two scripts. Since the two groups also differed in some reading/writing performance measures (Table 1), to examine whether the difference in holistic processing was dependent on these measures, they were put as covariates in separate ANCOVA tests. We found that the interaction between congruency and group was still significant when putting shared character naming accuracy ( $F(1, 46) = 4.72, p < .05$ ) or RT ( $F(1, 46) = 5.25, p < .05$ ), copying accuracy ( $F(1, 46) = 4.97, p < .05$ ), or dictation accuracy ( $F(1, 46) = 4.74, p < .05$ ) as a covariate. When putting shared character copying RT ( $F(1, 46) = 3.44, p = .07$ ), as a covariate, the interaction became marginally significant. However, when putting simplified character copying accuracy as a covariate, the interaction became very marginal ( $F(1, 46) = 2.52, p = .12$ ), and when putting simplified character dictation accuracy as a covariate ( $F(1, 46) = .60, p = .43$ ), the

interaction became insignificant. Also, participants' shared character holistic processing significantly correlated with simplified character dictation ( $r = -.36, p < .05$ ) but not with any other reading/writing performance measures. These results suggested that the difference in holistic processing of shared characters could not be completely accounted for by their performance difference in reading/writing shared characters; rather, it was dependent on their writing performance of simplified characters. Thus, the holistic processing difference was likely due to a transfer effect from simplified Chinese readers' expertise with simplified characters.

Figure 3: Performance of simplified and traditional Chinese readers in the holistic processing task with shared characters.

## Discussion

Here we examined whether simplified and traditional Chinese readers processed Chinese characters differently in terms of holistic processing, and whether their writing and reading performance measures could uniquely predict these differences. We found that when processing simplified characters, simplified Chinese readers were less holistic than traditional Chinese readers, and the difference was dependent on their word dictation performance rather than reading or copying performances. This finding is consistent with Tso et al.'s (2001) study, which showed a close relationship between writing experience and reduced holistic processing in Chinese character recognition. In contrast, although simplified Chinese readers performed much worse in both reading and writing traditional characters than traditional Chinese readers, their performance in holistic processing of traditional characters did not differ from traditional Chinese readers. This effect may be because processing simplified characters generally requires more analytic processing due to higher visual similarity among characters compared with traditional characters. Thus, simplified Chinese readers may have developed a better analytic processing skill in reading Chinese characters in general, and it could be more easily transferred to reading traditional characters compared with the generalization from traditional to simplified characters in traditional Chinese readers. This speculation is consistent with the recent finding that simplified Chinese readers have

better visual skills than traditional Chinese readers (e.g., McBride-Chang et al., 2005; Peng et al., 2010).

When processing characters that are the same in the two scripts (shared characters), simplified Chinese readers were also less holistic than traditional Chinese readers, even though both groups were experts in processing shared characters. Although simplified Chinese readers had better dictation performance in shared characters, further analysis showed that this difference in holistic processing was not dependent on their writing abilities of shared characters, but on their writing abilities of simplified characters. These findings further support our hypothesis that recognizing simplified characters requires more analytic processing than recognizing traditional characters, and this enhanced analytic processing skill is transferrable to the processing of characters that are shared in both scripts, and even to traditional characters.

Note however that the enhanced analytic processing in the simplified Chinese readers compared with the traditional Chinese readers here may also be accounted for by the difference in Chinese teaching method adopted in Mainland China and Hong Kong. In Hong Kong, children learn to read and write Chinese mainly through rote repetition, whereas in Mainland, children are taught explicitly about character components. As the result, simplified Chinese readers in Mainland may be generally more sensitive to the internal constituent components of characters than traditional Chinese readers in Hong Kong (McBride-Chang et al., 2005). To rule out the influence from the teaching methods in accounting for the current results, future work will examine whether similar effects can be found in traditional Chinese readers in Taiwan, where Children are also taught about character components explicitly.

In conclusion, here we show that expertise in reading and writing simplified Chinese characters equips readers with better analytic processing skills that are transferrable to the processing of shared and even traditional characters.

## Abstract

The Chinese Room argument describes a thought experiment that suggests that for symbols to become meaningful, they must be grounded in perceptual experiences. Embodied cognition theorists frequently use this argument to claim that cognition requires perceptual simulation. We shed light on the symbol grounding problem by arguing that the structure of natural language provides language users with cues that allow them to bootstrap meaning from non-grounded symbolic co-occurrences, such that the statistical linguistic structure can bootstrap meaning with minimal grounding. Two studies show that co-occurrences of both Chinese and Arabic city names can reliably predict their longitude and latitude in China and in the Middle East. Using the statistical linguistic technique Latent Semantic Analysis, similarity ratings were obtained for Chinese city names (Study 1) and for Arabic city names (Study 2). Multidimensional scaling (MDS) coordinates of these similarity ratings correlated with the actual longitude and latitude of these cities, showing that cities that are located together share similar semantic contexts. These results suggest that the Chinese Room argument might be substituted with a Chinese Route argument: statistical linguistic frequencies of word co-occurrences provide language users with implicit cues about how to form perceptual representations.

**Keywords:** symbol grounding problem; geography; spatial cognition; latent semantic analysis; symbolic cognition; embodied cognition

## Chinese Room Argument

A monolingual English speaker sits in a room; all he has is a Chinese newspaper. Even though there is a wealth of Chinese language at his disposal, few would argue that he understands Chinese. In fact, even if he can successfully find a specific Chinese word, e.g., 上海, in his newspaper, and the collocations of that word, say, 北京, and 香港, there is little evidence he knows the meaning of those words. This Chinese room argument has been used by Searle (1980) to illustrate the symbol grounding problem in cognition (Harnad, 1990), which questions a computational account of meaning acquisition.

Many cognitive scientists place a strong theoretical emphasis upon how symbols become grounded (Barsalou, 1999; Glenberg, 1997; Harnad, 1990; Pulvermüller, 1999; Searle, 1980). These researchers express an increased concern regarding symbolic representations of meaning, and do not endorse analogies between computational and human approaches towards deriving meaning (Pecher & Zwaan, 2005; Semin & Smith, 2008). Embodiment theorists state that meaning cannot lie within arbitrary amodal symbol systems; instead, meaning extraction continuously involves the activation of perceptual experiences. Indeed, learning Chinese as a monolingual English speaker with only a Chinese-Chinese dictionary would lead to a symbolic merry-go-round (Harnad, 1990). Computationally translating symbols into other symbols is however what computer models do, and computational simulations are therefore fundamentally different from human cognitive processes (Glenberg & Robertson, 2001). One computational model of meaning extraction that is frequently used is latent semantic analysis (LSA; Landauer, McNamara, Dennis, & Kintsch, 2007). LSA establishes meaning representation based on co-occurrences of words in same contexts. The words *Beijing* and *Shanghai* therefore have a high similarity in (computational) meaning. However, because *Beijing* is not grounded in perceptual experiences, it does not have human-like meaning (Glenberg & Robertson, 2001). For instance, when humans process the word *Beijing* they might see a map of China and are able to 'see' the city in the northeast of the country. Estimating the location of *Beijing* using a corpus-based computational model would seem impossible, because of the Chinese Room argument. If the location of *Beijing* were to be estimated using amodal symbol systems, explicit spatial cues, such as prepositions and cardinal directions are needed (e.g., *Beijing is north of Shanghai*). Such spatial cues would lead to a combinatorial explosion with each city being added (*Beijing is north of Shanghai, Chongqing is southwest of Beijing, Chongqing is west of Shanghai, etc.*).

Returning to the Chinese room with the monolingual English speaker described earlier, how could our English speaker possibly extract geographical locations from Chinese newspapers without seeing a map of China and seeing the cities marked on the map? Louwerse and Zwaan (2009) concluded that language encodes geographical information. Louwerse and Zwaan took the 50 largest cities in the United States and computed their co-occurrence frequencies in the New York Times, Wall Street Journal, and Los Angeles Post. None of these newspaper corpora necessarily described the spatial locations of the American cities. Yet, using LSA, Louwerse and Zwaan (2009) were able to estimate the longitude and latitude of the 50 cities using statistical linguistic frequencies for each of the three corpora (for a detailed description of the method being used, see below). Moreover, the population size of these cities could be estimated using frequency in the newspapers. The computational estimates were on par with human performance. The findings in this study showed that statistical linguistic frequencies can be used to estimate the location and the size of cities. Determining the semantic associations between cities in a corpus allows for estimating physical distance between cities. In fact, a heuristic like this might be used during cognitive map construction (Goldstein & Gigerenzer, 2002).

Harnad (1990) suggested that ungrounded symbolic representations can inherit meaning from grounded words related to them; we similarly propose that with minimal grounding of some symbols, the meaning of all symbols can be bootstrapped. If language encodes geographical information, we will be at least one step closer towards a bootstrapping solution. That is, the vacuum of the Chinese room now becomes an opportunity for a Chinese route: with very limited symbol grounding, the native speaker of English can bootstrap the geography of China.

### Latent Semantic Analysis

To test the possibility of a Chinese Route Argument, i.e., the Chinese language encodes geographical locations in China, we used LSA on a sample of texts segmented into paragraphs as input. Mathematical transformations created a large term-document matrix from the input. For example, if there are  $m$  terms in  $n$  paragraphs, a matrix of  $A = (f_{ij} \times G(j) \times L(i, j))_{m \times n}$  is obtained. The value of  $f_{ij}$  is a function of the integer that represents the number of times term  $i$  appears in document  $j$ ,  $L(i, j)$  is a local weighting of term  $i$  in document  $j$ , and  $G(j)$  is the global weighting for term  $j$ . Such a weighting function is used to differentially treat terms and documents to reflect knowledge that is beyond the collection of the documents. As in most LSA studies (Dumais, 2007; Martin & Berry, 2007), we used natural log as the local weight and log entropy as the global weight in the current analyses. The large matrix of  $A$  has, however, much redundant information. Singular Value Decomposition decomposes the matrix  $A$  into three matrices  $A = U \Sigma V^T$ ; where  $U$  is an  $m$  by  $m$  square matrix and  $V$  is an  $n$  by  $n$  square matrix, with  $\Sigma$  being an  $m$  by  $n$  diagonal matrix

with singular values on the diagonal. Removing dimensions corresponding to smaller singular values and keeping the dimensions corresponding to larger singular values reduces the representation of each word to a low dimensional vector. Although the new representation for the words (the reduced  $U$  matrix) is no longer orthogonal, each word now becomes a weighted vector on 300 dimensions, with only the most important dimensions that correspond to larger singular values being kept. The number of dimensions can be determined *ad hoc*, but we followed the trend set by most LSA studies and used 300 factors (Landauer & Dumais, 1997). The semantic relationship between words can be estimated by taking the cosine between two vectors. With LSA the semantic relatedness is not only determined by the relation between words, but also by the words that accompany a word (Landauer & Dumais, 1997).

Two studies each tested two hypotheses: 1) Cities that are located together are debated together. That is, cities that are in close geographical proximity are also in close proximity in the text, so that language structure itself provides cues to derive perceptual-semantic information. 2) Cities that are populated more are debated more. That is, larger cities are talked about more, so that city word frequency provides cues about the importance of the city. In Study 1 we tested these hypotheses with city names in China in a Chinese text corpus, in Study 2 with city names in the Middle East in an Arabic corpus.

### Study 1: China

In Study 1 we used a Chinese corpus collected online, consisting of 4 of the most popular classic fiction books, 29 popular modern fiction books, 26 history books, 49 philosophy books, 34 economy books, 15 politics books, and 8 military books. These books provided 86MB of text in 14768 documents (paragraphs) and 47,226 word types. In terms of text size, 33.4% texts are in history, 24.6% in philosophy, 10.4% in economics, 9.3% in modern fiction, 9.3% in politics, 7% in military and 6% in classic fiction. Note that the texts did not explicitly describe geographical relations between Chinese cities, and that the corpus was very heterogeneous.

The standard procedure was used when creating the LSA space, whereby each word was a weighted vector on 300 dimensions. The 50 largest cities in China were selected, and their latitude and longitude were determined using census data. All cities had a population size of more than one million ( $M = 2,393,188$ ,  $SD = 2,340,707.88$ ) (Table 1).

Cosine values were computed for each of the city pairs. Two cities resulted in cosine errors and were removed from the analysis, resulting in a 48 x 48 cosine matrix. This matrix was submitted to an MDS analysis using the ALSCAL algorithm. A Euclidean distance measure transformed the semantic similarities into dissimilarities, such that the higher the value, the longer the distance. Default MDS criteria were used with an S-stress convergence of .001, a minimum stress value of .005, and a maximum of 30 iterations.

We chose a low-dimensionality to rule out over-fitting the data. The fitting on a two-dimensional scale was moderate, with a Stress value = .33 and an  $R^2 = .59$ . The LSA estimated coordinates of the 48 cities were compared with the actual coordinates of the cities.

The loadings of the 48 cities on the two dimensions generated by the MDS analysis correlated with the longitude and latitude of the cities, latitude – dimension 1,  $r = .64$ ,  $p < .001$ ,  $n = 48$ ; longitude – dimension 2,  $r = .33$ ,  $p = .02$ ,  $n = 48$ .

To do justice to the geometry of the 2D variables, we used bi-dimensional regression analyses to compare the computational estimates with the actual coordinates of the 50 cities. Tobler (1964) and Friedman & Kohler (2004) introduced bi-dimensional regressions in order to compute the mapping of any two planes under consideration. Whereas in a uni-dimensional regression each data point is shifted by intercept and slope, each actual and predicted

value of the dependent variable are presented by a point in space, whereby vectors represent intercept and slope.

A bi-dimensional regression yielded a significant correlation between the LSA estimates and the actual city coordinates,  $r = .57$ ,  $p < .001$ ,  $n = 48$ . This result supported the hypothesis that Chinese cities that are located together in China are debated together in the Chinese language.

The question can be raised whether the bi-dimensional regressions not always yield significant correlations. To answer this question we conducted 1000 Monte Carlo simulations on the 48  $x$  and  $y$  pairs. The average bi-dimensional regression of these simulations yielded no significant result, average  $r = .13$  ( $SD = .06$ ),  $p = .37$ ,  $n = 48$ .

In addition, we tested the hypothesis that cities that are populated more are debated more by comparing the frequency of the 50 cities in the Chinese corpus with their actual population size. A Pearson correlation was significant,  $r = .47$ ,  $p < .001$ ,  $n = 50$ .

Table 1: Chinese Cities

## Study 2: Middle East

In order to determine whether the findings could be generalized beyond China and the Chinese language, we

used a different language (Arabic) and a different geography (the Middle East) in the second study.

An LSA space was created using an Arabic corpus collected online, consisting of books and news on history (49%), fiction (42%), politics (3%), philosophy (2%), economy (1%) and other unknown types of texts (3%). The total size of the corpus was 71.8 MB, including 27,937 paragraphs and 147,535 word types. Again, the texts did not specifically discuss the geography of the Middle East. Instead, the corpus covered many topics and was, again, very heterogeneous in nature.

Similar to the previous analysis, 50 of the largest cities across the Arabic speaking countries in the Middle East were selected ( $M = 1,304,154$ ,  $SD = 1,451,579$ ). These cities were located in Egypt, Iraq, Jordan, Kuwait, Lebanon, Oman, Syria, United Arab Emirates, and Yemen (Table 2).

Some countries were not included because the Arabic notation of cities for those countries was unavailable (Saudi Arabia, Ethiopia, Eritrea, Somalia, Djibouti).

As in the Chinese analysis, geographical location (longitude and latitude) as well as population size for these 50 cities were determined. A 50 x 50 cosine matrix was submitted to an MDS ALSCAL analysis, and the MDS coordinates were compared with the actual coordinates.

Again, the fitting on a two-dimensional scale was moderate, with Stress = .35,  $R^2 = .69$ . The LSA estimated

coordinates of the 50 cities were compared with the actual coordinates of the cities.

The loadings of the 50 cities on the two dimensions generated by the MDS analysis correlated with the longitude and latitude of the cities, latitude – dimension 1,  $r = .41$ ,  $p < .001$ ,  $n = 50$ ; longitude – dimension 2,  $r = .57$ ,  $p < .001$ ,  $n = 50$ .

A bi-dimensional regression also yielded a significant correlation between the LSA estimates and the actual city coordinates ( $r = .53$ ,  $p < .001$ ,  $n = 50$ ). These results again supported the hypothesis that cities in the Middle East that share geographical context, share textual context (cities that are located together are debated together).

As in Study 1, we ran 1000 Monte Carlo simulations to rule out the possibility that the significant bi-dimensional regressions could be obtained from an accidental pairing of the estimates. The average regression coefficient again ruled out that the findings could be obtained by chance, average  $r = .13$  ( $SD = .07$ ),  $p = .37$ ,  $n = 50$ .

Finally, as before, we compared the frequency of the 50 cities in the Arabic corpus with their actual population size. A Pearson correlation was significant ( $r = .61$ ,  $p < .001$ ,  $n = 50$ ), providing evidence for the hypothesis that cities in the Middle East that have a higher population, are talked about more frequently.

Table 2: Middle Eastern Cities

## General Discussion

This study showed that statistical linguistic frequencies can be used to estimate the location and population size of cities. In the first study we estimated the location and size of cities in China using Chinese text, in the second the location and size of cities in the Middle East using Arabic texts. These findings show that the results reported by Louwerse, Cai, Hu, Ventura, & Jeuniaux (2006) for France, those reported by Louwerse and Zwaan (2009) for the United States, and by Louwerse and Benesh (in press) for (the fictional) Middle Earth can be extended to China and the Middle East. Moreover, the current study has demonstrated that geographical locations are not only encoded in English (Louwerse et al., 2006; Louwerse & Benesh, in press; Louwerse & Zwaan, 2009), but also in Chinese and Arabic.

There are several questions that should be addressed with regards to the findings reported in this study. First, we should address the question whether the findings reported in this study should be attributed to LSA or to statistical linguistic frequencies. Louwerse and Zwaan (2009) addressed this question by demonstrating that geographical locations of cities in the United States could be predicted using higher-order co-occurrences (using LSA), but also by first-order co-occurrences. Louwerse (2011), however, pointed out that for first-order co-occurrences a corpus needs to be approximately 25,000 times larger than a corpus that is the appropriate size for an LSA analysis. A second question concerns the explicit spatial cues potentially present in the corpus. After all, the argument could be made that the Chinese and Arabic corpora we used for our semantic spaces consisted of explicit spatial cues (e.g., cardinal directions, prepositions) that explained our findings rather than implicit semantic relationships. This seems extremely unlikely for two reasons. First, the LSA algorithm shows minimal sensitivity to explicit cues because it uses higher-order co-occurrences (see Landauer, McNamara, Dennis, & Kintsch, 2007). Secondly, the corpora were so diverse in nature that the results can better be explained by statistical linguistic frequencies than by the specifics of the texts.

We began this paper with the Chinese Room Argument, which suggests that meaning cannot be extracted from symbols unless a referent is perceptually activated (Searle, 1980). Even though this study did not compare the computational results with experimental data (see Louwerse and Zwaan, 2009 and Louwerse and Benesh, in press, for such a comparison), it does provide some insight in the Chinese Room argument. The current study puts forward that, with minimal grounding of some symbols (city names), the meaning of all symbols (city names) can be bootstrapped, because of the organization of the symbolic network. The language system has many built-in regularities that are utilized during cognitive processing (Louwerse, 2011; Louwerse & Jeuniaux, 2010). To illustrate this further, the current study has shown that if a language user knows the location of the city 乌鲁木齐, and knows only that the other Chinese words are Chinese city names, the

language user can bootstrap the geographical locations of these other cities on a country map of China. Moreover, they can make estimates about the size of each city, because frequency correlates with population size.

Obviously, we do not deny the essence of the symbol grounding problem: the language user must ground at least one symbol and must also have partial meaning with regards to the other words (i.e., know that they are city names). Moreover, the geographical estimates are relative estimates, rather than a specific longitude and latitude. However, findings like these do challenge an extreme view of symbol grounding that dismisses the possibility of statistical linguistic frequencies playing a significant role in cognition. Experimental evidence has shown that statistical linguistic frequencies often explain experimental findings better than perceptual simulations account do (Louwerse, 2008; Louwerse, 2011), yet whether humans rely more on statistical linguistic frequencies or perceptual simulations depends on at least the cognitive task and the stimulus (Louwerse & Jeuniaux, 2010). We therefore advocate the pursuit of a unified account in which both statistical linguistic frequencies and perceptual simulation help establishing meaning. In line of this research agenda, this study has shown that with minimal grounding the symbolic vacuum of the Chinese Room can become a guiding Chinese route.

# Modeling Multiple Strategies for Solving Geometric Analogy Problems

Andrew Lovett (andrew-lovett@cs.northwestern.edu)

Kenneth Forbus (forbus@northwestern.edu)

Qualitative Reasoning Group, EECS Department, 2133 Sheridan Road  
Evanston, IL 60208USA

## Abstract

We present an improved computational model for performing geometric analogy. The model combines two previously modeled strategies and makes explicit claims about when people will use one strategy or the other. We compare the model to human performance on a classic problem set. The model's strategy shifts, along with working memory load, account for most of the variance in human reaction times.

**Keywords:** geometric analogy; visual problem-solving; structure-mapping

## Introduction

Visual problem-solving has long been a popular tool for evaluating people's cognitive abilities (Raven, Raven, & Court, 1998; Dehaene et al., 2006). Problem-solving tasks frequently involve a sequence of images (e.g., Figure 1). Individuals must compare the images, identifying some pattern across them. They must then apply this pattern, finding the answer that best completes (or violates) it.

Visual problem-solving depends on a comparison process for identifying commonalities and differences in images. We have previously argued that structure mapping (Gentner, 1983), a theory of analogical comparison, may also explain concrete visual comparison in humans (Markman & Gentner, 1996; Lovett et al., 2009a; Sagi, Gentner, & Lovett, in press). According to structure mapping, people compare stimuli by aligning the common relational structure in symbolic, qualitative representations. We have posited that structure mapping may play a ubiquitous role, identifying commonalities and differences and estimating similarity. Based on this hypothesis, we have built models of three visual problem-solving tasks: geometric analogy (Lovett et al., 2009b), Raven's Progressive Matrices (Lovett, Forbus, & Usher, 2010), and the oddity task (Lovett & Forbus, 2011a).

Here, we complement our model of visual comparison with a model of *visual inference*. Visual inference explains how individuals apply a set of differences to one image to create a novel image representation. It plays a key role in tasks such as geometric analogy (Figure 1), where participants are asked "A is to B as C is to..." We show how this leads to a new model for geometric analogy. Rather than assuming participants always infer the correct answer, the model makes explicit claims about when visual inference will succeed and when it will fail, requiring a shift to an alternate strategy. The model's strategic shifts correlate well with human reaction times on a classic geometric analogy problem set (Evans, 1968).

In the following section, we provide some background on the geometric analogy task. We then present our computational model, which utilizes two strategies for performing the task. Afterwards, we compare the model against human performance and discuss the results. We close with related work and conclusions.

## Background

Geometric analogy involves comparing images to identify differences. However, researchers disagree on which comparisons people make. The debate encompasses two competing strategies. The first involves inserting each possible answer into the analogy to evaluate it. Consider Figure 1A. The strategy proceeds as follows:

- 1) Compare A and B to get  $\Delta(A,B)$ , the differences between A and B. Here there is a change from two overlapping objects to one object inside the other.

- 2) For each possible answer  $i$ , compare C to  $i$  to get  $\Delta(C,i)$ , the differences between C and that answer. Then, perform a second-order comparison: measure the similarity of  $\Delta(A,B)$  to  $\Delta(C,i)$ . Whichever answer produces the most similar set of differences is chosen. Here answer 3 produces an identical set of differences to  $\Delta(A,B)$ , so it is chosen.

The second strategy solves for the answer directly:

- I) Compare A and B to get  $\Delta(A,B)$ .

- II) Compare A and C to get the corresponding objects. In Figure 1A, the large leftmost shapes correspond, and the small rightmost shapes correspond.

- III) Apply the differences in  $\Delta(A,B)$  to the corresponding objects in C to infer  $D'$ , a representation of the answer. Here the small rectangle in C would move inside of the larger shape. Pick the answer most similar to  $D'$ .

Mulholland, Pellegrino, and Glaser (1980) call the first strategy *infer-infer-compare* and the second strategy *infer-map-apply*. However, this assumes that different processes are used to compare images in steps 1), 2), and II). We believe structure-mapping can determine differences, identify correspondences, and measure similarity. Therefore, we instead call the strategies *second-order comparison* and *visual inference*.

Sternber (1977) argued that people use visual inference to perform geometric analogy. However, Mulholland, Pellegrino, and Glaser (1980) found evidence that second-order comparison was being used. Bethell-Fox, Lohman, and Snow (1984) suggested that individuals may adjust their strategy, depending on problem difficulty. Their eye-tracking data demonstrated that people typically use visual inference, solving directly for the answer. However, as problems become more difficult, people may abandon this

Figure 1: Geometric analogy problems with average response times and percent selecting each answer (Lovett et al., 2009b).

approach, instead trying out each possible answer in the analogy.

One might conclude that people use visual inference when problems are easy and second-order comparison when problems are relatively difficult. However, this is not the full story. Sternberg (1977) found that participants used visual inference on multiple choice problems, where they had to consider several possible answers. Mulholland, Pellegrino, and Glaser (1980) found that participants used second-order comparison on true/false problems, where they saw a completed analogy and simply judged whether it was correct. The Sternberg problems appear more difficult—at the very least, they put more load on working memory, as there are multiple answers to consider. Why, then, would people use second-order comparison on the easier Mulholland et al. problems?

We believe the answer lies in the algorithmic complexity of the two strategies. In the analysis below, we compute each strategy's complexity by counting the number of comparisons necessary to solve a problem. We concede that this may be a simplification; for example, second-order comparisons may require more time and effort than others.

However, our model predicts that a common process (structure-mapping) is used for all comparisons. Thus the number of times this process repeats should provide a reasonable approximation of a strategy's complexity.

Consider second-order comparison. If there are  $n$  possible answers, then the number of comparisons is  $1$  (A to B) +  $n$  (C to each answer) +  $n$  ( $\Delta(A,B)$  to  $\Delta(C,n)$  for each answer) =  $2n + 1$ .

Now consider visual inference. The number is  $1$  (A to B) +  $1$  (A to C) +  $n$  (D' to each answer) =  $n + 2$ . However, this strategy also requires a non-comparison operation: inferring D' by applying  $\Delta(A,B)$  to the corresponding objects in C.

Suppose we have a true/false problem. Then the number of answers  $n = 1$ . The number of comparisons is 3 for both strategies. In this case, one might prefer second-order comparison, as it doesn't require inferring D'. This explains why Mulholland et al. found that participants used second-order comparison.

Suppose we have a multiple-choice problem. The number of answers  $n > 1$ . Now, there will be fewer comparisons for visual inference, and this should be the preferred strategy, as Sternberg found. However, if a problem is particularly

complex, participants may be unable to perform the inference operation. In this case, they may fall back on the second-order comparison strategy, which requires only comparison operations.

Our model, described below, attempts to solve problems via visual inference. When it fails, either because it cannot perform the inference or because the inferred image doesn't match any of the answers, the model reverts to second-order comparison. Thus, the model can help explain why some problems take longer to solve than others: certain problems require a shift from the default visual inference strategy to a less efficient second-order comparison strategy.

## Model

Our model depends on three core processes: perception, visual comparison, and visual inference. Below, we describe each process and then show how the model combines these processes to implement different problem-solving strategies.

### Perception

Our model uses the CogSketch sketch understanding system (Forbus et al., 2011) to generate a qualitative representation for each image. Qualitative, or *categorical*, representations are abstract, describing features like relative position (**right of**) or relative orientation (**parallel**), rather than exact numerical sizes and orientations. There is abundant psychological evidence that people are sensitive to such features (e.g., Huttenlocher, Hedges, & Duncan, 1991; Rosielle & Cooper, 2001).

CogSketch performs sketch understanding, rather than full vision. It requires users to draw separate line drawings of each object in a visual scene (e.g., the rectangle and triangle in image A of Figure 1A). Given these objects, CogSketch automatically computes spatial relations between objects and attributes for individual objects.

Our model takes the process a step further. It can automatically segment an object into edges and build an edge-level representation, describing qualitative spatial relations between the edges. Alternatively, it can group several objects together based on similarity to build a group-level representation. See Lovett and Forbus (2011b) for details on this process, as well as the full vocabulary of qualitative terms at the edge, object, and group levels.

### Visual Comparison

We model visual comparison using the Structure-Mapping Engine (SME) (Falkenhainer, Forbus, & Gentner, 1989), a computational model based on Gentner's (1983) structure-mapping theory. Given two cases described in predicate calculus, it computes a mapping between them by aligning their common relational structure. SME is biased to prefer aligning deep structure. For example, at the edge level, a first-order relation might indicate that there is a convex corner between two edges. A second-order relation might indicate that two convex corners are adjacent. These higher-order relations, which take other relations as their arguments, receive priority during mapping.

SME computes up to 3 mappings between the compared cases. Each mapping contains: A) a similarity score based on the breadth and depth of aligned structure; B) correspondences between the entities and expressions in the two cases; and C) *candidate inferences* (CIs), inferences based on expressions in one case that failed to align with the other. For example, consider the A/B comparison in Figure 1A. A forward CI (A->B) would indicate that the two shapes no longer partially overlap. A backward CI (B->A) would indicate that one shape no longer contains the other. CIs are useful for identifying differences between the cases.

The model compares two images via the following steps:

- 1) Compare the qualitative image representations using SME. This produces a mapping indicating the corresponding objects, commonalities, and differences.

- 2) For each pair of corresponding objects, compare the objects' shapes to identify a shape transformation. This is done by comparing the objects' edge-level representations to get corresponding edges, and then using those correspondences to compute a transformation, such as a rotation or reflection (see Lovett & Forbus, 2011b).

Sometimes there are multiple valid transformations. For example, in Figure 1C, there is both a rotation and a reflection between the 'B' shapes. In such cases, the model picks the simplest transformation, according to the following rankings: identity, reflection, rotation. Objects can also change scale, becoming larger or smaller.

- 3) Compute the similarity between images. This is primarily based on SME's similarity score, but it is updated according to the shape comparisons: if two objects are identical, the images will be rated more similar.

- 4) Compute a qualitative, structural representation of the differences between the images. This describes differences of the following types:

- A) Spatial relation addition/removals, based on the CIs.

- B) Reversals of spatial relations. This is a special case of A) where two objects swap places in a relation. In Figure 1D, the dot and triangle swap places in an **above** relation.

- C) Object additions/removals, where objects are added or removed between images (e.g., Figure 1B).

- D) Object transformations, where there is a shape transformation between corresponding objects.

### Visual Inference

The visual inference operation applies a set of differences to an image to produce a novel image representation. In geometric analogy, the A/B differences are applied to C to produce D', a representation of the answer image. Consider Figure 1A. Inference proceeds as follows:

- 1) Compare image A to image C to get the corresponding objects.

- 2) Apply the A/B differences to the corresponding objects in C to produce a new qualitative representation:

- A) Add or remove spatial relations.

- B) Reverse the arguments of spatial relations.

- C) Add or remove objects. If an object is added, create a new object in CogSketch, basing it off some existing object.

If an object is removed, remove any spatial relations referring to that object.

D) For all other objects, apply the appropriate shape transformation to the object in C to create a new object for D'. This might mean leaving the shape unchanged (identity), rotating it, reflecting it, scaling it, etc.

E) Compute shape attributes for all the newly created objects, and add them to the D' representation.

Note that D' contains: a) a qualitative, structural image description; and b) a set of concrete, quantitative objects. Thus, it contains just enough to support visual comparisons between D' and other images. However, D' is not a concrete image: the model lacks exact, quantitative locations for each object.

There are several ways that visual inference can fail:

A) When a spatial relation cannot be added because the objects it describes are not found in C (there are no corresponding objects).

B) When a spatial relation cannot be reversed. In Figure 1D, there is a reversal of **above** in the A/B differences. However, there is no **above** in C to reverse.

C) When an object cannot be removed or transformed because the object is not found in C.

D) When transforming an object doesn't produce the desired effect. On Figure 1E, the model reflects the 'B' shape over the x-axis. However, when it compares the result to the original 'B' shape, they appear identical (recall that identity is ranked before reflection). The model treats this as a failure to transform.

The model is focused on generation: adding expressions to C's representation to produce D'. Thus, visual inference fails when a spatial relation cannot be added to C or reversed in C, but it does *not* fail when a spatial relation cannot be removed from C. For example, in Figure 1B, the A/B differences include removing a **rightOf** relation. There is no such relation in C to be removed. Visual inference succeeds here, whereas it fails in 1D, where there is no **above** relation in C to be reversed. Thus, the model explains why 1D is a harder problem (compare the reaction times).

## Geometric Analogy

Our new geometric analogy model solves problems via two strategies: visual inference and second-order comparison. For visual inference, the model compares A and B to get  $\Delta(A,B)$ , the differences between them. It applies  $\Delta(A,B)$  to C to get D', a representation of the answer image. It compares D' to each possible answer. If an answer is sufficiently similar, it selects that answer.

For second-order comparison, the model compares A and B to get  $\Delta(A,B)$ . For each answer *i*, it compares C and *i* to get  $\Delta(C,i)$  and then compares  $\Delta(C,i)$  to  $\Delta(A,B)$  (again, using SME). If an answer's  $\Delta(C,i)$  is sufficiently similar to  $\Delta(A,B)$ , it selects that answer.

In each case, an answer is sufficiently close if either a) SME detects no differences; or b) the SME similarity score lies above a *similarity threshold*. We use a similarity threshold of 0.8 (where 1.0 is a perfect match). However, a

sensitivity analysis shows that our results would be the same for values ranging from .67 to .87. If multiple answers tie for the best score, this is treated as a failure.

Note that when SME compares  $\Delta$ 's for second-order comparison, it is possible to find a perfect match even for non-identical  $\Delta$ 's. SME supports tiered identity (Falkenhainer, 1990), where non-identical predicates can align when they are members of a common category. For example, in Figure 1D,  $\Delta(A,B)$  and  $\Delta(C,3)$  each involve reversal of a positional relation (**above** and **rightOf**). Thus, Figure 1D is not solvable by visual inference, but it is easily solvable by second-order comparison.

**Strategic Shifts** The model first attempts to solve a problem via visual inference. This can fail in two ways: either the inference operation may fail (Figures 1D, 1E), or D' may fail to match any of the answers. For example, in Figure 1F, the A/B differences show the inner shape being removed. The model applies these differences to C to infer an image with a large circle, which matches none of the answers.

If visual inference fails, the model reverts to second-order comparison. When the model utilizes this strategy, it must make two other strategic decisions: the comparison mode when comparing A to B, and the comparison mode when comparing C to each answer *i*. The comparison modes are:

A) Normal: Images are compared as described above.

B) Reflection: Instead of preferring identity during shape comparison, the model prefers reflection. In Figure 1E, the C/3 comparison will find a y-axis reflection between the 'B' shapes, instead of treating them as identical.

C) Rotation: Instead of preferring identity during shape comparison, the model prefers rotation.

D) Alternate: The model looks for an alternate mapping between the images. In Figure 1F, an alternate A/B mapping aligns the small triangle in A with the large triangle in B.

The model only considers an alternate mapping when SME finds more than one mapping between the images. It only considers the Reflection/Rotation modes when the images each contain a single object, allowing the model to focus on different ways of comparing that one object.

The model independently varies the mapping mode for A/B and C/*i* comparisons, beginning with Normal for each. It terminates when it identifies a sufficient answer. If no such answer is found, it picks the highest-scoring answer.

## Experiment

We evaluated our model on 20 geometric analogy problems from Evans (1968). We recreated each problem in PowerPoint and then imported the problems into CogSketch. This required us to manually segment each problem into images (image A, image B, etc) and segment each image into objects (each object was drawn as a separate shape in PowerPoint). Beyond this, the model automatically segmented each object into edges and generated representations at the edge and object levels—this problem set did not contain any groups of objects.

Our prior behavioral study (Lovett et al., 2009b) provides data on human performance which our simulation models, so we summarize it next.

### Behavioral Study

The Evans problems were shown to 34 adult participants. They were given a description of the geometric analogy task followed by two simple example problems (without feedback) before they saw the 20 problems. Both the ordering of the problems and the ordering of the five possible answers were randomized across participants.<sup>1</sup>

Before each problem, participants clicked on a fixation point in the screen’s center to indicate readiness. After the problem was presented, participants clicked on the picture that best completed the analogy. Participants were instructed to be as quick as possible without sacrificing accuracy. The two measures of interest were the answer chosen and the reaction time, i.e., the time taken to solve the problem.

**Results** The results show a high degree of consistency across participants. All participants chose the same answer for 9 of the 20 problems, while over 90% chose the same answer for 7 additional problems. The greatest disagreement was on Figure 1F, where only 56% chose the same answer. Henceforth, we refer to the answer chosen by the majority as the *preferred answer*. In reporting and analyzing reaction times (including Figure 1), we consider only responses with the preferred answer, filtering out minority responses.

### Simulation & Analysis

The model chose the preferred answer on all 20 problems. This indicates that our approach—qualitative representation, comparison via structure mapping, and visual inference—is sufficient for matching human performance on the task.

We next asked whether people take longer to solve problems where our model must make a strategy shift. We coded each problem for three factors: Alt-Strategy, Alt-Mapping, and Alt-Transform. Alt-Strategy indicates that our model reverts to second-order comparison to solve the problem. Alt-Mapping indicates that it uses the Alternate image mapping mode. Alt-Transform indicates that it uses the Reflection or Rotation mapping modes. We group these mapping modes together, as our model uses the same mechanism for computing both transformation types.

We also coded each problem for working memory load. Previous research has shown that geometric analogy problems get harder as either the number of elements or the number of transformations increases (Mulholland, Pellegrino, & Glaser, 1980; Bethell-Fox, Lohman, & Snow, 1984). Mulholland et al. found that this effect was non-linear: there was a higher cost when the numbers of both

elements and transformations increased. They suggested this was because at some point the problem exceeds people’s working memory capacity, requiring a shift in strategy.

We coded for working memory load by counting the number of elements in  $\Delta(A,B)$ , the differences between images A and B. This is a key representation for both visual inference and second-order comparison. Because Mulholland et al. found a non-linear effect of working memory, we discounted the first two elements. Thus, if  $\Delta(A,B)$  was one or two, the WM Load was coded as zero.

We ran a linear regression to identify the effect of the above factors on human reaction times. Table 1 shows the results. Overall, this model achieves an  $R^2$  of .95 (.93 adjusted), meaning it explains almost all the variance in human reaction times. The grayed cells indicate which factors made a significant contribution to the model ( $p < .01$ ). The intercept of 6.4 indicates that the easiest problems took around 6.4 s, while the various factors increased the time to complete a problem.

Note that with correlations, extreme values can result in an overestimation of the explained variance (the  $R^2$  value). In this case, participants took far longer to solve the two problems requiring the Alt-Mapping shift (e.g., Figure 1F). If we remove these data points and rerun the analysis, Alt-Mapping ceases to be a factor, and  $R^2$  drops to .80 (.76 adjusted). Thus, even discounting these difficult problems, the regression explains most of the variance in performance.

Table 1. Linear model for human reaction times on geometric analogy (grayed cells are significant factors).

Intercept	WM Load	Alt-Strategy	Alt-Transform	Alt-Mapping
6.4 s	5.7 s	4.4 s	- 0.7 s	10.5 s

The only factor that did not contribute significantly was Alt-Transform. Alt-Transform refers to problems like Figure 1E, where the model must switch to a Reflection mode to identify a reflection between the identical ‘B’ shapes. The analysis suggests there is no increased cost for Alt-Transform problems. However, this does not mean such problems are easy; they are difficult in that the model must make the Alt-Strategy shift to solve them, changing to second-order comparison. Once this strategy shift has been made, there is no additional cost for the Alt-Transform shift.

### Related Work

Evans’ ANALOGY (1968) was the first computational model of analogy. A ground-breaking system, it solved the same 20 geometric analogy problems as our model using second-order comparison. However, its brute-force comparison processes do not align well with human cognition (see Lovett et al., 2009b for a discussion).

Our own previous model (Lovett et al., 2009b) also solved problems via second-order comparison. The present approach builds on that model by implementing visual inference as a complementary strategy. The previous model explained .56 of the human variance on the Evans problems,

<sup>1</sup> Due to experimenter error, some participants received the same random orderings. As many as five received one ordering, but on average only 1.5 received the same ordering. When we randomly selected one instance of each ordering, the participant number dropped to 22, and the pattern of results remained the same.

whereas the current model explains .95 of the variance. However, the previous analysis did not consider multiple factors or filter out reaction times for minority responses.

Several other approaches have utilized visual inference strategies, but these suffer from important limitations. Some (Schwering et al., 2009; O'Donoghue, Bohan, & Keane, 2006) use hand-coded symbolic inputs, rather than automatically generating representations. This means the models are unable to reason about quantitative spatial information, e.g., shape transformations. Others (Ragni, Schleipen, & Steffenhagen, 2007) are unclear on their comparison processes. Finally, because these models have not been systematically evaluated on a pre-existing problem set, it is unclear how well they match human performance.

## Conclusions

We believe our model is the first to combine two established problem-solving strategies: visual inference and second-order comparison. Beyond utilizing both strategies, the model makes explicit claims about when people will abandon visual inference and fall back on second-order comparison. Our analysis shows that these claims help explain human reaction times on the 20 Evans problems: people take longer to solve problems where the model reverts to second-order comparison, and they take even longer when the model must find an alternate mapping.

Importantly, our two problem-solving strategies are not unique to geometric analogy. We recently (Lovett & Forbus, in prep) integrated these strategies into a new model of Raven's Progressive Matrices, a more complex task that is popularly used to evaluate general intelligence. As that model and the present model show, successful problem-solving requires flexibly moving between different comparison strategies. These models, along with our oddity task model (Lovett & Forbus, 2011a), also demonstrate the utility of structural alignment across qualitative representations. In the future, we plan to evaluate the generality of our approach on new problem-solving tasks.

## Abstract

A successful theory of causal reasoning should be able to account for inferences about counterfactual scenarios. Pearl (2000) has developed a formal account of causal reasoning that has been highly influential but that suffers from at least two limitations as an account of counterfactual reasoning: it does not distinguish between counterfactual observations and counterfactual interventions, and it does not accommodate backtracking counterfactuals. We present an extension of Pearl's account that overcomes both limitations. Our model provides a unified treatment of counterfactual interventions and backtracking counterfactuals, and we show that it accounts for data collected by Sloman and Lagnado (2005) and Rips (2010).

In addition to reasoning about actual states of affairs, humans find it natural to reason about what might have been. A doctor may ask “if Alice had not been treated with the experimental drug, would she have survived?” and a parent might tell a child that “if you had been paying attention, you wouldn't have gotten hurt.” Researchers from several disciplines have developed formal models of counterfactual reasoning, and recent empirical studies have evaluated the psychological merits of some of these models (Rips, 2010; Dehghani, Iliev, & Kaufmann, 2012). This paper describes a new model of counterfactual reasoning and evaluates it using data sets from the psychological literature.

The problems that we consider can be illustrated using a causal chain over three variables (Figure 1a). For example, suppose that  $A$ ,  $B$ , and  $C$  are variables that indicate whether three transponders are active. Transponder  $A$  is active about half of the time, and whenever it is active it tends to activate  $B$ , which in turn tends to activate  $C$ . Suppose that we observe on a certain occasion that all three transponders are active. We can now ask counterfactual questions such as “if  $B$  had not been active, would  $C$  have been active?”

The formal approach that we present is inspired by the work of Pearl (2000), who developed a model of counterfactual reasoning that we refer to as the *modifiable structural model*, or MSM for short. The MSM assumes that the causal system in question is a *functional causal model*, where *exogenous* variables are introduced if necessary so that the variables of primary interest are deterministic functions of their parents. For example, the system in Figure 1a may be represented more precisely by adding exogenous variables  $U_A$ ,  $U_B$  and  $U_C$  such that  $U_A$  determines whether or not node  $A$  is active, and  $U_B$  and  $U_C$  capture factors such as atmospheric conditions that determine whether the links in the chain operate successfully. Suppose now that  $A$ ,  $B$  and  $C$  are all observed to be active, and that we want to know whether  $C$  would be active if  $B$  were not active. The MSM addresses this question by using the observations in the actual world to update

Figure 1: (a) A causal chain in which  $A$  causes  $B$ , which causes  $C$ . (b) A functional causal model that captures the causal chain in (a). Exogenous variables  $U_A$ ,  $U_B$  and  $U_C$  have been added, and nodes with double edges are deterministic functions of their parents. (c) A twin network where  $A'$ ,  $B'$  and  $C'$  represent counterfactual values of  $A$ ,  $B$ ,  $C$ . (d) An augmented twin network which allows for the possibility that the exogenous variables take different values in the counterfactual scenario.

prior beliefs about the status of the exogenous variables, then *modifying* the resulting causal model to reflect a counterfactual intervention where  $B$  is forced to be inactive. Inferences about any other variables can be computed using the modified causal model—for example, if  $B$  were inactive, then  $C$  would probably also be inactive. Several psychological studies of counterfactual reasoning have evaluated the predictions of the MSM and have found that some counterfactual inferences do appear to be treated as inferences about counterfactual interventions (Sloman & Lagnado, 2005; Kemp, Shafto, & Tenenbaum, 2012).

The approach we present builds on the key ideas behind the MSM, and we refer to it as the *doubly-modifiable structural model* or DMSM for short. Like the MSM, the DMSM works with causal systems that are represented using functional causal models and allows these systems to be modified via counterfactual interventions. In addition, however, the DMSM permits a second kind of modification where exogenous variables are altered not because of a counterfactual intervention, but simply because the counterfactual world might have turned out differently from the real world. An important consequence of this difference is that the DMSM alone accounts for backtracking counterfactuals. For example, suppose again that all three transponders in  $A$  were observed to be active, and we are asked to decide whether  $A$  would be active if  $B$  were inactive. The DMSM allows for the possibility that variables upstream of  $B$  might explain the counterfactual premise that  $B$  is inactive, and thus predicts that  $A$  is likely to be inactive. The MSM, however, can only reason about

the downstream consequences of a counterfactual intervention that renders  $B$  inactive.

The inability of the MSM to deal with backtracking counterfactuals is widely acknowledged, and Hiddleston (2005) has developed a *minimal networks* model that overcomes this limitation. Rips (2010) has recently evaluated the psychological merits of Hiddleston’s account, and reports that Hiddleston’s model can account for human inferences about backtracking counterfactuals when supplemented with additional psychological assumptions. Although this variant of Hiddleston’s approach accounts relatively well for the data collected by Rips, the minimal networks model is not well suited for reasoning about counterfactual interventions, and does not account for empirical data suggesting that counterfactual inferences are sometimes treated as inferences about counterfactual interventions.

At present, then, the psychological literature on counterfactual reasoning is fragmented. The MSM provides an elegant account of reasoning about counterfactual interventions but does not account for inferences about backtracking counterfactuals. The minimal networks model can handle backtracking counterfactuals, but does not give a clear account of inferences about counterfactual interventions. In contrast, the DMSM accommodates both counterfactual interventions and backtracking counterfactuals, and we will show that it accounts for previously-published experiments that explore both kinds of inferences. As we discuss towards the end of the paper, the DMSM is not a complete account of counterfactual reasoning, but we believe that it comes closer to this goal than any previous model.

### The Modifiable Structural Model (MSM)

The MSM was introduced informally above, and we now describe how the predictions of this model can be computed by constructing and manipulating a twin network (Pearl, 2000). The first step is to specify a functional causal model such as the example in Figure 1b that captures the causal system under consideration. Functional causal models are described in detail by Pearl (2000), but for our purposes, their most important feature is that they represent noise or randomness using unobserved exogenous variables, rather than inherently stochastic relationships. This functional model is converted into the twin network in Figure 1c by adding nodes  $A'$ ,  $B'$  and  $C'$  that represent counterfactual versions of  $A$ ,  $B$ , and  $C$ . The counterfactual nodes  $A'$ ,  $B'$  and  $C'$  and the original nodes  $A$ ,  $B$ , and  $C$  have the same exogenous variables as parents, which captures the idea that the causal mechanisms in the counterfactual world are identical to the causal mechanisms in the actual world. Given the twin network, a counterfactual premise can be captured using an intervention that fixes the value of one of the counterfactual variables. For example, suppose again that  $A$ ,  $B$  and  $C$  are all active and we are asked about a scenario where  $B$  is inactive. The counterfactual premise is captured using graph manipulation to modify the twin network. In other words, we set  $B'$  to 0, and remove all arrows between  $B'$  and its parents to reflect the fact that  $B'$

was fixed by an intervention instead of being brought about by  $U_b$  and  $A'$ . We can now use the manipulated twin network to compute predictions about the other counterfactual variables. Because  $A$  must have been caused by  $U_A$  and  $U_A$  also causes  $A'$ , the MSM infers that  $A'$  is active. Because  $B'$  is inactive, the MSM infers that  $C'$  is also inactive.

Two aspects of the MSM are worth emphasizing for comparison with the DMSM described in the next section. First, the MSM handles all counterfactual queries by reasoning about counterfactual interventions. The model therefore does not distinguish between counterfactual interventions (“imagine that someone had disabled transponder B”) and counterfactual observations (“imagine that you had observed that B was inactive”). Second, the MSM cannot make inferences about backtracking counterfactuals. If asked to imagine that  $B$  were inactive, the MSM fixes the status of  $B'$  by means of an intervention and therefore cannot reason about upstream variables such as  $A'$  which may explain the inactivity of  $B'$ .

### The Doubly-Modifiable Structural Model (DMSM)

Just as the MSM can be characterized in terms of computations over a twin network, the DMSM can be characterized in terms of computations over an *augmented twin network*. The augmented twin network for the three element chain is shown in Figure 1d. Note that the network includes nodes for counterfactual versions of the exogenous variables  $U_A$ ,  $U_B$  and  $U_C$  in addition to nodes for counterfactual versions of  $A$ ,  $B$  and  $C$ . The value of each counterfactual exogenous variable is either copied across from the corresponding real-world variable or generated from the same distribution as the corresponding real-world variable. More precisely, if  $P_i(\cdot)$  is the prior distribution on exogenous variable  $U_i$ , the value of  $U'_i$  is drawn from the distribution

$$P(U'_i|U_i) = s\delta(U_i) + (1-s)P_i(U_i)$$

where  $\delta(U_i)$  is a delta distribution that takes value 0 at every point except  $U'_i = U_i$  and  $s$  is a stability parameter where  $0 \leq s \leq 1$ . If  $s = 1$ , then the exogenous variables are perfectly stable, which means that  $U'_i = U_i$  for all  $i$  and that the DMSM is equivalent to the MSM<sup>1</sup>. If  $s = 0$ , then the exogenous variables are maximally unstable, and the values of  $U'_i$  and  $U_i$  are independently drawn from the distribution  $P_i(\cdot)$ . We will refer to this special case as the USM, or “unattached structural model” because setting  $s = 0$  decouples the counterfactual nodes from the actual nodes, meaning that the model effectively discards all observations of the actual world.

We propose that people are sensitive to both the true state of the world and base rate information, and therefore hypothesize that the judgments of most individuals reflect stability values between 0 and 1. A second hypothesis is that some individuals always use  $s = 0$  and others always use  $s = 1$ . A third hypothesis is that each individual uses  $s = 0$  in some

<sup>1</sup>A stability of 1 for counterfactual observations can lead to mutually incompatible or impossible states, so we assume that all counterfactual premises are treated as interventions when  $s = 1$ .

Figure 2: Human judgments and predictions of the DMSM, MSM and USM models for Sloman and Lagnado’s Experiments 2 and 6. The four bars in each plot show inferences about backtracking (B) or forward (F) counterfactuals that were either interventional (I) or observational (O).

contexts and  $s = 1$  in other contexts. We return to these hypotheses later and describe some preliminary evidence that supports the first hypothesis. Different individuals may use different settings of  $s$ , but for all analyses we set  $s = 0.77$  which is the value that maximizes model performance across the entire set of studies reported by Rips (2010).

The augmented twin network can be used to address two kinds of counterfactual queries. Queries about counterfactual *interventions* are addressed by manipulating the network in the standard way—for example, counterfactual interventions on  $B$  are captured by fixing the value of  $B'$  and removing all arrows between  $B'$  and its parents. Queries about counterfactual *observations* are carried out by reasoning over the unmanipulated network. For example, if  $A$ ,  $B$  and  $C$  are observed to be active and we want to reason about a case where  $B$  is observed to be inactive, we set  $A = B = C = 1$  and  $B' = 0$  and can subsequently compute the posterior distribution induced on any other node. For instance, if the stability parameter is less than one then the posterior distribution  $P(A' | A = B = C = 1, B' = 0)$  will indicate that  $A'$  is relatively likely to take value 0.

### Counterfactual interventions vs. observations

A key conceptual difference between the MSM and the DMSM is that the DMSM allows for counterfactual observations and counterfactual interventions, but the MSM treats all counterfactual queries in terms of interventions. To the best of our knowledge, two experiments reported by Sloman and Lagnado (2005) are the only psychological studies that contrast counterfactual observations and counterfactual interventions. This section compares the predictions of the DMSM with the results of these experiments.

Experiment 2 of Sloman and Lagnado (2005) considers a three node chain where  $A$  causes  $B$  and  $B$  causes  $C$ . The experiment included three different cover stories—one scenario involved a rocket ship, and a second involved a causal chain where smoking causes cancer which causes hospitalization. The third involved abstract events  $A$ ,  $B$ , and  $C$  and participants were told that “when  $A$  happens, it causes  $B$  most of the time” and “when  $B$  happens, it causes  $C$  most of the time.” In all cases, participants were told that  $A$  and  $C$  happened and were asked to make counterfactual inferences about a situation where  $B$  did not happen. The counterfactual questions

asked about both counterfactual interventions and counterfactual observations. In the abstract scenario, the backwards intervention (BI) question stated that “someone intervened directly on  $B$ , preventing it from happening,” and asked participants to rate the probability that  $A$  would have happened. The forward intervention (FI) question was similar except that it asked participants to rate the probability that  $C$  would have happened. The backwards and forwards observation questions (BO and FO) asked participants to rate the probability that  $A$  and  $C$  “would have happened if we observed that  $B$  did not happen.”

Average human responses are shown in Figure 2a. Responses were originally provided on a 1 to 5 scale, but we map them to probabilities for comparison with model predictions. Following Sloman and Lagnado (2005), responses are collapsed across the three different cover stories. Both the intervention and observation questions produce the forward inference that  $C$  is unlikely to occur. The two kinds of questions, however, lead to different backward inferences about  $A$ . Participants tend to infer that  $A$  would still have occurred if a counterfactual intervention had prevented  $B$ , but find it less likely that  $A$  would have occurred if  $B$  had been *observed* not to occur.

Experiment 6 of Sloman and Lagnado (2005) is similar in structure but involves a two node chain rather than a three node chain. The cover story described a rocket ship with two components where “movement of component  $A$  causes component  $B$  to move.” Participants were informed that both components are moving and asked to reason about counterfactual cases where either  $A$  or  $B$  was not moving. The counterfactual intervention questions were of the form “suppose component  $A$  were prevented from moving, would component  $B$  still be moving?” The counterfactual observation questions were of the form “suppose component  $A$  were observed to be not moving, would component  $B$  still be moving?”

The proportion of participants who responded “yes” to each question is shown in Figure 2b. As for Experiment 2, forward inferences about  $B$  given  $A$  are similar regardless of whether  $A$  is prevented from moving or simply observed not to move. Backward inferences about  $A$  given  $B$  again reveal a difference between counterfactual observations and counterfactual interventions. As for Experiment 2, participants tend

to infer that  $A$  would still be moving if  $B$  were prevented from moving, but are less likely to infer that  $A$  would be moving if  $B$  were observed not to move.

We generated model predictions for the two experiments by making the simplest possible assumptions about the parameters in each causal structure. The base rate for node  $A$  was set to 0.5, and the strength of each causal link was set to 0.8 to capture the fact that causes produce their effects “most of the time.” To keep the analysis simple we assumed that nodes  $B$  and  $C$  had no background causes. Given these assumptions, predictions of the DMSM and the MSM are shown in Figures 2c and 2d. The DMSM accounts for the result that counterfactual interventions and counterfactual observations are treated differently. The MSM accounts for human responses to the intervention questions, but makes identical predictions about responses to the observation questions.

Although the DMSM performs better than the MSM, the quantitative predictions of the DMSM depart from human inferences in some cases. For example, humans give non-zero responses to the forward questions in Experiment 6, but the DMSM infers that component  $B$  is definitely not moving if component  $A$  is not moving. Including a background cause of  $B$  would allow the DMSM to match the human responses to the forward questions more closely.

The MSM can be viewed as a special case of the DMSM where the stability parameter  $s$  is equal to 1, and the USM model in Figure 2e is the special case where  $s = 0$ . The USM distinguishes between counterfactual observations and interventions, but its inferences in the BI case are not shaped by the observation that event  $A$  occurred in the real world. As a result, the model falls back on the baseline probability that  $A$  occurs, and does not account for the human inference that  $A$  probably occurred in the counterfactual scenario. Note, however, that these data do not permit us to distinguish between the DMSM and a mixture of MSM and USM strategies. The analysis in the next section will partially address this issue.

## Backtracking counterfactuals

The previous section suggested that the DMSM improves on the MSM by distinguishing between counterfactual interventions and counterfactual observations. One important consequence of this distinction is that the DMSM alone is able to handle backtracking counterfactuals, or queries where a reasoner must think about causes that might be responsible for a counterfactual premise. Rips (2010) has carried out an extensive psychological study of backtracking counterfactuals, and this section argues that the DMSM accounts for Rips’ data about as well as the minimal network model that he advocates. Dehghani et al. (2012) have also developed a theory that handles backtracking counterfactuals, and have presented some data in support of their theory. They do not describe a fully-specified computational model, but we were able to implement a model that we believe is consistent with their core assumptions. This model, however, did not account for Rips’ data as well as the minimal network model, and we there-

fore focus here on comparing the DMSM with the minimal network model.

Experiment 3 in Rips (2010) asked participants to reason about four causal systems shown at the top of Figure 3. Each system includes components  $L$  and  $H$  which cause component  $C$  to operate. The systems in Figure 3a include two cases where the operation of  $C$  is *jointly caused*: arcs between edges in Figure 3a indicate that  $L$  and  $H$  operate together to cause  $C$  to operate. The remaining systems are cases where the operation of  $C$  can be *separately caused* by either  $L$  or  $H$ . Two of the systems include probabilistic causal relationships shown as dashed arrows. For example, the probabilistic jointly caused system was described as a system where component  $L$ ’s operating and component  $H$ ’s operating together usually cause component  $C$  to operate. The remaining two systems include deterministic causal relationships. For each of the four systems, base rates for causes  $L$  and  $H$  were provided. Participants were told that  $L$  operates 5% of the time, and that  $H$  operates 95% of the time.

In each case participants were told that components  $L$ ,  $H$ , and  $C$  “are all operating.” They then responded to the question “if component  $C$  were not operating, would component  $L$  be operating?” and answered a similar question with respect to component  $H$ . The red points in Figure 3b show the proportion of participants who said yes to each question. For the deterministic separately caused system, most participants inferred that neither  $L$  nor  $H$  would be operating in the counterfactual scenario. For all remaining systems, participants tended to infer that the cause with higher base rate would be operating.

Predictions for four models are shown in Figure 3 using black lines. To generate these predictions, we again assumed that the probabilistic causal relationships had a strength of 0.8. The experimental materials did not explicitly specify whether each counterfactual scenario involved an intervention or an observation, and the predictions for the DMSM and the USM are based on counterfactual observations.

The DMSM predicts that average responses for the deterministic separately caused system should be low, and accounts for the base rate effects observed for all other systems. In contrast, the MSM predicts that the answer to all eight questions should be yes. Since the counterfactual premise is treated as an intervention, the model infers that  $L$  and  $H$  are operating in each counterfactual scenario. The USM makes predictions that are fairly close to the predictions of the DMSM, but inferences about the deterministic separately caused system reveal one important difference. Because the rare cause  $L$  was observed to operate in the actual world, the DMSM assigns non-negligible probability to the conclusion that  $L$  is operating in the counterfactual scenario. The USM ignores all information about the actual world, and therefore generates a much lower probability. Of these two models, only the DMSM successfully predicts that the probability of  $L$ ’s operating is higher for the probabilistic separately caused system than for any other system.

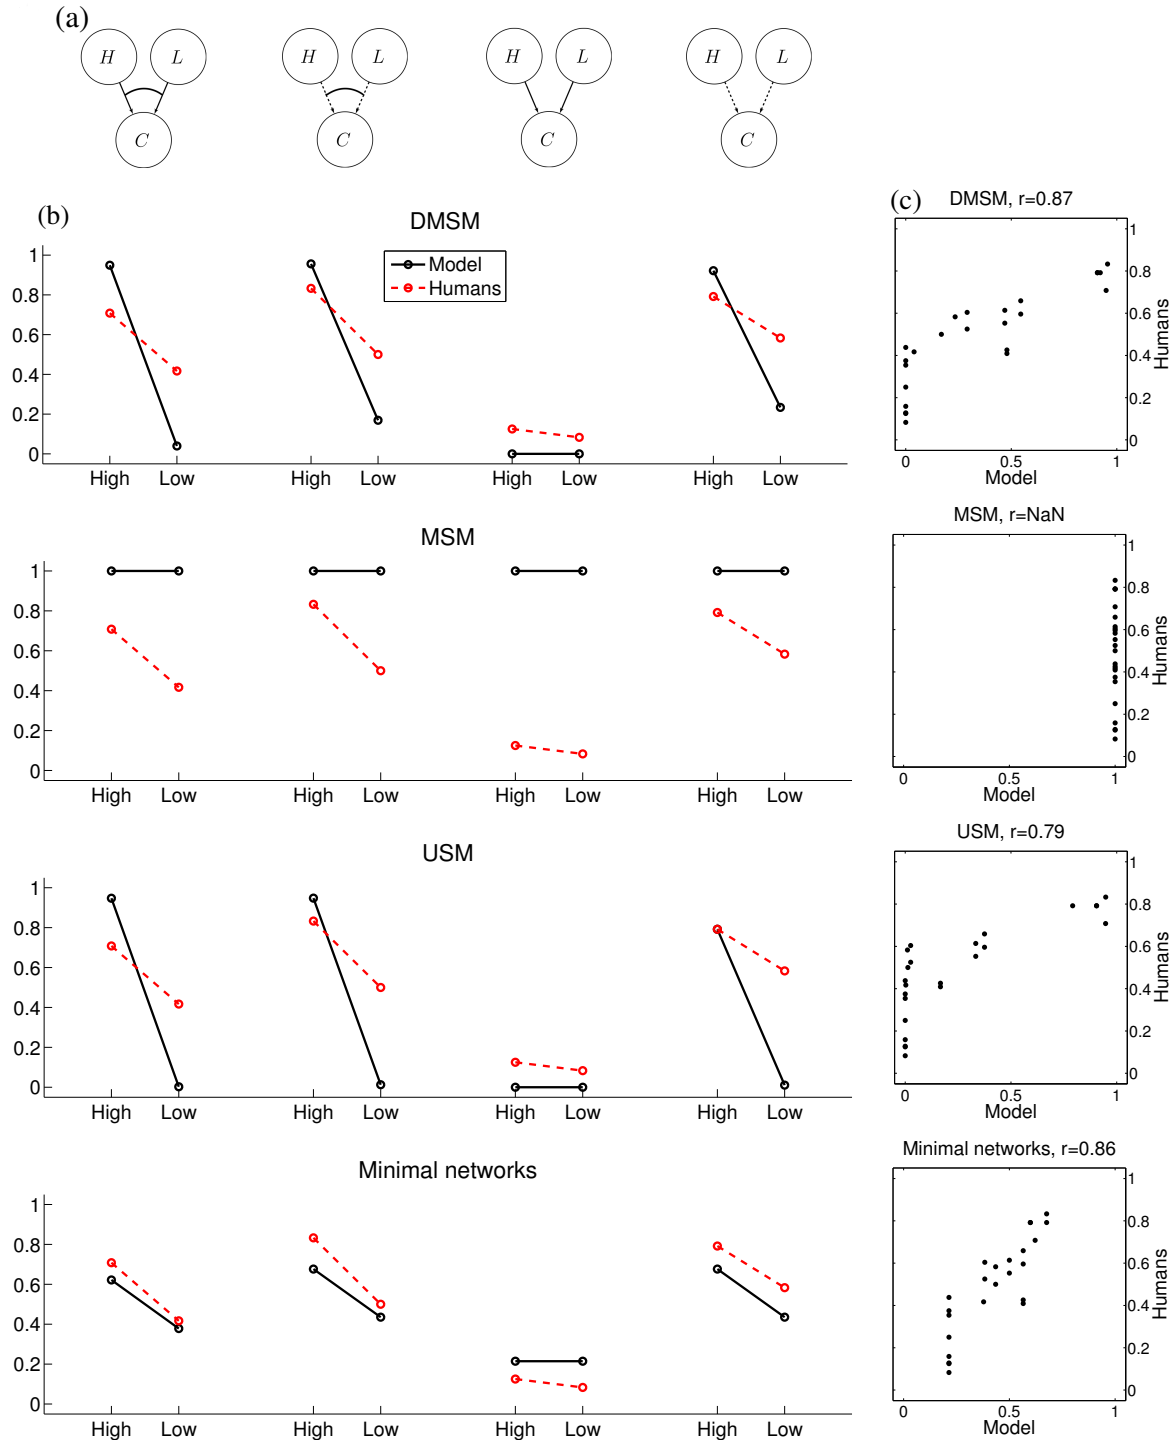

Figure 3: Model predictions and human responses for the experiments of Rips (2010). (a) Causal systems used in Rips's Experiment 3. Dotted lines represent probabilistic relationships and solid lines represent deterministic relationships. The edges linked by arcs represent AND relationships, where both causes must be active for the effect to occur, while un-linked edges represent OR relationships. Base rates differed between variables, with  $H$  or "High" variables occurring with probability .95 and  $L$  or "low" variables occurring with probability 0.05. (b) Results for counterfactual queries about the systems in (a). Proportions of "yes" judgments (human data) and probabilities (model predictions) are grouped according to the causal systems in (a). (c) Model predictions versus human judgments for all conditions across all four experiments in Rips (2010).

Because the MSM makes constant predictions across all of the different cases, an account in which individuals adopt either an MSM or USM strategy yields the same correlation with the data as the USM. Consequently, the DMSM fits the data better than accounts where some individuals always use  $s = 0$  and others always use  $s = 1$ , or where each individual tosses a coin to set  $s = 0$  or  $s = 1$  on a question-by-question basis. Even so, our data do not decisively show that most individuals are characterized by intermediate values of  $s$ , and future empirical work is needed to address this question.

The final plot in Figure 3b shows predictions for the minimal network model described by Rips. Unlike the three models considered thus far, the minimal networks approach works with causal models such as Figure 1a instead of functional models such as Figure 1b. Given observations of the actual world (e.g.  $L = H = C = 1$ ) and a counterfactual premise (e.g.  $C = 0$ ), the minimal networks approach assumes that the counterfactual scenario contains a minimal set of breaks, or cases where variables differ from their actual values while their immediate causes do not.<sup>2</sup> In Hiddleston's (2005) original version of minimal networks theory, counterfactual queries receive affirmative answers only if they are true in *all* minimal networks. This version of the theory accounts poorly for the data in Figure 3, and the predictions shown there are based on a variant of the original theory that incorporates two additional assumptions suggested by Rips. First, if multiple configurations are minimal then participants are assumed to respond based on just one of these networks. With probability  $\theta_1$  participants sample one minimal network at random, and with probability  $1 - \theta_1$  minimal networks are sampled according to their prior probabilities. Second, Rips proposes that with probability  $\theta_2$ , a participant will ignore the evidence that they see and pick an answer at random. We set the parameters  $\theta_1$  and  $\theta_2$  to values that maximize the correlation between model predictions and human data.

Figure 3b shows that the minimal networks model accounts well for the data, and produces quantitative predictions that are superior to the DMSM. Note, however, that the DMSM has one free parameter and the minimal networks model has two. The DMSM can be adjusted in the same way as the minimal network model to allow for the fact that some participants responded randomly, and making this modification will bring the quantitative predictions of the DMSM into closer correspondence with human judgments.

We have focused so far on Experiment 3 of Rips (2010), but the scatterplots in Figure 3c summarize the performance of the four models across all four of Rips' experiments. The two best performing models are the DMSM and the minimal networks model. The DMSM therefore accounts for Rips' data as well as his own model despite requiring fewer free parameters. The DMSM performs better than the USM and the mixed-strategy account, but recall that the DMSM has one free parameter and the USM has no free parameters. Addi-

tional studies are therefore needed to confirm that sensitivity to observations about the actual world is critical when modeling human inferences about backtracking counterfactuals.

## Discussion

We presented a model of counterfactual reasoning that accounts for inferences about both counterfactual interventions and backtracking counterfactuals. Our approach is closely related to the modifiable structural model developed by Pearl and inherits the ability of this model to reason about counterfactual interventions. Our model, however, differs from the MSM in one critical respect: we allow for the fact that exogenous causal variables may take counterfactual values. We showed that this difference between the models allows the DMSM but not the MSM to account for Rips' experimental study of backtracking counterfactuals.

Although we believe that the DMSM is a step towards a unified theory of counterfactual reasoning, there are important theoretical and empirical questions that still need to be addressed. The DMSM accommodates both counterfactual observations and counterfactual interventions, but additional work is needed to characterize the conditions under which a generic counterfactual premise is interpreted as an observation or an intervention. A second direction for future work is to draw a sharper contrast between the DMSM and accounts that combine the predictions of the MSM and the USM using a weighted average, and to better understand individual differences in counterfactual reasoning.

## Abstract

We introduce a new approach for exploring how humans learn and represent functional relationships based on limited observations. We focus on a problem called *superspace extrapolation*, where learners observe training examples drawn from an  $n$ -dimensional space and must extrapolate to an  $n + 1$ -dimensional superspace of the training examples. Many existing psychological models predict that superspace extrapolation should be fundamentally underdetermined, but we show that humans are able to extrapolate both linear and non-linear functions under these conditions. We also show that a Bayesian model can account for our results given a hypothesis space that includes families of simple functional relationships.

## Introduction

People regularly face situations where they must reason about functions defined over continuous variables. For example, consider a truck driver who wants to predict how quickly his truck can accelerate based on the mass of his cargo. If the driver has transported similar masses in the past, he can generate an accurate prediction by recalling the accelerations observed on these previous occasions. The real test of whether and how he has learned the function is how he extrapolates from past examples and makes predictions about loads that are much lighter or heavier than those he has seen in the past. Figure 1a, for example, shows how a learner might use linear extrapolation to generalize on the basis of two examples.

In any function learning setting, extrapolation judgments are shaped by the examples observed and the assumptions or *inductive bias* that the human brings to the problem. Minimizing the information carried by the training examples makes the role of the inductive bias especially apparent. Here we explore how humans learn functions from impoverished training data, and focus in particular on the problem of *superspace extrapolation*. Given training examples that fall within an  $n$ -dimensional space, we study how learners extrapolate to an  $n + 1$ -dimensional superspace that encloses the training examples. If the underlying function is one-dimensional, superspace extrapolation requires the learner to generalize on the basis of a single training example (Figure 1b). We focus on the corresponding problem in two dimensions, where the learner observes training examples drawn from a one-dimensional space and must generalize to the full two-dimensional space (Figures 1c-f).

Superspace extrapolation is an interesting problem in its own right, but also provides a way to distinguish between competing accounts of function learning. The psychological literature on function learning includes two prominent approaches that we will call the rule-based approach and the

similarity-based approach. The rule-based approach proposes that humans rely on a set of parametric functions that have explicit mental representations, including linear functions, polynomial functions, and others (Carroll, 1963; Brehmer, 1974; Koh & Meyer, 1991; Koh, 1993; Bott & Heit, 2004). The similarity-based approach proposes that humans remember specific examples encountered during training, and make predictions about test points based on similarity to the training points (Busemeyer, Myung, & McDaniel, 1993; Kelley & Busemeyer, 2008). Similarity-based approaches have traditionally struggled to account for extrapolation, and superspace extrapolation is especially challenging for these approaches. We show that humans are able to learn several different functions in a superspace extrapolation paradigm, which supports the idea that people can formulate and use explicit representations of both linear and nonlinear functions.

The hybrid approach to function learning proposes that humans can make both rule-based and similarity-based inferences. We show that this approach can account for our data by evaluating a hybrid model that builds on the Gaussian process account of Griffiths, Lucas, Williams, and Kalish (2009). Other models of function learning are prominent in the literature, and here we mention two representative examples. The Population of Linear Experts (POLE) model (Kalish, Lewandowsky, & Kruschke, 2004) proposes that humans learn functions that are piecewise linear (in the 1D case) or piecewise planar (in the 2D case). Since the training examples in a superspace extrapolation task are collinear, any given piecewise planar function belongs to an infinite family of piecewise planar functions that make very different extrapolation predictions but fit the training examples equally well. For example, Figures 1c and 1d show two different extrapolation functions that account perfectly for the same set of training examples. As a result, models that rely exclusively on linear extrapolation suggest that superspace extrapolation problems are fundamentally underdetermined and are unlikely to lead to consistent patterns of human responses. The Sigma model (Juslin, Karlsson, & Olsson, 2008) is an alternative approach which proposes that humans can acquire explicit representations of linear functions, but that knowledge about non-linear functions is “carried implicitly by memory for exemplars.” We show that people are successfully able to extrapolate non-linear functions in a superspace extrapolation paradigm, which suggests that the rule-based component of a hybrid approach should include room for non-linear functions.

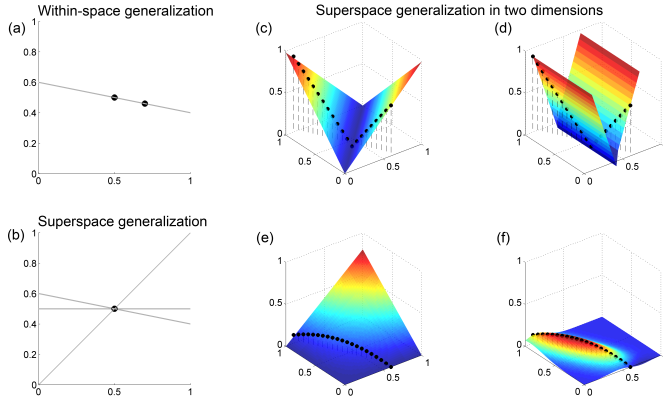

Figure 1: Examples of superspace extrapolation in one and two dimensions. Black dots are training points. (a) Standard function learning with one cue dimension; (b) Extrapolating from cues in a zero-dimensional subspace; (c) Superspace extrapolation in two dimensions, where  $f(x, y) = |x - y|$ ; (d) A second example of superspace extrapolation applied to  $|x - y|$ , assuming a difference piecewise linear function; (e) Superspace extrapolation where  $f(x, y) = xy$ ; (f) A second example using  $xy$ , with similarity-based extrapolation.

## Experiment

We developed a behavioral experiment with two goals in mind. The first and most basic goal is to find out whether superspace extrapolation is possible at all. Expecting participants to make generalizations about a function given a single training point seems unreasonable (Figure 1b), and it is possible that participants will find the two dimensional version of superspace extrapolation equally underdetermined. If superspace extrapolation turns out to be possible, our second goal is to understand how this kind of extrapolation is achieved. In particular, we aimed for a task that could address whether participants use explicit rules to make inferences that go beyond linear and similarity-based extrapolation.

We hypothesized that participants could learn a range of two-dimensional functions and chose to focus on five specific functions that are relatively simple and qualitatively different from one another. These functions are shown in Table 1 and plotted in Figure 2. Note that the family of functions includes both linear and non-linear functions. Consider one such function, the absolute difference function plotted in Figure 1c. Suppose that a learner observes the training points shown in black, which happen to fall along a line. There are many possible ways to extrapolate from the training points to the entire space—for example, Figure 1d shows an extrapolation to an axis-aligned function that is especially simple in the sense that it is invariant with respect to one of the dimensions. If people extrapolate by fitting a piecewise linear (i.e. planar) function to the training points, then there seems to be no reason to prefer the extrapolation in Figure 1c to Figure 1d or the infinitely many alternative extrapolations that fit two planes to the training points. On the other hand, if  $|x - y|$  is in human

learners' representational toolkit, we might predict that their extrapolations would resemble Figure 1c.

If extrapolation in cases like Figure 1c does depend on explicit rules, then extrapolations might vary dramatically if the positions of the training points are rotated. For example, the function  $f(x, y) = |x - y|$  turns into the function  $|x - 1 + y|$  when rotated by  $\pi/2$  around the line  $(0.5, 0.5, t)$  which passes through  $(0.5, 0.5)$  in the  $xy$ -plane and is perpendicular to the  $z$ -axis. It seems plausible that participants rely on a hypothesis space of rules that can accommodate the original but not the rotated function. We therefore compare each extrapolation problem to a rotated variant where the training points are rotated around the line  $(0.5, 0.5, t)$ , and predict that participants will be able to learn the unrotated but not the rotated version of each function. Linear extrapolation is equally possible in the rotated and unrotated cases, and a linear extrapolation account therefore predicts no qualitative difference between these two versions of the problem. Many similarity-based approaches also predict that the rotated and unrotated versions should lead to similar results, since similarity metrics (e.g. Euclidean distance) are often rotation-invariant.

## Methods

**Participants.** 33 participants were recruited from Carnegie Mellon's participant pool and the local community and received course credit or ten dollars for participating.

**Materials.** Cues were presented using adjacent horizontal bars and participants made predictions by adjusting a third horizontal bar centered under the midpoint between the cue bars. Each bar had a bounding box, so the range of valid values—which we denote with  $[0, 1]$  for simplicity—was evident to participants. No numerical information was provided about any of the variables. Feedback presentations took the form of a green bar overlaid on the prediction bar.

**Procedure.** Participants were told that they would have to learn several cause-effect relationships through trial-and-error. Each participant was presented with the five distinct functions listed in Table 1 in random order, in either *rotated* or *unrotated* form. For a given unrotated function  $f(x, y)$  and a rotation angle  $\theta_r$ , we define a rotated function  $g(x, y) = f(x', y')$  where  $(x', y')$  is the result of rotating  $(x, y)$  around the point  $(0.5, 0.5)$  by  $\theta_r$ . Table 1 contains explicit definitions of the unrotated and rotated versions of all functions. For each function, participants saw a training phase followed by a test phase. Both phases consisted of a series of trials in which participants were presented with cues  $(x, y)$  and asked to predict  $f(x, y)$ .

The training phase included 40 randomly-ordered examples that fell along a single line. Specifically, training examples fell at equal intervals along a line segment with length 0.9 centered at  $(0.5, 0.5)$ , making an angle of  $\theta_t$  (see Table 1) with the  $x$ -axis. After each training prediction, participants who gave guesses within 0.04 of the true value moved to the next example point, while inaccurate guesses were followed by feedback in which the correct value of  $f(x, y)$  was presented and participants had to adjust their prediction to match

Name	Unrot. $f(\cdot)$	$\theta_r$	Rot. $f(\cdot)$	$\theta_l$
Projection	$x$	$\frac{1}{2}\pi$	$1 - y$	$\frac{1}{8}\pi$
Average	$\frac{1}{2}(x + y)$	$-\frac{1}{2}\pi$	$\frac{1}{2}(x + 1 - y)$	$\frac{3}{8}\pi$
Product	$xy$	$\frac{1}{2}\pi$	$x(1 - y)$	$\frac{5}{8}\pi$
Difference	$ x - y $	$\frac{1}{2}\pi$	$ x + y - 1 $	$\frac{5}{8}\pi$
Max	$\max(x, y)$	$-\frac{1}{2}\pi$	$\max(x, 1 - y)$	$\frac{7}{8}\pi$

that value in order to continue.

In the subsequent test phase, participants received no feedback and were presented with 10 equidistant points along the original training line, 10 within-space points that fell beyond the extrema of the original line, and 36 superspace extrapolation points in a uniform 6-by-6 grid over the  $[0, 1] \times [0, 1]$  range. After each test phase, participants were prompted to describe what they thought the function was before moving on to the next function. The bars corresponding to variables  $x$  and  $y$  were selected randomly.

## Experimental Results

We excluded one participant who did not attempt to learn the functions, indicated by a mean absolute error exceeding 0.25. Ten of the 32 participants who remained did not complete all of the functions in the allotted hour, but each version (rotated or unrotated) of each function was completed by at least 11 participants. The side on which  $x$  and  $y$  were presented had no significant influence on performance, so the two orientations were grouped together.

The five panels labeled (iii) in Figure 2 show average human responses for the five unrotated functions. The black dots show responses for the training points, and the surfaces show responses for the extrapolation points. In all cases, participants were able to learn the function values for the training points, and their extrapolation judgments were qualitatively similar in all cases to the true functions. Note that superspace extrapolation was possible even for the three non-linear functions in the set. The panels labeled (iv) in Figure 2 show average responses for the rotated functions. Participants appeared to learn the rotated projection function, but extrapolation judgments for the four other rotated functions appear qualitatively different from the true functions. Table 1 shows that the rotated version of the projection function is  $f(x, y) = 1 - y$ . Recall that the cues were presented using sliders on horizontal bars, and that the value of each cue corresponds visually to the proportion of the bar to the left of the slider. The rotated projection function can be learned by paying attention to the complement of the  $y$  cue, or the proportion of the  $y$ -bar to the right of the slider. Although responses for the rotated projection function suggested that participants

Function	$\text{MAE}_u$	$\text{MAE}_r$	p
$x$	0.039	0.055	0.51
$(x + y)/2$	0.071	0.151	0.00088
$xy$	0.092	0.140	0.042
$ x - y $	0.123	0.247	0.0015
$\max(x, y)$	0.046	0.130	0.0077

Table 2: Mean absolute error for test points in learning rotated  $\text{MAE}_r$  and unrotated functions ( $\text{MAE}_u$ ). p-values were obtained using a two-tailed permutation test, using 200,000 samples per test.

are sensitive to complements in some cases, responses for the remaining rotated functions suggest that participants find it difficult to learn simple functions defined in terms of complements.

The descriptions provided by individual participants indicated that many had acquired explicit representations of the unrotated functions. Five examples of these descriptions are: “effect was identical to cause B” (projection); “roughly the average of the two causes” (average); “fraction multiplication” (product); “difference of the causes” (difference); “the larger of the two values” (max). Responses for the rotated functions sometimes indicated complex hypotheses, but more often indicated confusion or uncertainty about the nature of the function. These descriptions indicate that some individuals had clearly learned the functions. To further explore responses at the individual level, we looked at the extent to which individual participants’ judgments fit the true functions versus several alternatives, for both unrotated and rotated functions, shown in Figure 3. The space of candidate functions included all true unrotated and rotated functions, along with a set of simple alternatives shown in the caption to Figure 3. The alternatives include a function that captures complete uncertainty ( $f(x, y) = 0.5$ ), floor and ceiling responses ( $f(x, y) = 1$  and  $f(x, y) = 0$ ), and some simple linear combinations of  $x$  and  $y$ . For all of the unrotated functions, most participants’ extrapolation judgments were best fit by the true function. For the rotated versions, the modal judgment only matched the true function for rotations of  $f(x, y) = x$  and  $f(x, y) = \max(x, y)$ .

Additional evidence that individual participants often learned the true functions relatively well is provided by examining the mean absolute error with respect to the true function. Performance for the projection function was near-ceiling for both unrotated and rotated versions, but in all other cases participants had lower mean absolute error for the unrotated functions than the rotated functions. Table 2 shows mean absolute error for the extrapolation points, and a similar pattern held for the training points, with significantly better performance in the unrotated cases for  $f(x, y) \in \{x, |x - y|, xy, \max(x, y)\}$  at  $\alpha = 0.05$ .

Previous experiments have explored the relative learnability of one-dimensional functions, and our results provide some initial evidence about a learnability ordering for two dimensional functions. The results in Table 2 suggest that the

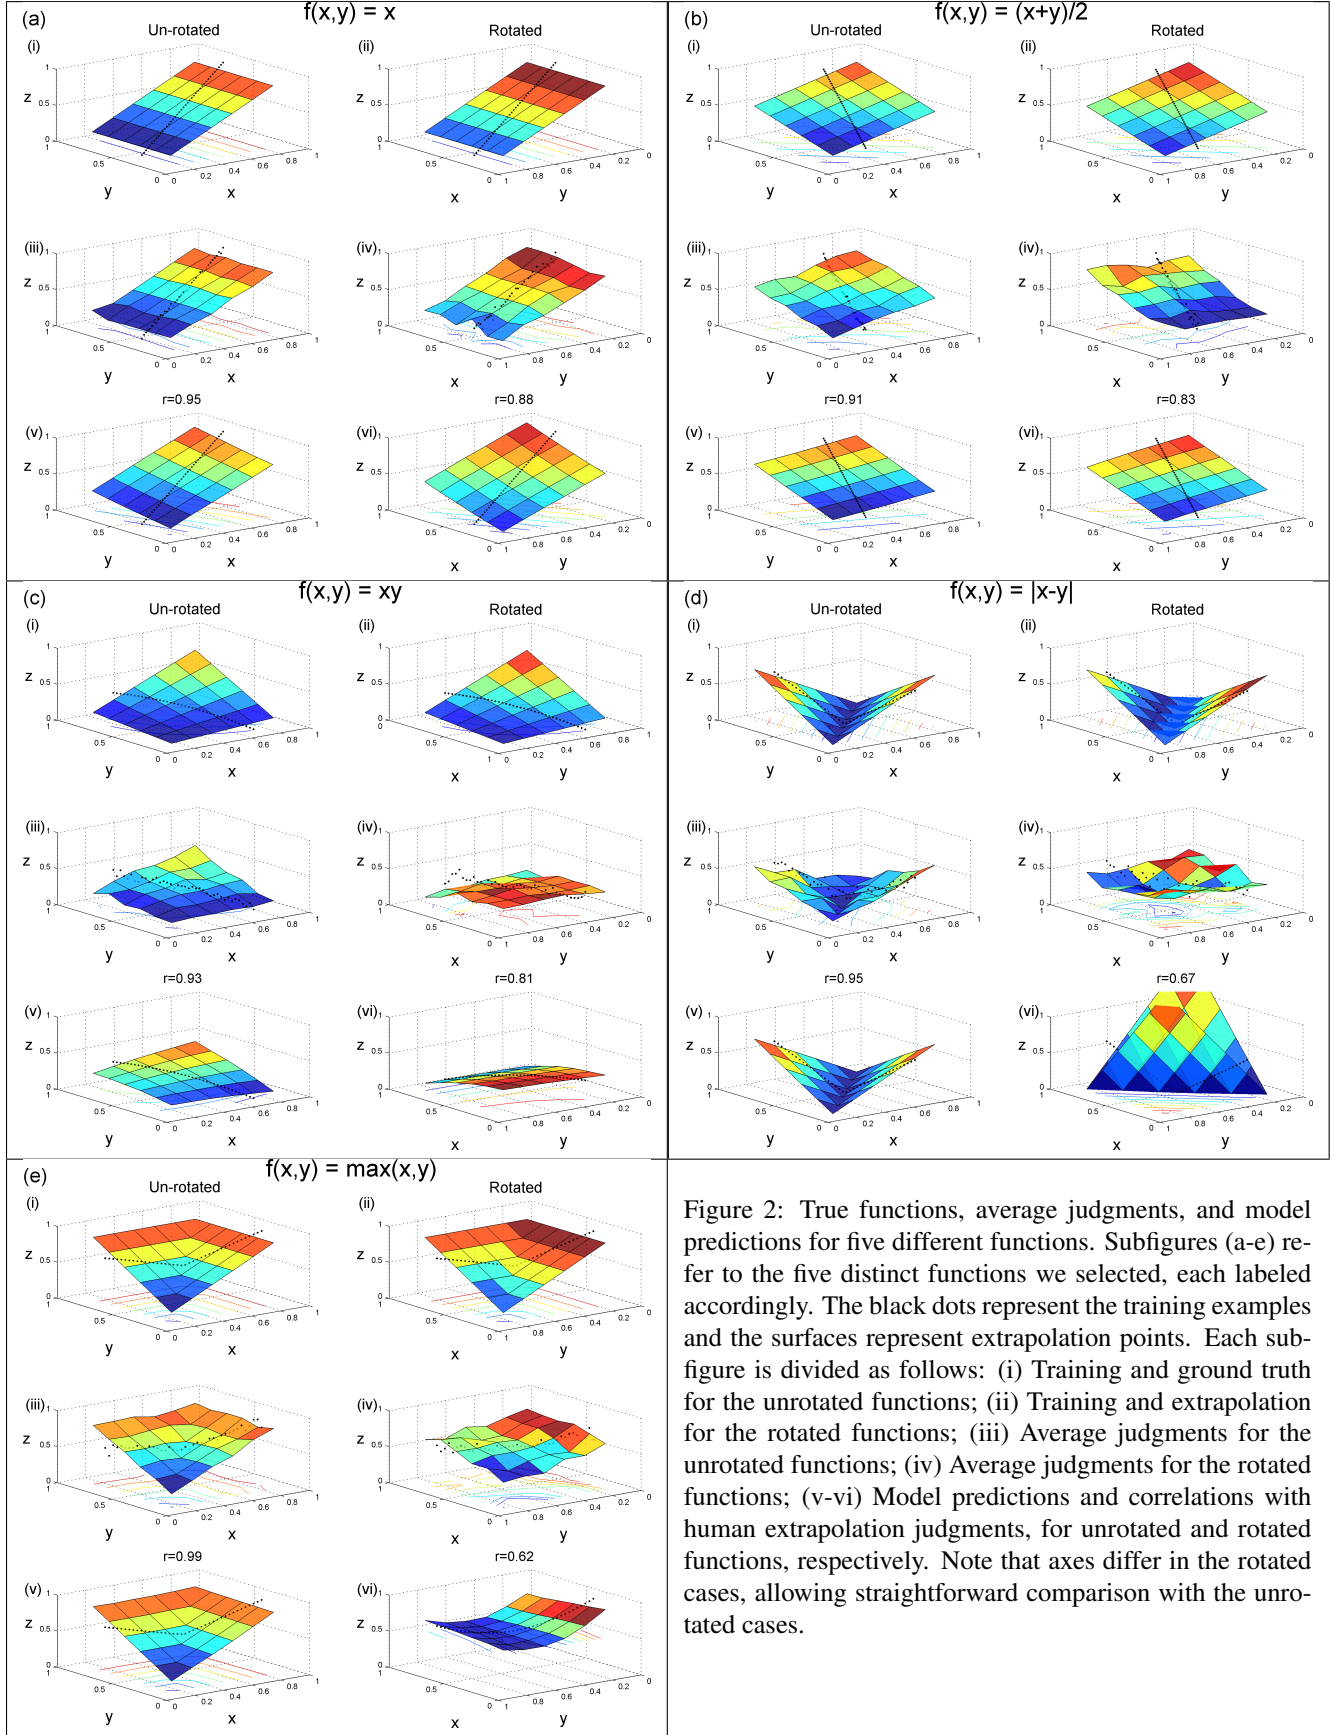

Figure 2: True functions, average judgments, and model predictions for five different functions. Subfigures (a-e) refer to the five distinct functions we selected, each labeled accordingly. The black dots represent the training examples and the surfaces represent extrapolation points. Each subfigure is divided as follows: (i) Training and ground truth for the unrotated functions; (ii) Training and extrapolation for the rotated functions; (iii) Average judgments for the unrotated functions; (iv) Average judgments for the rotated functions; (v-vi) Model predictions and correlations with human extrapolation judgments, for unrotated and rotated functions, respectively. Note that axes differ in the rotated cases, allowing straightforward comparison with the unrotated cases.

Figure 3: Trained functions versus functions that best fit participants’ judgments. The *other* group includes  $f(x, y) \in \{1, 0.5, 0, 0.5x, 0.5y, 0.75x + 0.25y, 0.25x + 0.75y\}$ . Best-fitting functions were those that minimized mean squared error.

projection and maximum functions are easiest to learn, and that the product and difference functions are most difficult to learn.

Taken together, our data provide strong evidence that humans are capable of superspace extrapolation, and can learn both linear and non-linear functions under this paradigm. The lower performance for the rotated functions suggests that the space of learnable functions is restricted. Both results are compatible with the idea that people can acquire explicit representations of rules, but raise challenges for approaches that focus on similarity-based computations alone. Our data, however, are compatible with a hybrid approach, and the next section describes one such approach that accounts for our data relatively well.

### Modeling superspace extrapolation

The hybrid approach to function learning is motivated by the idea that humans readily learn certain rules but fall back on similarity-based computations when no simple rule is consistent with the observed examples. The rule-based component of this approach can potentially explain how humans carry out superspace extrapolation when learning the unrotated functions in our experiment, and the similarity-based component may help to explain responses for the rotated functions.

To demonstrate that the hybrid approach can account for our data, we developed a computational model which assumes that humans make use of a hypothesis space that contains several families of functions. Some of these function families correspond to simple rules, and others are more generic and include all smooth functions. The first column of Table 3 shows one such hypothesis space that includes linear, quadratic, difference, maximum and product functions, along with one generic family of smooth functions. Given this hypothesis space and a set of training examples, extrapolation judgments can be made by using the posterior distribution over the space of functions.

The model we implemented builds on the hybrid approach of Griffiths et al. (2009), which uses Gaussian processes to

Function family	Prior	Mean function
$\beta[1 \ x \ y]^T$	0.5	$\mu_0 = 0, \mu_1 = \mu_2 = 1$
$\beta[1 \ x \ y]^T$	0.4	$\mu_0 = 1, \mu_1 = \mu_2 = -1$
$\beta[1 \ x \ y \ x^2 \ y^2]^T$	0.09	$\mu_0 = \mu_1 = \mu_2 = \mu_3 = 0$
$\beta_1  x - y $	0.001	$\mu_1 = 1$
$\beta_1 \max(x, y)$	0.001	$\mu_1 = 1$
$\beta_1 xy$	0.001	$\mu_1 = 1$
Smooth functions	0.01	$f(x, y) = 0$

Table 3: Hypothesis space captured by the Gaussian process model. Un-normalized prior probabilities are given for each function family for readability. For the first five families, coefficients  $\beta_i$  are distributed normally around  $\mu_i$  with a common variance for each coefficient. The difference, maximum, and product families are not described by Griffiths et al. (2009), but the prior probabilities on all remaining families and the  $\mu_i$  values for these families are drawn from Griffiths et al. (2009).

capture both rule-based and similarity-based function learning. As originally presented, this model takes kernel functions that express linear and quadratic rules as well as a standard similarity-based kernel function for which the covariance between any two points  $\mathbf{x}$  and  $\mathbf{x}'$  is  $K(\mathbf{x}, \mathbf{x}') = \theta_1 \exp(-\frac{1}{\theta_2^2} \|\mathbf{x} - \mathbf{x}'\|^2)$ , where  $\theta_1$  and  $\theta_2$  determine the smoothness of the function. Intuitively, this last kernel expresses the assumption that functions are locally smooth, and was used to produce the extrapolations in Figure 1f. The model generates predictions by integrating over all possible functions for all function types, integrating out all applicable parameters. For a more detailed description, see Griffiths et al. (2009).

Our extension to the original model was to add a kernel capturing each of the three non-linear rules in our experiment, which are equivalent to Bayesian regression models of the form  $\beta|x - y|$ ,  $\beta\max(x, y)$ , and  $\beta xy$ , where  $\beta$  is a coefficient distributed normally around one. We assigned each new kernel a prior probability of 0.001, or one tenth that of the least-

probable kernel in the original model, before renormalizing kernel probabilities. See Table 3 for a summary of all of the kernels in the model and their corresponding probabilities.

Model predictions are shown in Figures 2e and f, along with correlations with human extrapolation judgments. In most cases the predictions of this model closely matched participants' superspace extrapolations for both unrotated and rotated functions. The latter result is the more striking of the two, as the predictions arise from averaging over several kernels rather than choosing suitable ones in advance.

The one major discrepancy between model predictions and human judgments occurs for the rotated version of  $|x - y|$ , where the extrapolation judgments predicted by the model are substantially more extreme than the human responses. This result is driven by the fact that the family of difference functions in Table 3 can perfectly account for the rotated training points if  $\beta_1$  takes a value larger than 1. Unlike the model, humans may be unable to learn weighted versions of the difference function in Table 3, which could be captured by setting the coefficient  $\beta_1$  for this family to 1. The model represents the simplest possible extension of the Gaussian process account of Griffiths et al. (2009), but adjusting the priors on the coefficients may result in a more accurate model of human learning.

### Alternative models

Several recent models that address extrapolation in function learning and multiple cue judgment, including POLE (Kalish et al., 2004), EXAM (DeLosh, Busemeyer, & McDaniel, 1997), and Sigma (Juslin et al., 2008), all suggest that humans extrapolate according to linear functions. In their present forms, none of these models appear to account for our results. We fit the POLE model to our data and found that extrapolations were consistently piecewise linear in one cue dimension, and invariant to the other, taking a form like that in Figure 1c. This approach to superspace extrapolation seems plausible *a priori* but it does not reflect the behavior of our participants. The EXAM model makes extrapolation predictions using the nearest past examples to a new point, implying that peoples' judgments are invariant to the rotation of a given function, which is inconsistent with our data. Finally, the Sigma model (Juslin et al., 2008) proposes that humans can acquire explicit representations of linear functions but that extrapolation of non-linear functions relies on similarity-based generalization. The Sigma model is therefore inconsistent with our finding that people were able to learn several non-linear functions.

### Conclusion

We introduced the problem of superspace extrapolation, which provides a new way to explore the inductive biases that people bring to the task of function learning. Our data suggest that these inductive biases include a toolkit of linear and non-linear rules that can be compared against the available data. Our results challenge several popular accounts of function learning, but we showed that they are compatible with a

hybrid approach to function learning that accommodates both explicit rules and similarity-based inferences.

Superspace extrapolation requires learners to go beyond the available data in a fundamental way, and other problems where humans make inferences based on limited data have also provided important evidence about human inductive biases (Shepard, 1994; Feldman, 1997). Psychologists sometimes study what can be learned from textual corpora and other massive data sets, but exploring what humans learn from highly constrained data sets can be equally valuable.

## Abstract

A critical aspect of human cognition is the ability to actively query the environment for information. One important (but often overlooked) factor in the decision to gather information is the cost associated with accessing different sources of information. Using a simple sequential information search task, we explore the degree to which human learners are sensitive to variations in the amount of utility related to different potential observations. Across two experiments we find greater support for the idea that people gather information to reduce their uncertainty about the current state of the environment (a “disinterested”, or cost-insensitive, sampling strategy). Implications for theories of rational information collection are discussed.

**Keywords:** information sampling, active learning, information access costs

## Introduction

From controlling the movement of our eyes to determining which sources of news to consult, judging the quality of alternative sources of information is a critical part of adaptive behavior. Research exploring how people make information gathering (or “sampling”) decisions has shown that people can discern subtle differences in the potential information value of various aspects of the environment. For example, measurements of eye movements during object categorization show that people preferentially allocate attention to object features that are most useful for making subsequent classification decisions (c.f., Nelson & Cottrell, 2007; Rehder & Hoffman, 2005).

One aspect that typically complicates the analysis of information sampling behavior is that information rarely comes for free. All natural tasks involve information access costs, even if the only cost is the time required to gather information (Fu, 2011). In addition, different pieces of information may be more useful depending on how one will be tested in the future. Optimal search behavior must weigh the costs of collecting particular bits of information against the benefit it is expected to convey (Edwards, 1965; Juni, Gureckis, & Maloney, 2011; Tversky & Edwards, 1966), a point frequently made in research on animal foraging (Stephens & Krebs, 1986).

Despite its importance, previous work on information sampling has often failed to test whether people take into account costs related to different sources of information. For example, Nelson (2005) provides a comprehensive review of various ways an optimal Bayesian agent might value potential information sources in the absence of task-specific costs (see also Nelson et al., 2010). One conclusion from this line of work is that people make information search decisions that are consistent with normative measures of information value (many of which often make similar predictions). For example, Nelson et al. (2010) studied information sampling in a diagnostic

reasoning task where the predictions of these measures could be readily distinguished. Learners who could query different stimulus features before making classification decisions were found to prefer to learn about features that maximized *probability gain*, a measure of how well a potential observation is expected to improve classification accuracy.

In these studies, however, costs were not explicitly manipulated or controlled. Taking costs into account can alter the optimal strategy in a given task, but it is unclear whether people adjust their behavior in a similar way. The goal of the present paper is to explore the impact of costs on sampling decisions. We begin by evaluating two alternative objectives that people may adopt when deciding what information to gather. Like the models reviewed by Nelson (2005), the first ignores the implications of task-specific costs and casts information sampling strictly in terms of uncertainty reduction (i.e., information gain). The second approach balances the costs and expected benefits of information in the context of the task. We then describe the results of two experiments that manipulate the concordance between these two approaches, in one case creating an environment where the goals of minimizing uncertainty and maximizing utility predict different patterns of information sampling. Our results show that people tend to value information (in terms of the number of hypotheses ruled out by a new observation) over situation-specific costs and benefits. The implications of these results for theories of information sampling are discussed.

## The rational analysis of information sampling: comparing “interested” and “disinterested” search

How should a rational agent make information sampling decisions? Existing proposals fall into two broad categories which, borrowing from Chater, Crocker, and Pickering (1998), we call “interested” and “disinterested.” Unlike the distinctions explored by Nelson (2005), these two proposals differ significantly in terms of the overall goal of information sampling.

**Interested (or cost sensitive) sampling** The first approach represents a decision-theoretic approach to information sampling. In particular, the agent considers the cost for collecting a piece of evidence and weighs this against the expected benefit it should convey with respect to the goals of the task. For example, a car shopper might decide if the possible savings available from obtaining information contained in a vehicle history report is worth the cost of the report. Similarly, preferentially fixating the features of an object that are diagnostic of its category membership may be a cost-sensitive strategy under the

assumption that additional fixations cost time and the number of fixations needed to reach a correct decision should be minimized. Sampling in this case is “interested” in that information acquisition is focused on some purpose or goal beside acquiring the information itself. In many ways, “interested” sampling is a fully rational strategy and this formulation is often adopted in economics research.

**Disinterested (or cost insensitive) sampling** The second approach values information to the degree that it reduces our uncertainty about the world. Chater et al. liken this to basic research where the goal is learning without regard for the ultimate utility of this knowledge for society. In their words, “inquiry is valuable for its own sake, because it leads to knowledge” (Chater et al., p.4). Disinterested inquiry can be conveniently expressed as actions which have a high probability of reducing the Shannon entropy over the agent’s beliefs (Lindley, 1956; Mackay, 1992). Critically, disinterested inquiry doesn’t depend on the costs associated with collecting information or using it to make subsequent decisions.

The basic premise of the experiments reported in this paper is that these two strategies or ways of valuing information can be dissociated on the basis of observed choice behavior. We gave participants a simple, intuitive information search task where they were asked to make sequences of decisions to reduce their uncertainty about a hidden target. Mathematical models instantiating each of the two theories just described are then fit to the choice patterns of individual subjects. This fitting procedure (common in the reinforcement learning literature) allows us to evaluate which of the approaches we have described gives the best account of participants’ choices.

### The Experimental Task: The Shape Search Game

Participants in our task are presented with a 10 by 10 grid that contains non-overlapping hidden shapes made up of individual grid cells. The hidden targets are randomly drawn from a set that is known to the participant. There are two phases in each game: a *sampling phase* and a *painting phase*. In the sampling phase, the player learns about the form and location of the hidden shapes by choosing squares in the grid to uncover. On each trial, they make an observation at one location, revealing either part of a hidden shape or an empty square. When they think they know the location and form of all the shapes they can stop sampling and enter the painting phase. In the painting phase, the player is tested for their knowledge of the shapes by “painting” any remaining squares they believe belong to one of the shapes in the appropriate color.

The player is penalized one point for every observation made in the sampling phase and two points for every error committed in the painting phase (e.g., failing to fill in a square that belongs to a shape). These costs promote efficient information search in two ways. First, the observation cost discourages sampling in locations whose contents can be inferred from evidence that has already been uncovered. Second, it encourages continued sampling while there is still uncertainty about the hidden shapes, since painting errors are more costly

### Experiment 1: Rectangle Search

Figure 1: The generative process underlying the shape search game. A fixed set of possible shapes is specified. A hidden gameboard is created by sampling from this set of shapes and randomly arranging the targets in the grid. During the sampling phase the participants clicks on grid locations to reveal their contents. In the painting phase, the subject draws in the remaining squares using the mouse and is rewarded for accuracy.

than observations. The goal of the game is to finish with the lowest score possible, which is achieved by learning the most about the hidden shapes in the fewest number of observations.

Based on past work with this task (Gureckis & Markant, 2009), we have found that the overall objective of the game is easily understood by the participants. A critical feature of the task (which we exploit in our second experiment) is that it allows for arbitrarily defined targets (i.e., the target shapes may be composed of any configuration of squares) that can be manipulated to vary the complexity of the task.

### Formal task analysis

In order to evaluate both “interested” and “disinterested” information search in the task, we compare the search behavior of subjects to that of a rational learner who updates their beliefs about the gameboard in an optimal way. Formally, players make a sequence of observations in order to learn the hidden gameboard,  $g_h \in G$ , where  $G$  is the universe of legal gameboards. Each individual gameboard is defined by an arrangement of  $N$  non-overlapping shapes  $\{r_1, r_2, \dots, r_N\}$  with unique labels  $\{l_1, l_2, \dots, l_N\}$ , and each shape consists of a set of squares such that  $o_{ij} \in r_n$  (where  $i$  and  $j$  index the  $x$ - and  $y$ -coordinates of the square).

On each trial the player makes an observation  $o_{ij}$  and receives feedback in the form of a label  $l_n$ , where  $l_0$  indicates the observed square is empty,  $l_1$  means it contains part of shape  $r_1$ , and so on. Since each square in the grid is deterministically assigned to either one or zero shapes, we assume that the likelihood of a particular observation  $o_{ij}$  belonging to one of the shapes (i.e.,  $o_{ij} = l_n$  for  $n > 0$ ) for a particular gameboard  $g$  is deterministic (i.e.,  $p(o_{ij} = l_n | g) = 1$  if the location falls within a target and 0 otherwise).

The prior belief about the likelihood of each individual gameboard is represented by  $p(g)$ . In our experiments, participants were instructed that the shapes were chosen at random and that all legal gameboards were equally likely (i.e.,  $p(g) = 1/|G|$  for all  $g$ , a uniform prior).

Bayes rule can be used to compute the posterior belief

about the identity of the hidden gameboard and to predict the marginal probability of any point in the grid having any particular label  $l_n$  (this is a very straightforward Bayesian approach to the problem, see Gureckis and Markant, 2009).

**Interested (cost-sensitive) Sampling** The objective of the game is to minimize the number of points accumulated, where each individual observation costs  $C_{obs}$  points and each error during painting costs  $C_{error}$  points. Given these constraints, we can quantify the value of observations with respect to the overall goal of minimizing total costs. We assume that the likelihood of labeling a point  $o_{ij}$  with label  $l_n$  during the painting phase is simply the marginal probability  $p(o_{ij} = l_n | \mathcal{B})$ , and the cost associated with that action is tied to the uncertainty about its label when the sampling phase ends (e.g., if  $p(o_{ij} = l_n | \mathcal{B}) = 1$ , the true label is known with certainty and there is no chance of committing an error during painting)<sup>1</sup>. On each trial, the total expected cost  $EC(\mathcal{B})$  of ending the sampling phase and entering the painting phase is defined as:

$$EC(\mathcal{B}) = C_{error} \cdot \sum_i \sum_j \sum_n p(o_{ij} = l_n | \mathcal{B}) \cdot [1 - p(o_{ij} = l_n | \mathcal{B})] \quad (1)$$

For a new observation and its observed outcome ( $o_{ij} = l_n$ ) we then calculate the resulting cost *savings*, or reduction in expected costs:

$$S(\mathcal{B}, o_{ij} = l_n) = EC(\mathcal{B}) - EC(\mathcal{B} | o_{ij} = l_n) \quad (2)$$

The savings achieved from feedback is offset by the cost of making the observation ( $C_{obs}$ ). To account for uncertainty about the true outcome we find the *expected savings* by weighting the savings for each outcome by its likelihood of occurring:

$$ES(\mathcal{B}, o_{ij}) = -C_{obs} + \sum_n p(o_{ij} = l_n | \mathcal{B}) S(\mathcal{B}, o_{ij} = l_n) \quad (3)$$

For each trial,  $ES(\mathcal{B}, o_{ij})$  is calculated for all  $o_{ij}$ , giving a distribution of the expected saving for remaining observations in the grid. An ideal learner maximizes this value by choosing the location  $o_{ij}$  with the highest  $ES(o_{ij})$  on each trial.

**Disinterested (cost insensitive) Sampling** A “disinterested” sampling norm values observations according to their effect on the learner’s beliefs without account for task-specific costs and benefits. This captures the intuition that observations that produce a large change in the agent’s beliefs tend to be more useful than observations that have little or no effect (i.e., nothing new is learned). In our approach this was modeled using *information gain*, which values an observations according to the expected reduction of uncertainty about the hidden gameboard. This uncertainty can be quantified by the Shannon entropy measured over the current belief distribution ( $H(\mathcal{B})$ ).

Entropy is maximized when all hypothesized gameboards are equally likely (as with our initial uniform prior), and minimized when there is only one possible hypothesis. For a given

<sup>1</sup>For shorthand,  $\mathcal{B}$  represents a vector of probabilities  $p(g | o_{ij} = l_n)$ , for all  $g \in G$ , that represents the full posterior distribution over the entire space of gameboards. This is the agents current “belief distribution” about which gameboard is the current target.

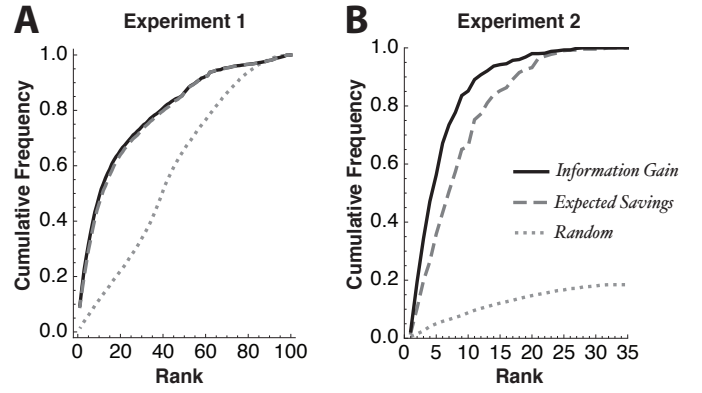

Figure 2: Cumulative frequency of ranks assigned to participants’ samples. A: In Experiment 1, the average rank of participants’ choices is higher than expected from a random sampling strategy, but there is no difference between rankings assigned by the two models. B: In Experiment 2, participants’ samples are more highly ranked according to EIG than ES.

observation and its observed outcome ( $o_{ij} = l_n$ ) we can calculate information gain as:

$$I(\mathcal{B}, o_{ij} = l_n) = H(\mathcal{B}) - H(\mathcal{B} | o_{ij} = l_n) \quad (4)$$

To account for uncertainty about the true outcome of an observation, information gain for each possible outcome is weighted by the predicted probability of that outcome occurring, giving the *expected information gain* for an observation  $o_{ij}$ :

$$EIG(\mathcal{B}, o_{ij}) = \sum_n p(o_{ij} = l_n | \mathcal{B}) I(\mathcal{B}, o_{ij} = l_n) \quad (5)$$

As above, on each trial we compute  $EIG(\mathcal{B}, o_{ij})$  for all locations in the grid, and assume that the optimal model chooses the location with the highest value on each trial<sup>2</sup>.

In applying each model to human choice data, the model is “yoked” to the decisions of the player. On each trial, the models assign a value (either  $EIG$  or  $ES$ ) to each point in the grid. These utilities can be used to compute choice probability of various grid locations. After revealing what the subject actually chose on a given trial, the model updates its posterior beliefs about the current gameboard configuration. These new beliefs then feed into new predictions about the utility of choosing each grid location. The process ends when the participant ends the game.

## Experiment 1: Rectangle Search

The first experiment re-analyses a previously published result which introduced explicit task-specific costs (Gureckis &

<sup>2</sup>It is important to note that this represents a “greedy” policy that chooses the best observation available on any given trial, but this may not reflect the globally optimal solution. The current framework could be extended to account for how participants might estimate the value of sequences of observations. However, due to the computational complexity of finding this solution given the large number of potential observations on any trial, for the present studies we focus our analysis on the greedy model.

Markant, 2009). Six participants played a series of games in which they searched for three rectangular shapes, randomly drawn from the set shown in Figure 1. The set of shapes was displayed on screen throughout the game. Participants were instructed that the three shapes in each gameboard were non-overlapping and were shown a large number of examples gameboard configurations prior to the experiment.

Each observation made by a participant during the sampling phase was ranked according to the predictions of both models (the median rank was used when multiple observations had equal value). Overall, the results show that people consistently sampled points that were assigned a high value by both models, with approximately 50% of their samples falling within the top 10 ranked observations available to them (see Figure 2A). In this experiment, however, the hypothesis set that was used (rectangular shapes of varying shape and size) led to highly similar predictions for both information gain and expected savings, precluding a test of whether people were sensitive to the costs in the task.

It is important to consider why the predictions of the two models converged in this case. As discussed previously, a cost-sensitive learner should value observations that have higher utility—that is, those that will reduce the likelihood of committing errors in the painting phase by the greatest amount. Intuitively, this implies that learning about bigger shapes is especially useful, since it will allow one to correctly label a greater number of squares. This idea is illustrated in Figure 3A for a simple hypothesis set made up of three rectangles in different locations. While observing a “hit” on any shape determines the true hypothesis (middle column), observing a “miss” (righthand column) has different utilities depending on the size of the shape it rules out. For example, ruling out the smallest shape (top row) leaves uncertainty about how to label eight other squares, whereas ruling out the largest shape (bottom row) leaves uncertainty about only four.

While the shape set used in Experiment 1 contained a range of sizes, the fact that the hypotheses were “nested” (i.e., the largest shapes overlapped with a set of progressively smaller ones) meant that learning about larger shapes also tended to rule out many hypotheses. As a result, the predicted choice values according to both models were highly similar. For our second experiment we created an alternative hypothesis space in which there were clearer differences in both the size of alternative hypotheses and the choices that were related to shapes of different size, leading to a greater number of potential observations where the predictions of the two models diverged.

## Experiment 2: Letter Search

In Experiment 2, we simplified the task to involve searching for a single target in the grid. For the hypothesis space we created a set of simple “letter” shapes (see Figure 3B). There were two types of games: L/D games, where the hidden letter could be an L or D, and C/U games, where the hidden letter could be a C or U. In each game a single point belonging to the hidden shape was revealed before the participant began sampling.

These modifications resulted in a much less complex hypothesis space (e.g., only 15 hypotheses were possible at the beginning of an L/D game, and 14 for C/U games). Importantly, because the two shapes involved in each type of game differed in area (for example, the ‘D’ shape contained a greater number of filled squares than the ‘L’), the predictions of information gain and expected savings diverged in the task.

## Methods

**Participants** Sixteen NYU undergraduates completed the study for course credit or for a \$10 payment. The experiment was presented on a standard Macintosh computer.

**Materials** A gameboard consisted of one of the four letter shapes seen in Figure 3 placed in any location on the grid. All possible gameboards were generated, resulting in 56 gameboards for each letter, or 112 for each game combination (L/D or C/U). For L/D games, 15 gameboards were randomly selected from the pool of L and D gameboards. This was repeated for C/U games. The resulting total of 30 unique games were used for all participants. The order of games played was randomized for each person.

**Procedure** Many aspects of the design were identical to Experiment 1 (described in Gureckis and Markant, 2009), so we highlight differences below. In Experiment 2 we sought to reduce any reliance on the visual display for recalling the specific shapes being used. Participants began the experiment with two training phases to memorize the four shapes. In the first, a letter cue (e.g., the character ‘L’ in a standard computer font) was presented at the top of the screen along with its corresponding shape, which appeared inside a 4x3 grid. The participant was asked to copy the same shape onto an empty 4x3 grid below. This was done twice for each letter (L, D, C, U) in randomized order. In the second training phase, they were presented only with the letter cue and an empty 4x3 grid, and asked to fill in the correct letter shape from memory. This was repeated three times for each letter in random order. In order to progress from one training trial to the next, the participant was required to successfully reproduce the correct shape. Training was followed by on-screen instructions which were modified to reflect the new hypothesis spaces.

Before the sampling phase began, a 2-second cue was displayed on the screen that indicated the type of game about to be played (the characters “L D” or “C U”). This cue was also displayed on the right side of the display during the game. This ensured that participants were aware of the shapes that were possible but that they had to use their memory of the actual shapes to guide their observations.

Sampling and painting phases proceeded in the same way as Experiment 1. The final score was then displayed, including how many points were the result of sampling and how many were the result of painting errors. The lowest score obtained by the participant in any game so far was shown to provide motivation and a means to evaluate their performance over time. Each participant played 30 games at their own pace, resulting in a total of 480 games collected.

## Results

**Sample rank** On each sampling trial, the ideal models were used to compute the expected information gain and expected savings for all remaining observations available. A participant’s decisions were ranked according to EIG and ES (if multiple observations had the same value, the median rank was used). The relative frequency of each sample rank was computed for each participant across all trials, and averaged across participants (see Figure 2B). The rank frequency shows that participants’ choices were more highly ranked on average according to EIG than ES. Participants’ samples were ranked within the top 5 observations according to EIG on approximately 57% of trials, whereas according to ES only 35% of samples fell in the same range.

Figure 3: **A:** Illustration of the divergence between information gain and expected savings. **Left:** A hypothesis space is comprised of three possible rectangles,  $h_1$ ,  $h_2$ , and  $h_3$ . **Middle:** A hit on any one rectangle leads to the same number of hypotheses being ruled out, and no uncertainty about the label of any square in the grid. **Right:** A miss in any of the three locations rules out a single hypothesis, but the *predictive utility* of the sample differs based on its location. The labels for 8 squares are uncertain following a miss that rules out rectangle  $h_1$ , 6 squares following a miss ruling out  $h_2$ , and 4 squares following a miss ruling out  $h_3$ . **B:** Gameboard design and example model predictions in Experiment 2. Two types of games were possible: L/D games, where the hidden shape could be an L or D, and C/U games, where the hidden shape could be a C or U. Predicted value distributions for EIG and ES are shown for the first sampling trial in each kind of game, with a darker value indicating a higher value according to the model.

**Model fits** We next computed the likelihood of participants' decisions under the two alternative models. For each trial, the value of available observations was transformed into choice probabilities using the softmax function:

$$P(o_{ij}) = \frac{e^{\beta \cdot V(o_{ij})}}{\sum_{x,y} e^{\beta \cdot V(o_{xy})}} \quad (6)$$

The parameter  $\beta$  was fit on an individual basis for each model by maximizing the log-likelihood summed across all observations made by a participant. In all cases, EIG provided a better fit to participants' data than ES (Table 1).

**Stopping decisions** Our final analysis focused on participant's decisions to stop sampling. While EIG and ES make the same prediction as to when sampling should stop<sup>3</sup>, we were interested in whether people showed any sensitivity to the cost of collecting information. If people uncovered more squares than necessary it would suggest a failure to account for the cost of new observations (either in terms of ES or EIG). We classified each game according to whether the person decided to stop sampling before the trial predicted by the model ("early"), on the same trial ("optimal"), or after that trial ("late"). On average, participants ended sampling early ( $M = 0.46$ ,  $SD = 0.14$ ) or on the optimal trial ( $M = 0.50$ ,  $SD = 0.14$ ) on a similar proportion of games. In contrast, participants oversampled very rarely ( $M = 0.04$ ,  $SD = 0.01$ ).

<sup>3</sup>This convergence was due to the cost structure we used, in which the penalty for stopping before the hidden target was known was greater than the cost of an additional sample. Increasing the cost of sampling relative to the cost of errors would lead to ES predicting earlier stopping decisions than EIG.

## Discussion

The results of our second experiment show that people performed well compared to the ideal searcher model, frequently choosing highly ranked observations and consistently performing better than expected by a random search strategy. In addition, participants rarely gathered more information than necessary, which is consistent with prior work showing that people are sensitive to costs incurred by oversampling (Fu & Gray, 2006). Most importantly, we found that participants' sampling choices were better described by information gain than a cost-sensitive utility measure (expected savings).

Prior studies of human information collection have focused to a large extent on "disinterested" accounts of sampling decisions, showing that people are sensitive to the amount of information conveyed by different sources of information (Nelson, McKenzie, Cottrell, & Sejnowski, 2010). However, this line of work has often failed to consider whether people account for variations in task-specific utility when making sampling decisions. In our task, we introduced penalties for information access and uncertainty that altered the optimal sampling strategy. By manipulating the set of hypotheses in Exp. 2, we showed how sampling based on an information-maximizing strategy can be distinguished from cost-sensitive sampling. With respect to the distinction we began this paper with, our results suggest that people (at least in this task) prefer to gather information according to a "disinterested" measure of value.

Notably, differences in value between choices were not directly observable by the participant (as opposed to when some observations are more costly or difficult to make than others). Whether a given observation was valued differently according to EIG and ES depended upon the set of hypotheses remaining, and this divergence could change from trial to trial in response to new data. As a result, establishing which model pro-

vided a better account required fitting them to participants' decisions across a variety of choice contexts. This highlights a feature of our approach in that we could evaluate different sampling strategies using a set of highly variable choice sequences. Through the use of a well-defined hypothesis set and explicit cost structure, the "shape-search" task provides a useful framework for studying how information search decisions and task demands interact over the course of learning.

Of course, one potential caveat of the current study is that (due to computational demands) we evaluated a greedy decision policy such that the predicted value of a new observation does not take into account the consequence or utility of subsequent actions. It is possible that fully accounting for sequential dependencies in the search problem may alter the optimal utilities computed by the model. However, one might reasonably question if the computational demands of such a multi-step planning process are within reach of human reasoners. In addition, it is unclear that accounting for multi-step planning strategies would alter the choice utilities in a way that would bias for or against the results we report. Also note that comparing Exp. 1 and 2 illustrates that expected saving is not always at an advantage (i.e., in some choice environments the models become less distinguishable).

## Conclusion

So, why might human reasoners preferentially adopt "disinterested" sampling over "interested" sampling? One possibility is that sampling based on information gain (or other "disinterested" norms) may reflect a general purpose strategy that is useful in a variety of contexts. In particular, information gain can still be computed even when the cost of uncertainty (i.e., not knowing which hypothesis is true at the end of sampling) is difficult to predict. In addition, in many natural environments it may be consistent with the predictions of a cost-sensitive utility function, as illustrated by our first experiment. At the very least, our results highlight the need to understand the kinds of problems that lead people to adapt to task-specific costs in lieu of a general-purpose, "disinterested" approach to information search.

# One piece at a time: Learning complex rules through self-directed sampling

## Abstract

Self-directed information sampling—the ability to collect information that one expects to be useful—has been shown to improve the efficiency of concept acquisition for both human and machine learners. However, little is known about how people decide which information is worth learning about. In this study, we examine self-directed learning in a relatively complex rule learning task that gave participants the ability to “design and test” stimuli they wanted to learn about. On a subset of trials we recorded participants’ uncertainty about how to classify the item they had just designed. Analyses of these uncertainty judgments show that people prefer gathering information about items that help refine one rule at a time (i.e., those that fall close to a pairwise category “margin”) rather than items that have the highest overall uncertainty across all relevant hypotheses or rules. Our results give new insight into how people gather information to test currently entertained hypotheses in complex problem solving tasks.

**Keywords:** self-directed learning, categorization, active learning, information search, rule learning

## Introduction

A cornerstone of many educational philosophies is that people learn more effectively when they direct or control their own learning experiences (Bruner, 1961). While there are many ways that control might influence learning, an important factor is the ability to actively gather information that one considers potentially useful while avoiding data that is potentially redundant, a behavior referred to as *self-directed sampling* (Gureckis & Markant, in revision).

One recent study directly examined the interaction of self-directed information sampling and learning (Markant & Gureckis, 2010, in revision). In this study, people attempted to learn simple dichotomous categories of objects that varied along two perceptual dimensions (circles that differed in size and the orientation of a central line segment, see Figure 1). In contrast to traditional categorization training procedures, we allowed participants to “design” stimuli that they wanted to learn more about on each trial. Like a child asking their parent to label an unfamiliar object, self-directed “designing” or “sampling” allows the learner to focus on information they want rather than be limited by the flow of passive experience.

The major finding from this study was that for simple unidimensional rules, self-directed learners acquired the correct category rule faster than “passive” participants who were provided samples from an experimenter-defined distribution. In addition, self-directed learners out-performed a set of “yoked” learners who viewed the same examples but did not get to make information sampling decisions themselves (consistent with studies of causal learning with similar yoked comparisons, Lagnado and Sloman, 2004; Sobel and Kushnir, 2006).

## How do people make information sampling decisions?

In light of evidence that self-directed sampling can speed learning, it is important to understand *how* people decide what data to collect. Given a potential observation, what information do people rely on to decide if it will be useful?

One aspect that may help explain a person’s decision to sample an item is their uncertainty in how to classify it (or more generally, their uncertainty about the outcome of any test performed on the item). Intuitively, a self-directed learner should direct their attention to items that are high in uncertainty while ignoring items that can already be confidently classified or predicted. Consistent with this strategy, the pattern of stimuli sampled by self-directed learners in our previous study (see Figure 1) revealed that participants systematically directed their samples toward the category boundary as the task progressed. Intuitively, the learner is mostly likely to be uncertain about these items (e.g., most of the errors in classification occur near the category boundary).

In the current study, we examine how subjective uncertainty in how to classify an item can be used to predict whether or not it is sampled. We begin by presenting three psychologically motivated proposals for how sampling decisions relate to judgments of uncertainty, and then test these models in a new experiment that extends the “self-directed” classification learning paradigm used in Markant and Gureckis (2010). Our results highlight the need for models of sampling behavior that go beyond monolithic measures of information value to consider how people collect and use data during the sequential learning of concepts.

## Three models for relating uncertainty and information sampling decisions

The following sections lay out three possible ways in which uncertainty might guide information sampling decisions.

### Model 1: Sampling to reduce global uncertainty

Prior work on how people gather information has often focused on diagnostic reasoning problems in which the learner is given a set of alternatives (e.g., different diseases) and asked to sample observable features (e.g., symptoms) in order to identify the true diagnosis (Nelson, McKenzie, Cottrell, & Sejnowski, 2010; Skov & Sherman, 1986; Trope & Bassok, 1982). From a computational perspective, various authors have proposed *sampling norms* that attempt to predict information sampling decisions based on a learner’s representation of the task (Nelson, 2005; Nelson et al., 2010; Oaksford & Chater,

Figure 1: A: Abstract stimulus space used in Markant and Gureckis (2010, in review) and which is adapted for the current study. Stimuli were circles which varied in size and orientation of a central diagonal. In Markant and Gureckis, these objects were assigned to one of two categories (“A” or “B”). Participants “designed” a stimulus they wanted to learn about using the mouse. Clicking the mouse button reveals the category membership of the item. B: The pattern of sampling behavior observed by self-directed learners in Markant and Gureckis (2010) across eight training blocks. Each dot represents a single stimulus which was selected by a participant. In the first block, participants distributed their samples widely over the entire stimulus space but then gradually focused their choices on the region surrounding the category boundary.

1994). Much of this work has focused on what we will call “prospective” models (e.g., *probability gain*, *information gain*, etc.) that estimate the expected drop in uncertainty that will result from making an observation (taking into account all possible outcomes). While in many contexts these models make similar predictions, Nelson et al. (2010) designed a diagnostic reasoning task which found that participants’ choices were best fit by *probability gain*, which values a potential observation according to how much it increases the chance of classifying an item correctly.

In the context of learning a classification rule, this approach is consistent with a preference for sampling items that the learner is least certain about how to classify. Assume that for a given stimulus  $x = (f_1 \dots f_d)$  with  $d$  observable features the learner represents the probability that  $x$  is a member of each possible category  $y$  in the distribution  $P(y|x)$ . We can then define the *least certain* measure as:

$$LC(x) = 1 - \max(P(y|x)) \quad (1)$$

for all stimuli  $x$ . Note that there are alternative norms that make similar predictions to *least certain*, such as using the Shannon entropy of the marginal distribution to calculate uncertainty (see Settles, 2009 for a review). Regardless of the particular form, the important property of this approach is that the most valuable observation is always an item that is considered equally likely to belong to all possible categories. In general, choosing items which maximize  $LC(x)$  should convey the greatest amount of information to the learner.

### Model 2: Isolating individual rule components through margin sampling

While focusing on items that are the most “globally” uncertain or unpredictable seems intuitively useful, there is reason to expect that it may not be the sampling strategy humans use, particularly when learning in complex, multivariate environments. One natural strategy, not captured by *least cer-*

*tain*, might be to decompose a complex task into a series of simpler problems. For example, when multiple features may be related to an outcome, a learner might choose to hold one feature constant while varying the other across multiple samples (Rottman & Keil, 2012). Such a strategy is related to the “control of variables” strategy which is essential to scientific reasoning. Isolating variables often helps people to more efficiently search the space of potential hypotheses (Klahr & Dunbar, 1988) and is a key part of “learning to learn” about complex concepts (Kuhn & Dean, 2005). In an experiment similar to that of Markant and Gureckis (2010), Avrahami et al. (1997) had participants choose samples to teach a partner about a single-dimensional rule and found that the “teachers” frequently used a strategy of isolating individual features. Moreover, their students learned better from this strategy than when given items that were closest to the category boundary.

We can formalize the strategy of focusing on separate components in a sampling model that values uncertainty about any individual boundary between only two categories. *Label margin* predicts that the learner will prefer instances for which the likelihood of any two categories is similar, independent of any other categories. For example, when there are three categories and the marginal distribution is defined as  $P(y|x) = (p_1, p_2, p_3)$ :

$$LM(x) = 1 - \min[|p_1 - p_2|, |p_1 - p_3|, |p_2 - p_3|] \quad (2)$$

Critically, label margin does *not* preferentially select items for which the learner is globally uncertain. Instead, by this approach, a learning problem is decomposed into simpler problems and items are selected which are expected to resolve uncertainty about the sub-components.

### Model 3: Seeking confirmation

While the previous two models propose that people search for uncertain items, previous work on hypothesis testing suggests that people may prefer items that they already know how to

Figure 2: Comparing predictions of sampling norms (red = more highly valued choices, blue = less valued choices) **Top:** For a binary classification problem, a new observation in stimulus space will correspond to a location on the probability judgment scale, where the leftmost point reflects confidence that the observation will be classified “A” and the rightmost point reflects confidence it will be classified “B”. For the binary problem, the predictions of *least certain* and *label margin* are identical. **Bottom:** In a ternary classification problem, an item in stimulus space will correspond to a location in the 3-category simplex depending on the learner’s uncertainty. Here the predictions of *least certain* and *label margin* diverge, allowing us to test which of the two models better account for sampling behavior.

classify. For example, people have a well-documented bias toward seeking positive evidence of the hypothesis they are considering (Klayman & Ha, 1989; Wason, 1960), a strategy that in certain conditions is aligned with the goals of maximizing uncertainty reduction (Austerweil & Griffiths, 2011; Navarro & Perfors, 2011; Nelson & Movellan, 2001). To quantify this strategy, we define the *most certain* measure as:

$$MC(x) = \max(P(y|x)) \quad (3)$$

The predictions of this model directly contrast those of *least certain*, with the highest value assigned to items that can already be classified with confidence. One may also think of the *most certain* measure as instantiating confirmation bias—it shows a preference for items for which the learner has a strong prediction about the category label.

### Empirically distinguishing these alternatives

Given these various approaches, a key question is if they are distinguishable based on empirical data. The predictions of each model are shown for a binary classification problem (like the task used in Markant and Gureckis, 2010) in the top row of Figure 2. Each heatmap describes the value assigned to a potential observation depending on the learner’s uncertainty in how to classify it. For example, an item that can be confidently classified (e.g.,  $p(y|x) = (1, 0)$ ) would be assigned a high value by *most certain* and a low value by *least certain*. Note that for the binary classification problem, *least certain* and *label margin* make identical predictions about how items will be valued (i.e., items close to the center of the space are preferred), making it impossible to separately test these models. However, an interesting observation made by Settles (2009) is that the predictions of these models strongly diverge when considering more complex categorization tasks. For example, in a ternary classification task (see bottom row of Figure 2), *label margin* assigns the maximum value to any items for which one

category is highly unlikely but the learner is uncertain about the other two (shown in Figure 2 by the high predicted value along the radial axes of the simplex, including the midpoints of each edge). In short, this model predicts that samples are likely to be allocated close to any boundary (i.e., “margin”) between two categories. In contrast, *least certain* predicts sampling close to the *junction* of the category boundaries, where all three classes are likely.

### Overview of the current study

The design of our experiment capitalizes on the distinction described in the previous section by extending the paradigm used in Markant and Gureckis (2010) to a ternary classification problem. In the experiment participants collect data by sampling new instances and receiving feedback about their category membership. As shown above, using the ternary classification problem allows us to separate the predictions of the three sampling models, two of which were confounded in our previous design. In order to obtain an estimate of the learner’s uncertainty at any point in time, on a subset of sampling trials participants report how likely they believe the instance they created will belong to each of the three categories (before receiving feedback). The goal of our analysis is to use these subjective judgments to test which model provides the best account of their sampling decisions.

## Experiment

**Participants** Fifty-seven undergraduates at New York University participated in the study for course credit. The experiment was run on standard Macintosh computers in a single 1-hour session.

**Stimuli** Stimuli were defined by a two-dimensional continuous-valued feature space corresponding to the size (radius) of a circle and the angle of a central diameter. These feature values were mapped to a limited range of orientations and sizes on the display. Orientation could vary over only 150 degrees, ensuring that a full rotation of the stimulus was not possible. The two halves of the central diameter were given different colors, further reducing the perceptual similarity of stimuli at the two extremes of the orientation dimension.

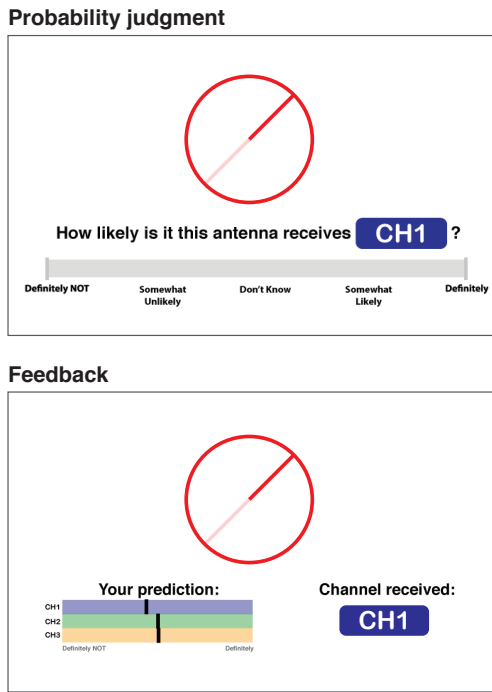

Figure 3: **Top:** Probability judgments were entered by clicking on a scale for each of the three categories (CH1, CH2, and CH3). **Bottom:** Probability judgments were displayed alongside the category label during feedback.

The minimum radius and orientation were randomized so that the boundary between the categories corresponded to a unique boundary in perceptual space for each participant. A total of 256 stimuli were sampled from a uniform grid over the feature space and used as test items for all participants, presented in random order.

The category label associated with each stimulus was deterministically defined by a conjunctive, ternary classification rule of the form shown in Figure 2. In addition to the structure that is shown, three more rules were created through different rotations (90, 180, and 270 degrees) of the same boundaries in stimulus space. Each participant was randomly assigned to one of the four rules.

**Procedure** Participants were instructed that the stimuli in the experiment were television “loop antennas” and that each unique antenna received one of three channels (CH1, CH2, or CH3). Their goal was to learn the difference between the three types of antennas so that they could correctly classify new antennas during the test blocks. Participants were told that the experiment would end when they correctly classified 20 consecutive test items. If a participant failed to reach that goal the experiment ended after 32 blocks or at the end of an hour (whichever occurred first).

**Training Trials.** Participants “designed” antennas by adjusting the size and orientation and receiving feedback about which channel was received. They were instructed that they should design antennas they thought were useful and that would help them to predict the TV channel for other designs they had not yet tested.

Each trial began with the presentation of a randomly generated antenna. Participants then adjusted the size and orientation by moving the mouse from left to right while holding either the ‘Z’ or ‘X’ key, respectively. Only one dimension could be changed at a time, but participants could make any number of changes and were self-paced. When the stimulus was the desired size and orientation, they pressed the mouse button to reveal the channel received, displayed above the stimulus for 4 seconds.

**Probability judgments.** Half of the training trials in each block were randomly selected to include probability judgments. On these trials, after participants had designed an antenna but before the category label was shown, they judged the likelihood that the antenna would receive each of the three channels using a sequence of rating scales (shown in Figure 3). The three scales were presented independently such that only one was visible at a time. When each scale appeared, the participant clicked on a location in the scale according to their belief that the antenna they had designed would receive that channel. A response was required for each scale, and there was no time limit for entering the response. The initial position of the mouse cursor within each scale was randomized, allowing us to record whether responses were influenced by the starting position. After probability judgments were recorded, they were displayed alongside the category label for the same duration as in regular training trials. This allowed the participant to evaluate the accuracy of their prediction given the true category label.

**Test Trials.** Each block of 6 training trials was followed by 8 test trials. On each test trial, a single item was presented in the center of the display and the participant classified the item according to the channel they believed it was most likely to receive. A response was required to complete the trial, and participants responded at their own pace. No feedback was provided on individual test trials. At the end of each block participants were told their accuracy during the block they just completed, as well as the number of consecutive correct responses.

## Results

Three participants were excluded from analysis for failing to complete the task, leaving  $N = 54$ . Thirty-one people reached the goal of correctly classifying 20 items in a row. However, there were a number of additional people who achieved similarly high rates of accuracy. For each subject we computed a moving average of their classification accuracy with a window of 3 blocks, and found 43 people for whom this average exceeded 83% at any point in the experiment (i.e., they correctly classified 20 of 24 items within any three consecutive blocks).

**Probability judgments.** On half of participants’ sampling trials they judged how likely the stimulus they selected belonged to each of the three categories, resulting in three values between 0 and 1. In order to verify that participants were not simply responding based on the position of the cursor, for each rating we measured the difference between the initial (random) position and the participant’s response. One participant was excluded from further analysis because the majority of their ratings (82%) did not change by more than 0.01% from the initial values (for the remaining subjects, the average proportion of samples that met the same condition was  $M = 0.04$ ,  $SD = 0.05$ ).

**Fitting the alternative sampling models.** Our first goal was to assess the overall fit of the three sampling models to each participant’s full set of probability judgments. For each model we computed the normalizing constant necessary to define the probability density function. Each triplet of ratings was normalized so that they summed to one. We then calculated the log-likelihood of each judgment made by a participant and summed across all trials to get an overall score for each model.

Classifying participants according to the model with the highest log-likelihood, we found that 3 people were best-fit by *least certain*, 25 people were best-fit by *label margin*, and the

Figure 4: A: Probability judgments are plotted using the 3-category simplex for participants best-fit by each of the three models (see Figure 2 for reference). Each point represents a single judgment after normalization. B: Each judgment was classified according to the model assigning it the highest likelihood, effectively dividing the probability space into three regions. Participants were divided into two groups based on the number blocks they required to complete the task (“fast” and “slow”), and the relative frequency of sampling in each region is shown at right.

remaining 25 people were best-fit by *most certain*. Judgments made by participants, separated by the best-fitting model, are plotted using the 3-category simplex in Figure 4A, with each point a single sample chosen by a participant. A higher density of points reflects an increased tendency (as a group) to sample stimuli in a given region of probability space. Upon visual inspection, the overall pattern for each group corresponds to the predictions of the best-fitting model (Figure 2).

**Relating sampling decisions to learning efficiency.** We next tested whether a participant’s overall success at learning the target concept was related to the sampling behavior reflected in their probability judgments. Our approach was to divide participants into two groups based on the number of blocks they required to complete the task. We performed a median split on the number of blocks (median = 16) to create a group of “fast” ( $N = 26$ ) and “slow” ( $N = 27$ ) learners. With respect to overall model fits, however, there was no difference in the proportion of participants best fit by each model between groups (fast learners:  $N_{LC} = 1$ ,  $N_{LM} = 12$ ,  $N_{MC} = 13$ ; slow learners:  $N_{LC} = 2$ ,  $N_{LM} = 13$ ,  $N_{MC} = 12$ ).

While overall model fits provide a measure of each participant’s sampling behavior in general, inspection of the data showed that most subjects had relatively mixed strategies. For example, a participant best-fit by *most certain* may have made a number of judgments consistent with *label margin*. Given this heterogeneity, we classified individual probability judgments according to the model that assigned it the highest likelihood, effectively dividing the probability space into three regions corresponding to each model (Figure 4B). Multinomial logistic regression was used to test for differences between the relative frequency with which fast and slow learners sampled in each of the three regions. Overall frequency differed significantly between the two groups ( $\chi^2 = 24.7$ ,  $df = 2$ ,  $p < .001$ ). Post-hoc tests showed that fast learners sampled somewhat more frequently in the *label margin* region ( $t(51) = 1.68$ ,  $p = .09$ ) and less frequently in the *least certain* region overall ( $t(51) = -1.91$ ,  $p = 0.06$ ), suggesting that this pattern of sampling was related to success in the task.

## Discussion

Theories of rational information acquisition propose that the decision to make an observation is related to the amount of information it conveys (Nelson, 2005; Oaksford & Chater, 1994). Sampling norms such as *probability gain* prospectively evaluate the change in uncertainty that is expected to occur following an observation, and a rational learner should choose the data that maximizes that measure. Our results illustrate the relative inadequacy of these models when applied to even a basic rule learning task. Very few of our participants were best fit assuming they preferentially selected observations they were least certain about. In addition, the heterogeneity of participants’ sampling strategies is a noteworthy finding. For example, about 20% of samples in the first 4 blocks were “confirmatory” (i.e., data that the learner could already classify with relative confidence), and overall there was no difference in the frequency of this kind of sampling between fast and slow learners. Confirmatory sampling could serve a number of purposes, including helping to organize the representation of a rule in mind (Mathy & Feldman, 2009) or to facilitate comparisons between successive observations, but further work is required to understand its exact role in this task.

**Margin sampling vs. information maximization** A second way in which participants’ behavior diverged from the “rational” prediction was their preference for samples that fell along the category margins over items that offered information about all three categories (i.e., those located at the junction of the boundaries). From the perspective of an ideal observer (i.e., a model that can represent the full set of possible hypotheses and use Bayesian inference to update its beliefs), the most efficient strategy is to maximize the amount of information contained in each observation. Sampling at the category margins should only decrease the efficiency of learning since it will tend to rule out a smaller number of hypotheses, which raises the question of why this kind of behavior was so common in our task.

In our discussion we motivated the margin sampling model by noting that people might decompose a complex prob-

lem into simpler pieces. The use of such a strategy may reflect a participant's limited ability to simultaneously represent all possible alternatives and to remember prior observations. Thus, margin sampling may reflect an adaptation whereby people isolate individual components to learn in succession. Separately testing the role of different features is an important part of scientific thinking in general (Klahr & Dunbar, 1988; Kuhn & Dean, 2005), particularly when intervention is necessary to remove the effect of confounding variables. Importantly, our results do not reveal the particular cognitive processes underlying participants' decisions, but merely provide a descriptive account of their overall behavior. Nonetheless, they provide a useful constraint for theories of information sampling, particularly when applied to more complex tasks that involve sequential learning and memory demands.

**Measuring subjective uncertainty.** It is important to consider that the probability judgments we collected provide an incomplete picture of participants' uncertainty over the course of the task. Although we found some evidence that fast and slow learners differed in the kinds of samples they collected, because uncertainty judgments were assessed on only half of sampling trials it is difficult to draw strong conclusions about the impact of those samples on classification accuracy. Moreover, we cannot be sure that the judgments reported by participants accurately reflected their subjective belief since there were no costs for failing to report accurately<sup>1</sup>. These issues arise whenever considering sampling models based on a learner's subjective uncertainty rather than objective measures of value such as *information gain*, and as such present an important challenge to be addressed in future work.

## Conclusion

Past accounts of information sampling have suggested that a single normative model might account for people's decisions across many learning problems, and that people tend to seek out data that lead to the greatest reduction in uncertainty. In contrast, we found little evidence of a single sampling norm that was consistently applied across individuals. Instead, participants' sampling choices seem to reflect ongoing aspects of constructive problem solving. Our approach highlights the need for theories of self-directed learning to move beyond individual measures of information value to capture interactions with task demands and cognitive constraints.

<sup>1</sup>Two aspects of our procedure may lessen the impact of this concern. First, we were able to measure a failure to respond by randomly initializing the cursor position before each rating, and found that people changed the position in about 95% of ratings. Second, because judgments were displayed alongside the category label feedback, participants may have been encouraged to respond accurately in order to facilitate processing of that feedback

any copyright annotation thereon. The views and conclusions contained herein are those of the authors and should not be interpreted as necessarily representing the official policies or endorsements, either expressed or implied, of IARPA, DOI, or the U.S. Government.

## Abstract

SimStudent is a computational model of learning with its cognitive fidelity of learning being demonstrated especially in the way it makes human-like errors. Using SimStudent as a teachable agent in an interactive peer-learning environment, we have investigated how tutee (i.e., SimStudent) learning affected tutor (i.e., human student) learning. In this paper, we are particularly interested in how tutees' shallow learning affects tutor learning. We are also interested in how the errors that the tutee makes affect tutor learning. The results show that teaching SimStudent on a fixed set of problems makes students easy to tutor SimStudent, which in turn helps students learn, but is likely to allow SimStudent to commit shallow learning, which is harmful for tutor learning. It is thus crucial to let the student detect SimStudent's shallow learning and extend teaching until SimStudent and the student achieve satisfactory competence.

**Keywords:** Learning by teaching; teachable agent; SimStudent; shallow learning; learning from errors.

## Introduction

Studying the effect of learning by teaching through the use of teachable-agent technology is a rapidly growing research field. There have been a number of teachable agents used in empirical classroom studies, for example, Betty's Brain (Biswas, Leelawong, Schwartz, Vye, & Vanderbilt, 2005) and TAAG (Pareto, Arvemo, Dahl, Haake, & Gulz, 2011).

Researchers have explored different aspects of the effect of tutor learning, including learning meta-cognitive skills for self-regulated learning (Biswas, Jeong, Kinnebrew, Sulcer, & Roscoe, 2010), the protégé effect (Chase, Chin, Oppizzo, & Schwartz, 2009), the adaptive assistance (Walker, Rummel, & Koedinger, 2009), and the effect of self-explanation (Matsuda, Keiser, et al., 2012).

The teachable agent we have developed is called SimStudent. SimStudent is a machine-learning agent that learns procedural problem-solving skills from examples (Matsuda, Cohen, Sewall, Lacerda, & Koedinger, 2008). SimStudent can be interactively tutored (aka, learning from tutored problem-solving), and has been integrated into an on-line,

game-like learning environment, called APLUS (Artificial Peer Learning environment Using SimStudent). The current version of APLUS allows students to learn Algebra equations by teaching SimStudent. Using APLUS, we have conducted a number of classroom studies to advance cognitive and social theories of tutor learning (Matsuda, Keiser, et al., 2012; Matsuda et al., 2011).

The goal of this paper is to investigate the relationship between tutee- and tutor-learning. As previous empirical studies show (e.g., Cohen, 1994), peer tutoring is known to be beneficial both for tutors and tutees. We thus hypothesize that there must be a strong correlation between SimStudent's and human students' learning. We are particularly interested in how a tutee's shallow learning affects tutor learning. When tutoring, the tutor might fail to detect the tutee's shallow learning by observing the tutee's satisfactory performance at the surface level without actually probing for underlying deep understanding of the domain knowledge. However, if there is actually a symbiotic relationship between tutee and tutor learning, then the tutee's shallow learning should be detrimental to tutor learning.

We are also interested in studying how tutee errors help not only tutee but also tutor learning. In a previous experiment, we studied a theoretical account of the impact of corrective feedback on SimStudent's learning (Matsuda, et al., 2008). We found that committing errors and receiving explicit corrective feedback facilitates tutee learning. On the other hand, it is also known that (human) students learn by explaining erroneous worked-out examples (Grosse & Renkl, 2006; Siegler, 2002). Therefore, tutee errors would also help tutors learn when tutors explain errors committed by tutees. The cognitive fidelity of SimStudent has been demonstrated especially in the way it makes human-like induction errors to learn incorrect skills and hence makes human-like errors when solving problems (Matsuda, Lee, Cohen, & Koedinger, 2009). Therefore, using SimStudent to understand how tutee errors affect tutor learning would be a valid research methodology.

To test the above hypotheses, we conducted a secondary data analysis using the data we collected from our previous classroom studies in which we tested the effect of APLUS.

In the remaining sections, we will first briefly introduce an overview of SimStudent and APLUS in enough detail to understand the research questions and hypotheses. We then describe the data we analyze and the classroom studies from which the data were collected. Finally, we show results followed by a discussion.

## Learning by Teaching SimStudent

### SimStudent

SimStudent is a machine-learning agent that learns procedural skills from examples. When serving as a teachable agent, SimStudent commits to guided problem solving. That is, SimStudent attempts to solve problems given by the student, suggesting one step at a time by applying a learned production. SimStudent asks the student about the correctness of the suggestions. If the student provides negative feedback, SimStudent may attempt to provide an alternative suggestion. When SimStudent has no suggestion that receives positive feedback from the student, then it asks the human student to demonstrate the step as a hint.

The student's feedback and hints become examples that SimStudent generalizes using domain specific background knowledge. As a result, SimStudent generates hypotheses about how to solve problems in the form of *production rules*. SimStudent uses a hybrid learning algorithm that involves (1) inductive logic programming to learn when to apply a production rule, (2) a version space to learn upon what to focus attention, and (3) an iterative-deepening depth-first search to learn how to change the problem state.

SimStudent occasionally prompts students to explain their tutoring actions by asking "why" questions. Such questions include (1) the reason for selecting a particular problem to solve, (2) the reason for an incorrect suggestion, and (3) the reason for the student's demonstration.

### APLUS

APLUS has a Tutoring Interface on which the student and SimStudent collaboratively solve problems. To pose a problem, the student enters an equation into the first row of the Tutoring Interface. As SimStudent makes suggestions for each step, they are placed into the Tutoring Interface. When SimStudent requires a hint, the student demonstrates the next correct step in the Tutoring Interface.

In the regular version of APLUS, the goal of the student is to tutor SimStudent well enough to pass the Quiz. At any time while tutoring, the student may click on the [Quiz] button. SimStudent's productions learned thus far are applied to a set of Quiz problems, and the summary of the results appears in a separate window showing the correctness of the steps suggested by SimStudent. See (Matsuda, et al., 2011) for more details about APLUS.

There have been two versions of APLUS implemented so far, and each version was used in different classroom studies

(see Section "Classroom Studies" for details about the classroom studies). The two versions differ in the structure of the Quiz. In the earlier version, the Quiz problems were fixed. SimStudent took the exact same set of Quiz problems each time it was quizzed. In the later version, the Quiz problems were randomly generated based on a fixed problem *type*. That is, the coefficients and constants were randomly generated each time SimStudent was quizzed.

### How does SimStudent commit Shallow Learning?

In APLUS, one potential pit-fall that may induce SimStudent's shallow learning is the usage and structure of the Quiz. In the earlier study (called the Self-Explanation Study), since the problems in the Quiz were fixed, students could have focused on tutoring only those fixed problems. SimStudent's learning might have been "shallow," or overly specific to solve only those problems, which could have also led human students to "shallow" learning.

On the other hand, the problems in the Quiz for the later study (called the Game Show Study) were randomly generated each time SimStudent took a Quiz (although, they are always in the fixed *type*). Therefore, if SimStudent passes the Quiz in Game Show study, it is likely that SimStudent has learned a high quality set of productions – i.e., "deep" learning. In fact, there were 19 SimStudents that passed the Quiz in the Self-Explanation study, but no SimStudents passed the Quiz in the Game Show study.

An example would help to understand SimStudent's shallow learning. In one instance, SimStudent in the Self-Explanation Study learned to divide both sides of the equation in the form of  $Ax=B$ , where  $x$  is a variable,  $A$  is a coefficient, and  $B$  is a constant term. The production for division says "divide both sides by a chunk of digits before the variable." The "chunk of digits" by definition only perceives a number before the variable without a sign. This piece of background knowledge was designed to model human student's common induction errors (Matsuda, et al., 2009).

As a consequence, this SimStudent could solve equations  $Ax=B$  only when the coefficient  $A$  is a positive number. In the fixed set of the Quiz, this SimStudent learned to solve the equations in such a way that it always happened to have a positive coefficient on the last step, i.e.,  $Ax=B$  (or  $A=Bx$ ). However, even when the same productions were applied, the randomized Quiz problems sometimes produced negative coefficients when combining like terms or balancing the equation. Because of such an accidental transformation, this SimStudent was not able to pass the randomized quiz.

### Research Questions and Hypotheses

This paper addresses the following three research questions and hypotheses.

Q1: *How do tutee and tutor learning relate?* We first hypothesize that SimStudent's learning and human students' learning are correlated. To test this hypothesis, we quantify SimStudent's learning as the "quality" of productions learned by SimStudent. Human students' learning will be quantified using test scores.

Q2: *Is a tutee's shallow learning detrimental to tutor learning?* We hypothesize that letting SimStudents do shallow learning is harmful for tutor learning. To test this hypothesis, we will validate the production rules of SimStudents who passed the fixed Quiz to see if they can also pass the randomly generated Quiz. We will then examine if students who allowed their SimStudents to commit to shallow learning showed poor learning.

Q3: *How do tutee errors influence tutor learning?* We hypothesize that the effect of learning from erroneous examples would apply for tutor learning, that is, detecting SimStudent's errors correctly and explaining those errors would facilitate tutor learning.

## Method

### Sample

The analysis was done on the data we previously collected from two classroom “*in-vivo*” studies; the Self-Explanation Study (Matsuda, Keiser, et al., 2012) and the Game Show Study (Matsuda, Yarzebinski, et al., 2012). Both sets of data are available (upon request) on the large-scale educational database, DataShop (Koedinger et al., 2010), maintained by Pittsburgh Science of Learning Center.

The data include the outcome data and process data. The outcome data are test scores. Students took pre- and post-tests before and after tutoring SimStudent. The test consists of (1) ten equation-solving items, (2) twelve items to determine if a given operation is a logical next step for a given equation, and (3) five items to identify the incorrect step in a given incorrect solution. The pre- and post-tests are isomorphic.

The process data shows the interaction between individual students and SimStudent. It contains (among other things) problems tutored, feedback provided by the students (and their correctness), steps performed both by students and SimStudent (and their correctness), hints requested by SimStudent, and quiz attempts (and their results).

### Classroom Studies

Two classroom studies were conducted in the same school near Pittsburgh, PA, but for different Algebra I classes. The Self-Explanation (SE) study included 111 students from advanced 8th grade and regular & remedial 9th grade classes. The Game Show (GS) study included 141 students from advanced 7th and regular 8th grade classes.

Both studies were conducted as randomized control trials. There were three intervention days (a single class period per day) when students used APLUS. All students took pre- and post-tests before and after the intervention.

For the current study, only the data from the treatment condition in the SE Study and the control condition in the GS Study were used, because the students in those conditions used the same version of SimStudent and APLUS with the same goal for tutoring (i.e., passing the Quiz). As a result, there were 44 students in each condition who took both pre- and post-test and completed the intervention (meaning,

Figure 1: Scatter plot showing SimStudent's validation scores (X-axis) and students normalized gain (Y-axis).

they either attended all three days of the intervention or passed the Quiz sooner).

### Measures

In the following analysis, human students' learning is measured as the normalized gain of the test score, which is computed as  $(\text{post-test} - \text{pre-test}) / (1 - \text{pre-test})$ .

SimStudent's learning is measured as the accuracy of productions learned to solve equations. The productions were applied to a total of 30 equation problems taken from the actual tests that the human students took.<sup>1</sup> For each step in solving an equation, the correctness of each of the applicable productions (i.e., the conflict set) was judged by using the expert model of the Algebra Cognitive Tutor. The *step score* was then calculated as the ratio of correct production firing to all applicable productions. The step score is zero when there are no applicable productions. The *problem score* was computed by averaging the step scores across all steps. Finally, the *validation score* was computed as the average problem score for the 30 equation problems.

The quality of students' responses to SimStudent's “why” questions was also evaluated by three human coders. The coders categorized the student's responses into “deep” and “shallow” responses.

## Results

### Tutor-tutee Learning Correlation

*How does tutee learning correlate with tutor learning?* To answer this question, we first tested the correlation between SimStudent's learning gain and human students' learning gain.

Figure 1 shows the scatter plot with SimStudent's learning represented by the validation score (X-axis) and the human students' learning as the normalized gain on the test scores (Y-axis). Data points from the Self-Explanation

<sup>1</sup> In the classroom studies, there was also a delayed-test. Thus, the students took three tests each containing 10 equation problems.

Study and the Game Show Study are represented using circles and triangles, respectively.

There is a significant correlation between SimStudent's learning and human students' learning for the Game Show Study;  $r(43)=0.331, p<0.05$ .

The correlation between SimStudent's learning and human student's learning was not significant for the Self-Explanation Study;  $r(43)=0.115, p=0.463$ . This might be partly because of the large variance in the human student's learning;  $M=0.07, SD=0.59$ .

*Was there any difference in SimStudent's and human students' learning between the two studies?* The study (SE vs. GS) is a main effect for the SimStudent's validation score;  $t(86)=10.488, p<0.000$ . SimStudents in the Self Explanation Study learn better than the Game Show; mean validation score  $M_{SE}=0.59 (SD=0.08)$  vs.  $M_{GS}=0.41 (SD=0.08)$ .

There was, however, no study difference in the human students' learning; mean normalized gain,  $M_{SE}=0.07 (SD=0.59)$  vs.  $M_{GS}=0.14 (SD=0.27)$ ;  $t(59)=-0.644, p=0.522$ .

## Depth of Learning

The strong correlation between tutee and tutor learning indicates that when the tutee commits shallow learning (which by definition shows good behavior at the surface level without actual learning gain), then the tutor might not learn well.

As mentioned earlier, one potential pit-fall for SimStudent's shallow learning in the APLUS environment is the structure of the Quiz. The likelihood of shallow learning would become higher when the Quiz problems are fixed. To test if the fixed set of Quiz problems actually induced SimStudent's shallow learning, and, if so, whether SimStudent's shallow learning also induced human students' shallow learning, we analyzed both human students' and SimStudent's shallow learning.

To test SimStudent's shallow learning, we investigated if SimStudents in the SE study who passed the (fixed) Quiz could also pass the (randomly generated) Quiz used in the GS study. There were 19 SimStudents who passed the Quiz in the SE study (SE passing SimStudent). We first extracted productions learned by those 19 SE passing SimStudents from the process data. Ten sets of the GS study Quiz (each with eight problems) were randomly generated. For each SE passing SimStudent, we then applied productions for each problem in the ten sets of the Quiz from the GS study.

Figure 2 shows the results of the SE passing SimStudents taking the GS study Quiz. The table shows the number of SE passing SimStudents that passed at most the specified number of quiz sets (out of 10).

There were 8 SE passing SimStudents who passed one or more sets of GS quiz. Only 7 (37%) SE passing SimStu-

Maximum Num. Quizzed Passed	0	1	10
Num. of SimStudent	11	1	7

Figure 2: Result of the SE SimStudents who passed the SE Quiz (N=19) taking the GS Quiz

dents could pass two or more sets of GS Quiz. Interestingly, if SimStudent could pass two GS Quizzes, it could also pass all ten sets of GS Quizzes. To our surprise, 63% of SimStudents in the SE study passed the SE Quiz by committing "shallow" learning that was enough to pass the fixed set of Quiz problems.

*Was SE SimStudent's shallow learning detrimental for human students learning?* To see if human students actually committed shallow learning by quitting the tutoring session after seeing that their SimStudents passed the Quiz, we re-examined relationship between human students' learning and SimStudent's learning.

Figure 3 plots human student's plain test scores (Y-axis) and SimStudent's validation scores (X-axis). The figure only includes those 19 students who passed the Quiz in the SE Study. Data taken from a single human student are plotted as two dots connected with a vertical line. A large and a small dot show a human student's post- and post-test scores, respectively, both on the Y-axis.<sup>2</sup> The vertical line represents the pre- to post-test gain, with an upward line showing a positive gain and a downward line negative gain. SimStudent's learning (measures as the validation score) is shown as the position of the connected dots on the X-axis.

If there were students who committed shallow learning, then we should see the pair of dots connected with a relatively short upward line (i.e., a small positive gain) or a downward line (i.e., a negative gain) in the lower left corner. The human students with relatively short lines in the top area are likely to be ceiling students, and SimStudents in the right half are not likely to have committed shallow learning.

As can be seen in Figure 3, there are a group of human students who have relatively short or downward line at a relatively low pre-test score. They are the students who managed to have their SimStudents pass the Quiz, but the students themselves achieved very little learning gain.

## Impact of Tutee Error for Tutor Learning

*How do tutees' errors help tutor learning?* To answer this question, we probed the process data to quantify several tutoring activities related to error detection and correction, and tested their correlations with tutor learning.

On average, SimStudent made 3.3 errors per problem ( $SD=2.4$ ). The number of errors made by SimStudent per problem was not correlated with tutor learning;  $r(84)=-.012, p=0.92$ . The average probability for SimStudent making an error, which was computed as a ratio of incorrect suggestions to all suggestions per problem and averaged for all problems aggregated across all SimStudents, was not correlated with tutor learning;  $r(85)=-.087, p=0.429$ .

On average, human students correctly detected SimStudent's errors 2.3 times per problem ( $SD=1.9$ ). There was no correlation between the number of times human students

<sup>2</sup> Test scores can be negative, because a point was subtracted for a wrong selection on multiple-choice items.

Figure 3: Relation between human students' test scores (Y-axis) and SimStudent's validation scores (X-axis). Large filled dots show post-test scores, whereas small circles show pre-test scores. Only students in the SE study who managed their SimStudents passing the Quiz are included.

correctly detected SimStudent's errors and tutor learning;  $r(84) = -0.178, p = 0.105$ .

The tutors' probability of correctly detecting tutee errors (PED) significantly predicts tutors' normalized learning gain (NRG). The regression coefficient in predicting NRG with PED was  $NRG = 0.17 * PED, p < 0.05$ . It is important to note that part of the test requires error detection within worked examples; success on the test therefore depends on this skill.

However, the NRG does not significantly predict the PED. It appears that tutor learning does not solely contribute to the ability of tutors to detect tutee errors. The regression coefficient in predicting PED with NRG was  $PED = 0.69 + 0.07 * NRG, p < 0.001$  and  $p = 0.17$ , respectively.

As explained earlier, when a student provided negative feedback during tutoring, SimStudent asked the student to explain why the step was incorrect. The theory of self-explanation on erroneous examples predicts that responding to SimStudent's questions about its errors facilitates tutor learning (e.g., Grosse & Renkl, 2007). This is actually the case in our study as well. The ratio of "deep" explanations to all explanations on the "why am I wrong?" type of questions (DXP) was also significantly predictive of normalized gain (NRG). The regression coefficient was  $NRG = 0.44 * DXP$  with  $p < 0.05$ .

The above observations suggest that having tutors correctly detect tutee errors and elaborately explain the error would likely facilitate tutor learning. The current APLUS does not provide explicit assistance for the students to ensure such a good tutoring behavior. As some of the previous studies demonstrated (Leelawong & Biswas, 2008; Walker, et al., 2009), integrating a meta-tutor that guides the human student tutoring into APLUS might, therefore, improve the efficacy of APLUS.

## Discussion

Shallow learning is an inevitable natural pathway for deep learning. When students engage in inductive learning, they usually search through a huge problem space with limited search heuristics that hardly avoid making errors. Indeed, there are very many different types of errors that students can make when doing induction (Matsuda, et al., 2009).

About 2/3 of SimStudents (12 out of 19) who passed the fixed Quiz in the SE Study were actually shallow learners (i.e., failed to pass the randomized Quiz in the GS study). On the other hand, there were no SimStudents who passed the Quiz in the GS study. Since there was a difference in the student's grade level for these two studies, the results must be interpreted with caution. Nonetheless, the GS Study data show a high correlation between SimStudent learning and human student learning. This means that the better SimStudent learns, the better the human student also learns. Therefore, a fixed set of quiz problems should work better than a randomized set of quiz problems, because it helps students tutor SimStudent, which makes a better SimStudent. In turn, this should lead to better tutor learning. In the SE Study, students who passed the Quiz used a higher percent of the failed Quiz problems for tutoring ( $M = 0.95, SD = 0.11$ ) than students who did not pass ( $M = 0.59, SD = 0.42$ );  $t(28) = -4.079, p = .000$ , suggesting that copying the failed Quiz problems helped students in managing to pass the Quiz.

On the other hand, the high correlation between SimStudent's and (human) students' learning also suggests that failing to detect SimStudent's shallow learning is likely to cause students' poor learning. Therefore, the students must detect SimStudent's shallow learning. Our data show that catching SimStudent's shallow learning is rather inexpensive – only two sets of Quiz problems are enough. Having SimStudent take two or more different sets of Quiz problems should help students detect SimStudent's shallow learning.

Our current data also show that tutors learn from errors that the tutee makes. The probability of correctly detecting tutee errors is significantly predictive of tutor learning. Also, the ratio of elaborated explanations to all explanations given to incorrect steps is significantly predictive of tutor learning.

In conclusion, our data suggest that the inevitable nature of inductive learning, i.e., the tutee's *intermediate* shallow learning and errors of commission, facilitate tutor (as well as tutee) learning. In a certain situation (such as APLUS), letting the tutee reach shallow learning might help the tutor manage to teach the tutee without too much of a teaching burden. However, it is crucial for the tutor to detect the tutee's shallow learning and continue teaching toward deeper understanding. Our data also suggest that errors that the tutee makes during tutoring are beneficial both for the tutor and tutee. For the tutee, corrective feedback expedites its learning. For the tutor, elaborated reflective explanations on tutee errors facilitate learning.

The above findings also suggest that weaving fixed and randomly generated sets of quiz problems should induce

optimal learning both for SimStudent and human students. One realization would be to provide a set of randomly generated Quiz problems and let SimStudent try the same (fixed) set of problems until SimStudent passes them, and then provide another set of randomly generated Quiz problems. As shown in Figure 2, passing only two sets of randomly generated Quizzes would be enough to ensure SimStudent's deep learning, which in turn prevents students from shallow learning.

## Abstract

The TRACE model of speech perception (McClelland & Elman, 1986) is used to simulate graded sensitivity to mispronunciations of familiar words as reported by White and Morgan (2008). Our simulations predict that phoneme or lexical competition may be absent in the mental lexicons of the 19-month-old infants tested experimentally.

**Keywords:** Word learning; speech perception; language acquisition; inhibition

## Introduction

Research on infant spoken word recognition has made dramatic advances over the past two decades. Spurred on by the refinement of experimental techniques such as the familiarisation head turn preference procedure (Jusczyk & Aslin, 1995), the switch task (Stager & Werker, 1997) and the mispronunciation task (Swingley & Aslin, 2000), our understanding of *what* infants and young children know about the sounds of words, both familiar and newly learnt, has expanded incrementally. However, our appreciation of the representations and processes underlying early phono-lexical knowledge and *how* these develop is less advanced. Although these approaches offer important insights as to how infants and young children develop knowledge about the sounds of words, they do not provide a precise computational account of the representations and processes involved. In this paper, we describe our attempt to apply the TRACE model of word recognition (McClelland & Elman, 1986) to simulate aspects of spoken word recognition during infancy and early childhood.

TRACE was originally proposed as a model of adult spoken word recognition. In TRACE, spoken word recognition is modelled as an incremental process involving the elimination of competing candidates that are represented in the individual's mental lexicon. Various accounts have emphasised the role of cohort competitors (Marlsen-Wilson & Welsh, 1978) and phonological neighbours (Cutler, 1995; Goldinger, Luce, & Pisoni, 1989) in this competition. Allopenna, Magnuson, and Tanenhaus (1998) have argued that the TRACE model of speech perception provides a satisfactory accommodation for the role of cohorts and phonological neighbours in the resolution of the competitive process.

In TRACE, acoustic-phonetic features are mapped over time onto phoneme nodes that map onto lexical nodes,

with lexical-phonemic feedback and lateral inhibition at the phonemic and lexical levels (see Fig. 1).

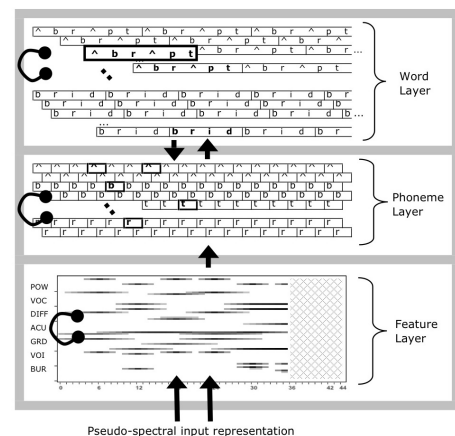

Figure 1: Schematic diagram of TRACE architecture. Drawing by Ted Strauss.

Allopenna et al. (1998) found that the time course of spoken word recognition indexed by eye movements in human participants can be modelled by such continuous mapping models: Adults were instructed to move one of four objects that were on a screen, while they were simultaneously monitored by an eye-tracker. Along with the referent, three competitors were displayed on screen; a cohort competitor (object starting with the same onset and vowel), a rhyme competitor and an unrelated competitor. Using the TRACE model, implementing a forced choice with Luce's choice rule (Luce, 1959), Allopenna et al. (1998) accurately reproduced the typical pattern of eye-gaze of the participants. For example, adults were likely to be distracted by both cohort and rhyme competitors in this task. TRACE also exhibits enhanced activation for these competitors resulting in enhanced levels of "eye fixations" when using Luce's choice rule. More recently, TRACE has been used to model adult's gradient sensitivity to within-category voice onset time manipulations in a visual world task (McMurray, Tanenhaus, & Aslin, 2009) and individual differences in online spoken word recognition, including individuals at risk for specific language impairment (McMurray, Samelson, Lee, & Bruce Tomblin, 2010). In both these applications, exploration of TRACE's parameter

space identified factors (phoneme inhibition and lexical decay, respectively) that might account for observed human performance.

We adopt the same approach and try and refine the potential architecture underlying infant word recognition by simulating with TRACE the finding that infants display a graded sensitivity to the severity of mispronunciations (White & Morgan, 2008).

### Graded sensitivity to the severity of mispronunciations; Implications

Infants show graded sensitivity to mispronunciations of familiar words, as a function of the severity of the mispronunciation. White and Morgan (2008) have shown that 19-month-olds show a graded response in their looking behaviour when presented, in an Inter-Modal Preferential Looking (IPL, Golinkoff, Hirsh-Pasek, Cauley, & Gordon, 1987) task, with a correct pronunciation, 1-feature, 2-feature or 3-feature mispronunciation of the onset consonant of a target word: Infants look longer at the target object when supplied with more accurate renditions of the target object's name. In their experiment, the two pictures corresponded to a target object and a novel object. In contrast to other mispronunciation experiments (Mani & Plunkett, 2007; Swingley & Aslin, 2000), the distracter image is name-unknown and thus does not represent a potential competing lexical entry as it is a novel image. White and Morgan (2008) argued that using a novel object as a distracter is important for demonstrating graded sensitivity as it offers the infant the opportunity to consider the mispronunciation as a label for the novel distracter. This possibility is not available to the infant when the distracter is a name-known object. On the basis of their experimental findings, White and Morgan (2008) argue that lexical processing in toddlers is affected by sub-segmental phonological detail. In this simulation, we examine the adaptations of the TRACE architecture that are needed to simulate the (White & Morgan, 2008) results, and explore the ramifications of these adaptations for interpreting their experimental findings.

### Method

We used jTRACE (Strauss, Harris, & Magnuson, 2007), a re-implementation of the TRACE model (McClelland & Elman, 1986). We created typical lexicons for 18 month olds by compiling British CDIs ((Hamilton, Plunkett, & Schafer, 2000), a British adaptation of the MacArthur-Bates CDI, (Fenson et al., 1993)) using words that are understood by at least 50% of the infants at 18 months of age. The lexicon is specified using data from 179 infants and count 131 words.

Recognition time for spoken words is affected not only by the number of phonological neighbours (Cutler, 1995), but also by their frequency (Goldinger et al., 1989). Therefore, we identified individual token frequencies, by extracting word frequencies on all tiers based on the Manchester corpora (Theakston, Lieven, Pine, & Rowland, 2001) from

the CHILDES database (MacWhinney, 1991), where 12 English children were recorded weekly from 20 to 36 months of age. Word frequencies used in the simulations are raw word counts on the whole corpora, converted to frequency per million. When implementing frequencies in the model, we follow the suggestions advocated by MacKay (1982) and implemented by Dahan, Magnuson, and Tanenhaus (2001), i.e., frequency modulates the connection weights associated with lexical units, using the same value for the scaling parameter (0.13) used in (Dahan et al., 2001). The modulation of frequency effects via phoneme-lexicon connection strengths is consistent with a learning basis for frequency (e.g., of the Hebbian type). In addition, Dahan et al. (2001) found this type of bottom-up connection strength implementation to have qualitative advantages over resting state and post-perceptual frequency manipulations.

Given the large size of the infant lexicon at 18 months of age, many of the phonemes needed to represent the different words were not encoded in the original TRACE model (McClelland & Elman, 1986) nor in its re-implementation (Strauss et al., 2007). Therefore, we added feature values for all phonemes used in the infant's lexicon<sup>1</sup>.

Correctly pronounced words and mispronounced words are presented to the model and activation levels of two competitors (the target and a distracter) are monitored. We adopt the same linking hypothesis as (Alloppenna et al., 1998) in order to map the activation levels to fixation durations. Activation of a word is the result of both its direct activation due to phonological overlap with the input and the result of competition with all other words that are activated with that same input. Only items that are on display are available as potential responses. Similarly to (Alloppenna et al., 1998), the activation levels  $a$  of the displayed items are then transformed into response strengths following (Luce, 1959). Given the high salience of the images, we assume that total looking time is split entirely between the target and distracter objects, enabling us to convert the response strengths into fixation durations using the Luce choice rule. The proportion of looking to the target at time  $t$  is given by:  $p_{target}(t) = \frac{e^{ka_{target}(t)}}{e^{ka_{target}(t)} + e^{ka_{distractor}(t)}}$  where  $k$  is a free parameter determining the amount of separation between units of different activations (value set to  $k = 2$ ). All other parameters used in jTRACE were set to their default values. Proportion of looking times to the target and distracters are reported as the average over 100 processing cycles starting with the onset of the pronounced word.

We used the stimuli described in Experiment 1 of (White & Morgan, 2008), reproduced in Table 1, with the exception of the word "cookie", which is not present in the British version of the CDI that we used to create the new jTRACE dictionaries. Since the distracter is name-unknown in the White and Morgan (2008) experiment, the activation level associated with the novel object on display is set to zero. It is noteworthy that, however, due to the application of Luce's

<sup>1</sup>Thanks to Ōiwi Parker-Jones for help in assigning feature values for phonemes not present in the original TRACE model.

rule, both images share some amount of the total looking time spent during each trial<sup>2</sup>.

Table 1: Correctly pronounced and mispronounced labels presented to infants in Experiment 1 of White & Morgan (2008). The unfamiliar words used by White and Morgan (2008) are not listed here because they do not compete for recognition in TRACE. The table also includes the cohort size as a function of pronunciation type for the stimuli used in White & Morgan (2008).

Correct pronunciations	Mispronunciations		
	1-feature	2-feature	3-feature
keys	teys	deys	zeys
book	dook	took	sook
bear	gear	tear	sear
foot	soot	zoot	goot
car	par	dar	zar
ball	gall	kall	sall
bird	gird	kird	sird
bottle	gottle	kottle	sottle
shoe	foe	voe	goe
cup	tup	bup	vup
hand	fand	zand	dand
Mean cohort size (SD)			
18.7 (12.1)	7.7 (7.2)	11.7 (9.9)	4.4 (2.5)

In this approach, mispronunciations cannot act as potential labels for the distracter image since the distracter image is name-unknown. The unfamiliar words used by White and Morgan (2008) do not belong to the lexicon, and therefore do not compete for recognition in TRACE. Simulations were run with the 18-month-lexicon to mimic the behavior of 19-month olds.

## Results

First, we ran simulations with jTRACE’s default parameters for the same stimuli used by White and Morgan (2008). The top panel of Figure 2 depicts the proportion of looking time associated with the target in the correct, 1-feature-, 2-feature- and 3-feature-mispronunciations. No graded sensitivity is observed as a function of the severity of mispronunciation. Since the metrics used by White and Morgan (2008) to derive the severity of mispronunciation may differ slightly from jTRACE’s, we also evaluate the impact of the severity of mispronunciations on the level of activation of the target words within jTRACE’s metrics. The bottom panel of Figure 2 depicts the reduction in activation level as a function of the magnitude of the mispronunciation (Euclidean distance between the two phonemes in jTRACE’s feature space) for all stimuli. The absence of any correlation suggests that activation levels of target words are not directly sensitive to the severity of mispronunciations, in contrast to White and Morgan (2008) findings.

Closer examination of the stimuli used by White and Morgan (2008) reveals that the number of cohort competitors in the typical lexicon of an 18-month old differs dramatically with mispronunciation type. Table 1 presents an analysis

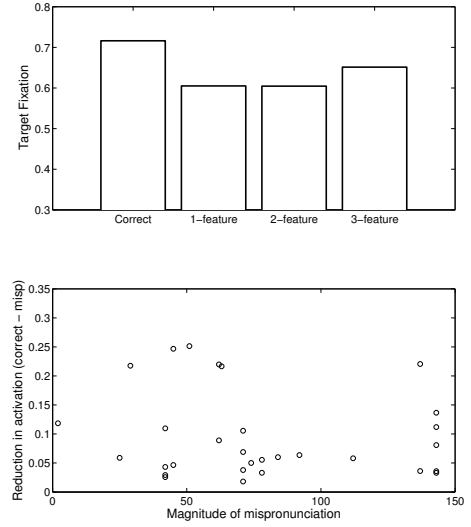

Figure 2: Top Panel: Simulation of White and Morgan (2008) with jTRACE’s default parameters. The unbalanced cohort sizes in each condition interferes with the bottom-up activation flow favoring graded sensitivity to the severity of the mispronunciations. In particular, looking times in the three-feature mispronunciation condition are longer than in the one- and two-feature mispronunciation conditions. Bottom panel: Mispronunciation effect (reduction in activation due to the mispronunciation) as a function of the magnitude of the mispronunciation in jTRACE’s feature space. No correlation is observed between looking times and the severity of mispronunciations.

of the cohort size associated with correct pronunciations and each mispronunciation type. It is apparent that 3-feature mispronunciations have far fewer cohort competitors than any of the other mispronunciation conditions. An item-analysis of variance of the number of cohort competitors across types of pronunciation yielded a main effect of pronunciation condition ( $F=5.53$ ,  $df=3$ ,  $p=0.0028$ ). Two feature mispronunciations have marginally more cohort competitors than 1-feature mispronunciations ( $t=1.34$ ,  $df=10$ ,  $p=0.21$ , n.s.), and more importantly, more than 3-feature mispronunciations ( $t=2.40$ ,  $df=10$ ,  $p=0.038$ ).

An important characteristic of TRACE is that it implements competition within the different layers of the network. As a consequence, cohort competitors impact the activation levels associated with a target word. A low number of cohort competitors leads to reduced inhibition which, in turn, leads to higher activation of the target word. For the stimuli used in (White & Morgan, 2008), we expect the cohort competition in TRACE to interfere with any mispronunciation effect. In particular, the low number of cohort competitors in the case of the 3-feature mispronunciation would lead to an *increase* in the activation of the target word, rather than to a *decrease*

<sup>2</sup> $p_{target}(t)$  being an exponential function of word activation.

in its activation level. Clearly, this outcome would be incommensurate with White & Morgan’s finding of a graded sensitivity to severity in the mispronunciation and explains why a graded sensitivity to the severity of mispronunciations was not observed with jTRACE’s default parameters. Therefore, we conducted a series of simulations so as to evaluate the impact of word-layer and phoneme-layer inhibition on sensitivity to mispronunciation.

First, we investigate the impact of reducing the level of lexical inhibition. Both theoretical and experimental considerations motivate this adaptation of TRACE: Lexical inhibition may be reduced in infancy due to the sparseness of the lexical space (Gaskell & Marslen-Wilson, 1997). Also, several recent experimental findings provide evidence that word to word interactions do not reach adult levels of competition before about 21 months of age. For example, Arias-Trejo and Plunkett (2009) and Styles and Plunkett (2009) used a semantic priming task with infants to demonstrate evidence for lexico-semantic networks in 21- and 24-month old infants. However, they failed to find evidence of semantic priming in 18-month olds. Arias-Trejo and Plunkett (2009) suggest that entries in the 18-month old lexicon may be best characterised in terms of *lexical islands* that are not in competition with each other because they are unconnected. More direct evidence is provided in a phonological priming task (Mani & Plunkett, 2011) conducted with 18- and 24-month old infants. Mani and Plunkett (2011) reported cohort effects in 24-month olds (less target looking for words from large cohorts than words from small cohorts) but no cohort effects for 18-month olds. It is likely that these age differences in cohort effects are driven by differences in the vocabulary sizes of the infants involved in the study, even though both age groups were tested on the same set of words. This set of findings, together with the findings from (Arias-Trejo & Plunkett, 2009) and (Styles & Plunkett, 2009), provide a convergent rationale for reducing lexical competition in the simulation of White & Morgan’s 19-month old infants.

The top panel of Figure 3 displays the proportion of target looking in jTRACE associated with the stimuli used by White and Morgan (2008) for correct, 1-feature, 2-feature and 3-feature mispronunciations when lexical inhibition is essentially turned off ( $C = 0.0001$ )<sup>3</sup>. A graded sensitivity to the severity of mispronunciations emerges, similar to the 19-month-olds tested by White and Morgan (2008). However, correlations between the reduction of activation levels associated with target words and the magnitude of the mispronunciations in TRACE’s feature space did not reach significance ( $p = 0.13$ , see bottom panel of Figure 3). For  $C \geq 0.001$ , cohort effects counteract the effect of mispronunciation such that the activity level associated with the 3-feature mispronunciations is higher than the activity level associated with the 2-feature mispronunciations.

<sup>3</sup>For comparison, the value commonly used to model adult sensitivities to mispronunciations is  $C = 0.03$  (see for example (Allopenna et al., 1998)) which means inhibition in the word layer is 300 times stronger than the value used here.

Figure 3: Top Panel. Simulation of White and Morgan (2008) with TRACE with reduced lexicon competition. Cohort effects are reduced and the bottom-up activation flow favoring graded sensitivity to the severity of the mispronunciations is not disrupted. Bottom panel. Mispronunciation effect (reduction in activation due to the mispronunciation) as a function of the magnitude of the mispronunciation in TRACE’s feature space. A weak, non-significant, correlation is observed between looking times and the severity of mispronunciations.

A second manipulation that may lead to a reduction in the influence of imbalanced cohort sizes when simulating White & Morgan’s findings is to reduce phoneme inhibition. McMurray et al. (2009) suggest that phoneme-level inhibition in TRACE is incompatible with recovery from “lexical garden-paths” initiated by ambiguous phonemes early in a word. We now consider the impact that the absence of phoneme-level inhibition may have on simulations of White & Morgan’s findings. The top panel of Figure 4 depicts the proportion of looking time at the target when correctly pronounced, and with three levels of mispronunciation severity, when phoneme level inhibition is eliminated in TRACE. A clear, graded reduction in activation level emerges as the number of feature changes increases. Furthermore, the bottom panel of Figure 4 indicates that, within TRACE’s feature metrics, a significant correlation ( $R = 0.753$ ,  $p = 1.56 \cdot 10^{-6}$ ) is present between the magnitude of the mispronunciation and its impact on activation levels. Cohort effects are effectively reduced and the bottom-up flow from the feature level to the lexical level, via the phoneme level, is not disrupted by cohort effects.

## Discussion

(White & Morgan, 2008) reported a graded sensitivity in 19-month old infants to the severity of the mispronunciation of

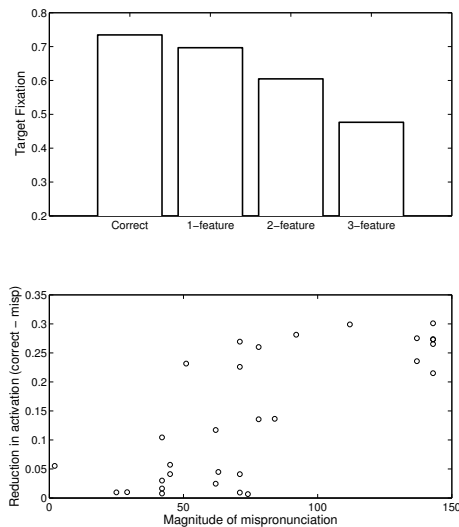

Figure 4: Top Panel: Simulation of White and Morgan’s (2008) findings in jTRACE with no phoneme inhibition. Cohort effects are reduced and the bottom-up activation flow favouring graded sensitivity to the severity of the mispronunciations is well established. Bottom panel: Mispronunciation effect (reduction in activation due to the mispronunciation) as a function of the magnitude of the mispronunciation in TRACE’s feature space. A strong, significant, correlation is observed between target preference and the severity of mispronunciations.

a target word and argued that this finding demonstrated fine-grained sensitivity at the sub-segmental level. The gradual decrease in looking time at the target object as the number of modified features increased was observed despite the fact that the number of cohort competitors for mispronunciations, as evaluated by an analysis of CDI reports, was smaller for the 3-feature mispronunciations than for the 2-feature mispronunciations. Competition between word activation levels in TRACE has an opposite effect on target word activation to mispronunciation severity for the stimuli used by White and Morgan (2008), leading to an apparent incompatibility between White & Morgan’s findings and the predictions of jTRACE. The fact that White and Morgan (2008) report that target looking decreased with mispronunciation severity suggests that either inhibition between competing words in the lexicon is not present (or extremely reduced) at 19 months of age (consistent with Mani and Plunkett (2011); Arias-Trejo and Plunkett (2009) or that phoneme-level inhibition should be removed (consistent with McMurray et al., 2009).

An alternative possibility is that the apparent asymmetry between cohort sizes used in (White & Morgan, 2008) is illusory. It is recognised that parental reports provide under-estimates of actual vocabulary sizes (Mayor & Plunkett, 2011). A proper estimate of vocabulary composition

may result in a more balanced lexicon structure, in turn reducing the impact of cohort imbalance disrupting the graded sensitivity to mispronunciation severity. However, an analysis of a dense recording at 30 months of age, the Haggerty corpus (Haggerty, 1929), revealed that /b/-onset words (89 words) are almost twice as numerous as /p/-onset words (48 words). Better descriptions of the lexical composition in infancy would no doubt help refine the distribution of cohort sizes associated with different onsets. However, they are unlikely to reveal an even profile in cohort sizes.

Taken individually, neither a reduction in lexical-level inhibition, the removal of phoneme-level inhibition, nor a finer-grained estimate of vocabulary composition in infancy can fully account for the graded sensitivity to mispronunciations described in (White & Morgan, 2008) while also capturing the findings that both onset consonant and medial-vowel mispronunciations lead to a reduction in target preferences reported by Mani and Plunkett (2007)<sup>4</sup>. A proper explanation of both phenomena will likely incorporate all of these explanations to a certain degree.

In an attempt to adjudicate between these different hypotheses, or to confirm the contribution of multiple contributing factors (reduction in overall inhibition and a slightly more balanced lexicon), one might ask whether 24-month olds would also display graded sensitivity to the severity of mispronunciations. Indeed, an important prediction of the TRACE simulation of White & Morgan’s (2008) results is that graded sensitivity to mispronunciation severity will be affected by cohort and neighbourhood effects if lexical competition is active. We justified switching off lexical competition in the model on the grounds that empirical studies have reported lexical island effects and lack of cohort effects with 18-month old infants (Arias-Trejo & Plunkett, 2009; Mani & Plunkett, 2011). However, these studies also report that lexical competition effects are apparent by 24-months of age. If the lexical-level inhibition hypothesis holds, we would predict, therefore, that when a task like White & Morgan’s (2008) study is conducted with 24-month-old infants, then the impact of severity of mispronunciation is likely to diminish when using the same stimuli.

It is noteworthy that the acceleration of rapid word learning, often dubbed the “vocabulary spurt” (Bloom, 1973), between 18 and 21 months of age coincides with the potential emergence of lexical competition. Of course, TRACE only implements lexical competition at a phonological level. Lexico-semantic competition, which is outside the purview of TRACE, may follow a different developmental trajectory and lead to different patterns of competition.

Finally, it should be noted that many simplifying assumptions were adopted in the simulations reported in this research. The dictionaries used in the simulations were created by assessing typical vocabularies as assessed by the Oxford CDI (Hamilton et al., 2000). However, individual differences in lexicon sizes and composition would lead to a

<sup>4</sup>A full analysis is reported in (Mayor & Plunkett, *Submitted*).

distribution of phonological sensitivities and looking patterns rather than a single uniform result in TRACE for a given age group. Moreover, the nonlinear impact of lexical competition in TRACE implies that a mean looking pattern based on a mean lexicon would not match the mean of looking patterns associated with different lexicon sizes. Fitting TRACE to individual lexicons rather than a standardised lexicon would provide yet another series of novel experimental predictions against which to evaluate the model.

# Causal Status meets Coherence: The Explanatory Role of Causal Models in Categorization

Ralf Mayrhofer (rmayrho@uni-goettingen.de)

## Abstract

Research on causal-based categorization has found two competing effects: According to the causal-status hypothesis, people consider causally central features more than less central ones. In contrast, people often focus upon feature patterns that are coherent with the category's causal model (coherence hypothesis). Following up on the proposal that categorization can be seen as inference to the best explanation (e.g., Murphy & Medin, 1985), we propose that causal models might serve different explanatory roles. First, a causal model can serve as an explanation why the prototype of a category is as it is. Second, a causal model can also serve as an explanation why an exemplar might deviate from the prototype. In an experiment, we manipulated whether typical or atypical features were linked by causal mechanism. We found a causal-status effect in the first case and a coherence effect in the latter one, suggesting both are faces of the same coin.

**Keywords:** categorization; causal reasoning; causal status effect; coherence effect; explanation.

## Introduction

The question how people organize objects into categories and form abstract concepts about the world to make sense of it has puzzled philosophers for centuries. It is therefore not surprising that categorization has been an important topic in cognitive science since its beginnings. Early but nevertheless prominent accounts concentrated on the role of similarity between exemplars, or exemplars and category prototypes, or rules with respect to defining features of a category (e.g., Nosofsky, 1986; Rosch & Mervis, 1975; for an overview see Ashby & Maddox, 2005). In contrast, more recent accounts emphasize the role of abstract conceptual, mostly causal knowledge as an integral part of category representations (see Murphy & Medin, 1985; Rehder, 2010; Rehder & Hastie, 2001; Sloman, Love, & Ahn, 1998): People do not only know which features are typical for a category and which not. They often represent knowledge about how strongly and *why* features are correlated with each other within a category (Ahn, Marsh, Luhmann, & Lee, 2002; Murphy & Medin, 1985). For instance, people do not only know that birds typically have wings, can fly, and build nests on trees. People also know that birds build nests on trees because they can fly and that they can fly because they have wings.

This kind of causal knowledge underlying category concepts can be formalized in causal graphical models or Bayes nets (see Rehder, 2003a, 2003b; Waldmann, Holyoak, &

Fratianne, 1995). A causal Bayes net consists of nodes, which represent causally relevant variables (i.e., in case of categorization: the presence or absence of features or—more general—properties of objects), and arrows, which stand for counterfactual or statistical dependencies between these variables. The arrows are placeholders for underlying causal mechanisms (Pearl, 2000) and render the variables into causes and effects. Figure 1 shows an example of a common-cause network that relates a cause feature  $F_C$  to three effect features  $F_{E1}$ ,  $F_{E2}$ , and  $F_{E3}$ . The features of a category are usually coded such that the typical feature value is 1 (i.e., presence) and the atypical value is 0 (i.e., absence).

Figure 1: An example of a simple common-cause structure that connects a cause feature  $F_C$  with three effect features  $F_{E1}$ ,  $F_{E2}$ , and  $F_{E3}$ . Due to the causal relations, the state of each effect feature depends counterfactually or statistically upon the state of the cause feature.

Nowadays, it's quite uncontroversial that causal knowledge is an important part of people's concepts that underlie category representation (see Rehder, 2010, for a review). But it is still in controversial debate *how* causal knowledge affects the classification of objects.

In a typical causal-based categorization task people are introduced to a target category that possesses a set of mostly three or four features. In addition, it is pointed out how these features are causally related to each other due to some causal mechanisms that hold for the category (e.g., a common-cause model as shown in Figure 1). Then, participants are presented with several potential exemplars with the category's features being either present or absent. For each of the presented exemplars, membership ratings are obtained. The enduring controversy, then, spans around the question how the instructed causal model interacts with the presence and

Figure 2. Predicted patterns for category membership ratings are shown according to (a) the *causal status hypothesis* and (b) the *coherence hypothesis*. The predicted ratings are computed for a category possessing four features that are connected as a common-cause model (as shown in Figure 1). The ratings depend upon the presence of the cause feature ( $F_C = 0$  vs.  $F_C = 1$ ; dashed vs. solid lines) and upon the number of effect features being present,  $\#(F_E = 1) = \{0, 1, 2, 3\}$ .

absence of features with respect to the membership ratings of the presented exemplars.

Some researchers propose that causal knowledge is an important determinant of individual feature weights in these judgments (e.g., Ahn, Kim, Lassaline, & Dennis, 2000; Marsh & Ahn, 2006). According to this account, the *causal status* of a feature matters. Others, however, emphasize the importance of feature configurations that are more or less *coherent* with the category's causal model (Rehder, 2003a, 2003b; Rehder & Hastie, 2001; Rehder & Kim, 2010). Although the effects are conceptually independent of each other (Rehder, 2010), both sides claim (and have—puzzlingly—shown empirically) that the other effect plays only a marginal, if any, role in human categorization.

In the following sections, we will describe the causal status hypothesis and the coherence hypothesis in more detail. Then, we will offer an account that—in our view—makes sense of the diverging evidence, and present an experiment that tests our claims.

### Causal status effect

According to the causal status hypothesis, features that are causally more central (i.e., that have more dependents in the causal model or that appear earlier in a causal chain) have greater influence in categorization decisions when other perceptual (e.g., salience) or statistical (e.g., cue validity) properties of the material are held constant or controlled for (e.g., Ahn et al., 2000). The causal status of a feature is, therefore, an important determinant of its decision weight.

For example, with respect to a common-cause model (see Figure 1), the presence vs. absence of the cause feature  $F_C$  should have more influence on the membership rating of an exemplar than the presence vs. absence of an effect feature. In Figure 2a, such an idealized causal status effect is shown: The membership ratings increase with the number of features being present; the increase, however, is higher for the cause feature ( $\Delta C$ ), than for effect features ( $\Delta E$ ).

Conceptually, the causal status effect has been linked to psychological essentialism (Ahn et al., 2000). Hence, people believe in things having essences that make them the objects they are. An essence, then, is the (unobservable) root cause for the surface features that can be observed in category members (Gelman & Wellman, 1991). Features that have a high causal status might be seen as most diagnostic for an object's essence and, therefore, category membership (Ahn et al., 2000; see also Rehder & Kim, 2010).

### Coherence effect

Whereas the causal status effect is defined with respect to the weight of individual features, the coherence effect arises from the impact of feature interactions (Rehder, 2010). According to the coherence hypothesis, exemplars whose feature configurations are most coherent with the category's causal model are seen as the best members. Causal models, therefore, provide us with information about which features should go together in an exemplar. Features that are connected by a causal link should be either both present, or both absent (Rehder, 2003a; Rehder, 2010). With respect to a

common-cause model (see Figure 1), for example, membership ratings should be an increasing function of the number of effects being present when the cause feature is present, but a decreasing function in its absence. Figure 2b shows such an idealized coherence effect. Membership ratings are expected to be highest when all features are either present or absent. In this case, all causal links are preserved (i.e., such an exemplar is most coherent). The worst (i.e., most incoherent) exemplars, in contrast, are those that preserve none of the links: The cause feature is present but all effect features are absent, or the cause feature is absent but all effect features are present (three violated links in both cases).

Coherence in the proposed manner, however, faces a problem when assessed intuitively in real world cases that pop into one's mind: It does not make sense. An animal that does not have wings, does not fly, and does not build nests on trees is not a bird, although the absence of these features is perfectly coherent with the causal model of the concept "bird". Marsh and Ahn (2006) therefore suggested that the coherence effect may be not more than an experimental artifact arising from the artificial material used by Rehder and colleagues (e.g., Rehder 2003a, 2003b; Rehder & Hastie, 2001). Nevertheless, we propose otherwise.

### Explanatory roles of causal models

So far, the whole debate has neglected the fact that causal models may play different roles in the representation of concepts that underlie categories. Causation in those models is implemented (or thought) in a way that causes, when present, have the power to bring about their effects, but are causally inactive when absent (Cheng, 1997; Rehder, 2003a). At first glance, this might not matter anyway: Usually, the presence of the cause goes together with the presence of its effects, as well as the absence of the cause goes together with the absence of its effects (Note, that this superficial symmetry is the basis for the coherence hypothesis). However, whereas the first fact is a direct consequence of causal mechanism, the latter is just an indirect "side effect" of it (Dowe, 2000, aptly mentioned that in this case the absence of the cause prevents the presence of its effect by omission, i.e., just by not causing it). Although this difference hasn't received much attention yet, we think it is crucial for understanding causal-based categorization.

Categorization can be seen as a kind of inference to the best explanation (Jameson & Gentner, 2008; Lombrozzo, 2009; Murphy & Medin, 1985; Rips, 1989), according to which causal models provide a system of explanatory links that tie the features of a category together. Therefore, exemplars whose configuration of features can be best explained in the light of the category's causal concept are rated as the best members. With respect to the causal analysis given above, we propose—in contrast to the coherence hypothesis—that only those feature combinations matter that are relevant with respect to the underlying causal mechanisms (e.g., when both are present, but not when both are absent), because it is the mechanism but not the regularity that has explanatory value (see Keil, 2006, for an overview).

From this point of view, we can at least differentiate two explanatory roles of causal models. First, when causal mechanisms are established in terms of typical features, the causal model serves as an explanation why the category's prototype or prototypical exemplar (i.e., all features present) is as it is. The bird example given above belongs to this type of explanation. With respect to a common-cause model (see Figure 1), we would expect a strong increase of membership ratings with more effect features being present when the cause feature is also present. In this case more and more explanatory links are served (i.e., the exemplar becomes more and more coherent with the provided explanation). But when the cause is absent, the effect features are conceptually unrelated to each other. Therefore, we would expect a much smaller increase when more and more effects are present. Since the presence vs. absence of the cause feature modulates the positive influence of the effect features, we expect membership ratings that—in the aggregate—exhibit a strong causal status effect.

Second, however, it is also possible to establish causal mechanisms with respect to atypical feature values (usually coded as absences). In this case, the causal model serves as an explanation for why a category member might deviate from the category prototype (e.g., fouling that makes an apple not looking like an apple anymore). When now presented with an exemplar that lacks all typical features, you would probably be much more willing to judge this exemplar a category member than in the bird example, because the causal model provided you with an explanation why this atypical exemplar deviates from the prototype. Thus, in case the causal model links atypical feature values, we expect a pattern that looks quite like the prediction of the coherence hypothesis (see Figure 2b). First related evidence for this proposal comes from Ahn, Novick, and Kim (2003): In their studies, participants judged persons who showed a set of abnormal characteristics (e.g., suffering from insomnia, memory deficits, and episodes of extreme anxiety) as more "normal" when provided with plausible causal relations between these abnormal characteristics compared to a condition in which no such links were provided.

To summarize, we believe that the diverging evidence found in the literature regarding the causal status and the coherence effect stems from the fact that causal models play different roles in categorization and that those studies might differ with respect to the explanatory role of the instructed causal model. In the next section we present an experiment that tests our claim.

### Experiment

To test our hypothesis we adapted the material used in the experiments of Rehder (2003a; in similar versions also used in Marsh & Ahn, 2006; Rehder, 2003b; Rehder & Kim, 2008, 2010, and others). Rehder presented subjects with instructions about several artificial categories (e.g., Kehoe Ants, Mya Stars) possessing four features that were linked in a common-cause model (see Figure 1). Features were introduced without giving precise base rate information

(e.g., “Some Kehoe Ants have blood that is very high in iron sulfate. Others have blood that has normal levels of iron sulfate.”, “Some Kehoe Ants have an immune system that is hyperactive. Others have a normal immune system.”)<sup>1</sup>. Then, causal mechanisms were introduced by plausible descriptions (e.g., “Blood high in iron sulfate causes a hyperactive immune system. The iron sulfate molecules are detected as foreign by the immune system, and the immune system is highly active as a result.”). After participants have learned the category, they had to rate all possible exemplars (all possible combinations of features being present or absent) regarding their category membership. In his studies, Rehder found evidence for the coherence effect (but see Marsh & Ahn, 2006, for a critical discussion).

In our experiment, we used the same procedure and same material. To manipulate the explanatory role of the instructed causal model, we explicitly instructed which of the feature values were described as *typical* for the category (e.g., hyperactive immune system or normal immune system). So, between conditions, the typicality of the feature values changed but the description of causal mechanisms remained constant for the same feature values. By that, however, we manipulated the explanatory role of the causal mechanisms (i.e., whether *typical* or *atypical* values were linked by mechanisms). Furthermore, we added a replication condition that was identical to Rehder (2003a), to ensure that our procedure (and translated material) yields the same findings.

## Method

**Participants** 96 students (62 women, mean age 22.4 years) from the University of Göttingen, Germany, participated in this experiment as part of a series of various unrelated computer-based experiments in our computer lab. Participants received either course credit or were paid €8 per hour.

**Material** Two categories used in Rehder (2003a) were translated into German: Kehoe Ants (a biological kind) and Mya Stars (a non-living natural kind).<sup>2</sup> Each category possessed four binary features. Depending on condition, each feature had a typical value (coded throughout this paper as “1”) and an atypical value (coded as “0”). For example, Kehoe Ants have an immune system that was either hyperactive or working normal. Which of the two values was described as typical depended on the experimental condition (e.g., in the *typical* condition, it was stated: “Typically, Kehoe Ants have an immune system that is hyperactive. A few have a normal immune system.”, in the *atypical* condition, it was stated: “Typically, Kehoe Ants have a normal immune system. A few have an immune system that is hyperactive.”).

Additionally, the features were causally linked in a common-cause network. Each causal relationship was described as one feature causing another in the same way Rehder

(2003a) did (see above). The description of causal mechanism was identical for all conditions.

**Procedure** Participants were randomly assigned to one of the two categories and to the *typical*, *atypical*, or *replication* condition. They completed the experiment individually on desktop computers. The experiment consisted of two phases, an instruction phase and a test phase.

In the instruction phase, we presented subjects with information about the category (Kehoe Ants, Mya Stars). Subjects were introduced to the four binary features and their typical values (depending on *typical* or *atypical* condition, respectively). Then, subjects were provided with information about how the features are causally connected. (As stated above, in all conditions the causal links were instructed between the same feature values. However, the typicality of these feature values and, therefore, the explanatory role of the causal model differed depending on condition.) In the *replication* condition the causal links were presented in the same way, but no information about the typicality of the values was given (as in Rehder, 2003a). The instructions were followed by a multiple choice test in which participants were required to demonstrate that they had learned all given information about the assigned category. In case of incorrect answers they had to reread the instructions and had to take the test again until they committed 0 errors.

In the test phase, subjects were presented sequentially with all 16 possible exemplars (all combinations of the four binary features) in two consecutive blocks. Order of exemplars was randomized in each block. For each exemplar, subjects were requested to give a category membership

Figure 3. Results of the replication of the experiment of Rehder (2003a). Membership ratings of exemplars are shown with cause feature present ( $F_C=1$ ) vs. absent ( $F_C=0$ ). X-axis displays the number of effect features being present (i.e., having typical value). Error bars indicate 95% confidence intervals.

<sup>1</sup> Note that normal values were coded as “0” (= absence).

<sup>2</sup> Rehder (2003a) used six categories, but no differences for membership ratings were obtained. Therefore, we only used two randomly chosen categories.

rating on a scale from 0 (not a member at all) to 10 (definitely a member).

**Design** The membership ratings were aggregated for each subject across blocks and with respect to the cause feature being present ( $F_C = 0$  vs.  $F_C = 1$ ) and the number of effect features being present ( $\#F_E = 1 = \{0, 1, 2, \text{ or } 3\}$ ). This yielded a 3 (*typical*, *atypical*, *replication* condition)  $\times$  2 (category: Kehoe Ants vs. Mya Stars)  $\times$  2 ( $F_C = 0$  vs.  $F_C = 1$ )  $\times$  4 ( $\#F_E = 1 = \{0, 1, 2, \text{ or } 3\}$ ) ANOVA design with condition and category as between-subjects factors and the presence of the cause or effect features, respectively, as within-subjects factors and average membership rating as dependent variable.

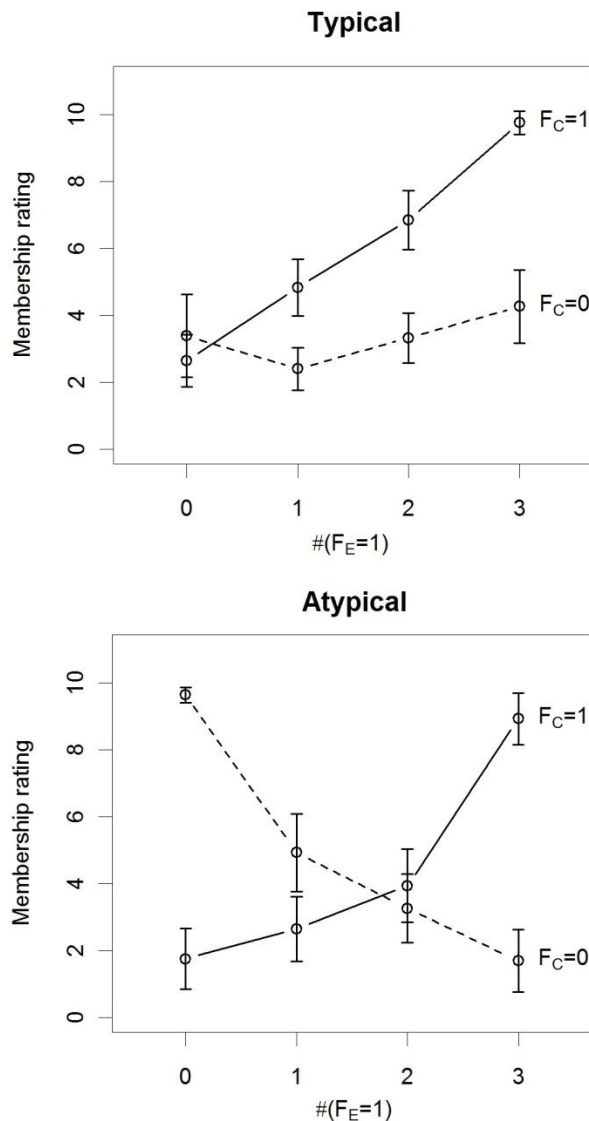

Figure 4. Average category membership ratings are shown for (a) *typical* condition and (b) *atypical* condition with cause feature present ( $F_C=1$ ) vs. absent ( $F_C=0$ ). X-axis displays the number of effect features being present (i.e., having typical value). Error bars indicate 95% confidence intervals.

## Results

**Category** In line with previous studies, the category (Kehoe ants, Mya stars) revealed no significant influence on membership ratings, neither as main effect nor in any interaction (all  $ps > .1$ ). Therefore, the factor is aggregated over in the following analyses.

**Replication** In Figure 3, the results of the replication condition are shown. When the cause feature was present ( $F_C = 1$ ) membership ratings increased with increasing number of effects being present. In contrast, when the cause feature was absent ( $F_C = 0$ ) membership ratings decreased, yielding a significant interaction ( $F_{3,99}=62.5, p < .001$ ). This replicates the findings of Rehder (2003a) and is in line with other studies using the same material.

**Explanatory Role** Figure 4 displays the aggregated membership ratings for the *typical* and *atypical* condition. In both *typical* and *atypical* conditions, subjects rated exemplars with a present cause feature ( $F_C = 1$ ) better members the more typical effect features were present. So, the exemplar with all features being present was rated very high (9.8 and 8.9 in *typical* and *atypical* condition, respectively) whereas the exemplar with all effects being absent was rated very low (2.6 and 1.7, respectively).

Exemplars, however, with the cause feature being absent ( $F_C = 0$ ) exhibit a significant interaction between conditions ( $F_{3,198}=28.2, p < .001$ ) (The three-way interaction was also significant,  $F_{3,198}=17.79, p < .001$ ). In *typical* condition, ratings' increase was only marginal significant ( $F_{3,102}=2.24, p=.088$ ). In *atypical* condition, subjects rated exemplars lower, the more effect features expressed the typical value. So, the exemplar with all effects being absent (and, therefore, all features being absent) was rated very high (9.6), whereas the exemplar with all effects being present was rated very low (1.7).

Thus, the *atypical* condition looks like the prototypical case of a coherence effect. In fact, individual influence of features (i.e., marginalized across the states of the other features) are negligible and even negative ( $\Delta C = -0.67, \Delta E = -0.14$ ). In contrast, the *typical* condition revealed a strong causal status effect ( $\Delta C = 2.83$  vs.  $\Delta E = 1.37$ ), as we have predicted.

## Discussion & Summary

It is widely accepted that causal knowledge is an important part of people's concepts that underlie category representations. Nevertheless, it is still quite controversial how causal knowledge affects membership ratings: Some researchers propose that causal knowledge determines the individual feature weights in categorization judgments (causal status hypothesis; see Ahn et al., 2000), whereas others, however, emphasize the role of feature combinations and whether those are coherent with the statistical regularities imposed by the category's causal model (coherence hypothesis; see e.g., Rehder, 2003a, 2003b; Rehder & Kim, 2010). We presented one possible solution to this puzzle: According to
